SECTION 5

Transplant Procedure and Surgical Technique

CHAPTER 55

Kidney Transplantation Procedure and Surgical Technique

Paul L. Tso and Thomas C. Pearson
Emory University School of Medicine and Kidney Transplant Program, Emory Transplant Center, Atlanta, GA, USA

Introduction

As eloquently alluded to by Dr. Joseph Murray in his Nobel Prize lecture [1], advances in surgical technique, along with understanding and finding solutions to immunologic barriers, and the development of renal replacement therapies to sustain individuals with renal failure were three interrelated pathways leading to the success we enjoy today in clinical kidney transplantation. Surgical determination was an important trait held by a long list of pioneers who were responsible for the development and refinement of technical aspects of the transplant operation currently in practice today. Recent advances in imaging modalities, percutaneous and endoscopic interventions, and minimally invasive surgical techniques have also fostered significant strides forward in identifying and managing technical complications post transplantation that previously often would have required reoperation with greater potential morbidity, mortality, and risk for organ loss. Most would agree that the evolution of kidney transplantation to become the established best therapy for many patients with end-stage renal disease is the culmination of all the above contributions. This chapter will focus on technical aspects of the transplant operation as well as management of technical complications encountered following the procedure.

Preoperative considerations

Upon admission for impending renal transplantation, an updated history is obtained and physical examination performed on the intended recipient to bring to light any significant interval events or physical findings impacting the patient's health or proposed procedure since he or she was last evaluated. Specific issues to be addressed include sensitizing events, infections, and changes in the patient's cardiovascular reserve (also see Chapter 37, which covers kidney transplant list management). Laboratory and imaging studies, cardiac testing, and specialty consultations are obtained or brought up to date as indicated to ensure that the patient is a suitable candidate for transplantation—able to withstand and benefit from the rigors of the operation and long-term immunosuppression. As detailed in Chapter 89, ABO and HLA compatibility between the recipient and donor organ is confirmed. Available information regarding the donor kidney should be reviewed to confirm the appropriateness of organ quality (organ selection criteria are discussed in detail in Chapter 53). Informed consent for the procedure must be obtained from the patient or responsible party.

In preparation for the procedure itself, the surgical team should review the use of warming devices and venous thromboembolism prophylaxis, availability of blood products, and administration of preoperative antibiotics and intraoperative medications, including immunosuppressive therapy, with the anesthesia and nursing personnel prior to incision. Central venous access may be advisable in patients with poor peripheral veins or in cases where more invasive hemodynamic monitoring is indicated. Similarly, an arterial catheter may be warranted to more closely monitor blood pressure or allow frequent blood sampling. The operation is performed under general anesthesia with the patient in the supine position. An indwelling catheter is placed within the urinary bladder or conduit. Sterile antibiotic solution, with or without methylene blue, may be gently instilled to facilitate identification of the bladder in the operative field during the urinary drainage reconstruction. Special care is needed in patients with previous prostatic or urethral pathology or surgery or atrophic bladders from longstanding anuria to avoid iatrogenic injury during catheter insertion, such as false urethral passages or bladder rupture during instillation of irrigation. The authors prefer distention of the bladder by gravity drainage, as this prevents the potential for rupture of an atrophic bladder, and provides some insight into the capacity of the recipient bladder, and its implications for ureteral reconstruction.

Back-table preparation of kidney

Back-table preparation of the renal allograft is performed either previous to or concurrent with the recipient exposure. In cases where there is concern that trauma, surgical damage, or aberrant anatomy may have rendered the donor organ not suitable for transplant, it should optimally be examined by the surgeon prior to the recipient being brought into the operating room. In the deceased donor scenario, a Carrel patch of aorta is typically maintained on the renal artery, allowing a larger, technically less demanding vascular anastomosis which does not involve the renal artery ostium. This is especially desirable in the case of a pediatric donor kidney with a small artery [2] to facilitate performing the anastomosis and to alleviate concern that the ostium may be

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

restricted by the suture line as the recipient and organ grow with time.

Multiple arteries are commonly encountered and there are multiple options for reconstruction. Trivial accessory arteries (especially to the upper pole) may be sacrificed without apparent negative outcomes; however, care is taken to preserve significant accessory vessels, especially those supplying the lower pole likely critical for ureteral perfusion [2,3]. Multiple arteries may be maintained on or reconstructed to form a common Carrel aortic patch on the back table to allow a single relatively straightforward arterial anastomosis in the recipient [4,5]. Conversely, when indicated, multiple renal arteries may be kept separate and anastomosed to the recipient vessels independently to prevent excessive tension, angulation, or compression of the adjacent renal vein [3]. Atherosclerotic disease of the donor aorta or at the renal artery ostium may make the aortic patch not fit for use, in which case the artery is transected at a point relatively disease free and suitable for anastomosis. Multiple arteries in the living donor kidney or other situations where there is not a suitable aortic patch may be spatulated and sewn together in "pair of pants" fashion [4] to allow a single arterial anastomosis in the recipient. Alternatively, an accessory artery may be sewn to the main artery in end-to-side fashion [3] or multiple vessels may be reconstructed to a Carrel patch fashioned from PFTE or autogenous tissue, if available, to facilitate the vascular anastomosis in the recipient. Gonadal, lumbar, and adrenal tributaries to the renal vein are controlled with clips or silk ties. Small accessory renal veins may be ligated, as renal veins typically intercommunicate via collaterals. However, if there exist two main renal veins of equal caliber draining the kidney, it is recommended to salvage both to reduce the risk of venous thrombosis and infarction [2]. The deceased donor right kidney graft optimally presents with a full cylinder of vena cava, which can be fashioned into a vascular conduit using suture or a stapler to effectively increase length of the renal vein [2,5]. This makes the venous anastomosis less technically challenging and decreases the likelihood of tearing the delicate right renal vein. Lymphatic structures in the allograft are believed to be a potential source of post-transplant lymph leakage and resultant lymphocele [3,6] and therefore are carefully controlled with ties or clips as they are encountered during the back-table dissection. Care is taken to maintain sufficient periureteral tissue and preserve the perirenal fat bordered by the ureter and the lower pole of the kidney (the "golden triangle") to reduce the likelihood of ureteral ischemia, which may predispose to subsequent urinary leak or stricture [7,8]. Figures 55.1 and 55.2 show the typical reconstruction and placement of a left and right kidney (inclusive of a vena caval conduit), respectively.

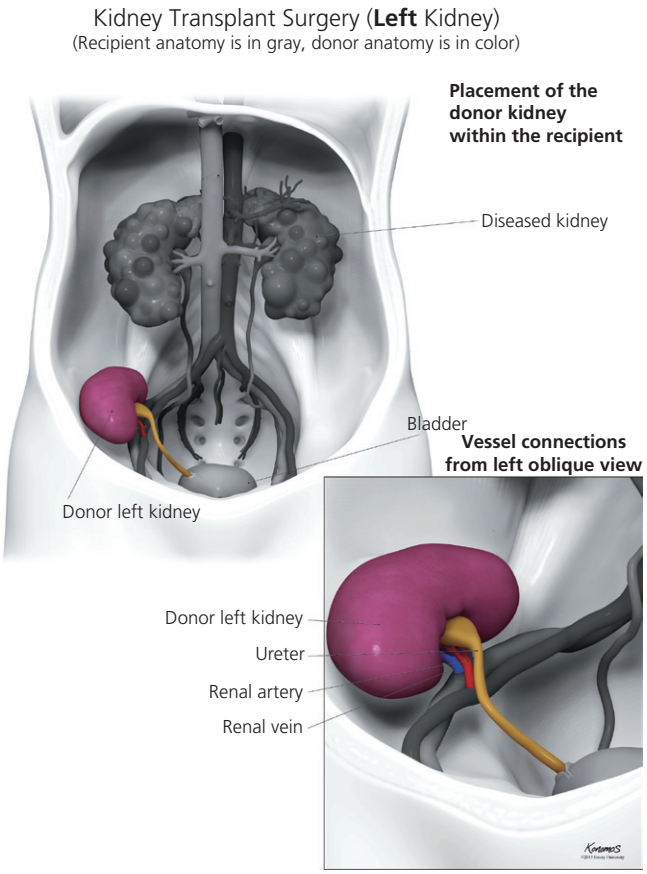

Figure 55.1. Placement of a left kidney allograft in the right iliac fossa. This is by far the most common orientation, as most live donor kidneys are left kidneys (due to the longer left renal vein). Shown are the typical relationships of the renal artery and vein to the external iliac artery and vein, respectively. The ureteral anastomosis is a standard Lich-type extravesical ureteroneocystostomy. Note that when a kidney from the contralateral side is used, the collecting system is medial/anterior, facilitating access to the ureter and collecting system in the event of a ureteral complication. The iliac vein has been mobilized laterally to accommodate a direct lie of the vein once it is anastomosed.

Incision and exposure

Typically, an oblique Gibson [4] or J-shaped "hockey-stick" [5] lower quadrant incision is made and extraperitoneal exposure obtained to prepare the external iliac artery and vein for the vascular anastomoses. The superficial inferior epigastric vessels are often ligated and divided to facilitate exposure, as is the round ligament in females [5]. In cases where the ipsilateral superior epigastric vessels have been divided recently (for example as a result of a concomitant liver transplant or recent subcostal incision), some surgeons advocate preserving the inferior epigastrics to avoid acute rectus muscle ischemia. If the donor kidney is found during the back-table preparation to have a small divided accessory artery or arterial branch requiring salvage, the superficial inferior epigastric artery may be preserved or divided with good length maintained as a potential option for revascularization [2,9]. Conscious effort is made to control lymphatic channels and nodes with cautery, clips, or ligatures as they are divided and/or resected in the process of exposing the vessels to help prevent lymph leakage and subsequent lymphocele formation [2,3,10].

As shown in Figures 55.1 and 55.2, the kidney is commonly transplanted to the recipient's right external iliac vessels, due to the relative superficial location of the right external iliac vessels and overall facility for right-handed surgeons. The left external iliac vessels may be utilized based on surgeon preference, if the right side is being reserved for a pancreas allograft, if there has been a previous transplant on the right side, or the right-sided anatomy is otherwise unsuitable [5]. Some sources advocate contralateral placement of an allograft (i.e. right donor kidney to recipient left lower quadrant and vice versa) to allow the transplant renal pelvis and ureter to lie medially, thus facilitating future urinary revision if necessary [2,4]. In general, the external iliac vein lies posterior to the external iliac artery, and, as shown in Figures 55.1 and 55.2, its

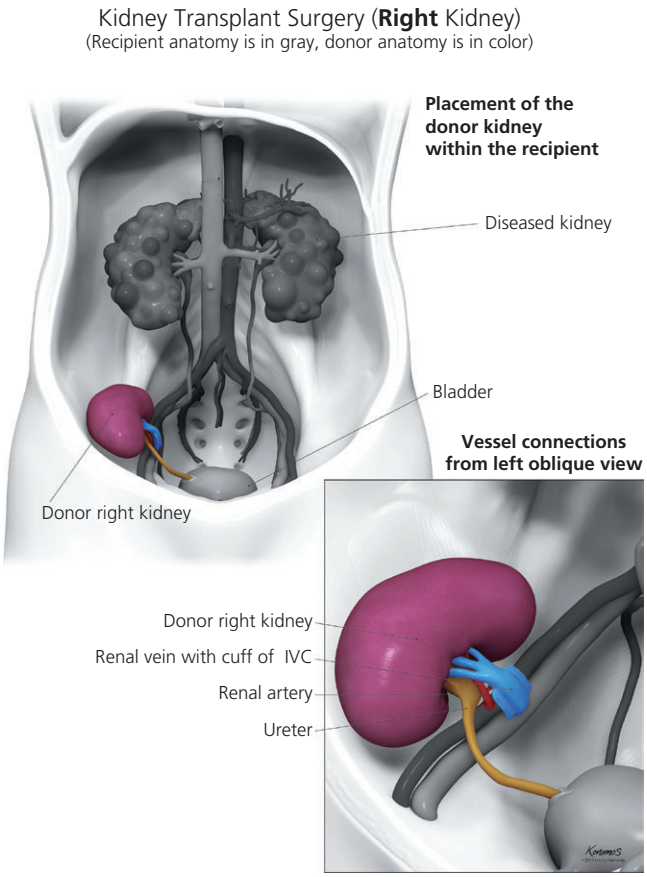

Figure 55.2. Placement of a right kidney allograft in the right iliac fossa. Shown are the typical relationships of the renal artery and renal vein to the external iliac artery and vein, respectively. The ureteral anastomosis is a standard Lich-type extravesical ureteroneocystostomy. Note that when a kidney from the ipsilateral side is used, the collecting system is lateral/posterior, hindering access to the ureter and collecting system in the event of a ureteral complication. The iliac vein has been mobilized medially to accommodate a direct lie of the vein once it is anastomosed. The right renal vein is often short. In this case, a conduit of vena cava that is fashioned by stapling across the suprarenal and infrarenal donor vena cava and using the donor's left renal vein orifice as the eventual site of the end-to-side venous anastomosis is shown.

mobilization can be varied from lateral to medial to accommodate a natural lie of the renal vein anastomosis, with contralateral placement favoring lateralization of the iliac vein, and ipsilateral placement favoring medialization of the vein. If bilateral external iliac vessels have been previously utilized, subsequent transplants are generally performed transperitoneally via a lower midline incision, to allow assessment of and access to the more proximal iliac vessels or aorta and inferior vena cava for anastomosis if necessary [5]. History of previous lower extremity deep venous thrombosis or hemodialysis access should prompt appropriate preoperative imaging to evaluate for potential iliac or caval venous stenosis or obstruction requiring intervention and affecting selection of allograft venous outflow. Transplantation ipsilateral to an active thigh arteriovenous fistula is generally avoided if possible due to concern for potential vascular complications such as venous hypertension affecting graft function. Ligation and division of the internal iliac vein may be helpful in cases with a short renal vein, deep recipient pelvis, or vertically oriented iliac vein to increase mobility of the common and external iliac veins and thereby facilitate the anastomosis [2,5].

Revascularization

Systemic heparinization is employed by some centers during the period of vascular occlusion for the anastomoses [2,4]; however, this is not universally practiced. Vascular clamps are carefully applied to obtain proximal and distal control of the iliac vessels. The allograft renal vein is typically sewn in end-to-side fashion to the recipient external iliac vein using a fine (generally 5-0) running polypropylene suture. After fashioning the arteriotomy with fine scissors or a vascular punch, the renal artery is usually anastomosed in end-to-side fashion to the external iliac artery using a running fine (5-0 or 6-0) polypropylene suture. Another option is to sew the renal artery to the recipient internal iliac artery in end-to-end fashion [2]. In cases involving multiple donor renal arteries, both external and internal iliac arteries may be utilized for inflow [5]. If the internal iliac artery is considered for inflow, its origin should be carefully examined for significant atherosclerotic disease potentially compromising allograft perfusion. The internal iliac artery should not be used if the contralateral internal iliac artery has previously been divided due to the increased likelihood of impotence, claudication, or other vascular complications [3,4]. Care must be taken while handling and suturing diseased recipient and donor vessels to avoid creating an intimal flap or dissection. In cases involving small pediatric donor organ vessels, consideration should be given to performing at least part of the anastomosis with interrupted sutures [2] to allow for growth in cross-sectional area over time.

Once the vascular anastomoses are completed, the vascular clamps are released to restore flow from and to the lower extremities as well as to the newly revascularized kidney. Hemostasis is achieved. Ideally, the kidney promptly displays a healthy pink color, good turgor, and production of urine. Initial poor allograft perfusion demands vigilance. In many cases this will be the result of prolonged preservation or other donor factors portending slow or delayed graft function. Recipient hemodynamic issues or use of vasopressors may also play a role in initial hypoperfusion. In these instances the appearance of the organ often improves over the ensuing minutes as recipient hemodynamics and perfusion are optimized and vasospasm in the allograft resolves. In some cases, the allograft may appear unusually engorged with the artery pulsatile as opposed to being characterized by a pulsating thrill or bruit. These findings suggest possible venous outflow obstruction. If perfusion to the allograft remains questionable over the course of the operation, there must be a high index of suspicion for a technical problem such as a twisted vessel, thrombosis, embolus, retractor causing vessel occlusion, flow limiting dissection (particularly at the site of a previously placed vascular clamp), or a faulty suture line. A hand-held Doppler probe is invaluable to quickly confirm the absence or presence of flow in vessels and the renal parenchyma. There should be a low threshold for taking down vascular anastomoses if necessary to eliminate the possibility of technical error or a thromboembolic event. In situations where additional complex procedures may result in prolonged warm ischemia, it may be best to re-flush the kidney with cold perfusate and perform any necessary technically demanding reconstruction on the back table. It is far better to definitively establish vascular patency including reconstructing the anastomoses than to close with a question left as to the integrity of the anastomoses.

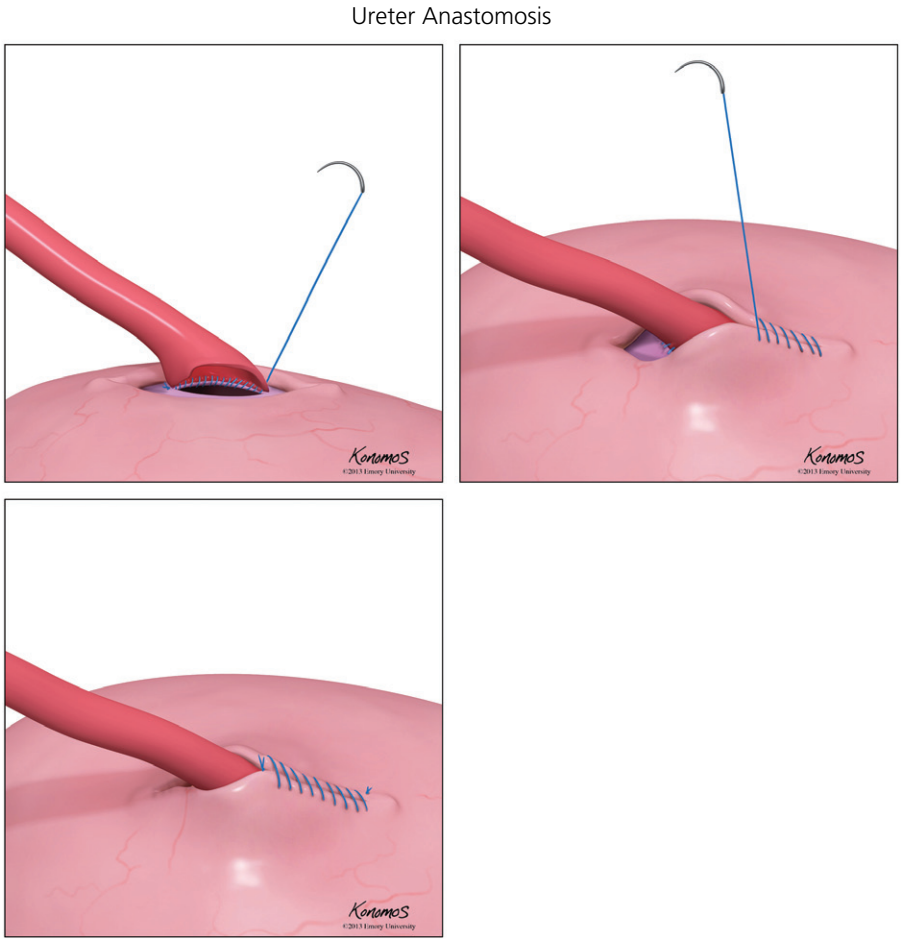

Figure 55.3. The Lich ureteroneocystostomy. This is the most common method for establishing ureterovesical continuity. After splitting the muscle of the bladder to expose the bladder mucosa, an anastomosis is created between the ureteral and bladder mucosa using a fine (5-0) absorbable suture (e.g. PDS). This anastomosis is imbricated under the approximated muscle to create an antireflux anatomy. Some centers stent this anastomosis (not shown).

Urinary reconstruction

After satisfactory perfusion of the allograft has been achieved, attention is then directed to the urinary drainage component of the operation. The type of reconstruction performed is dependent on the length and quality of the donor ureter, as well as the condition of the recipient ureter and bladder. Commonly, a Lich ureteroneocystostomy or modification of this technique is carried out (Figure 55.3). In contrast to the classic Ledbetter–Politano transvesical procedure, the extravesical Lich procedure does not require an extra cystotomy or as much donor ureteral length. As a result, the latter technique is believed to be associated with shorter operative time as well as lower incidence of ureteral ischemia, obstruction, hematuria, and urine leak [2,8,11,12]. The transplant ureter is usually routed posterior to the spermatic cord to prevent potential tenting and obstruction by this structure [2]. In general, this is easily accomplished; however, the spermatic cord can be divided to facilitate the ureteroneocystostomy without lasting adverse consequences in most cases. The ureter is trimmed to appropriate length and spatulated to allow a tension-free anastomosis to the bladder. It should be carefully inspected for adequate perfusion at its distal extent to decrease the likelihood of ischemia leading to ureteral stricture or leak. Methylene blue tinted irrigation instilled via the Foley catheter is helpful to eliminate any confusion in identifying the bladder while creating the cystotomy. Particularly in obese patients and patients on peritoneal dialysis, the peritoneum can be mistaken for the bladder resulting in a ureteroperitonostomy—a complication that should be contemplated during the bladder mobilization so as to always be avoided. The mucosa-to-mucosa ureter to bladder anastomosis is usually sewn with a fine absorbable monofilament suture (typically 5-0 PDS) in running fashion (Figure 55.3). The use of absorbable suture is important to avoid a persistent intravesical foreign body, which will be a nidus for stone formation and urinary tract infection. A double-J ureteral stent is either routinely or selectively employed based on surgeon's preference. Selective use would occur if there exists concern over integrity of the ureteroneocystostomy (or other urinary tract reconstruction) prior to completion of the anastomosis. The practice of routine prophylactic ureteral stenting is not universally accepted, but a meta-analysis of multiple randomized controlled studies and case series found that renal transplants with stented extravesical ureteroneocystostomies have significantly lower urologic complication rates than those with non-stented anastomoses [13]. Typically, the bladder detrusor musculature is reapproximated over the mucosa-to-mucosa anastomosis (Figure 55.3) to provide a potential antireflux mechanism [5,9] and prevent excess tension on the anastomosis when the

bladder is distended. Care is taken to avoid creating an excessively tight tunnel potentially leading to obstruction.

A ureteroneocystostomy allows subsequent use of the native ureter(s) should a complication requiring revision of the urinary drainage arise. Initially performing a ureteroureterostomy may be preferable in cases where the recipient bladder is extremely atrophic, inaccessible, or otherwise not suitable for anastomosis. If the donor ureter is ischemic or otherwise deemed not usable, a pyeloureterostomy may be performed. Care must be taken to preserve adequate blood supply to the native ureter in the course of mobilization in preparation for anastomosis to reduce the incidence of subsequent leak or stricture. Anastomosis involving the native ureter is often technically demanding and generally performed over an indwelling stent. If both the donor and recipient ureters appear unsuitable for use, a pyelovesicostomy is a potential consideration. To allow the bladder and a short ureter or renal pelvis to approximate without tension, it may be necessary to mobilize the bladder and perform a psoas hitch or Boari flap [2]. In cases where the donor kidney is found to have double ureters, two separate ureteroneocystostomies may be performed. If the ureters are in very close proximity or the bladder is not amenable to a second cystotomy, it may be preferable to sew the medial walls of the ureters together with absorbable monofilament after spatulating the ureters and then perform a single anastomosis to the bladder. In cases where the recipient has a history of a bladder augmentation or urinary conduit created from bowel or stomach, it is essential to give adequate forethought to the urinary drainage. Important considerations include selecting the appropriate recipient structure to which to anastomose the transplant ureter, blood supply of the augmentation or conduit, and on which side of the recipient to place the kidney. Generally, more complex urinary reconstructive procedures are performed over a protective indwelling ureteral stent.

Closure

The abdominal wall closure receives relatively little attention but is an integral part of the operation, potentially affecting long-term outcome. The position of the graft should be oriented to avoid obvious twisting, kinking, or obstruction of vessels or ureter. In cases where the recipient's extraperitoneal space is relatively small and there is concern that allograft perfusion may become compromised once the fascia is closed, consideration may be given to opening the peritoneum widely to allow the kidney to rest intraperitoneally. Drains are not routinely placed at the time of operation but may be considered in cases where there are heightened concerns for perigraft collection of blood, lymph, or urine [2,4,9].

Special circumstances

Pediatric recipients

For pediatric recipients, the exposure and vessels utilized for transplantation vary with patient size. Very small recipients weighing less than 15 to 20 kg may be best served with a transperitoneal vertical midline incision along with mobilization of the right colon to allow access to the proximal iliac vessels, distal aorta, and inferior vena cava for vascular anastomoses [14,15]. At the completion of the procedure, the kidney is allowed to rest on the psoas muscle and the ascending colon is placed back over the anterior surface of the kidney [2,5]. As recipient age and size increases, the incision should still be planned to allow the option to use the common iliac vessels, aorta, or vena cava if the need arises. If the lumen of the vascular anastomosis is limited by the diminutive size of the child's vasculature, it has been suggested to perform at least part of the anastomosis with interrupted suture to allow it to grow with the child and avoid a relative stenosis in the future [2].

Pediatric-en-bloc donor kidneys

Pediatric-en-bloc kidneys, as the name implies, are determined to be too small to be transplanted as single kidneys and are therefore maintained together as a unit on a segment of donor aorta and vena cava to allow the vascular anastomoses to be performed using these more reasonably sized conduits. Importantly, the capacity to technically perform anastomoses using pediatric kidney vessels is not at issue, as vessels of this size are well within the capability of most experienced transplant surgeons. However, small vascular anastomoses are less likely to expand and facilitate compensatory growth as the recipient and kidney grow, and experience has generally indicated that kidneys from donors less than 15–20 kg fare better in the long term when implanted en bloc rather than individually. Commonly, the suprarenal ends of the aorta and cava are oversewn and the infrarenal aspects of the aorta and inferior vena cava are sewn to the recipient external iliac vessels in end-to-side fashion [2]. The ureters may be implanted separately into the bladder or they may be spatulated and sewn together, as described previously. An alternate technique for revascularization of pediatric-en-bloc kidneys describes en bloc interposition of the donor aortic and caval segments into the recipient iliac vessels [16]. If cross-sectional area of the vascular anastomosis is limited due to small caliber of the donor vessel, consideration should be given to interrupting at least one side of the anastomosis to allow expansion of the anastomosis with growth of the graft over time [2].

Dual adult kidney transplants

Dual adult kidney transplantation, that is the placement of both kidneys from a deceased adult donor with marginal renal function into a single recipient, recently has been developed as a means of utilizing kidneys with marginal nephron mass (typically from extended criteria donors) for a patient in need of substantial clearance. This has been seen as one response to the shortage of available donor organs and resultant prolonged waiting times to transplant [17]. During this procedure, the transplantation of both donor kidneys may be carried out utilizing both right and left recipient iliac vessels through a lower midline incision via either an extraperitoneal or transperitoneal approach or through bilateral lower quadrant incisions [18,19]. More recently, increased experience with a technique of dual kidney transplantation implanting both grafts into the same iliac fossa extraperitoneally via a Gibson incision has been reported. This is reported to reduce operative time and trauma in comparison to the classic bilateral dual kidney transplant and leaves the contralateral iliac fossa intact for a future transplant if needed [20]. Outcomes from this approach have not definitively established the benefits of this over single kidney transplantation, but the utilization of "two for one" transplants maintains intuitive appeal in some centers.

Early postoperative period

In the immediate postoperative period, the Foley catheter is routinely left in place to decompress the bladder for 2–4 days. The catheter may remain for a longer period of time in patients with a difficult or tenuous urinary anastomosis, or in cases where a dysfunctional non-compliant bladder would subject the fresh

anastomosis to excessively high voiding pressures. If there is concern for a potential urine leak, a cystogram may be performed to document absence of extravasation of contrast prior to removal of the catheter. The ureteral stent in some cases is attached to the indwelling catheter at the time of transplant and is then removed along with the urethral catheter relatively early in the postoperative course. Otherwise it is routinely removed cystoscopically within the first few months post transplant. Drains, when placed, are typically removed when output has decreased to an acceptable level. Persistently high drain output should be analyzed for creatinine level to evaluate for a potential urine leak.

Technical complications

Improvements in surgical technique over the years have resulted in substantial reduction in the rate of technical complications associated with renal transplantation. The incidence of technical problems following kidney transplant is much lower than that associated with liver or pancreas transplant. However, recent improvements in immunosuppressive therapy have also brought about concomitant decreases in graft loss due to acute and chronic rejection. As a result, surgical complications remain a relatively important cause of graft loss following transplant [21].

Early postoperative problems

As with any other major abdominal procedure, the potential for early postoperative bleeding exists and should be suspected if any of the typical signs or symptoms present, such as tachycardia, hypotension, oligoanuria, excessive pain, tenderness, fullness, or mass at the operative site. Serial labs will typically reveal a decreasing hemoglobin and hematocrit, but, in cases of acute hemorrhage, may be unrevealing. As such, the diagnosis of hemorrhage is largely a clinical diagnosis and should be considered in any situation of hemodynamic instability. Potential sources of hemorrhage include a vascular anastomosis, the allograft itself, such as an uncontrolled vessel in the hilum or biopsy site, or the recipient operative field, such as a torn vessel in the retroperitoneal fat or abdominal wall musculature. Bleeding is often self-limited, not detrimental to graft function, and manageable by conservative medical measures. However, significant or persistent bleeding, as reflected by sustained hemodynamic instability, ongoing transfusion requirement, or graft compromise as a result of compression merits consideration for a return to the operating room. Commonly, an active bleeding source is not identified upon re-exploration. However, reoperation allows evacuation of hematoma to relieve compression of the allograft, vessels, and ureter, and removes a medium for potential future septic complications. An opportunity is also afforded to inspect the integrity of the allograft and its anastomoses and obtain a biopsy in cases of poor function. In general, re-exploration is far superior to exsanguination or the long-term consequences of a large undrained hematoma.

Sudden oliguria/anuria in the immediate postoperative period demands ruling out a vascular catastrophe, that is allograft thrombosis as discussed below, and should also prompt a careful evaluation of the urinary drainage system to diagnose and remedy relatively common mechanical problems such as catheter occlusion due to kinking, displacement, or clots. The patient with a malfunctioning catheter will often complain of a full bladder. Thus, any patient complaining of bladder fullness or pain should have the patency of their catheter evaluated. Hematuria is often noted in the early postoperative course. It is usually self-limited and typically resolves without intervention. Although often appearing grossly bloody, it usually does not result in substantial blood loss requiring transfusion. Hematuria is more frequently problematic due to formation of clots, which obstruct the flow of urine via the catheter and may therefore stress the newly created ureteroneocystostomy. Clots are generally manageable by gentle irrigation of the Foley catheter with sterile water or saline. In some cases it may be necessary to replace or upsize the urinary catheter. It is desirable to avoid cystoscopy, aggressive manual bladder irrigation, or unmonitored continuous bladder irrigation systems in the early post-transplant period which could lead to disruption of the ureteroneocystostomy or bladder rupture [22].

Vascular complications

Vascular complications have been reported to occur in up to approximately 15% of patients following renal transplantation and may result in significant morbidity [23,24]. They include a variety of complex problems, such as allograft arterial or venous thrombosis, transplant renal artery stenosis (TRAS), arterial dissection, arteriovenous fistula, and pseudoaneurysm.

Allograft thrombosis

Early graft thrombosis occurs in approximately 2% of renal transplants [3,25,26] and has been reported to account for more than one-quarter of all renal allograft losses within the first year [27]. It usually occurs within 10 days of transplant [21,26]. Clinical hallmarks of thrombosis include the abrupt onset of anuria and loss of function or primary non-function of the organ. However, its detection is difficult in patients who have residual native kidney function, as native urine output will continue. Venous thrombosis is more frequent, and may be manifested by an enlarged and tender allograft and occasionally graft rupture [3,21,27,28]. Arterial thrombosis may be more occult and present without pain or allograft swelling [3,27]. With progression, both artery and vein may become occluded with thrombus and the site of origin may not be distinguishable [27].

The only intervention that can definitively rule out a vascular thrombosis in time to salvage the kidney is re-exploration. Thus, any reasonable concern for arterial or venous thrombosis should prompt a discussion of re-exploration with the attending surgeon early in the evaluation. Classic presentation for thrombosis (e.g. brisk urine output that abruptly stops without evidence of catheter malfunction) should lead to immediate re-exploration without additional diagnostic maneuvers. The window of opportunity for salvage of a thrombosed kidney is brief, 1–2 hours, and time spent confirming a diagnosis usually leads to graft loss.

Prompt Doppler ultrasound is often the preferred modality for initial evaluation when renal allograft vascular patency is in doubt, but the index of suspicion is low. The relatively superficial position of the transplant and normally robust flow make it conducive to effective sonographic interrogation. Ultrasonography is generally readily available, expeditious, portable, cost-effective, and avoids ionizing radiation and nephrotoxic contrast. Ultrasound techniques are very accurate for diagnosing vascular thrombosis, but delay in their acquisition or interpretation can make their diagnostic capabilities moot. Thus, an ultrasound obtained for real concern of a vascular complication should be considered an emergent procedure. Figure 55.4 shows examples of normal and aberrant flow waves.

Sonographic findings in the case of renal vein thrombosis typically include a swollen edematous allograft and lack of venous flow.

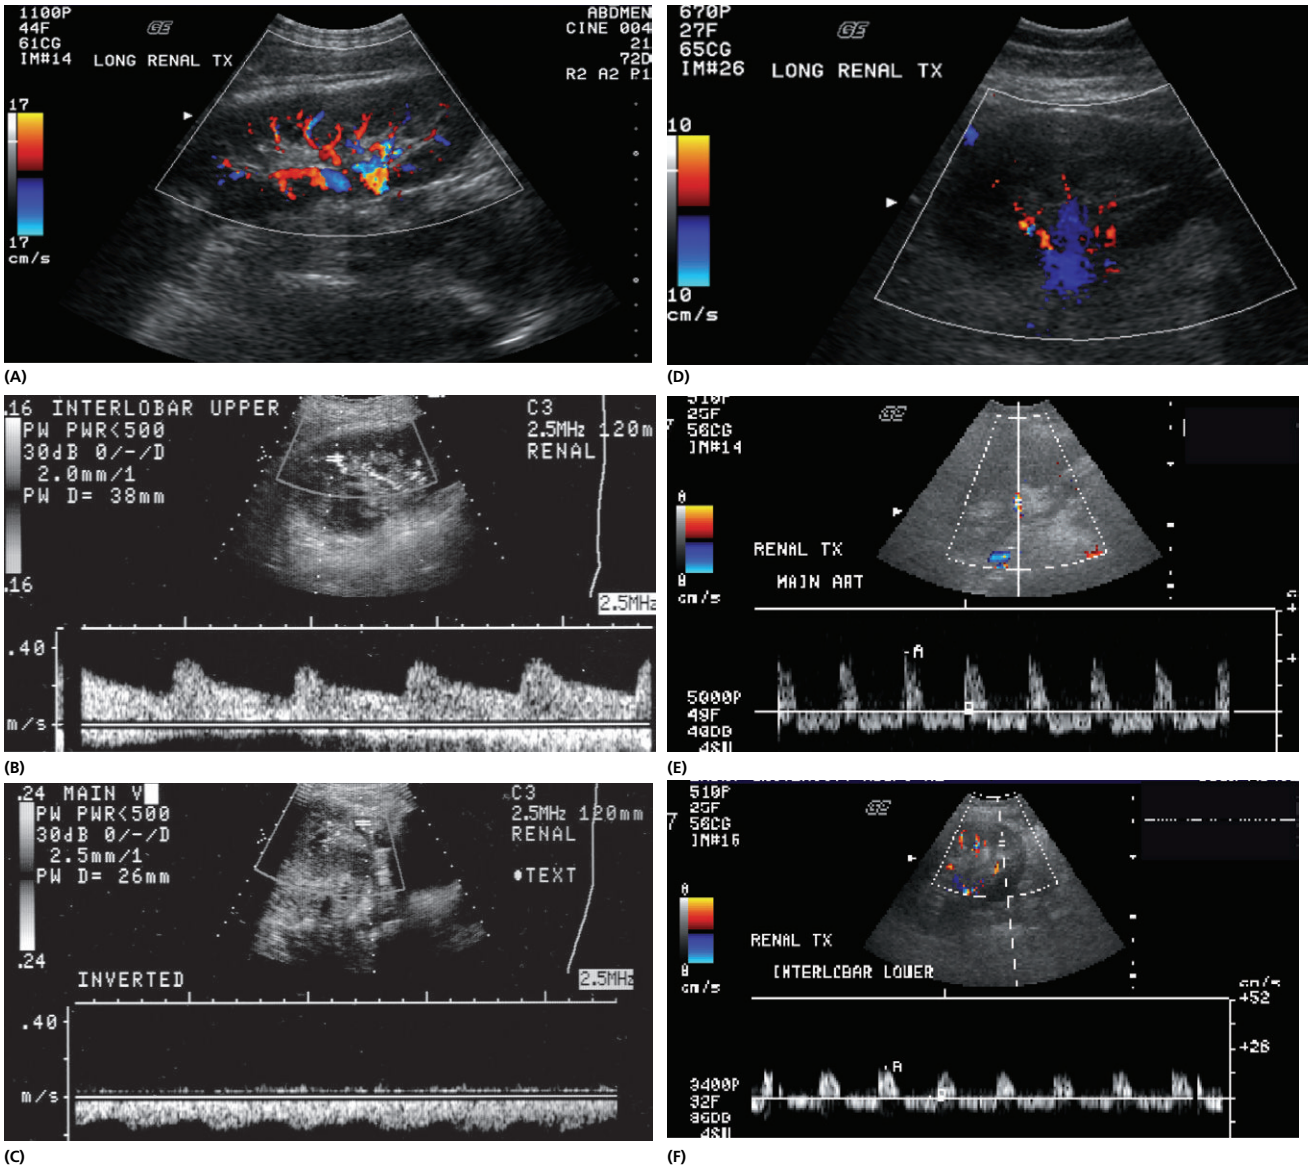

Figure 55.4. Ultrasound visualization demonstrating normal flow (A, B, and C) and the findings characteristic of venous thrombosis (D, E, and F). Note that in the normal situation, there is (A) a bright Doppler signal throughout the entire kidney, (B) a brisk upstroke of the arterial waveform with continuous flow through diastole, and (C) an easily detected continuous venous waveform. It is important to note that during venous thrombosis, (D) there may still be some flow detectable in the graft, although it is attenuated, (E) the arterial waveform may be present, but the arterial diastolic flow is reversed, and (F) no consistent waveform for the vein is seen (in this case an interlobar artery is seen with reversal of diastolic flow). Importantly, detection of flow without characterization of the proper waveforms *does not* rule out a vascular thrombosis.

Rarely, filling defects may be visible in the veins. Importantly, an arterial waveform may be present in patients with complete venous thrombosis, and thus arterial "flow" does not rule out venous occlusion. Due to outflow obstruction, the arterial waveforms show high resistive indices with reversal of diastolic flow. A proper arterial waveform should be accompanied by continuous diastolic component of flow (Figure 55.4), and in the absence of diastolic flow, venous thrombosis should be strongly considered, and with it, re-exploration. In the case of renal artery thrombosis, the allograft may appear small in size with filling defects and lack of flow in the renal artery [23]. Urgent surgical re-exploration with thrombectomy or less often catheter-directed thrombolytic techniques provide the only hope for allograft salvage when allograft arterial or venous thrombosis occurs, but in the majority of cases the organ is lost [21].

Catheter-directed thrombolytic therapy has been reported to be successful in managing selected cases of allograft thrombosis [29] but may be contraindicated in the early weeks following transplant due to increased risk of bleeding from fresh suture lines [23,24,29]. It is possible for only a branch of a renal artery or one of multiple renal arteries to thrombose, resulting in a wedge infarct or ureteral ischemia. This situation may have a more subtle clinical presentation and be manifested by poor function, hypertension, or urine leak [21]. Potential technical causes of allograft thrombosis include an intimal dissection, luminal compromise due to a twist or kink in a vessel or poor suturing technique, or extrinsic compression

such as from hematoma or lymphocele. Size mismatch between donor and recipient vessels (especially in pediatric transplants) and complex multiarterial reconstructions appear to be risk factors for thrombosis, as are hypotension, acute tubular necrosis, and rejection [26]. Often there is no technical factor or other reason found to explain this unexpected and seemingly random occurrence.

Previous reviews have reported numerous diverse markers of patients at increased risk for renal allograft thrombosis, including prior history of venous thrombosis or vascular disease, diabetes mellitus, systemic lupus erythematosus, retransplantation, use of peritoneal dialysis or cyclosporine, obesity, and inherited or acquired hypercoagulable states. Identification and better understanding of hypercoagulable conditions recently have resulted in more attention being given to thrombophilia as a potential explanation for allograft thrombosis [3,27]. The question of whether all potential transplant recipients should be screened for identified thrombophilic factors, such as factor V Leiden, prothrombin gene 20210A, or antiphospholipid antibodies, remains unresolved and specific therapeutic protocols to help prevent allograft thrombosis in higher-risk patients have not been validated in adequately powered randomized controlled trials [27,30]. It would seem prudent to at least test certain patients, such as those with lupus or previous significant personal or family history of thrombosis, who clinically appear at increased risk for allograft thrombosis for a hypercoagulable state to improve risk stratification. For patients assessed to be at high risk for allograft thrombosis, such as those with systemic lupus erythematosus testing positive for antiphospholipid antibodies or those with thrombophilia and previous thrombotic events, specific therapies, including heparin transitioned to warfarin and/or aspirin, appear to be beneficial in preventing allograft loss [27,31,32]. In the general transplant population, the incidence of renal allograft thrombosis appears to be decreased by the routine prophylactic use of low-dose aspirin [27,33,34].

Transplant renal artery stenosis

Transplant renal artery stenosis (TRAS) is likely the most common vascular complication following transplant, with a reported incidence of 1 to 23% [35,36]. The wide discrepancy in reported incidence may be attributable to variable diagnostic criteria as well as evolution of diagnostic methods over time. TRAS most commonly is diagnosed from 3 months to 2 years post transplant [3] and usually occurs at or near the arterial anastomosis [3,24]. Multiple etiologies have been reported to be responsible for TRAS, including atherosclerosis present at the time of transplant or progressing after transplant and fibrosis or intimal hyperplasia in response to vascular trauma incurred at the time of transplant. Other technical considerations include poor suturing technique, clamp injuries, flow-limiting arterial dissections or intimal flaps, kinking or twisting of the renal artery, or extrinsic compression [3,37]. A wide array of non-technical factors, such as extended criteria donors, increased donor and recipient age, delayed graft function, induction immunosuppression, ischemic heart disease [38], and CMV infection [39], have also been reported to have an association with TRAS. The clinical presentation of patients with significant TRAS reflects the effects of activation of the renin–angiotensin system [40] resulting from hypoperfusion of the renal parenchyma. Classically, refractory hypertension, edema, heart failure, an audible bruit over the graft, and allograft dysfunction have been described in association with TRAS. The diagnosis is supported by worsening of renal function with the use of renin–angiotensin system inhibitors [3]. It is noteworthy that these clinical findings may be present without TRAS being the cause. Conversely, significant TRAS may occur without any or all of these clinical manifestations being present. Therefore, imaging studies are necessary to help make the diagnosis.

Doppler ultrasound is often the initial diagnostic modality selected due to its sensitivity, ready availability, and non-invasiveness. Findings consistent with TRAS include peak systolic velocity in the transplant renal artery $>$2.0–2.5 m/s and a "parvus–tardus" waveform downstream with decreased resistive index, pulsatility index, and acceleration index and increased acceleration time intrarenally [23,24,41,42]. A velocity gradient of greater than 2 : 1 between the stenotic and prestenotic segments of the artery can also be seen in TRAS [23,24]. MRI or CT may be performed to better characterize and localize the lesion, but the risks of using iodinated contrast or gadolinium must be weighed against the beneficial information gained from the study. The gold standard investigative study continues to be conventional angiography due to the quality of anatomic definition, ability to measure pressure gradients across the narrowing, and potential for therapeutic intervention at the same setting. For TRAS detected by non-invasive techniques, close follow-up with serial ultrasound studies is reasonable if the narrowing is judged not to exceed 60%, if hypertension is adequately controlled on minimal medication, and graft function is satisfactory [3]. Data indicate that selected patients with TRAS can be medically managed without radiologic or surgical intervention and have good long-term outcomes [43]. Multicenter randomized prospective trials are lacking; therefore, recommendations for optimal mode of therapy for any particular patient with TRAS must be tempered by clinical judgment. Clinical deterioration, that is allograft dysfunction or poorly controlled hypertension along with sonographic findings consistent with significant or progressive TRAS or a stenosis of $\geq$80% on ultrasound, with or without clinical sequelae, merit consideration for angiography and intervention as indicated [3]. Angiographic findings consistent with hemodynamically significant TRAS include luminal diameter narrowing of $>$50% or a pressure gradient $\geq$10–20 mmHg across the stenosis [3,21,24].

Percutaneous transluminal angioplasty (PTA) with or without stenting is usually the primary therapeutic intervention for patients with significant TRAS. Technical success rates for TRAS-PTA are commonly reported exceeding 80% with complication rates generally under 10% [3,23,24,44–48]. Complications include arterial dissection, rupture, thrombosis, and rarely graft loss. Contrast nephropathy is another potential consequence and foresight along with careful planning are essential to limit dye load and institute renoprotective measures such as adequate volume status. Clinical success is variably measured in terms of improved renal function and blood pressure control. Although many studies report short-term improvement in hypertension and renal function in the majority of patients, long-term follow-up is limited [45–48]. Restenosis has been reported to occur in 10–60% of patients following endovascular treatment, and stenting appears to be associated with reduced recurrence of stenosis [3,47,49]. Patients with recurrent stenosis may be candidates for repeat PTA and stenting. Generally, stent placement is indicated if there is residual stenosis $>$30% or persistent systolic pressure gradient $>$10 mmHg following angioplasty, recurrent lesions, or in lesions showing high elastic recoil. Complications, such as a flow-compromising dissection or thrombosis of the renal artery, may also be amenable to percutaneous methods, including stent deployment and thrombolysis [3,23].

Surgical management may be favored for patients with TRAS due to arterial kinks, complex atherosclerotic disease, or other lesions considered poorly accessible or not amenable to PTA. These patients, along with those with recurrent or refractory lesions failing endovascular techniques, may require operative intervention as "rescue" therapy [3,24]. Options for operative repair include bypass grafting, resection of the stenotic segment with primary anastomosis, or placement of an interposition graft or patch angioplasty. Although reports claim similar or improved outcomes with surgical repair compared to endovascular techniques [37,48,49], operation for TRAS may be difficult and is associated with a rate of graft loss reported up to 20% [3,21,49]. Therefore, PTA is usually considered first-line therapy due to demonstrating reasonably good efficacy with relatively low periprocedural morbidity, while being less invasive than operation. PTA generally does not preclude subsequent surgical repair. Preanastomotic- or pseudo-TRAS occurs when a hemodynamically significant lesion proximal to the transplant renal artery (i.e. in the ipsilateral common or external iliac artery) limits flow to the allograft and presents with clinical findings similar to TRAS. Proximal TRAS has been reported to occur in up to 2.4% of recipients and appears to be associated with increasing age [23]. It is generally amenable to PTA or stent placement [24].

Postbiopsy arteriovenous fistula and pseudoaneurysm

With the increased frequency of percutaneous renal transplant biopsies in recent years has come recognition of vascular injuries associated with these procedures. Arteriovenous fistulas (AVF) and pseudoaneurysms have been reported to complicate up to approximately 15% of renal allograft biopsies [23,24,50]. Although typically self-limiting, large fistulas can become clinically relevant. An AVF may occur if an adjacent artery and vein are lacerated with resultant persistent flow between the vessels. A pseudoaneurysm may result after injury to an arterial wall. These technical complications may be asymptomatic or present with gross hematuria. A bruit may be audible over the allograft. Hemodynamic alterations in kidney perfusion due to a "steal" phenomenon from an arteriovenous shunt may result in allograft dysfunction. Less commonly, patients may present with high output cardiac failure. Enlarging pseudoaneurysms have the potential to rupture. Doppler ultrasound is usually the initial diagnostic modality to detect these lesions. Findings consistent with AVF include high velocity, low resistance flow patterns with turbulent flow outside the expected vascular boundaries, and an enlarged draining vein. Pseudoaneurysms may appear as anechoic round structures with flow which may be bidirectional [23,24]. Magnetic resonance angiography may be useful in diagnosing these lesions if sonography is inconclusive [51]. Most of these lesions may be managed conservatively [3].

It is believed that the majority (up to 70%) of AVF spontaneously resolve, usually within weeks or months [52]. Intervention is indicated for these iatrogenic complications; however, if clinical manifestations occur or if they progressively enlarge. Superselective embolization is the treatment of choice [23,24]. This usually involves angiography to identify the AVF or pseudoaneurysm followed by placement of a small catheter into the segmental or branch artery directly feeding the lesion to limit the amount of renal parenchyma infarcted by embolization. Carbon dioxide may be more sensitive than conventional contrast in detecting small AVF [23] and may be utilized to minimize nephrotoxicity . Although transcatheter embolization is usually technically successful with clinical improvement of the patient and preserved allograft survival [23,53], infarction of a clinically significant amount of parenchyma with resultant graft dysfunction is a potential complication [50,52]. Surgery is usually not favored as first-line therapy for intrarenal AVF or pseudoaneurysm as it would typically require partial or even total nephrectomy.

Urologic complications

Urologic complications, the most common of which are ureteral obstruction or urine leak, have been reported to occur in up to approximately 10–15% of transplanted patients [7,8,23,24,54]. These complications are most commonly attributed to ischemia or technical error, but may also be influenced by other factors including immunosuppressive management, inflammation, infection, and poor nutritional status [7,8]. Perfusion of the transplant ureter arises solely from the renal artery(ies) and is no longer supplemented by vessels in the retroperitoneum and pelvis. Therefore, the distal ureter is at risk for poor perfusion with resultant leak or stricture formation. Care must be taken to optimize the ureteric blood supply by preserving lower pole arteries and limiting dissection adjacent to the ureter, particularly in the "golden triangle" between the ureter and lower pole of the kidney [7,8].

Ureteral obstruction

Ureteral obstruction is commonly reported to occur in approximately 3% of transplant recipients [7,8,55], but higher rates approaching or exceeding 10% have been noted in previous series [56,57]. As alluded to previously, ureteral strictures involving the distal ureteral segment or ureterovesical junction are commonly attributed to ischemia compromising the distal transplant ureter or technical error. Ureteral obstruction may also result from other causes, including extrinsic compression from a lymphocele or spermatic cord or intraluminal calculus, clot, or foreign body. More recently, BK polyoma viral infection leading to ureteritis has been implicated in the pathogenesis of transplant ureteral strictures [7,58], and all patients with suspected stricture should be evaluated for BK viremia and/or viruria. Significant ureteral obstruction results in allograft dysfunction manifested by an elevated serum creatinine. Initial evaluation includes allograft ultrasonography, which typically shows hydronephrosis in cases of ureteral obstruction. If bladder distension is also noted, the bladder should be decompressed with a follow-up ultrasound study performed to eliminate obstruction occurring more distal to the ureter as the cause for hydronephrosis and related dysfunction. Persistent hydronephrosis with a decompressed bladder is very suggestive of ureteral obstruction. An antegrade nephrostomy is an appropriate next definitive diagnostic and temporizing therapeutic maneuver in cases of suspected ureteral obstruction. Percutaneous decompression of the collecting system relieves obstruction of the renal parenchyma and allows recovery of renal function. An antegrade nephrostogram provides a roadmap clearly delineating the location and extent of ureteral narrowing. If the obstruction has resulted in acute upper urinary tract infection, the patient should be treated with decompression and antibiotics and pyelography with contrast injection delayed until the infection has been adequately treated to reduce the risk of systemic sepsis. Occasionally, the transplant ureter may be accessed and imaged successfully in a retrograde manner cystoscopically; however, cannulation of the ureteral neoorifice on the anterior aspect of the bladder is typically difficult.

As open reoperation may be technically challenging, endoscopic and percutaneous interventions, including balloon ureteroplasty and stent placement, are commonly recommended first-line therapeutic measures for ureteral strictures. Short segment lesions

occurring distally at or near the ureterovesical junction and developing relatively early (≤3 months) after transplant are generally considered amenable to percutaneous techniques and have variable success rates reported at 50% and higher [7,24,55,59]. In contrast, longer, more proximal, and later-occurring strictures are not usually as responsive to minimally invasive techniques with success rates reported below 50% [55,59,60]. Ureteral strictures not amenable to or failing percutaneous intervention are addressed operatively to achieve long-term resolution. If adequate length of healthy ureter remains after resecting the distal strictured segment, ureteroneocystostomy may be repeated. If the bladder is of sufficient quality, it may be mobilized and surgically revised if necessary (i.e. psoas hitch or Boari flap) to allow approximation to the transplant ureter without tension. Ureteroureterostomy, pyeloureterostomy, and pyelovesicostomy are other options for reconstruction of the urinary drainage dependent on condition of the donor ureter as well as the recipient ureter and bladder. The procedure may be difficult and is facilitated by knowing prior to reoperation the orientation of the transplant renal pelvis (i.e. right or left donor kidney) and the status and proximity of native urinary tract structures.

Urine leak

Urine leak has been reported to complicate up to approximately 3–5% of renal transplants [7,8,23,24]. Patients may present with pelvic pain exacerbated with voiding, as well as swelling and tenderness over the allograft. There may be discharge of urine from the transplant incision as well as allograft dysfunction. The most common sites for urine leak include the distal ureter and ureteroneocystostomy due to failure of the anastomosis as a result of technical factors, or, more commonly, ureteral ischemia [7,23,24]. If due to technical error, the leak may often become apparent within the first 24 hours post transplant. A leak resulting from ischemic necrosis typically manifests within the first few weeks [7]. Wound drainage can be identified as urine by its elevated creatinine level relative to serum. A urine leak will result in a perigraft fluid collection on ultrasound or computed tomography and may be confirmed by sampling of the fluid. Extravasation may be noted on retrograde cystography, antegrade pyelography, or radionuclide imaging in cases of an active urine leak. Very early post-transplant leaks are often repaired surgically as reoperation is relatively straightforward in the presence of intact and identifiable tissue planes with minimal inflammation and adhesions. If the distal ureter appears well perfused, the leak may be simply repaired by placing additional sutures. Prolonged need for a nephrostomy tube, stent, percutaneous drain, and Foley catheter may be potentially avoided in these cases. If underlying ureteral necrosis is responsible for the leak, open repair is usually necessary to achieve a satisfactory long-term result. The ureter must be cut back to healthy viable tissue and an appropriate reconstruction performed. In cases where it is felt that the leak will likely heal without reoperation or the likelihood of successful reoperation to repair the leak is low, decompression and/or diversion of the urine stream is performed to reduce pressure and flow of urine across the leak to facilitate closure. Non-operative interventions typically include antegrade nephrostomy and double-J ureteral stent or nephroureteral stent placement, catheter drainage of the bladder, and percutaneous drainage of any associated urinoma. Percutaneous and endoscopic techniques are reported to be often successful in resolving appropriately selected cases of urine leak without need for open reoperation [7,60].

Lymphocele and other perigraft fluid collections

Perigraft fluid collections are quite common post-transplant, occurring in up to approximately 50% of recipients [61,62]. It is notable that the majority of these collections are inconsequential incidental findings revealed by commonly performed imaging such as computed tomography or ultrasonography. It is estimated that only 15–20% of these will be of clinical significance and require intervention [23,24,62,63]. In the absence of associated clinical findings, the vast majority may be safely observed without intervention. Principles of management for hematoma and urinoma have been previously discussed. An abscess may be suspected if the patient clinically presents with findings consistent with infection, such as fever, pain, swelling, and tenderness at the site, and imaging reveals a concerning fluid collection. Gas noted within the collection or enhancement of the wall is suggestive of infection. CT or ultrasound-guided sampling of the fluid for gram stain, culture, and sensitivity confirms the diagnosis and guides antimicrobial therapy. Along with antibiotic therapy, definitive management may include simple aspiration for small non-loculated collections. Larger infected collections may require a percutaneous drain to remain in place until output ceases and the cavity collapses. Large, complex infected collections are often best managed surgically to allow effective drainage of multiple loculations and debridement of non-viable tissue.

A lymphocele is a collection of lymphatic fluid developing in a non-epithelialized postoperative space. The source of the fluid is disrupted lymphatic channels in the operative field or from the allograft itself [3,6]. Meticulous ligation of lymphatics as they are encountered and divided in the course of exposing the external iliac vessels or alterations in surgical technique such as implantation to the common iliac vessels or placement of drains have been advocated to decrease the occurrence of lymphoceles [64,65]. Other modifiable factors, however, such as the alloimmune response as well as specific immunosuppressive agents such as sirolimus, have also been reported to play a role in their development [6,64,66]. In contrast to hematoma, urinoma, and abscess, lymphoceles are generally discovered later in the post-transplant course, usually weeks or months following surgery, with a peak incidence at approximately 6 weeks [62]. They are commonly located adjacent to the lower pole of the kidney posterolateral to the transplant ureter [3]. Large lymphoceles may cause subjective discomfort, such as pain, fullness, or urinary frequency or urgency if impinging on the bladder. Compromise of iliac venous drainage may result in lower extremity edema or deep venous thrombosis. A lymphocele compressing the ureter, transplant vasculature, or graft itself may obstruct urine flow or compromise perfusion resulting in allograft dysfunction. Clinically significant or symptomatic lymphoceles have been reported to occur in 1 to 26% of transplant recipients [10,67,68]. However, as alluded to previously, lymphoceles are often incidental findings detected on routine imaging studies and generally require intervention only if associated with symptoms or complications due to their size or location. The differential diagnosis for an elevation in serum creatinine developing shortly after ureteral stent removal in a recent transplant patient should include an obstructing lymphocele. Allograft dysfunction with hydronephrosis or hydroureter in conjunction with a fluid collection in proximity to the transplant ureter suggests a clinically significant lymphocele. Aspiration is helpful diagnostically: a lymphocele will have a creatinine level similar to that of serum in contrast to a urinoma which typically will have a markedly elevated creatinine level. Improvement in clinical symptoms or graft dysfunction

following evacuation of the fluid collection also supports the causative role of the lymphocele. Further definitive management is usually required as these fluid collections usually return following simple aspiration. A recent review reported a pooled recurrence rate of 59% following simple aspiration with individual series reporting rates from 10 to 95% [10]. Percutaneous drain placement as sole therapy to treat a lymphocele is associated with a 50% recurrence rate [10]. Percutaneous drainage with sclerotherapy has been reported to have success rates between 68 and 100% [23,24], and a recent review reported an overall recurrence rate of 31% with sclerotherapy [10]. Povodine–iodine solution has been commonly reported to be utilized as a sclerosing agent [10]. The use of a wide variety of other agents, including tetracycline, streptomycin, alcohol, bleomycin, or a cocktail of human fibrinogen, bovine protease inhibitor, human thrombin, calcium chloride, and gentamicin, as sclerosants instilled into the collection have been reported in the literature. Multiple treatments may be required to prevent reaccumulation of fluid and clinical resolution may take several weeks [10,23,24]. Some authors have expressed concern over potential nephrotoxicity associated with agents such as povodine–iodine and risk of infection associated with repeated aspiration or prolonged catheter drainage [3,10]. Operative management of clinically significant post-transplant lymphoceles is often preferred due to reported high rates of immediate clinical success with lower recurrence compared to aspiration, drain placement, or sclerotherapy [3,10]. Additionally, the discomfort and potential complications associated with a longstanding percutaneous drain are avoided. Operation consists of marsupialization or creation of a "peritoneal window" out of the lymphocele wall. This may be performed either as a minimally invasive laparoscopic procedure or as an open procedure utilizing the previous transplant incision or a lower midline incision. A recent review reported overall recurrence rates of 8% and 16% following laparoscopic and open operations, respectively [10]. The laparoscopic approach may be preferable for most cases due to decreased morbidity and lower length of stay associated with minimally invasive surgery [10]. Computed tomography is invaluable in preoperative planning to help determine the spatial relationship of the collection with adjacent vital structures such as the allograft and iliac vessels and transplant ureter to help avoid intraoperative complications. Use of ultrasonography in the operating room is also useful to positively identify the lymphocele as well as a safe point to enter it. The procedure is facilitated if the fluid collection is distended and the bladder is empty. The fenestration in the cavity wall should be at least 5 cm in diameter if possible. Tacking a mobilized pedicle of omentum in the cavity through the window has also been reported to help prevent fluid reaccumulation [3,69].

Summary

The techniques for kidney transplantation are well established, time tested, and have changed relatively little in the past several decades. Eventual success should be uniformly expected for every patient, and in large part relies on anticipation of common technical concerns with the iliac vasculature and the bladder and timely diagnosis and intervention when complications arise. A high index of suspicion is required for recognition of vascular complications within a time frame that allows for graft salvage, and a surgeon should have a low threshold for re-exploration in the rare circumstances that technical complications are suspected.

CHAPTER 56

Liver Transplantation Procedure and Surgical Technique

Joseph F. Magliocca, Steven I. Hanish, Eugenia K. Page, and Stuart J. Knechtle
Emory University School of Medicine, Atlanta, GA, USA

Introduction

Liver transplantation is a technically demanding procedure, made even more complex because it is generally performed in patients with portal hypertension, coagulopathy, and severe underlying illness. The surgical team must assign a premium to attention to hemostasis, avoidance of intraoperative misadventures, and expeditious performance of the surgical procedure. Clear communication among team members, including the anesthesia, surgical, and nursing components, is practiced. Use of a presurgical checklist or "timeout", preview of the surgical plan in the operating room, and review of the procedure at its conclusion add to the safety and success of the operation. Although liver transplantation is a long and complex surgical procedure, it nevertheless comprises a series of discrete steps which are detailed below. Each step must be completed satisfactorily to assure a favorable outcome for the patient.

The surgical techniques of liver transplantation have evolved considerably over the past 30 years and include better instrumentation, standardization of the operation, improved intraoperative management of fluid and blood components, improved hemodynamic monitoring, and better selection of donors and recipients. All these refinements have led to better outcomes, with the anticipated patient survival at 1 year greater than 90%, compared with 75% only 20 years ago. We herein summarize the technical approaches to the surgical aspects of adult liver transplantation that are commonly used at our center.

Back-table preparation of liver allograft

Preparation of the donor liver for implantation is a critical component of the implantation operation. Once the liver is removed from the donor by the procuring surgeon (see Chapter 19), it must be prepared to facilitate its transplantation. The procuring surgeon is careful during organ extirpation to avoid injuring the important vascular and parenchymal structures that are necessary for the operation. As a safety technique, and depending on the other organs procured, the procuring surgeon will commonly leave the diaphragm attached to the bare area of the liver, leave the aorta intact, and leave the pancreatic tissue attached to the bile duct and hepatic artery. All of this extraneous tissue must be removed during the back-table preparation.

The allograft preparation is performed in the operative suite on a separate, sterile back table (or "bench"). The donor liver is placed in an ice-lined basin along with its surrounding preservation solution. We begin by removing the diaphragmatic attachments to the bare area of the liver with scissors. Once this is accomplished, the supra- and infrahepatic vena cavae are skeletonized and small retroperitoneal perforators are secured with silk ligatures. The dissection is continued down to the hepatic vein confluence. The diaphragm is removed from the hepatic vein confluence and the phrenic veins are tied or oversewn. The adrenal vein is also tied or oversewn to prevent bleeding upon recirculation. Any remaining cardiac muscle is removed from the upper cuff of vena cava.

The caudad portion of the vena cava is then addressed. If one expects to replace the retrohepatic vena cava via the caval interposition technique, no additional preparation is necessary on the bench. If a piggyback technique is planned, the transplant surgeon must have a plan for controlling the lower portion of vena cava once recirculation has occurred. A number of strategies can be employed, including use of heavy ties or a vascular stapler after recirculation. Another popular technique is to oversew the lower vena cava cuff and place a tube into the vena cava that will be removed upon recirculation. Upon removal, the suture is then tied and the lower vena cava is controlled.

The hepatic artery is then skeletonized from the aorta up to the gastroduodenal artery (GDA). Dissection is not continued above this point due to the risk of injury to the hepatic lobar vessels. Care is taken to identify any aberrant arterial anatomy, which can be present in up to 20% of the population [1]. The most common two variants are a replaced right hepatic artery emanating from superior mesenteric artery or a replaced left hepatic artery originating from the left gastric artery. The handling of these variants will be addressed in the next section of this chapter.

The portal vein is skeletonized up to the portal vein bifurcation. Surrounding lymphatic tissue is removed and care is taken not to injure the hepatic artery or bile duct. At this point, many surgeons will place a silastic tube into the portal vein and secure it with a silk tie to facilitate flushing prior to reperfusion of the new organ.

The common bile duct is not manipulated on the bench. The vascular supply to the bile duct is variable, but it generally runs along the lateral and medial sides of the bile duct at three o'clock and nine o'clock. It is therefore crucial to leave the surrounding tissue associated with the duct to avoid bile duct ischemia [2].

If it is anticipated that either arterial or venous conduits will be necessary for the revascularization of the donor liver, a donor iliac

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

artery graft or iliac vein graft is prepared on the back table. Branches or defects are ligated or oversewn as needed. Vessel integrity is assessed by injecting heparinized saline under pressure to identify leaks. The grafts are then stored in University of Wisconsin solution on ice for future use. Vessels that are not used are stored in labeled containers in University of Wisconsin solution at 4°C.

Arterial reconstruction

The arterial anatomy of the liver is variable and thorough understanding of the common variations is required to safely prepare a liver for implantation [1].

Replaced right hepatic artery

The replaced right hepatic artery (RRHA) most commonly originates from the superior mesenteric artery (SMA) before the first jejunal perforator. Because it is not anatomically in continuity with the common hepatic artery, the vessel must be reconstructed so that a single arterial trunk can be anastomosed during the recipient phase of the operation. There are two common reconstructions for this aberrant anatomy: (1) RRHA to the donor gastroduodenal stump, and (2) SMA stump to the base of the celiac axis.

Preparation of the arterial vasculature for reconstruction is performed as described earlier. For reconstructing the RRHA to the GDA, the stump of the GDA is left patent and cut back to healthy tissue. Similarly, the RRHA is cut back to an appropriate length. Under loupe magnification an end-to-end anastomosis is performed between the two cut ends with fine polypropylene suture (Prolene; Ethicon Inc., Somerville, NJ). Care is taken to orient the main hepatic artery correctly to avoid twisting once reconstruction is complete (Figure 56.1A, option 1).

The second common vascular reconstruction option can only be performed when the procuring surgeon provides the RRHA on a segment of SMA. In this case, the SMA and RRHA are skeletonized up to the level of the common bile duct. The celiac axis is then cut back to an appropriate length and the SMA stump is sewn to the cut end of the celiac axis with Prolene suture (Figure 56.1A, option 2). It is imperative to ensure that both the common hepatic artery and the RRHA are oriented correctly to avoid twisting. In addition to these two common techniques, the RRHA can also be sewn to the splenic artery stump. The choice of splenic versus GDA stump for implantation of the RRHA depends on the lumen diameter, the length of the vessels, and other anatomic considerations.

Replaced left hepatic artery

The replaced left hepatic artery (RLHA) most commonly originates from the left gastric artery. For this reason, it is imperative to identify the artery in the gastrohepatic ligament, if present, during the procurement operation. The procuring surgeon should leave the left gastric artery intact and supply the benching surgeon with all of the tissue from the lesser sac of the stomach. This technique ensures that the RLHA will remain unharmed.

On the bench the common hepatic artery is skeletonized up to the GDA. Attention is then focused on the left gastric artery, following it until the RLHA branches off toward the umbilical fissure. The distal end of the left gastric artery beyond the RLHA is tied with silk ligatures and the remaining small branches of the RLHA are tied. Gentle flushing of the RLHA can identify small branches that need to be controlled with silk ties. Diligence on the bench will prevent bleeding issues during arterial recirculation. The RLHA is usually not shortened, even though it may seem redundant (Figure 56.1B).

There are other less common anatomic variants that may be encountered and each should be addressed individually. The main focus of back-table vascular reconstruction is to allow for a single

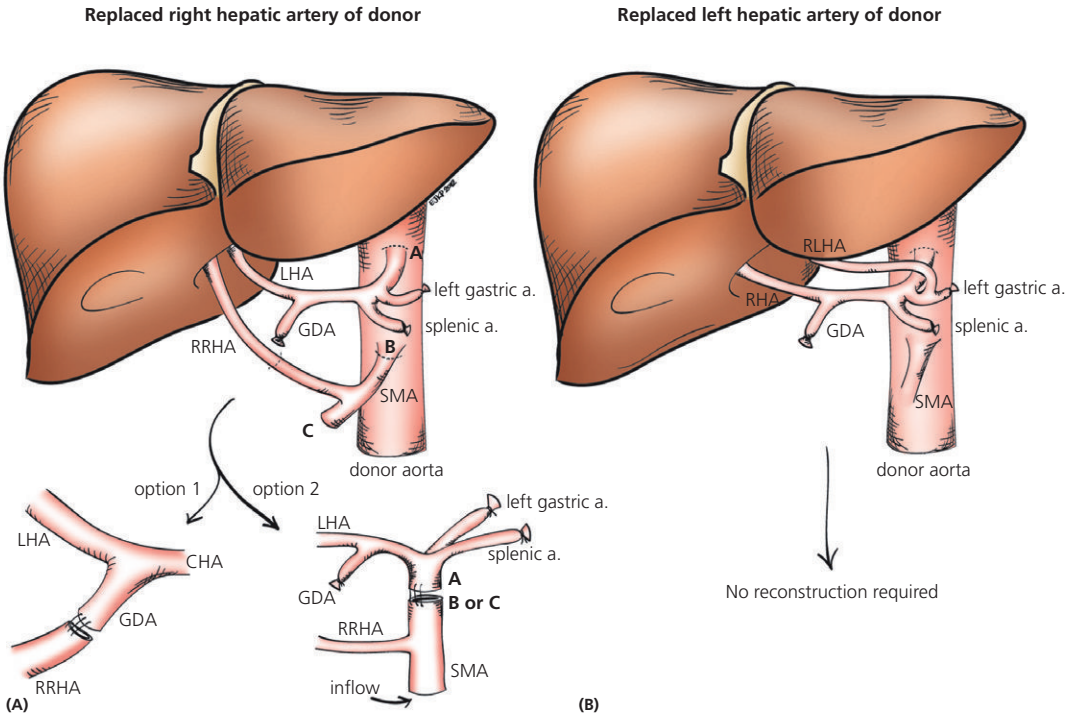

Figure 56.1. Arterial anatomy of donor liver with reconstruction options. RRHA, replaced right hepatic artery; LHA, left hepatic artery; GDA, gastroduodenal artery; SMA, superior mesenteric artery; CHA, common hepatic artery; RHA, right hepatic artery; RLHA, replaced left hepatic artery.

arterial anastomosis to be performed during the hepatic implantation. This anastomosis should be large enough to ease implantation and to avoid thrombotic complications.

Recipient hepatectomy

Control of bleeding

The recipient hepatectomy is generally considered the most difficult aspect of liver transplantation and the technical aspects of this portion of the surgery will significantly influence the patient's postoperative course and overall outcome. Particular attention is given to minimizing blood loss and the need for blood product transfusion, as this parameter significantly affects hemodynamic stability, renal function, pulmonary function, immune function, and cost.

Patients with severe portal hypertension tend to bleed considerably during hepatectomy, and this is exacerbated by the underlying coagulopathy due to liver failure and thrombocytopenia due to splenomegaly and splenic sequestration. Approaches to minimizing blood loss include maintenance of a low central venous pressure (CVP) during the procedure or at least until liver reperfusion is complete. Bleeding tends to be less when the CVP is <10 mmHg or as low as the patient will tolerate while maintaining hemodynamic stability. A cell saver may be used to allow for the re-administration of autologous blood aspirated during the case. While cell savers may minimize the need for allogeneic blood transfusion, it should be noted that cell saver blood must be treated with either heparin or citrate, which results in additional metabolic demands on the liver to clear these anticoagulants. The degree of care taken in dissection, with meticulous attention to hemostasis at all times, can greatly impact the need for blood transfusion. Technical aspects include liberal use of electrocautery and argon beam cautery, although not at the expense of thermal injury to blood vessels and biliary structures.

Pharmacologic approaches to reduce bleeding include the use of aminocaproic acid (Amicar; Xanodyne Pharmaceuticals, Inc., Newport, KY) for patients with evidence of fibrinolysis. Aprotinin is used in some practices to reduce blood loss prophylactically, although it has been associated in some cases with diffuse thrombosis [3]. Studies suggest that tranexamic acid may be used either prophylactically or as an alternative to Amicar. In our practice we avoid the use of these agents except in the event of fibrinolysis. In patients with fibrinolysis a loading dose of 5 g of Amicar is given and continued as an intravenous infusion of 1 g/h until resolution of clot lysis. A hemoglobin level of 8 mg/dL at the end of the liver transplant procedure provides adequate oxygen-carrying capacity and reduces the viscosity of blood such that hepatic artery thrombosis is less likely. Plasma and platelets are administered only if there is clinical evidence of excessive bleeding. The international normalized ratio (INR) likewise is not corrected unless there is evident bleeding, because the INR is also a useful means to monitor liver synthetic function post-transplant. The thromboelastogram has been used to measure the intraoperative coagulation status of patients and may be useful to guide the appropriate administration of blood products [4].

Hepatectomy

The abdomen is opened through a bilateral subcostal incision (chevron), often with a vertical midline extension up to the xiphoid process as needed for exposure of the suprahepatic inferior vena cava (IVC). The umbilical vein is doubly ligated and divided. An alternative incision is a right subcostal "hockey-stick" incision, which avoids extension to the left of midline. A potential advantage of this incision is improved wound healing compared with a T-shaped incision. A strong retractor is placed beneath the right and left costal margins, which are retracted cephalad to expose the liver.

The left triangular ligament is taken down with cautery, taking care to avoid the phrenic veins and left hepatic vein as well as injury to the stomach or spleen. The gastrohepatic ligament is inspected for a replaced left hepatic artery and divided with electrocautery. If present, the replaced left hepatic artery is doubly ligated. Adhesions to the liver from previous surgery or due to peritonitis are taken down with electrocautery. This may take considerable time depending on the severity and density of the adhesions. Care is taken to avoid injury to the transverse colon and duodenum. The cystic duct and artery are ligated and divided if the gallbladder is present. The porta hepatis is exposed and the peritoneal surface and lymphatics overlying the vascular structures and common bile duct are divided. The left and right hepatic arteries are dissected with care to avoid intimal injury or dissection. These structures are doubly ligated and divided adjacent to the liver.

The common bile duct is divided adjacent to the liver, and care is taken to preserve the blood supply of the remaining recipient common bile duct. The portal vein is then dissected free of surrounding connective tissue and lymphatic tissue such that it is ready to be cross-clamped. At this point, the right triangular ligament is taken down with electrocautery, taking care to avoid diaphragmatic injury or injury to the right adrenal gland. The dissection can remain anterior to the right adrenal gland and it is not necessary to ligate its main vein entering the IVC. When dissecting near the IVC, care is taken to avoid injury to the right hepatic vein.

Piggyback technique

The caudate lobe is dissected off the retrohepatic IVC by ligating and dividing all accessory hepatic veins. This is aided by rotation of the operating table from side to side. The caval dissection continues cephalad toward the main hepatic veins. Exposure of the upper IVC may be aided by division of the portal vein as the last structure holding the hilum down. After portal vein division adjacent to the liver, the liver parenchyma can be elevated off the IVC more easily. Again, care is taken during the piggyback dissection of the IVC to avoid injury to the right, middle, and left hepatic veins. When the liver is attached only by the major hepatic veins, these can be cross-clamped with a large Satinsky vascular clamp or a Klintmalm clamp and the liver excised, cutting close to the liver parenchyma to leave as much hepatic vein length as possible. With the liver excised and removed, the retroperitoneal bed and IVC can be inspected for hemostasis prior to implantation of the donor liver.

Caval interposition technique

The infrahepatic IVC is dissected enough to be encircled with a vessel loop or umbilical tape at the level of the caudate lobe and cephalad to the right renal vein and right adrenal vein insertions into the IVC. The suprahepatic IVC is encircled with a red rubber Robinson catheter by passing a clamp or finger behind the IVC at the level of the diaphragmatic hiatus. The advantage of using a rubber catheter is that the posterior jaw of a Klintmalm or similar clamp can be placed within the open end of the catheter, which is then gently withdrawn while guiding the clamp into position around the suprahepatic IVC. The infra- and suprahepatic IVC are clamped with large vascular clamps and the patient is checked for

hemodynamic stability by communicating with the anesthesiology team. If the patient tolerates caval clamping, the IVC is divided both above and below the liver as close to the liver parenchyma as possible. This will maximize the length of IVC remaining for implantation of the donor liver.

Venovenous bypass technique

This method was developed in order to prevent the hemodynamic insult associated with portal vein and IVC clamping [5]. It requires a trained perfusionist, and a BioMedicus (Medtronic Inc, Minneapolis, MN) or equivalent centrifugal pump with the necessary associated tubing. All tubing is primed with normal saline. A "Y" configuration to the inflow tubing is prepared to allow both the portal vein and infrahepatic IVC to be cannulated for inflow. A single outflow cannula to the upper body is placed via either an axillary or jugular vein. Catheter placement may be achieved percutaneously by Seldinger technique or by an open cutdown [6]. Large-bore catheters, such as modified chest tubes, are used for access. The infrahepatic IVC is usually accessed via the femoral or greater saphenous vein. The catheter is advanced cephalad into the IVC. The portal cannula is then placed and secured with an umbilical tape. Great care is exercised to avoid air entry into the circuit as this could result in air embolism. Small air bubbles can also be removed by the addition of a bubble detector to the circuit. All air is removed from the primed tubing and flow is initiated using the centrifugal pump. Optimal flow rates for venovenous bypass differ from patient to patient, but are generally in the 2–3 L/min range. Additional advantages to venovenous bypass include the ability to warm the patient by using a heat exchanger in the circuit, the ability to administer volume and blood rapidly, and the ability to perform hemofiltration via the same circuit, which adds the potential for rapid volume adjustments.

Disadvantages of venovenous bypass include longer operative times, consumption of blood and platelets by the circuit, the potential need for a cutdown for venous access at the groin, axilla, or neck, as well as the associated surgical complications (i.e. lymphocele formation or lymphedema).

Implantation of the whole-organ hepatic allograft

There are numerous techniques and styles in use for hepatic implantation, each with certain advantages and disadvantages. It is important for the liver transplant surgeon to be familiar with many of them because certain techniques may be superior in specific situations. However, here we will discuss the basic steps for liver implantation: vena caval outflow, portal vein inflow, hepatic arterial inflow, and bile duct reconstruction.

Vena caval outflow

Donor vena cava interposition

In the "classic" approach to liver transplantation, the recipient retrohepatic vena cava is excised along with the native liver. This method requires interposition of the donor vena cava in the recipient bed (Figure 56.2A,B). The suprahepatic caval anastomosis is performed first. The anastomosis is performed with 3-0 double-armed Prolene suture. Corner sutures are placed on the left and right and the vessel edges are everted to provide intima-to-intima approximation. A third traction suture is placed in the posterior wall in the middle of the anastomosis to pull the posterior wall anteriorly and provide excellent visibility. The liver is then placed in the hepatic fossa. It is helpful to place an icy laparotomy pad behind the right lobe to support it in the appropriate position. The suture on the patient's left is tied and the posterior wall is sewn

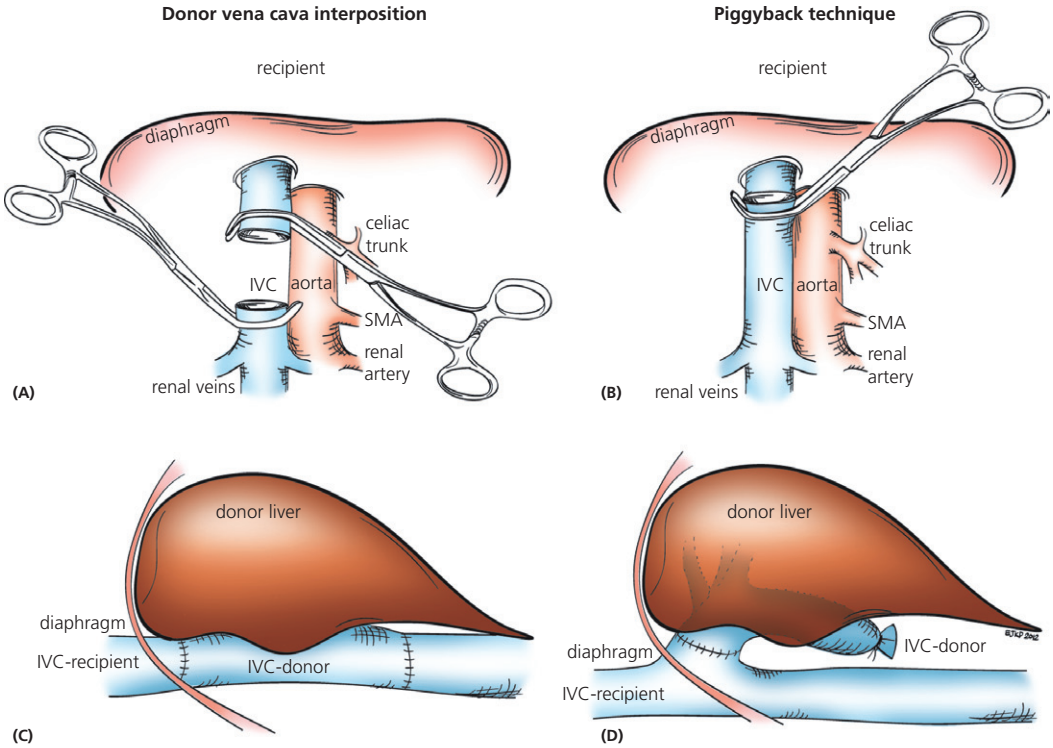

Figure 56.2. Management of vena cava in whole-organ liver transplantation. IVC, inferior vena cava; SMA, superior mesenteric artery.

from inside the vessel from left to right, ensuring good intimal apposition. The middle traction suture is excised when the suture line reaches it. The suture line is carried around the right corner anteriorly for a short distance. The anterior wall is then sewn left to right with the remaining tail, and the suture is secured leaving a 1-cm "growth factor" to prevent purse-stringing and narrowing of the anastomosis [7]. The remaining corner suture is then secured.

The allograft is flushed via the portal vein with 1 liter of ice-cold lactated Ringer's solution containing 10% human albumin, and effluent is evacuated via the graft infrahepatic cava. This serves to remove metabolic wastes that have accumulated during the cold storage interval and washes out the preservation solution. This is particularly critical if the organ has been preserved with University of Wisconsin solution, as this contains a high concentration of potassium that can cause cardiac arrest upon reperfusion. The infrahepatic vena cava anastomosis is performed in an end-to-end manner using 4.0 Prolene sutures using the technique described for the suprahepatic anastomosis. The flush is done prior to completing the infrahepatic caval anastomosis.

Piggyback technique

In the "piggyback" technique the recipient suprahepatic, retrohepatic, and infrahepatic vena cava is completely preserved and only the hepatic veins are clamped (Figure 56.2C,D). This obviates the need for complete clamping of the inferior vena cava. However, this technique results in a more time-consuming hepatectomy since the short hepatic veins must be meticulously ligated [8–10]. A large hepatic venous outflow tract is created by forming a single ostium from the left, middle, and right hepatic veins, which is anastomosed to the graft suprahepatic vena cava (Figure 56.2D). Similar to the caval interposition technique, corner sutures are placed while everting the vessel edges, and a middle traction suture is placed in the posterior wall. The liver is then placed in the hepatic fossa, the left corner suture is secured, and the posterior wall is sewn from left to right ensuring sound intimal apposition. The suture line is carried around the right corner anteriorly as above. Careful suture placement is critical in this location as outflow obstruction is a common pitfall, which can be exceedingly difficult to correct. The middle traction suture is excised. The anterior wall is sutured left to right using the remaining tail, and secured leaving a 1-cm growth factor. The allograft is flushed with 1 liter of ice-cold lactated Ringer's containing 10% human albumin via the portal vein that is evacuated via the graft infrahepatic cava. The donor infrahepatic cava is oversewn or secured with a vascular stapler.

A variation on the piggyback method is the side-to-side cavocavostomy [11]. In this technique, the recipient vena cava is side-clamped longitudinally with a large Satinsky or similar clamp. This results in only partial vessel occlusion. A single ostium is created from the recipient middle and left hepatic veins. It is often helpful to oversew the right hepatic vein for proper alignment, but alternatively it can be included in the anastomosis. The cava is then slit longitudinally for several centimeters from the single ostium, inferiorly. The posterior wall of the donor vena cava is then slit inferiorly for a similar distance. Corner sutures are placed at the superior and inferior-most aspects of the ostia, once again everting the vessel edges for sound intimal approximation. The liver is placed in the right hepatic fossa and rotated to the patient's right. An icy laparotomy pad may be required to support the liver and provide tension-free approximation. The right side of the anastomosis is performed first from the inside of the vessel. A traction suture is placed midway between the cephalad and caudad corners on the posterior (right) wall to provide alignment and excellent visualization. The inferior-most suture is secured and the anastomosis is sewn caudal to cranial. The suture line is carried around the cephalad corner and the middle traction suture is excised. The left wall is then sewn caudal to cranial and the tails secured. No growth factor is required. The remaining superior stay suture is secured. The allograft is then flushed with 1 liter of ice-cold lactated Ringer's containing 10% human albumin via the portal vein, which is evacuated via the graft infrahepatic cava. The donor infrahepatic cava is then oversewn or secured with a vascular stapler.

Portal vein inflow

End-to-end portal venovenostomy

Ideally, portal inflow is provided via the recipient's native portal vein. This can be accomplished in the vast majority of cases because portal vein thrombectomy can generally be performed in the presence of most organized clots. The recipient portal vein is controlled with clamps and the vascular clamp "flashed" to flush any fresh thrombus. The donor portal vein should be cut short to prevent redundancy while recipient portal vein length should be preserved, should future retransplantation be necessary. If there is a size discrepancy between donor and recipient portal veins, the smaller vessel can be spatulated for good size-matching. The anastomosis is then performed with double-armed 6-0 Prolene suture. Corner sutures are placed laterally and the vessel edges are everted to ensure good intimal apposition. A traction suture may be placed in the middle of the posterior wall to aid in alignment and visualization. The suture on the patient's left is tied and the posterior wall is sewn from inside the vessel from left to right, ensuring good intimal apposition. The suture line is carried around the right corner anteriorly for a short distance. The middle traction suture is excised. The anterior wall is sewn left to right with the remaining tail, and the suture is secured leaving a growth factor, which is approximately 75% of the diameter of the vessel [7].

At this point the liver is generally reperfused. The suprahepatic vena cava clamp is removed first to allow retrograde filling of the liver with blood and to check for bleeding from the anastomosis, followed by the infrahepatic vena cava clamp (if the caval interposition technique was used). Any significant hemorrhage is controlled. The portal vein clamp is then removed gradually. Portal inflow is modulated by finger compression while observing the patient's EKG tracing for ST wave changes on the electrocardiogram as well as blood temperature. Portal inflow should be slowed if significant EKG changes are noted or if blood temperature drops precipitously. In cases where there is any question about the quality of portal inflow (i.e. if a portal thrombectomy or jump graft is performed) it is preferable to perform the arterial anastomosis prior to reperfusion. This will ensure hepatic perfusion should portal vein inflow be inadequate.

Pre-existing portal vein thrombosis

Patients with suspected portal vein thrombosis should have preoperative imaging studies so careful operative planning can be carried out. In the majority of patients with portal venous thrombosis, a portal thromboendvenectomy can be performed [12]. Note that thrombectomy is performed *before* beginning the implantation, as it is crucial to have a plan for adequate portal inflow before removing the donor liver from cold storage. In most cases the portal vein thrombus extends down to the splenic vein confluence. The portal vein is dissected circumferentially down to the splenic confluence for secure control. The coronary vein and small pancreatic venous

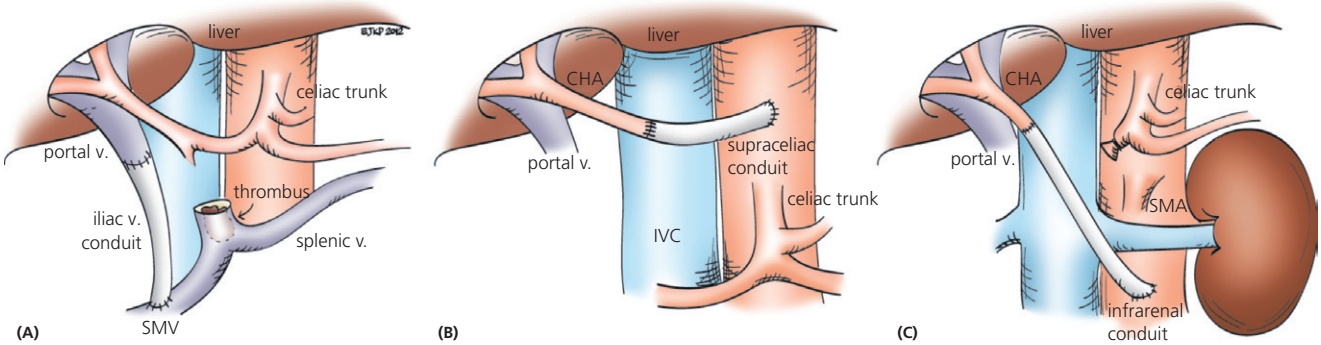

Figure 56.3. Portal venous and hepatic arterial conduit configurations. SMA, superior mesenteric vein; CHA, common hepatic artery; IVC, inferior vena cava; SMA, superior mesenteric artery.

branches are carefully ligated to prevent avulsion and unnecessary bleeding. An eversion thrombectomy is then performed, which can be aided with a Penfield elevator. The thrombus is then grasped with a Kocher clamp and pushed gently inward to peel the clot back, prior to removing. In most cases the entire clot can be removed in this manner. Extreme caution is used to prevent further injury to the portal vein. An end-to-end portal venovenotomy is then performed as above during the liver implantation.

If a thrombectomy cannot be performed safely, a portal venous jump graft should be used to ensure adequate inflow [13]. Again, this should be done prior to beginning hepatic implantation. A long segment of donor iliac vein should be prepared during the back-table preparation of the liver in anticipation of a portal jump graft. The superior mesenteric vein (SMV) is identified at the base of the transverse mesocolon to the right of the superior mesenteric artery. The vein is dissected distally beyond the area of thrombosis and skeletonized for several centimeters to accept a vascular clamp. The SMV is slit longitudinally and the iliac graft spatulated gently to allow the graft to lie directed cephalad. An end-to-side anastomosis is performed using 6-0 Prolene suture. The graft is then tunneled through a hole in the transverse mesocolon on a convenient side of the middle colic vessels. It is passed anterior to the pancreas toward the porta hepatis. An end-to-end anastomosis is then performed to the allograft portal vein in the standard fashion (Figure 56.3A). In cases with an inadequate SMV or in a reoperative abdomen, large portal collaterals can be used for portal venous inflow as a last resort. It should be noted that these collateral vessels are extremely friable and should be handled with the utmost caution.

In a small number of cases, none of the above procedures can be safely performed. Detailed preoperative imaging is mandatory in such cases and creative solutions can sometimes be achieved. For example, left renoportal anastomosis has been reported in cases of portal vein thrombosis with large splenorenal shunts [14]. In cases of complete splanchnic venous thrombosis, portocaval hemitransposition [15] or portal vein arterialization [16] has been described. Reports of the long-term outcomes of such techniques are sparse.

Hepatic arterial inflow

The recipient hepatic artery is carefully dissected proximal to the gastroduodenal artery. The distal gastroduodenal artery is doubly ligated and the common hepatic artery is clamped with a vascular clamp. A branch-patch is then fashioned from the recipient's GDA confluence. On the donor liver, a Carrel patch is cut from the aortic cuff. If the donor aorta is diseased, the anastomosis should be performed using the donor celiac trunk or a more distal site without vascular disease. It is our general practice to leave the donor vessel of adequate length so the vessel avoids tension on the anastomosis and does not kink. An end-to-end anastomosis is performed using either running or interrupted 6-0 or 7-0 Prolene suture [17,18]. If the gastroduodenal artery is unusually large, or if preoperative imaging suggests celiac stenosis, the GDA should be preserved and the anastomosis performed to the recipient's proper hepatic artery or a branch patch that is fashioned from the recipient's left and right hepatic arteries. Alternatively, an arterial conduit can be used to ensure adequate arterial inflow.

If the recipient hepatic artery is unsuitable for implantation due to diminutive size or poor quality, an aortic conduit using donor iliac artery should be performed. This can be done either in the supraceliac [19] or infrarenal [20] positions. Once again, it is preferable to place the aortic conduit prior to beginning hepatic implantation to minimize the time that the liver is without arterial inflow.

The supraceliac aorta is most accessible after the donor hepatectomy and prior to allograft implantation. The esophagus is retracted to the left and the diaphragmatic fibers overlying the supraceliac aorta are divided with electrocautery. Paraesophageal varices must be handled with extreme caution. The aorta is encircled with a vessel loop and skeletonized from the diaphragm for a short distance inferiorly. The aorta can be clamped with a side-biting clamp or two straight vascular clamps, as needed. An aortotomy is made and an end-to-side anastomosis is performed to the donor iliac conduit with running 5-0 Prolene suture. The conduit is clamped with a vascular clamp and the aortic clamps slowly released. Graft flow is assessed by briefly flashing the vessel before flushing it with heparinized saline and reclamping the graft. An end-to-end anastomosis is later performed to the donor hepatic vasculature in the standard fashion (Figure 56.3B).

The recipient's infrarenal aorta is accessed by retracting the small bowel to the patient's right. The descending colon is not mobilized because the aorta is approached by incising the overlying retroperitoneum. One should be vigilant for large collaterals, and meticulous hemostasis should be obtained. The aorta should be carefully dissected cephalad to the left renal vein. This often requires dividing the ligament of Treitz and retracting the fourth portion of the duodenum to the patient's right. The aorta is encircled with a vessel loop and clamped with a side-biting clamp or two separate vascular clamps as needed. The anastomosis to the donor iliac conduit is performed in the same manner as the supraceliac conduit. The conduit is tunneled cephalad to the lesser sac through the transverse mesocolon and in a retrogastric, antepancreatic position.

Figure 56.4. Options for bile duct management.

Alternatively, the graft can be tunneled to the patient's right by performing a Kocher maneuver and placing the graft posterior to the head of the pancreas and duodenum. An end-to-end anastomosis is later performed to the donor hepatic vasculature in the standard fashion (Figure 56.3C).

Measuring hepatic artery and portal vein blood flow

Vascular complications are the most catastrophic in the field of liver transplantation. To date, there is no uniformly accepted way to predict which grafts are at risk for portal vein or hepatic artery complications. Available to the surgeon at the time of operation is the Medistim Ultrasonic flow probe (Medistim ASA, Norway). These probes allow the surgeon to measure the flow of both the portal vein and/or hepatic artery in real time. In one study, a flow rate of $<$240 mL/min of hepatic arterial flow was a significant predictor of graft failure [21]. Interestingly, the rate of biliary complications was not influenced by hepatic arterial flow. With regard to portal flow, this same study demonstrated that portal flow $<$1300 mL/min negatively affected graft function in a univariate analysis, but this trend was not found in multivariate analysis. To date, there is no universal practice among surgeons, and a prospective trial would need to be performed to fully understand the role of flow measurement and graft outcomes.

Bile duct reconstruction

After portal venous and hepatic arterial perfusion has been established, a cholecystectomy is performed. The bile duct is then prepared for anastomosis by trimming the length and ligating the cut edges of the lateral and medial vessels with fine suture for hemostasis. It is advantageous to retain as much of the recipient duct's length as possible, and to shorten the *donor duct* to prevent redundancy. This is due to the fact that the blood supply to the distal donor duct is now entirely derived from the donor liver and it is crucial to avoid ischemia to prevent biliary anastomotic complications. This is most often achieved by transecting the duct above the cystic duct insertion. One should be cautioned that this is not possible in the case of a very high cystic duct insertion or a very low inserting posterior right hepatic duct. If the common hepatic duct is transected above the cystic duct insertion, the cystic duct should be excised completely to prevent mucocele formation. With a high cystic duct insertion, the cystic duct can simply be ligated and preserved, as long as there is free drainage into the common bile duct to prevent mucocele formation.

With typical-sized donor and recipient ducts, a simple end-to-end anastomosis is performed using running or interrupted 6-0 polydioxanone suture (PDS; Ethicon Inc., Somerville, NJ). In the case of small ducts or slight to moderate size mismatching, one or both ducts can be spatulated to prevent narrowing of the anastomosis [22]. In cases with a small or normal donor duct and an extremely large recipient duct, a portion of the recipient duct can be oversewn with 6-0 PDS suture and an end-to-end anastomosis performed to the remaining opening in the standard fashion (Figure 56.4A,B). Under most circumstances, we do not routinely use biliary stents. However, if a stent is thought to be useful, one is fashioned out of a short segment of an appropriate diameter silastic catheter with additional side holes cut in it. We do not use T-tubes and feel that their associated complications outweigh their usefulness [23] given the advances in modern endoscopy and interventional radiology [24,25].

In the case of a very large donor duct and small recipient duct, or with an unsuitable recipient duct, a Roux-en-Y hepaticojejunostomy is performed. All patients with a diagnosis of primary sclerosing cholangitis are reconstructed with a Roux-en-Y in order to excise a maximal amount of recipient common bile duct down to the level of the pancreatic head and to avoid postoperative stricture. Others have reported selective use of duct-to-duct anastomosis in such patients [26]. For liver retransplantation, a duct-to-duct reconstruction or Roux-en-Y may be used, depending on the quality of the recipient duct [27]. To form a Roux limb, a segment of proximal jejunum is selected approximately 30 cm distal to the ligament of Treitz and transected with a gastrointestinal stapler. The transection point is based upon the vascular arcades and the ability of the cut end to reach the porta hepatis. The distal staple line is oversewn with interrupted 3-0 silk Lembert sutures. A 40-cm Roux limb is then created and a two-layer, hand-sewn, end-to-side jejunojejunostomy is performed. The inner layer is sewn with running 4-0 PDS or vicryl suture and the outer layer is sewn with interrupted 3-0 silk Lembert sutures. Alternatively, this anastomosis can be performed with staplers, but this is not our preferred method. The Roux limb is then tunneled through the transverse mesocolon to the porta hepatis. A small enterotomy is made near the end of the Roux limb and a hepaticojejunostomy is performed using full thickness, interrupted 5-0 or 6-0 PDS suture. The Roux limb is then tacked to the transverse mesocolon and the mesenteric rent is closed with interrupted 3-0 silk sutures.

Closure

If an umbilical hernia is present, this may be repaired from within the abdomen using #1 PDS suture. Closed suction drains are placed in the dependent portions of the upper abdomen and a drain may be placed adjacent to the bile duct anastomosis. The fascia is closed using #1 PDS suture and the skin edges are reapproximated with surgical staples.

Summary

A remarkable amount of progress has been made in the field of liver transplantation since the first successful procedure in humans was done in 1967. Liver transplantation has evolved from an experimental procedure with high morbidity and mortality into a relatively standardized procedure with excellent long-term outcomes. This rapid progress is due to great strides in surgical instrumentation and techniques, immunosuppressive protocols, preoperative imaging, postoperative management, and critical care medicine, to name a few. The techniques described have been in routine use at our center with excellent outcomes and continue to evolve to make liver transplantation a safer and more universally available technology.

CHAPTER 57

Living Donor Liver Transplantation Procedure and Surgical Technique

Sung-Gyu Lee, Deok-Bog Moon, and Jung-Man Namgoong
Hepato-Biliary Surgery and Liver Transplantation, Department of Surgery, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea

Introduction

Soon after deceased donor liver transplantation (DDLT) became a standard treatment for patients with end-stage liver disease (ESLD), the supply of deceased donor liver grafts was outstripped. In order to overcome the rarity of deceased child donor liver grafts, reduced-size liver transplantation was developed [1]. Split-liver transplantation then allowed transplantation for one child and one adult recipient [2], and subsequently for two adult recipients using one liver graft [3]. In situ splitting further shortened the cold ischemic time and lessened the inevitable graft rewarming of various degrees during the back-table procedure [4]. These technical innovations paved the way for living donor liver transplantation (LDLT). With extensive experience in liver resection for tumors and reduced-size/split-liver transplantation, after the first successful LDLT using a left lateral segment from an adult to a child in 1989 [5], the ethical justification (also discussed in detail in Chapter 138) and technical success of this procedure resulted in its widespread application worldwide [5–7]. This chapter will cover the key factors contributing to a successful recipient procedure for LDLT. Specifics of the live donor liver donor procedure are covered in the companion Chapter 24. Technical aspects of deceased donor liver transplantation can be found in Chapter 56.

The greatest impact of LDLT in adult patients has been in Asian countries where cadaveric organ donation was uncommon or nonexistent [8]. LDLT using left lobe grafts for children [7,9] and adults [10] proliferated in Japan, although this procedure has not become widespread due to the inability of these relatively small-sized grafts to meet the metabolic demands of all adult recipients. To overcome the inadequate graft volume and poor results in the adult recipients with left lobe grafts, transplantation with a right lobe liver graft was introduced for adult recipients in 1996 [11]. Although this method rapidly led to the worldwide use of adult LDLT, right lobe hepatectomies are associated with a greater surgical risk for live donors than left lobe hepatectomies; they are also associated with increased morbidity and mortality rates owing to the reduced volume of remnant liver in the donor [12].

In LDLT, donor safety is of paramount importance and cannot be compromised regardless of the implications for the intended recipient. Moreover, right lobe graft without reconstruction of hepatic venous drainage to the right anterior section has often led to right lobe graft congestion and failure [13]. Although the graft size is critical for successful outcomes, the importance of uniformly successful venous drainage of the anterior section of the right lobe has been regarded as crucial for maximizing graft function. As a result, modified right lobe graft, that is right lobe graft with reconstruction of middle hepatic vein tributaries or extended right lobe graft (right lobe graft with the middle hepatic vein trunk) have been recognized as the preferred grafts based on consideration of the donor and recipient factors. Not all potential donors can donate their right hemiliver because safe donation is possible only when the estimated remnant liver volume is more than 30% [14]. If the volume of the right lobe in potential donors is more than 70% of the volume of the whole liver or if a large-size recipient requires more graft volume than the expected liver graft volume from a single donor, dual-graft LDLT may be an alternative in which two grafts from two donors are transplanted into one recipient.

Perioperative considerations

Compared with deceased donor liver transplantation, aggressive postoperative care of adult LDLT recipients is crucial in order to achieve the best possible outcome. The degree of portal hypertension is a crucial intraoperative risk factor for adult living donor liver recipients.

The favored skin incision of the recipient is a bilateral subcostal incision with midline extension or an inverted T-shape incision. The surgical technique used for recipients is based on whole liver resection with preservation of the inferior vena cava (IVC) [15]. In contrast to DDLT, LDLT is a more sophisticated operation and requires much more careful and delicate dissection of the hilum as high as possible and while leaving a long length of individual structures. Live-donor partial liver grafts have a much smaller hepatic artery, hepatic vein, and portal vein, making them technically more challenging. This usually allows for a variety of different reconstruction options because of the numerous variations in liver anatomy. For technically successful LDLT, we need to satisfy the following four conditions: (1) adequate graft volume in order to avoid small-for-size syndrome, (2) adequate outflow in order to avoid congestion, (3) adequate portal inflow to enhance graft regeneration, and (4) a secure bile duct anastomosis to avoid biliary leak (Figure 57.1) [16].

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

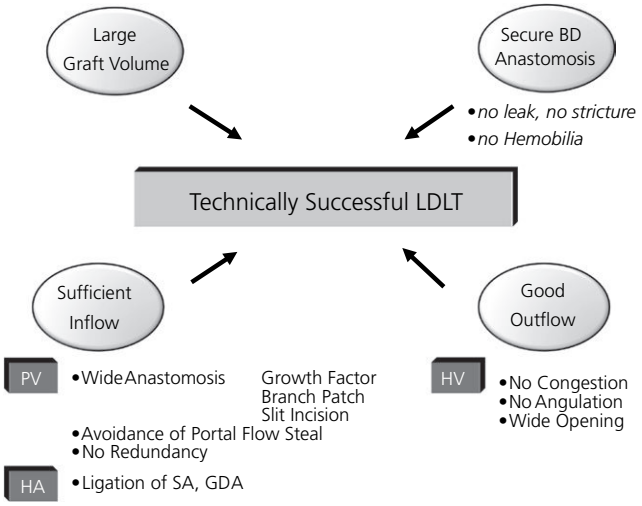

Figure 57.1. Interrelationship between graft volume, hepatic inflow and outflow, and bile duct anastomosis for determining technically successful, living donor liver transplantation (LDLT).

Operative procedure

Recipient hepatectomy

At the time of surgery, the surgeon must be well aware of the related anatomies of the recipient and donor, according to the expected graft type, and must also have a specific plan for how to manage the recipient's anatomical problems, including the hepatic artery (HA), portal vein (PV), hepatic vein (HV), and bile duct (BD). In addition there must be a plan for how to maintain adequate portal inflow without portal flow steal in the presence of large portosystemic collaterals, huge splenomegaly with an enlarged splenic artery, and a small graft size with less than a 1.0 graft-to-recipient weight ratio (GRWR).

At the time of the surgery, the recipient is placed in a supine position on the operating table. The abdomen is prepared and draped for a bilateral subcostal incision with midline extension or for an inverted T-shape incision; simultaneous preparation and draping of the left groin and thigh may also be required in order to access the autogenous great saphenous vein (GSV), which has a thick wall (used for bench work on the back table), and for graft implantation in the recipient. Electrocautery is commonly used to divide the subcutaneous tissue and to extend the incision through the fascia. At this point, division of the transverse wound should be performed earlier than the longitudinal wound, and a combination of electrocautery and ligature might be necessary so as to decrease bleeding from the wound as the courses and diameters of collateral veins developed in the abdominal wall of cirrhotic patients are longitudinal and often sizable. The xyphoid process should be removed in order to provide optimal exposure of the liver and some of the distal part of the sternum may also need to be removed on division of the longitudinal wound. The abdomen is entered by ligating and dividing the falciform and teres ligaments, although is it preferable to preserve large paraumbilical veins without interruption of their flow until completion of the total hepatectomy so as to decrease bowel edema and the amount of bleeding if paraumbilical veins are the main collateral routes draining the hypertensive portal flow.

The falciform ligament is divided toward the hepatic veins. The retractors are then placed so as to provide optimal exposure of the liver. Before beginning the perihepatic dissection, the condition of the intra-abdominal cavity should be checked and it should be decided whether the preoperatively planned tasks, including splenic artery ligation, splenectomy, isolation of portosystemic collaterals, etc., will be accompanied or not. Usually, splenic artery ligation or isolation of the splenorenal shunt causing portal flow steal is undergone at the initial stage because edematous changes of bowel and mesentery after liver graft implantation might hinder those procedures. Other tasks, such as isolation of other collaterals and ligation of portosystemic collaterals, are performed at a later stage, mainly before or after engraftment. Using electrocautery, the coronary ligament is taken down and the superior and anterior surfaces of the three major HVs are exposed. The left triangular ligament is then divided in order to mobilize the left lobe of the liver; likewise, the right triangular ligament and the peritoneal attachments on the right lobe of the liver are divided. During those procedures, the detachment should be performed along the avascular plane. However, we had better often peel off the hepatic capsule in some part by thorough cauterization of both the diaphragmatic and hepatic surfaces and ligation of sizable diaphragmatic vessel so as to reduce intraoperative bleeding when perihepatic collateral vessels or dense adhesions are present, such as in salvage liver transplantation. When it comes to division of the adrenal attachment from the posterior liver, incision of the peritoneum overlying the anterior surface of the IVC and division of adjacent several short hepatic veins should be done. Then, mass ligation with reinforcing sutures for the right adrenal attachment, including the adrenal vein, is performed under the guidance of the operator's left index finger positioned behind the adrenal gland and above the IVC, after which division of its attachment to the liver with thorough cauterization on the hepatic side and suture ligation of the adrenal vein on the IVC side are necessary. When hemostasis of the divided adrenal gland is not complete and is difficult, 3-0 Prolene matrix sutures using a pledget protective patch has been helpful in our clinical experience. After adrenal detachment, hemostasis of the perihepatic area is easy and there is not much bleeding before dissection of the retrohepatic IVC is begun. The next procedure, that is dissection of the hepatic hilum, is often done before dissection of the retrohepatic IVC, considering the usual bleeding tendency and/or the technical difficulty related to the encircling of the IVC by the caudate lobe, especially in the setting of a hypertrophied caudate lobe or Budd–Chiari syndrome, etc. Dissection of the hepatic hilum and/or encircling of the infrahepatic suprarenal IVC before dissection of retrohepatic IVC can be helpful to facilitate the next procedures with less bleeding and to control brisk bleeding from the torn short hepatic veins.

When copious bleeding and/or dense adhesion are expected during liver mobilization, particularly in salvage LDLT patients who underwent previous major hepatectomy or in secondary biliary cirrhosis patients who underwent repeated surgery for biliary problems such as intrahepatic duct stones and/or bile duct strictures, we first dissect the hepatic hilum after preparation of the venovenous bypass through the inferior mesenteric vein in order to reduce bleeding.

The main technical principle of dissection of the hepatic hilum is to preserve implantation options by maintaining the length and integrity of all hilar structures. In particular, meticulous dissection of the hepatic artery to obtain a sufficient length and adequate diameter is very important in order to match with the small hepatic artery opening of the partial liver graft without tension and to avoid intimal dissection of the recipient hepatic artery, such as is often

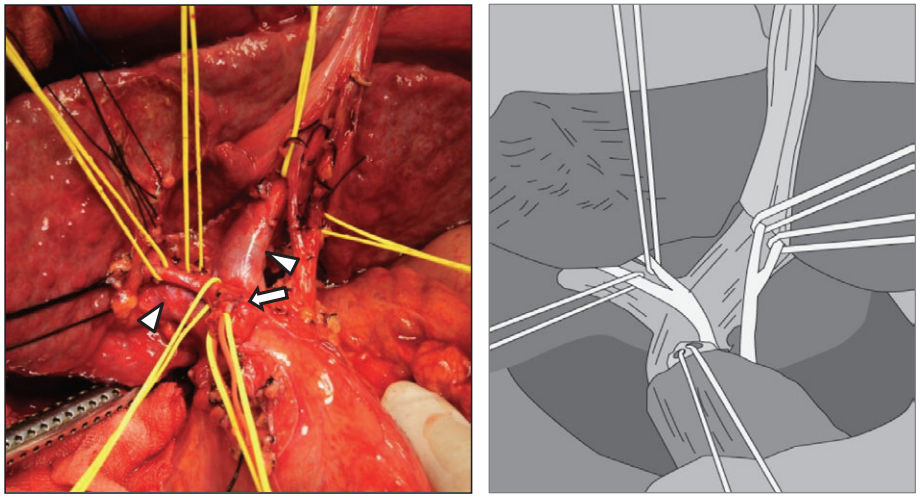

Figure 57.2. Operative view and schema for dissection of the hepatic hilum in the recipient. Second-order branches of the hepatic artery (HA), including the right anterior and posterior HAs, as well as the middle and left HAs, are dissected and taped by a yellow vessel loop. Divided bile ducts at the proximal site of the right and left hepatic ducts, indicated by a white arrow, are retracted by the yellow and red vessel loops. Finally, the portal vein (white arrow head) is dissected up to the right anterior, posterior, and left portal branches, and the main portal vein is mobilized down at least 2 cm in length and toward the pancreatic side.

encountered during hilar dissection of a recipient with portal hypertension. In addition, the available alternatives are not easily achievable because of its small diameter of usually less than 3 mm, in contrast to the diameters of BD and PV. Cholecystectomy is commonly performed first and then hilar dissection begins from the left side. When cholecystectomy is performed, the cystic duct is divided close to the neck of the gall bladder in order to preserve as much of its length as possible in case the cystic duct is needed for duct-to-duct anastomosis of the two BD openings of the liver graft. The left hepatic artery (LHA) is isolated first at the left hilum and then dissected up to the umbilical portion of the left hilum in order to get enough length and also to get the branch-patch of hepatic segment 2 and 3 HAs to accommodate the often larger graft hepatic artery. When right hemiliver implantation is planned, this step is a type of insurance procedure and it is important for a surgeon to proceed following dissection in a comfortable situation. Dissection of the middle and right HA should be performed with preserving the periductal connective tissue encompassing the axial periductal microcirculation in order to avoid post-transplant biliary complications related to ischemia. The right hepatic artery (RHA) should be freed up to the anterior and posterior branches so as to overcome size disparity between the graft and the recipient HAs. Division of HAs without ligation in the recipient side is better than ligation of both sides in order to obtain longer hepatic arteries and to avoid intimal injury. The divided ends of a recipient's HAs are left under microclamp to avoid intimal injury, and are declamped at a regular time interval (usually every 15 minutes) in order to avoid thrombus formation and propagation. In contrast to DDLT, the left and right HAs should not be dissected down toward the proper HA and gastroduodenal artery because previous dissection of the hilum alone is enough for reconstruction of smaller hilar structures in a partial liver graft. In addition, this procedure might be harmful for preserving the blood supply to the bile duct.

Dividing the site of the bile duct should be decided by the size and number of ductal openings of the graft. Pre- and intraoperatively, there should be communication between the recipient and donor surgeons about the cholangiogram. If multiple ductal openings are expected in the graft, the Glisson tissue containing the ducts in the recipient should be divided at a high level of the hepatic hilum in order to create multiple ductal orifices. Arterial bleeding from the cut end of the Glisson tissue ensures an adequate blood supply to the bile duct in both the recipient and the donor. Considering that more than two bile duct openings of the graft after ductoplasty requires at least one hepaticojejunostomy, more than three bile duct openings in the recipient except for the right anterior, posterior, and left duct openings, are usually unnecessary. As a result, the reported techniques for obtaining many bile duct openings in order to maximize the anastomotic options [17–19] seems not to be practical.

The last structure in the hilum to be further identified is the PV. All surrounding tissue of the PV, including lymph nodes, are ligated and divided. The PV is then circumferentially mobilized and, if possible, traced toward and beyond the takeoff of the right anterior, posterior, and left portal branches; all posterior and lateral branches to the caudate lobe are then ligated and divided for full-length mobilization. Regardless of the extent of the proximal dissection, the PV is mobilized down at least 2 cm in length from the portal bifurcation toward the superior margin of the pancreas (Figure 57.2).

The recipient can now be placed on portal bypass if this option is chosen for the remaining hepatectomy and liver graft implantation. During anhepatic phase in LDLT, portal bypass is usually not the preferred procedure because most recipients tolerate portal clamping without hemodynamic instability due to maintaining caval flow, and construction of hepatic and portal vein anastomoses requires less than 60 minutes. Even though portal bypass is not used, bowel edema soon subsides after portal reperfusion. LDLT using a right lobe graft, excluding extended right lobe, left lobe, and dual-lobe LDLTs, does not require systemic bypass because the piggyback technique allows partial clamping of the vena cava with a side-biting clamp and without hemodynamic instability. If much bleeding is expected during retrohepatic dissection of the IVC in

the presence of severe inflammation of the retrohepatic space or hypertrophied caudate lobe encircling the IVC, selectively portal bypass is be good option in order to facilitate dissection without much bleeding.

As the next procedure, the gastrohepatic ligament is divided. At the time of the left liver or dual-graft LDLT, however, the LHA coming from left gastric artery should be dissected as long as possible for arterial reconstruction of the implanted liver graft. The ligamentum venosum is then isolated beside the origin of the left hepatic vein (LHV) and is divided in order to easily obtain a sufficient length of the trumpet-shaped LHV and middle hepatic vein (MHV) stump. The peritoneal attachments on the left side of the IVC along the caudate lobe are divided using cauterization and ligation all the way up to the origin of the LHV. The caudate lobe of the liver is completely detached from the IVC using a left-side approach in order to enhance the retrohepatic dissection as much as possible. The right lobe of liver is then peeled off the IVC by ligating and dividing all retrohepatic veins entering the IVC, although this procedure can be tedious. If brisk bleeding occurs, infrahepatic IVC clamping sometimes helps to control the bleeding with suture ligation. After this procedure, the liver is fully mobilized and attached only by the HV pedicles and the PV.

Communication with the donor surgeon is important in order to share information regarding the anatomical variation of the liver graft and the recipient throughout the recipient's procedures, including the presence and size of the inferior right hepatic vein (IRHV) and the distance from the right hepatic vein (RHV), the size and number of BD openings, PV and HA, etc., because this information can help us to achieve adequate preparation for successful engraftment. Before removal of the recipient's liver, an autologous GSV is retrieved from the groin, most commonly on the left side, because the right groin is usually used for placement of the femoral artery and vein cannulation by the anesthesiologist. Procured GSV is dilated by hydrostatic pressure and bisected, and is mainly used for plasty of the donor HV by reconstruction on the back table.

Considering the harvest time of donor graft and the duration of the bench procedures, the diseased liver is removed as late as possible in order to reduce the length of the anhepatic phase. The PV is usually divided at the right and left branches, although sometimes at the main PV in order to obtain a Y-graft for reconstruction of two PV openings of the donor graft. HVs are divided individually using a vascular clamp. Stapling of the HV with an endovascular stapler is not preferred because the recipient's HV openings should be used for anastomosis with graft HVs after venoplasty.

Anhepatic phase

Recipient side

The PV and rarely HV are often dissected from explanted liver to obtain an autologous vessel graft used for venoplasty in the recipient or reconstruction of the MHV branches as a vascular conduit at the back table if cryopreserved iliac vessels or autologous GSV of a sufficient size are absent or short of length.

After removal of the recipient's liver, meticulous bleeding control should first be performed. A frequent bleeding site during this phase includes the retrohepatic dissection area, and particular care should be given to the inferior phrenic artery and the adrenal gland because they are difficult to expose after engraftment, and bleeding from those sites often occurs during the postoperative course.

Optimal venous outflow is critical for the success of LDLT. Making a wide HV orifice in the recipient in order to accommodate the corresponding donor HV is an essential preparatory step for the engraftment.

For anastomosis of the reconstructed MHV tributaries of the right lobe (RL) graft without the MHV trunk (modified RL graft), the septum between the recipient's middle and left HV is usually divided and a single opening is made using unification venoplasty. Several Allis clamps are placed at the end of the middle and left HV stumps, after which the previously applied clamp is removed so as to facilitate deep placement of the side-biting vascular clamp to the RHV and including the anterolateral wall of the IVC.

The inappropriate ventrodorsal matching of the graft–recipient RHV anastomotic site was found to be a significant risk factor for the development of RHV stenosis. Technical refinements to reduce this risk factor include widening of the recipient RHV orifice [20]. For RHV venoplasty adding the caudal ventral incision to the IVC, a large, side-biting clamp placed deeply on the RHV, and including the anterolateral wall of the IVC, is necessary. We perform an L-shape incision or a separate, longitudinal incision of the RHV with IVC caudally as well as a wide patch-plasty using bisected autologous GSV. These methods result in acceptably low incidences of early onset RHV stenosis (0–2%) [20].

For reconstruction of large, short, hepatic veins (SHVs), deep and secure side-clamping of the IVC is required in order to prevent unnecessary tension during anastomoses. Therefore, it is usually necessary to extensively dissect the more than right-half circumference of the suprarenal IVC, and some branches of the right adrenal vein to the vena cava need to be divided [21].

Back-table procedures

The donor graft is removed, after which the graft is brought to the back table for flushing with 4°C cold preservation solution, such as histidine–tryptophan–ketoglutarate (HTK) or University of Wisconsin (UW) solution. The graft weight is measured before perfusion in order to determine the GRWR. The graft is flushed through the PV until effluent from the HV is clear. The preservation solution is also used to flush the bile duct clean. The HA is carefully flushed so as to avoid intimal injury without insertion of a catheter into the HA using hydrostatic pressure alone. We prefer to use 2 liters of HTK solution for these procedures.

As preparation for the liver graft implantation, vascular reconstruction may be required. Tributaries of the graft's MHV require reconstruction with the autologous GSV, PV, dilated umbilical vein, and/or cryopreserved iliac vessel. The RHV of the right hemiliver graft and the trunk of the middle and left HV of the left hemiliver graft may require venoplasty with previously mentioned vessel grafts in order to prevent hepatic vein outflow obstruction (Figure 57.3). When a single or multiple major SHVs are present, we propose venoplasty guidelines for major SHV reconstruction (Figure 57.4) [21]. If two, separate or piggy-nose PV orifices (right anterior and posterior branches) in the right hemiliver graft are present due to type III or II PV variants, the recipient's Y-graft of PV bifurcation prepared from the recipient's hilar dissection can be used to make a single PV opening with adequate length of the neck for simple and safe anastomosis during engraftment [22,23]. Unification venoplasty of two PV openings or a pig's nostrils-shaped PV opening alone can result in intraoperative difficulty during anastomosis and/or postoperative PV stenotic complications because of the weak PV wall of the liver graft and the configuration mismatch between the liver graft and the recipient PV. When the recipient PV sometimes cannot be used for the Y-graft due to severe PV steonosis caused by thrombosis, circumferential fencing of the

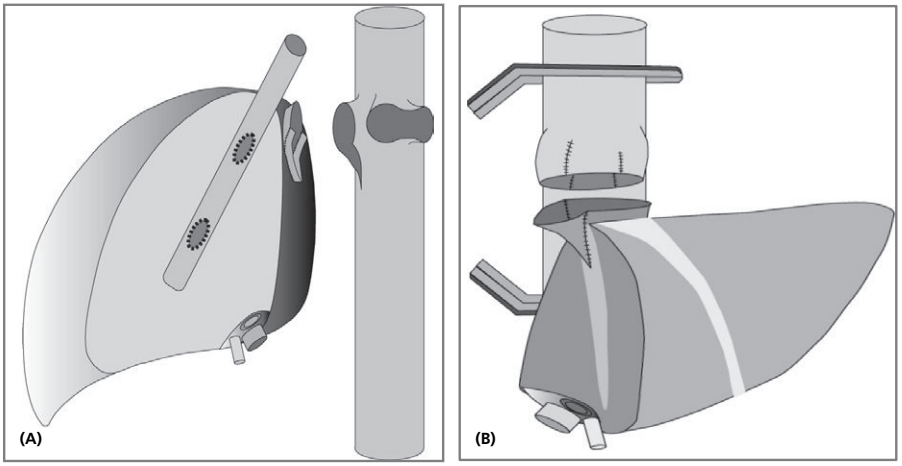

Figure 57.3. Hepatic venoplasty to create a large outflow in order to prevent its obstruction. (A) In the right lobe living donor liver transplantation (LDLT), a caudal incision and augmentation patch-plasty of the right hepatic vein (RHV) is performed in the graft. Corresponding to the enlarged RHV opening, the caudal incision of the recipient's RHV is extended to the IVC. (B) In left lobe LDLT, a common hepatic opening is made after division of the septum in the right, middle, and left hepatic veins in the recipient. Corresponding to the large common hepatic vein opening, the right-corner of the middle hepatic vein is incised and augmentation patch-plasty is performed in the graft.

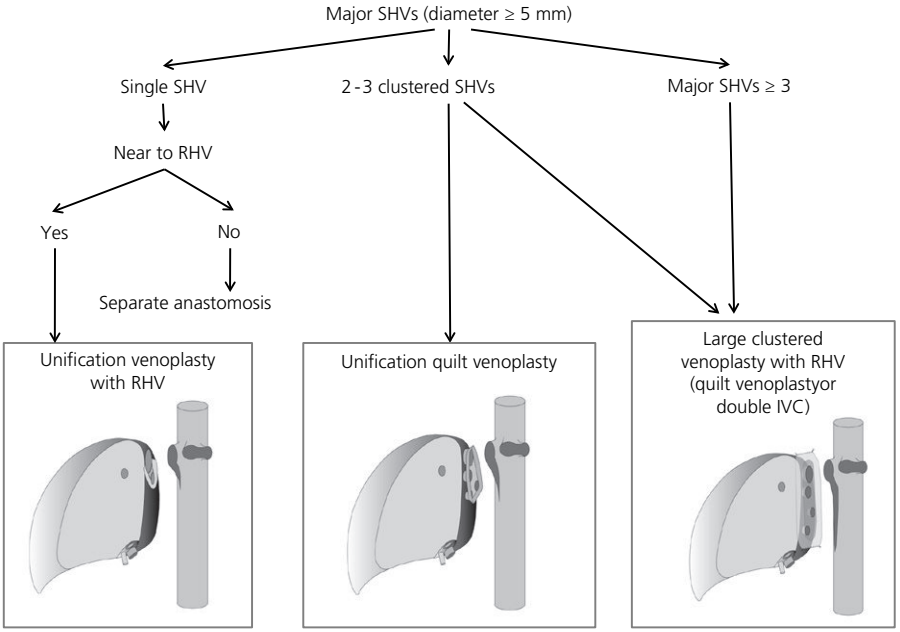

Figure 57.4. Current institutional guidelines for reconstructing a short hepatic vein (SHV) with respect to the main right hepatic vein (RHV). Quilt venoplasty is a complex patch-plasty procedure used to unify multiple SHVs without the application of a niche to the SHV stump.

PV using autologous bisected GSV or Y-graft from a cadaveric, fresh iliac vein can be used as an alternative. Likewise, if two arteries are present in the graft, arterial reconstruction can be performed using a Y-graft and including the appropriate right and left hepatic artery [24]. However, this Y-shape HA preparation may require wide dissection around the bile duct and can often result in biliary stricture. In addition, severe size discrepancy between segmental HAs (right anterior and posterior branches) of the donor and enlarged right and left HAs of the recipient, due to longstanding portal hypertension, are often encountered. Therefore, after portal perfusion we perform two, separate HA anastomoses under a microscope and using mostly the recipient's lobar or sectoral HAs, as, therefore, the recipient HA is dissected as high as possible in order to obtain a long length and size-matched HA.

If more than two separate orifices of the bile ducts are not too far apart or pig's nostrils-shaped orifices are present, unification ductoplasty can be performed in order to create a large single opening.

These back-table reconstructions may require up to 2 hours of warm ischemia time in the complex anatomy of HV, PV, and BD. Therefore, the procedures should be done by submerging the liver graft in 4°C cold preservation solution inside an ice-packed jar.

After completion of the back-table procedures, the liver graft is brought to the recipient room in a submerged state in the preservation solution and packed in ice.

Graft implantation

Hepatic vein anastomosis

Optimal venous outflow is critical for the success of LDLT for both maximal liver graft function and graft regeneration. In this respect, we consider not only the anastomosis itself, but also the positioning of the liver graft. Therefore, the graft should be placed in an orthotopic position, and care should be taken to consider the final position of the graft after the abdomen is closed.

Outflow problems can occur, however, because regeneration of the liver graft may result in a change of its position. Venoplasty of the recipient's HV extended to the IVC wall to make an oval-shaped, wide orifice with adequate length of the neck may help to minimize the outflow complications even though slight torsion of the anastomosis occurs and causes outflow stenosis. Because of this, the recipient HV should be maximally incised longitudinally, and then attached like a fence using an autologous vein patch with a thick wall. The most common and useful graft material is bisected GSV, with bisected recipient's PV being the next choice. For proper alignment at the time of the HV anastomosis, two 5-0 non-absorbable sutures with double needle arms are placed at the cephalic and caudal ends of both the graft and the recipient's HVs. All stitches are placed halfway between the two corner stitches on the anterior and posterior aspects of the donor and recipient HVs, respectively. The posterior wall is sewn, after which the anterior wall is sewn toward the middle. Filling the inside of the HV with heparinized saline is done in order to remove air bubbles before closure of the anastomosis. Venting of the liver graft on reperfusion is usually not necessary in LDLT when HTK perfusion solution is used as it has low potassium content.

Portal vein anastomosis

As mentioned above in Figure 57.1, adequate portal flow is essential for successful LDLT. The PV anastomosis is performed using the recipient's PV trunk or with PV bifurcation to avoid redundancy of the PV anastomosis. Occasionally, the recipient right or left PV branch is used due to its better size match or more favorable alignment than the PV trunk. The PV anastomosis must be constructed without tension, redundancy, or twisting. Before beginning PV anastomosis, the recipient PV should be opened to remove any possible thrombus newly formed during clamping. The preferred suture material is 6-0 Prolene, and the anastomosis is generally performed in a running fashion and incorporation of a sufficient "growth factor" [25].

Recipients with PV thrombosis, once thought to be an absolute contraindication to the already technically challenging living donor procedure, have undergone successful transplantation with partial grafts from living donors [26–28]. In recipients with severe PV thrombosis and who cannot undergo a thrombectomy and/or PV plasty to enlarge the diameter of PV, mesenteric or renoportal interposition grafts are necessary using a cadaveric, fresh iliac vein or a polytetrafluoroethylene (PTFE) vascular graft [29]. Patients who require caval transposition or arterializations of the PV, or both, are at significantly higher risk for morbidity and mortality and are, perhaps, inappropriate candidates for LDLT because adequate portal inflow is mandatory for partial liver graft regeneration.

With a GRWR $<$0.8%, small-for-size syndrome accompanied by hyperbilirubinemia, portal cholestasis, delayed synthetic function, and intractable ascites are more common than with a GRWR $\geq$0.8%. Portal hyperperfusion can cause excessive shear stress against sinusoidal cells of a partial liver graft with a small graft weight, and which is known to be the primary cause of the small-for-size syndrome [30–32]. Several kinds of portosystemic shunts have been described which attenuate portal venous over-perfusion and protect the small-for-size graft from excessive PV flow and pressure [33–35].

However, there is a fatal drawback of portosystemic shunts being seriously considered. It is the portal flow steal phenomenon to the transplanted liver graft that may result in graft dysfunction or even graft infarction in extreme situations and due to insufficient portal inflow to the implanted graft during the early postoperative period of 1 or 2 weeks [36]. Although many transplanted recipients recover without lethal complications, they might have delayed graft dysfunction or failure accompanied by hyperammonemia, hepatic encephalopathy, hyperbilirubinemia, etc. resulting from portal flow steal. To deal with those potentially fatal complications, perioperatively precise hemodynamic monitoring and interruption of pre-existing, large, portosystemic collaterals in an appropriate time are essential (Figure 57.5) [30,37]. However, if and when the collaterals should be interrupted remains a controversial and poorly studied question because there might be other significant problems to be solved, such as acute rejection, vascular complications of PV inflow or HV outflow, an existing small-for-size graft, etc. Other surgical techniques used to reduce portal hypertension are splenic artery ligation and splenectomy. Splenic artery ligation decreases the portal pressure without procedure-related complications during the early post-transplant period in small-for-size graft LDLT [38]. Although splenectomy must be an effective method to decrease portal pressure but has only rarely been recommended for chronic end-stage liver failure patients due to the risk of serious post-splenectomy infections [31]. However, in our clinical experience, concomitant splenectomy is a feasible procedure and does not provoke postsplenectomy sepsis. As for the portal flow steal phenomenon, it is not an issue limited to small-for-size grafts with GRWR $<$0.8% having undergone hemiportocaval shunt, but a common issue in the field of LDLT using partial liver grafts with GRWR $\geq$0.8% and having sizable spontaneous portosystemic collaterals [36,39].

At our medical center, the minimum graft volume should be more than GRWR $\geq$0.7% or $\geq$0.8% in a recipient with or without portal hypertension, respectively, in order to avoid small-for-size graft syndrome. When the graft volume is less than the minimum criteria, the preferred method is not a small-for-size graft LDLT added by hemiportocaval shunt, but a dual-graft LDLT to give adequate graft volume to the sick recipient and to ensure a successful postoperative outcome [40–43]. In contrast to DDLT using a whole liver graft having a large volume, basically most partial liver grafts in adult recipients are relatively small-for-size grafts that need rapid regeneration during the early postoperative period, even though LDLT is performed using more than a GRWR $\geq$0.8% liver graft. Therefore, the portal steal phenomenon through the pre-existing, sizable portosystemic collaterals may often result in graft dysfunction or failure. Intraoperative interruption of sizable portosystemic collaterals, possible routes of portal steal phenomenon during the postoperative period, is an essential step in adult LDLT. Surgical ligation is the first choice; however, as it is limited by complicated courses and the deep-seated location of portosystemic collaterals in many instances, we introduced intraoperative cine-portogram for complete interruption of sizable collaterals by

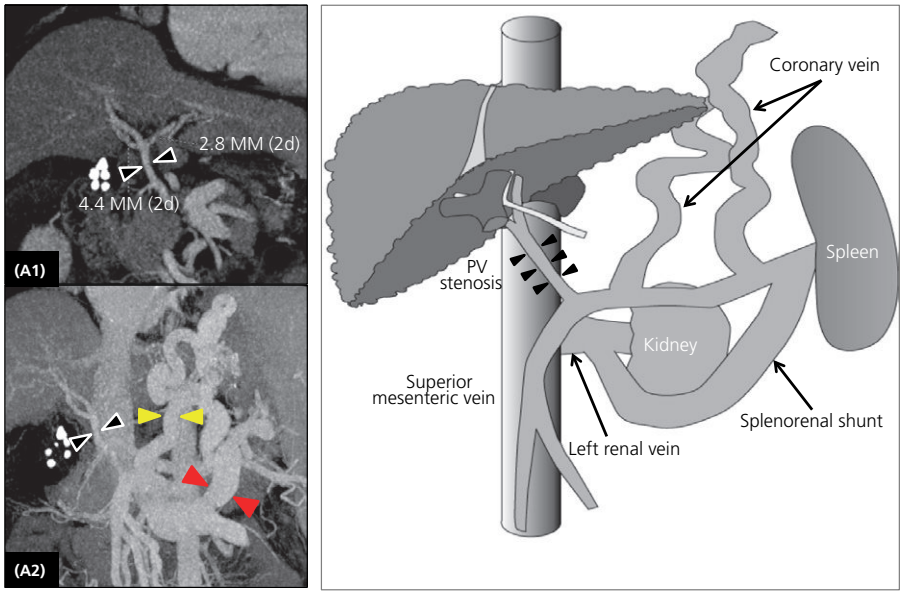

Figure 57.5. Preoperative evaluation of the splanchnic vein anatomy including the portal vein (PV) and collaterals, as seen on the recipient's three-dimensional computed tomography scans (3-D CT). Severe PV stenosis (black arrowheads) in (A1) and (A2), the coronary collateral (yellow arrows), and the splenorenal collateral (red arrowheads) in (A2) are visible. (B) The schema shows severe PV stenosis (multiple black arrowheads) and enlarged coronary and splenorenal collaterals draining splanchnic blood flow into the left renal vein and inferior venal cava.

obtaining the correct information regarding the portosystemic hemodynamics and by monitoring the completeness of surgical ligation or the further "coil embolization" of the deep-seated and surgically inaccessible, large portosystemic collateral veins. Intraoperative cine-portogram is important not only as a diagnostic tool but also as a therapeutic tool for portal vein stenosis and/or thrombus, commonly accompanied by large portosystemic collaterals, by placement of endovascular stent or balloon dilatation (Figure 57.6) [39,44].

Hepatic arterial anastomosis

Arterial anastomosis of DDLT can be performed either before or after reperfusion of the liver graft. In LDLT, arterial anastomosis is performed after reperfusion in most cases because the donor hepatic artery is thin, small, and short, the anastomosis is tedious and often time-consuming work and requires great attention until completion. The diameter of the donor hepatic artery, particularly in Asians, is less than 3 mm in more than three-quarters of the donors [45,46]. These small anastomoses are generally performed in an interrupted fashion with 9-0 or 10-0 Prolene sutures using an operating microscope. Introduction of microsurgical reconstruction technique instead of surgical loop magnification has resulted in a decreased HA complication rate [45]. The preferred recipient's HA is usually the counterpart HA to the donor HA, although selection of the recipient's HA is decided primarily by size matching between the donor and the recipient HA. When there is size disparity, the branch patch technique using small branches of the donor or recipient HA is useful for wide and tension-free anastomosis [47,48]. In addition, the length, status of the arterial wall, and feasibility of stable positioning during anastomosis are also important factors for choosing the anastomotic artery.

In many LDLT centers, a separate microsurgical team consisting of plastic surgeons performs the arterial anastomosis. However, they often experience technically challenging circumstances because the operating field is quite different from their familiar static field [49,50]. Recently, as transplant surgeons have performed HA anastomosis at large-volume LDLT centers, the clinical outcome has improved compared to that of the previous era [51].

In many cases of left hemiliver graft, and a few cases of right hemiliver graft, multiple donor hepatic arteries are present. Whether all accessory vessels require reconstruction or not remains debatable [52–55].

With pulsatile back bleeding from the smaller artery after anastomosing the main hepatic artery of the graft, assuming there is no patchy discoloration of the liver graft, ligation of the smaller arteries was recommended by Ikegami et al. [52]. Some form of hilar or intrahepatic communication can provide good pulsatile backflow, which is not normally demonstrable on angiography unless they are actively functioning as collaterals [56]. All hepatic arteries, including replaced and accessory arteries, however, are essentially necessary arterial inflows because hepatic arteries are end vessels that supply a specific area of the liver. In addition, it remains somewhat unclear what impact a smaller ligated artery, in the presence of good pulsatile backflow, has on the arterial blood supply to segmental bile ducts [55]. Therefore, we prefer to reconstruct all hepatic arteries to reduce possible HA complications, particularly related biliary complications that are the Achilles' heel of LDLT as they use first (lobar; right, left) and second (sectional; anterior, posterior, middle, left lateral), or even third (segmental) order branches of the recipient HA in consideration of the size match between them. When there are few HA inflow vessels for graft HAs due to the size disparity, the recipient's right gastroepiploic artery, cystic artery, and right hepatic artery can be useful alternatives because those arteries are of a relatively small caliber. If reconstruction of all HAs is technically difficult due to their small caliber (less than 1 mm in diameter) and/or poor operative vision related to a short HA stump positioned at the posterior side of the reconstructed PV, intraoperative Doppler ultrasound can be helpful to

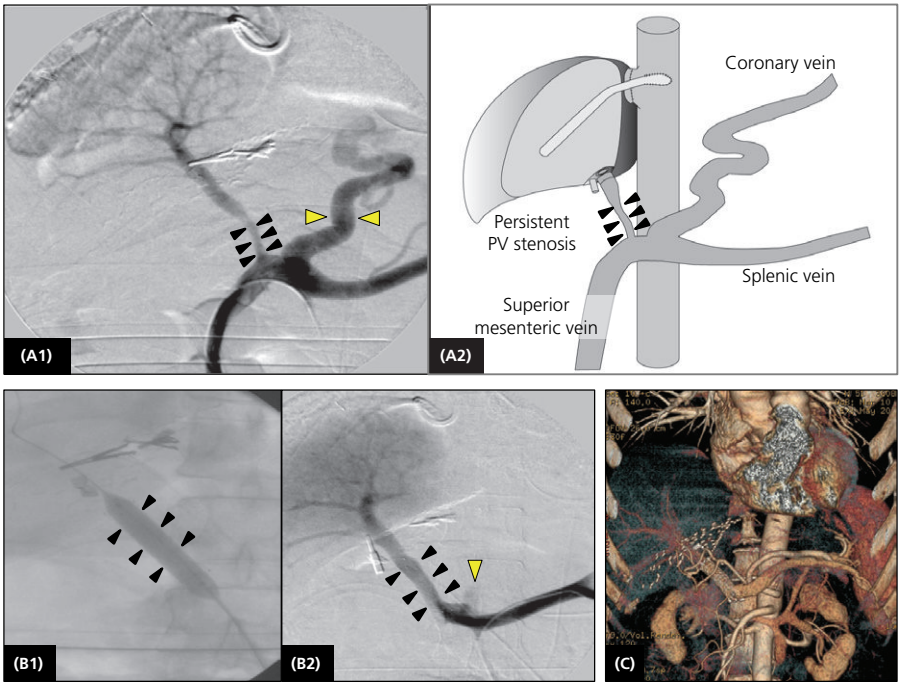

Figure 57.6. Importance of intraoperative cine-portogram. Intraoperative cine-portogram (A1) and the schema (A2) after engraftment showed severe remaining PV stenosis in the intrapancreatic portion (multiple black arrowheads) and portal flow steal through the coronary vein (yellow arrowheads) regardless of PV plasty using the bisected saphenous vein and left renal vein ligation to interrupt steal through the splenorenal collateral. Balloon dilatation (multiple black arrowheads) in B1 and subsequent PV stenting (multiple black arrowheads) in B2 was performed. The final intraoperative cine-portogram (B2) revealed the absence of PV stenosis and portal flow steal through the coronary collateral (yellow arrows). A follow-up CT scan at 27 months (C2) showed a patent PV stent and disappearance of all of the collaterals with no evidence of portal hypertension.

alleviate additional reconstruction by confirming sufficient arterial flow patterns in all segments of the liver graft.

When a right hemiliver graft has two hepatic arteries, direct anastomosis of the two donor HAs with the previously mentioned various HA branches of the recipient has been our standard approach. These anastomoses are technically more demanding, but the most important thing is meticulous and careful dissection of the recipient's hepatic hilum in order to obtain multiple branches of an HA having a small caliber and long stump length. Alternatively, the recipient proper HA, with the bifurcation into the left and right HAs, is divided as a Y-graft and anastomosed to the two HAs of the graft on the back table under optimal conditions [57]. This approach has two potential disadvantages. First, removing the recipient's proper HA may devascularize the proximal bile duct, thus requiring the creation of a Roux-en-Y biliary reconstruction. Second, it requires three anastomoses including on the back table (two) and in the recipient (one).

Compared to the donor HA, when the recipient hepatic artery is slender from intimal hypertrophy after multiple episodes of transarterial chemoembolization but maintains good pulsatile flow, the branch patch technique using segmental branches of the HA can be useful for size-matched HA reconstruction. When the extended intimal dissection occurs after hilar dissection of the recipient or a destroyed HA is present related to previous transarterial chemoembolization or HA thrombosis occurs after LDLT, the right gastroepiploic artery can be commonly usable for alternative HA inflow [58–61]; the reasons being that the right gastroepiploic artery is easy to perform dissection on, is free from limitation of its length, it is frequently enlarged as a compensatory mechanism, and it is feasible to perform anastomosis with a sizable graft HA. The right gastric artery, gastroduodenal artery, left gastric artery, splenic artery, inferior epigastric artery, internal iliac artery, sigmoid artery, inferior mesenteric artery, radial artery, and saphenous vein are also useful for interposition grafts for extra-anatomical HA reconstruction [62–68]. Arterial conduits may be preferred to a saphenous vein interposition graft because saphenous vein grafts tend to develop pseudoaneurysms and have an unsatisfactory long-term patency rate [65]. However, when saphenous vein graft for HA reconstruction in LDLT must be used, we prefer a saphenous vein harvested from the ankle area in order to reduce the possible rate of complications because it has a thick and strong wall and its caliber is usually well matched to that of the graft HA. Occasionally, an interposition graft from the infrarenal aorta using a fresh cadaveric artery or GSV is necessary for the arterial reconstruction when the recipient hepatic artery is thrombosed or obliterated all the way to the origin of the celiac axis.

Biliary reconstruction

Biliary complications in LDLT are more frequent and intractable compared to those of DDLT once considered the Achilles' heel of LDLT [69,70]. The two most probable causes are the small-sized and/or multiple graft-duct openings and the insufficient blood supply to the biliary anastomosis from donor and recipient hilar dissection. The segmental ducts are small, generally only 2–4 mm in diameter, and are cut flush with the hilar plate of the graft when multiple bile duct openings from liver graft hepatectomy come out. Even though there is only one bile duct opening of the graft, its diameter is only about half that of a common bile duct. These

biliary reconstructions of LDLT are technically more demanding than those of DDLT. As a consequence, the incidence of biliary complications, including leaks and strictures, is significantly higher in LDLT.

In our experience, 32% of right lobe and 12% of left lobe grafts required reconstruction of multiple ducts [71]. During the minimum 32-month follow-up period, the cumulative calculated 5-year biliary complication rate was 20.2%. The anastomotic leaks occurred within the first month, with an incidence of 2.9%, and biliary strictures developed after a median period of 6 months or after a mean period of 11.7 ± 11.8 months, and with an incidence of 17.8%. In other series, the overall incidence of biliary complications in recipients ranged from 8.4 to 40.6% [17,19,71–77]. The studies published since 2008 have shown a promisingly dramatic drop in the overall incidence of biliary complications in recipients (8.4–12.8% since 2008 versus 24.3–40.6% before 2008) [78]. However, the long-term studies, with more than a 2-year minimum follow-up period for a large patient population of more than 200 LDLT recipients, have shown at least 20% biliary complication rates [71,72]. In some medical centers, a separate and well-rested microsurgical team performs the biliary reconstruction in order to decrease the rate of biliary complications [77].

The standard biliary reconstruction of living donor grafts was initially the Roux-en-Y hepaticojejunostomy with or without a stent. A Roux jejunal loop must be of sufficient length so that the biliary anastomosis can be created without any tension.

In preparation for the hepaticojejunostomy, if only one donor bile duct needs to be anastomosed, a small stab incision is made smaller than the diameter of the donor bile duct [79]. If a serosa-splitting technique is used, the mucosa is tacked to the serosa with fine absorbable sutures [80]. Full-thickness bites should be taken about 5 mm away from the bile duct edge in order to decrease the risk of stenosis. The stitches should also not be placed too close together in order to reduce the risk of ischemia and subsequent stricture [79]. The posterior wall can be reconstructed using a 6-0 monofilament interrupted or with continuous sutures. From five to eight interrupted sutures of 6-0 absorbable monofilament, which depend on the diameter of the graft bile duct, are used for the semicircle of bile duct anastomosis at our medical center.

On completion of the posterior wall, an internal or external transanastomotic stent is placed in order to reduce the rate of biliary complications in patients undergoing LDLT [71,81,82]. Closure of the anterior wall is then always performed using interrupted sutures. If an external stent is used, a Witzel tunnel is created.

Currently, compared with Roux-en-Y hepaticojejunostomy, duct-to-duct anastomosis is recognized as a simple and the favorable method for adult LDLT and it is currently a standard technique because of its theoretical advantages [71,72,76,83,84]. Duct-to-duct anastomosis is believed to preserve the physiological sphincter of Oddi and, consequently, prevent reflux cholangitis and contamination by the intestinal contents. It also decreases the operative time and allows good access for the endoscopic management of postoperative biliary complications. In view of the occurrence of biliary strictures, however, duct-to-duct anastomosis has a higher risk of biliary stricture than Roux-en-Y hepaticojejunostomy [19,71,84]. In particular, duct-to-duct anastomosis involving a small-sized duct less than 4 mm in diameter has been found to be a significant risk factor [71].

Confirmation of the viability of the donor and recipient bile ducts before reconstruction of duct-to-duct anastomosis is important in order to reduce biliary complications, and the viability is decided by the presence of pulsatile arterial bleeding from the cut ends of the BD [17]. We prefer to prepare the recipient duct opening one and one-half times larger than the size of the fully expanded graft duct opening in order to reduce the possibility of anastomotic strictures. Anastomosis techniques for duct-to-duct anastomosis are similar to those for hepaticojejunostomy with a single-layer closure.

It also remains controversial whether internal or external transanastomotic biliary drainage is beneficial for reducing the rate of biliary complications. Liu et al. reported duct-to-duct anastomosis without a biliary stent in right lobe LDLT; and their rate of biliary complications was similar or superior to the rates in previous studies using biliary stents. A probable hypothesis is that the stent, itself, is a foreign body and will thus induce inflammation and subsequent stricture formation [85]. However, transanastomotic biliary stenting in LDLT is still a generally preferred procedure because it maintains the biliary flow despite swelling of the anastomosis and is an easily accessed route for cholangiography in case there is a suspected leak or stricture [71,75,76,81,84]. We prefer external stents to internal stents despite the several disadvantages, among which is that a long waiting period is necessary until external stents can be safely removed, thus preventing leaks at the insertion site. External stents are more effective for reducing biliary complications, including leaks and strictures, than internal stents, and, in particular, life-threatening bile leaks from the anastomosis have almost disappeared with the routine use of external biliary drainage.

The reconstruction of multiple graft ducts is sometimes a real challenge of LDLT when graft ducts are tiny, thin-walled, and prone to ischemia. Multiple, biliary anastomoses are definitely adverse factors that can lead to biliary leaks and stenosis [73,86–88]. When the two ducts are adjacent, unification ductoplasty may be applicable. Although this strategy can facilitate the feasibility of a single anastomosis, this artificial manipulation also increases the risk of bile-duct stump ischemia [87,88]. For double graft ductal openings, separate duct-to-duct, separate hepaticojejunostomy, or a combined duct-to-duct and hepaticojejunostomy were chosen depending on the circumstances. A compromise can be made between duct-to-duct and hepaticojejunostomy under unfavorable bowel loop conditions, such as marked edema, peritonitis-induced thickening, or shortened mesentery [71]. For duct-to-duct anastomosis for more than one bile duct opening, right and left hepatic ducts or more distal segmental ducts can be used. In addition, the cystic duct can be successfully used for duct-to-duct anastomosis [89], particularly when bile duct openings of the liver graft are widely apart, such as the right posterior or accessory duct arising from the common hepatic duct and which is unable to be reconstructed without hepaticojejunostomy (Figure 57.7). Before reconstruction of the cystic duct anastomosis, straightening the spiral valve of the cystic duct should be done by probing and dilatation with a metal probe until it is entirely passable. We routinely insert an external stent into a duct-to-duct anastomosis using the cystic duct in order to keep the lumen open and to avoid obstruction caused by fibrous tissue replacing the anastomotic site [89,90].

All biliary anastomoses should be fashioned tension free and, at their completion, should be checked for leakage. We use a dye test with methylene blue to detect leakage at the completion of the biliary reconstructions. Routine completion cholangiography should be performed when an externalized stent is placed. Leaks are best identified and corrected during the surgery [76].

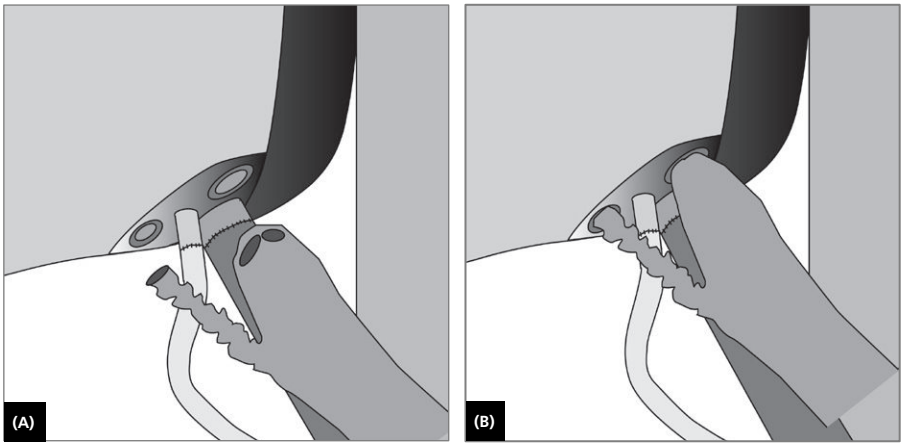

Figure 57.7. Duct-to-duct biliary reconstruction using a cystic duct. When the separate two ducts of the right-lobe graft are more than 1 cm apart and the size- and length-matched cystic duct is available in the recipient (A), we perform duct-to-duct biliary reconstruction (B).

Biliary complications adversely affect the recipient's quality of life and can occasionally even cause graft loss and death [85]. Avoiding biliary complications is very important, although currently there is approximately a 20% complication rate seen on the long-term follow-up results after LDLT and this seems to be inevitable despite the many types of preventive measures. Therefore, intraoperative and postoperative careful management to reduce or treat expected biliary complications is essential in order to prevent the worst outcome caused by bile leak or stricture.

Closure

Once all of the anastomoses are completed with satisfactory results, hemostasis should be assured at the cut surface of the liver graft and all of the recipient's dissection sites, including the perihepatic dissection area (e.g. inferior phrenic artery, adrenal gland, and perirenal space) and the hepatic hilum because postoperative bleeding is not an uncommon complication in LDLT. When we insert closed suction drains, puncture sites of the abdominal wall should be selected at a relatively avascular aponeurotic area lateral to the rectus muscle, in order to avoid injury to epigastric vessels. If bleeding is visible from the peritoneal side of the drain puncture site, we perform a two-thirds, circular stitch around the puncture site using absorbable suture materials and taking care not to bite the drain catheter. After complete hemostasis of the abdominal wall muscles, the abdominal fascia is closed with both absorbable monofilament sutures, in a running fashion, and with additional, interrupted reinforcement sutures.

Graft-type-specific operative procedures

Right lobe graft without middle hepatic vein trunk (right lobe or modified right lobe graft)

Initially, a right lobe graft with MHV trunk (extended right lobe graft) was used for adult LDLT by a Hong Kong group because it can assure optimal drainage of the anterior sector, thus avoiding venous congestion, and it offers better graft function even for a larger recipient [11]. However, LDLT using an extended right lobe graft poses the question of undue risk in the living donor and may be an important ethical issue regarding the aspect of donor safety [91]. We use extended right lobe graft only on the following two scenarios. First, donor age less than 35 years, with no fatty change and congestion-free remnant left liver volume $\geq$30% of the original liver volume. Second, congestion-free remnant left liver volume $\geq$35% of the original liver volume if the donor age is >35 years or mild fatty change is up to 30% [92]. As an alternative graft type, right lobe graft without MHV is commonly used for adult LDLT. However, MHV tributaries draining the anterior sector (Couinaud segments 5 and 8) had not been reconstructed before 1998, when SG Lee introduced use of a modified right lobe graft in which sizable (>5 mm) MHV tributaries are reconstructed using interposition vessel grafts into the recipient's hepatic venous system in order to prevent congestion of the anterior sector [93]. Before the introduction of MHV reconstruction in right lobe graft LDLT, severe congestion of the anterior sector immediately following surgery developed in two of five recipients and was followed by prolonged, massive ascites and severe hepatic dysfunction in early right lobe (RL) LDLT. One recipient died of sepsis with progressive deterioration of graft function 20 days post transplant [94]. Inomata et al. also reported a relatively poor outcome, that is 73% survival rate, after LDLT using a right lobe graft without MHV reconstruction [95]. After application of a modified right lobe graft, the 6-month recipient survival rate improved from 71% to more than 90% at our institution [96]. One study compared the regeneration rate of RL liver graft to three techniques: (1) without MHV trunk preservation or MHV reconstruction; (2) without MHV trunk preservation but with MHV reconstruction (modified right lobe graft); and (3) with MHV trunk preservation (extended right lobe graft). That study showed that if the MHV trunk is not retained, MHV reconstruction should be performed in 85% of all RL LDLT [97].

However, when functional mass of the right lobe graft is adequate (high GRWR) and the MHV tributaries are small (<5 mm in diameter), it means that RHV functions as the major outflow of the anterior sector and right lobe graft without reconstruction of MHV tributaries may be sufficient to assure good graft function [93]. Other researchers have suggested that the lack of anterior sector regeneration is resolved by compensatory regeneration of the posterior sector and that graft congestion in the sector does not affect overall graft regeneration, particularly if the GRWR is sufficient [98,99].

For implantation of a modified right lobe (MRL) graft, all sizable (>5 mm in diameter) MHV tributaries are preserved and

temporarily occluded by tying over a short rubber band or performing Hemolock clamping for future reconstruction during donor hepatectomy. After procuring the RL graft, the temporarily occluded MHV tributaries are opened and flushed with preservation solution at the back table until the perfusate is clear. The initial interposition graft material used for MHV reconstruction was the recipient's GSV after hydrostatic dilatation or two sheets of the GSV. In this situation, the anastomosis between MHV tributaries and autogenous vein grafts was performed using a continuous 6-0 Prolene suture. However, the size disparity between the small caliber of the single-lumen GSV graft and the larger MHV tributaries from segments 5 and 8 created a near occlusion [93]. As an alternative autologous vein graft to overcome this size disparity and to increase the long-term patency, that is to provide a relatively large-diameter recipient left portal vein, several other vein sources can be used, including paraumbilical vein, hepatic vein, superficial femoral vein, external iliac vein, or internal jugular veins [93,100–103]. If homologous vein grafts, such as iliac vessels, femoral vessels, and IVC or aorta, can be harvested from cadaveric organ donors, those are the most preferred vessel grafts for MHV reconstruction at our institution because they do not require time-consuming dissection of recipient tissue and are large and of a long enough length to be used for any variant type of MHV branch [104]. However, the recent increase in the number of adult LDLTs, coupled with the relatively limited number of cadaveric vessel allografts, has led us to search for new vessel substitutes [43]. Thin-walled expanded PTFE grafts were used for MHV reconstruction. The patient and graft survival rates after transplantation of an MRL graft were comparable to those of the extended right lobe (ERL) graft, although their patency rates appeared to be insufficiently low [105]. Ringed PTFE grafts have been preferred at our institution as they increase the patency rate, and they showed a high 6-month patency rate (75.3%) comparable to that of the cryopreserved iliac vein (76.6%). As a result, ringed PTFE graft can also be a good alternative interposition vessel graft when another sizable vessel allograft is not available [106].

In the recipient's side, the interposition vein grafts are anastomosed to the recipient's middle and left HV common opening or directly to the IVC by a continuous 6-0 or 5-0 Prolene suture after the liver graft was reperfused by portal blood flow. The recipient's middle and left HV trunk is the preferred site for anastomosis of interposition vein grafts for several reasons. First, its course and configuration of the anastomosis are more natural due to the use of orthotopic normal anatomic structures and the technical feasibility. Second, the outflow orifice of the interposition vein graft is exposed closer to the negative intrathoracic pressure system and thus promotes hepatic vein outflow drainage more smoothly [107].

Right lobe graft with middle hepatic vein trunk (extended right lobe graft)

Regarding the aspect of unimpeded outflow of the right lobe graft to avoid parenchymal congestion, the right lobe graft with MHV is the best type of right lobe graft if donors are corresponding to the previously described two occasions [92]. In particular, when the GRWR is not sufficient, that is less than 1.0%, in the presence of severe portal hypertension, an ERL graft may have an important role in reducing the small-for-size syndrome by securing a reliable venous outflow.

The Hong Kong group has been a proponent of the ERL graft from the beginning of LDLT. Their technique has evolved over time. In their initial experience, the MHV was anastomosed end-to-end to the ostium of the middle and/or left HV of the recipient [11]. The finding that medial rotation of the graft after reperfusion or later during regenerative growth could in certain cases cause compression of the MHV, caused a change in their initial reconstruction technique. The new technique consists of the construction of a triangular-shaped, common orifice of the right and middle HV of the graft. The distance between the ostia of the right and the middle HV of the graft can be eliminated by dissection of the interposed parenchyma, and horizontal suturing of the vertical incision can be performed on both adjacent walls [108]. In recipient side, circumferential control of the IVC is necessary during HV anastomosis. Several lumbar and phrenic veins must be ligated and divided before IVC is completely mobilized from the diaphragm down to the level of the right adrenal vein. The presence of an inferior RHV greater than 5 mm in the graft calls for freeing of the IVC more inferiorly for vascular anastomosis. When the liver graft is ready for implantation, the IVC is cross-clamped cranially and caudally to the hepatic veins. The longitudinal orifice of the RHV is enlarged by incising transversely across the anterior wall of the IVC corresponding to the transverse dimension of the common hepatic vein orifice in the graft. The cranial and caudal flaps are excised so that a large triangular opening is created and is matched with that of the graft [109]. The height of this triangular opening with the base on the right side and the apex on the left should be no longer than half of the IVC circumference in order to prevent its stricture. The implantation starts with the hepatic vein anastomosis in a triangular fashion using 5-0 polypropylene sutures. After the hepatic vein anastomosis is completed, the portal vein of the liver graft is clamped using a bulldog vascular clamp, and the IVC circulation is restored before PV anastomosis for maintenance of hemodynamic stability [110].

They insist that the described hepatic venoplasty technique converting the RHV and MHV to a single triangular cuff by venoplasty, shortens the caval cross-clamping time, does not necessitate the use of venovenous bypass, and ensures excellent venous drainage [11]. However, their method has several shortcomings. First, venoplasty to create a single, wide-open triangular cuff without using an interposition vein patch between the RHV and the MHV might cause undue tension on the liver parenchyma and thus result in ischemic portion when there is a wide distance between the RHV and the MHV. Second, PV anastomosis under clamping at both recipient's and donor's side, so as to reduce the cross-clamping time of the IVC, is not feasible because the graft PV is sometimes divided too short to clamp for fear of PV stenosis in the donor side. Third, the distance of the apex between the triangular cuff of the graft hepatic veins and the triangular opening of the recipient IVC during anastomosis is far away because there is no patch plasty and also the absence of vessel wall redundancy on both sides. As a result, the weakened vessel wall of the anastomosis might be torn from excessive tension, as indicated in their recent report [111]. Fourth, the adverse effect of venovenous bypass is not so worrisome. On the contrary, it allows decompression of the splanchnic and retroperitoneal circulations and prevents major hemodynamic changes during the anhepatic phase. It, therefore, provides more time for us to prepare the recipient IVC such as cavoplasty and to perform venous anastomosis without having to hurry.

At our medical institution, venovenous bypass is used for implantation of ERL grafts. The RHV and MHV of the graft is converted into a common cuff resembling a dome using the quilt venoplasty technique with the autologous saphenous vein, portal vein patch, and sometimes with homologous cryopreserved cadaveric veins.

At the same time, the orifices of the recipient's RHV, MHV, and LHV are opened altogether to make a large orifice in the recipient's IVC. The bisected saphenous vein segment is sutured to the middle and left sides of the common orifice in order to make a fence for thick-walled, tension-free anastomosis during reconstruction. This method is freely applicable to the extended right lobe grafts with preservation of the proximal MHV branches at the donor's remnant liver side because the corresponding defect at the graft MHV can be covered by the enlarged vein cuff [112].

Recently, an ERL graft leaving the proximal MHV to preserve the drainage veins of segment 4 to the MHV in the donor's remnant liver has been commonly used due to consideration of the donor's safety [99,113,114]. In this situation, the gap between the graft's MHV and the recipient's hepatic veins is wider than a conventional ERL graft, and separate anastomosis of the MHV to the recipient's middle and left HV trunk using an interposition vein graft such as a modified RL graft without venovenous bypass or a large single anastomosis after making a redundant common cuff using quilt venoplasty under venovenous bypass, can be performed for reconstruction of the MHV (Figure 57.8).

Left lobe graft with and without the caudate lobe

In adult-to-adult LDLT, a left lobe graft has a limited role because the graft volume is not sufficient to avoid the small-for-size syndrome in many patients. However, as long as the graft size is greater than 40% of the recipient's standard liver volume in small-body-sized recipients, a left lobe (LL) graft is still a useful graft for adult-to-adult LDLT [115,116]. Although the caudate lobe is a small part of the whole liver, its volume is not negligible in the partial liver graft and provides a 6 to 12% gain in LL graft weight [117,118]. When the pretransplant recipient's physical condition is good and without cirrhosis such as metabolic disorders, including citrullinemia or familial amyloid polyneuropathy, the minimally successful graft volume might be decreased to as low as 0.6% GRWR or 30% of the recipient's standard liver volume [119].

Considering the relatively small-sized graft volume, large hepatic vein outflow is essential for a functionally perfect graft after transplantation into the recipient. During total hepatectomy we mobilize the retrohepatic IVC from the retroperitoneal attachment. To ensure adequate hepatic vein outflow, venoplasty of the hepatic veins of the liver graft should be performed using an autologous, bisected GSV segment. The venoplasty technique is used to make a wide, single orifice with a sufficient length of the hepatic vein stump. The right side of the MHV only or both the right side of the MHV and the left side of the LHV are incised longitudinally and the bisected GSV segment is attached to the hepatic vein for venoplasty. In the recipient's side, the orifices of the recipient's RHV, MHV, and LHV are completely opened, and venoplasty making an adequate-sized, large orifice is performed in order to accommodate the enlarged hepatic vein orifice of the graft (Figure 57.9). Venovenous bypass under clamping of the supra- and infrahepatic IVC is a necessary step for the recipient's venoplasty and engraftment (Figure 57.10).

When the left lobe with the caudate lobe graft is used, complete revascularization of the caudate lobe may contribute to full graft regeneration [120]. The caudate hepatic vein resected with a cuff of the IVC, which resembles a Carrel patch, is first reconstructed, after which the enlarged hepatic vein orifice of the graft is anastomosed

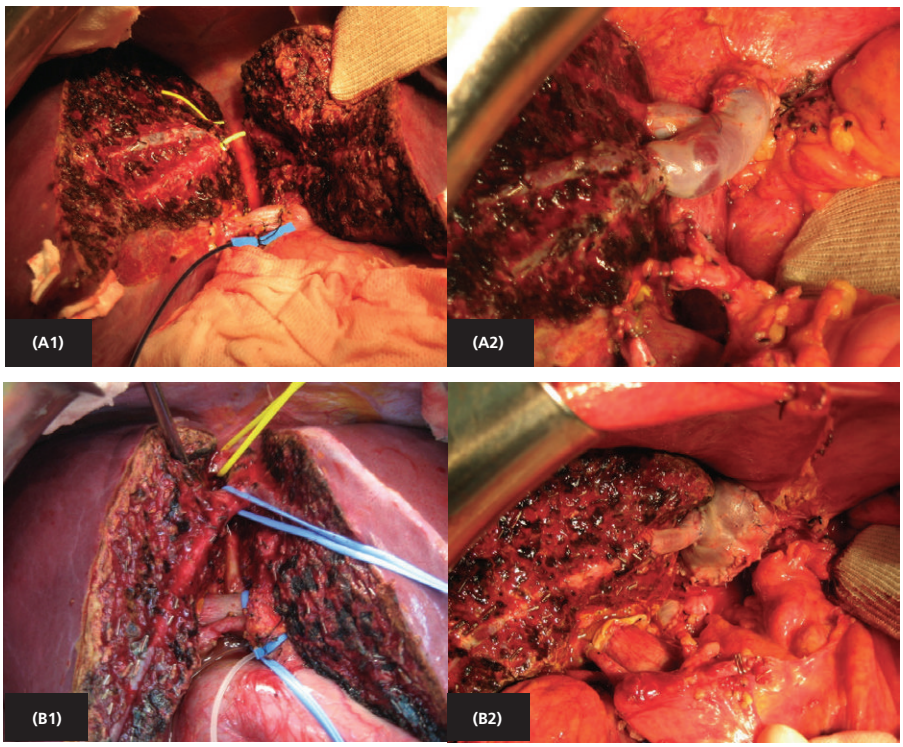

Figure 57.8. Extended right lobe graft leaving the proximal middle hepatic branch of segment 4 in the donor's remnant liver. Two openings, including the distal trunk of the middle hepatic vein and segment 8 of the middle hepatic vein branch (V8), are expected to come on procurement (A-1, B-1). Separate anastomosis of the MHV to the recipient's middle and left HV trunk using interposition vein graft such as a modified right lobe graft (A-2) or a large single anastomosis after making a redundant common cuff using quilt venoplasty under a venovenous bypass (B-2) can then be performed.

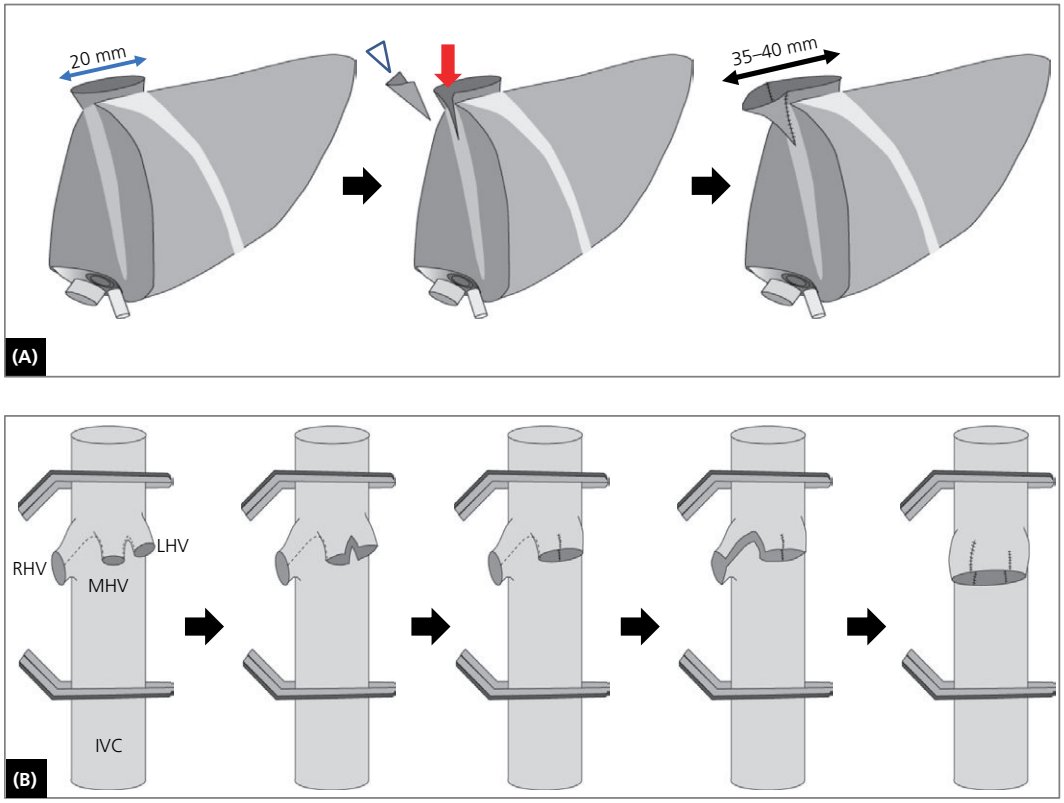

Figure 57.9. Hepatic vein plasty to create maximal outflow in left lobe, living donor liver transplantation. (A) When the common opening of the middle and left hepatic vein in the graft is small, that is approximately 20 mm in diameter, the right side corner of the middle hepatic vein is incised (white arrowhead) and patch-plasty using the bisected great saphenous vein (red arrow) is performed at the back-table to create an enlarged, common opening of approximately 35–40 mm diameter. (B) In the recipient's side, all three of the hepatic vein orifices are completely opened, and venoplasty is performed to make a large common orifice for accommodation of the enlarged hepatic vein orifices of the graft.

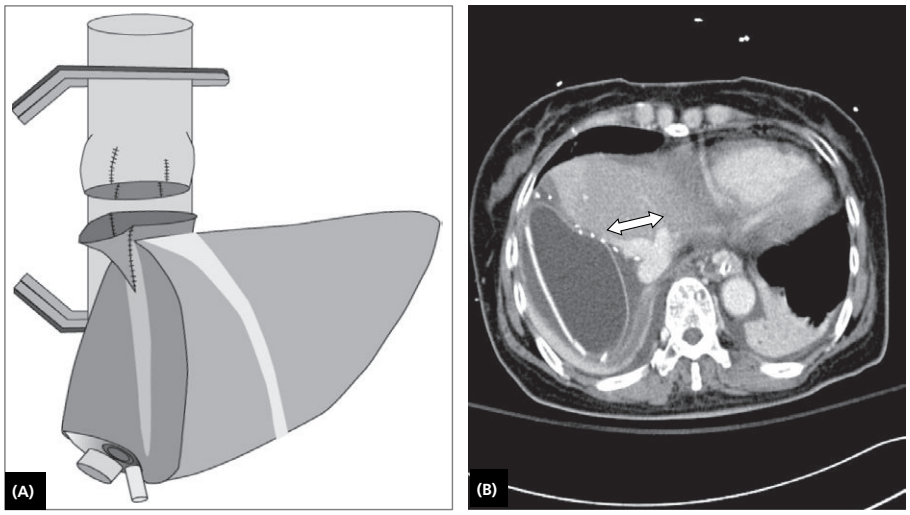

Figure 57.10. Reconstruction of the hepatic vein in left lobe, living donor liver transplantation. (A) Anastomosis between the donor and recipient's maximally enlarged, common hepatic veins is performed by clamping the supra- and infrahepatic inferior vena cava and by venovenous bypass. (B) Follow-up CT scan obtained on postoperative day 7 showed wide hepatic vein outflow and tissue expander filled with saline solution to prevent torsion of the hepatic vein anastomosis until there was adequate regeneration of the implanted graft.

to the large common opening of the recipient's hepatic veins. When the orifice of the caudate vein is located close to the left and middle hepatic veins, the caudate vein with the IVC cuff can be made into a single opening with a common orifice of the left and middle HV, and a single HV anastomosis is sufficient for the outflow reconstruction [121]. However, we have seldom observed any large caudate vein in such a location during harvesting of hundreds of left lobe grafts [117]. An isolated caudate PV originating from the main PV is present in 13% of recipients and reconstruction is necessary for a large, that is more than 5 mm, one [122]. However, during donor hepatectomy in our series, a large, isolated caudate PV was very rare and we only chose whether to meticulously excise the caudate PV branch as a common PV opening or to ligate it. Considering the reconstruction of the hepatic artery, all hepatic arteries of the left lobe graft might not be able to be reconstructed [52] because accessory hepatic arteries usually communicate with the original lobar arteries in the hepatic hilum [56]. However, we reconstructed all of the hepatic arteries of a liver graft when the size- and length-matched inflow arteries were present because individual hepatic arteries are basically end arteries and we occasionally encountered abnormally elevated liver enzyme and an ischemic area of implanted left lobe graft during the immediate post-transplant period when unreconstructed HA is present.

Reconstruction of the caudate duct can be performed in a single anastomosis when closely approximated or in a separate anastomosis when widely apart [17]. However, it is an optional procedure, not an essential procedure at our medical center. Instead of a preference for caudate duct reconstruction, we give special attention to determining the bile duct division site in order to avoid sizable, separate caudate ducts with exploration of the biliary tree, including the ducts of segments 9 and 1 through the cystic duct and using a 1.5-mm coronary artery dilator [117].

Dual-graft living donor liver transplantation

Partial liver graft from a single donor, regardless of whether it is a left or right lobe graft, cannot often meet the metabolic demands of a large recipient or of a critically ill recipient with portal hypertension. As an alternative approach in order to avoid the small-for-size graft syndrome and also to provide donor safety based on the established donor selection criteria, dual-graft LDLTs have been performed since 2000 at our institution and recently at many other hospitals as well [42,123–127].

During the recipient's surgery, both the right and left branches of the PV and the hepatic artery are dissected free from the surrounding tissue and as high as possible so as to obtain enough length for future bilateral vascular anastomosis. During the total hepatectomy, the recipient's IVC should be mobilized from its retroperitoneal attachment because venoplasty of the recipient's hepatic veins and graft implantation are performed under clamping of the supra- and infrahepatic IVC. Venovenous bypass is necessary in most cases in order to maintain stable hemodynamics and to avoid mesenteric congestion during the anhepatic phase.

Before implantation of liver grafts, venoplasty of hepatic veins in the recipient and/or liver grafts should be performed to make wide outflow orifices with a thick wall and a long cuff. The recipient's RHV is enlarged and elongated by longitudinal incision at the inferior corner and fencing with the bisected GSV. The middle and left HVs are converted to a single opening by division of the septum, and are then enlarged and elongated by a transverse incision at the right corner and fencing with bisected GSV. At the back table, venoplasty of hepatic veins of the liver grafts can be performed considering the size match between the recipient's and the graft hepatic veins. The methods are the same as those of the single-graft LDLT mentioned previously. The venoplasty is important so that the surgeon can perform engraftment without difficulty during the surgery and can also avoid postoperative outflow disturbance.

Engraftment procedures using two left liver grafts are as following. First, a 180° rotated left liver is placed into right upper quadrant space, and its hepatic vein anastomosis to the recipient RHV is performed. Second, an orthotopically positioned left liver is anastomosed to the common opening of the middle and left HV. Third, the PV anastomosis of the orthotopic graft is performed to the recipient's left PV. Fourth, a left-sided (orthotopic) graft is reperfused earlier in order to avoid bowel congestion and reduce the ischemic time. Before the procedure proceeds, a vascular clamp is applied to the recipient's RHV to prevent regurgitation of caval flow into the right-sided (heterotopic) graft after release of the caval clamp. Vascular clamps to the vena cava and the main PV are then removed together under clamping of only the recipient's right PV. Fifth, bile duct anastomosis of the right-sided (heterotopic) graft to the recipient's bile duct, is performed in a duct-to-duct fashion earlier than PV anastomosis because the bile duct comes to lie behind the PV and the hepatic artery from the reversed hilar structures of the graft. Sixth, the PV anastomosis is performed between the right-sided graft and the recipient's right PV, and is reperfused after removal of the vascular clamps on the recipient's RHV and right PV. Seventh, hepatic artery anastomoses are performed and finally a Roux-en-Y hepaticojejunostomy to the left-sided (orthotopic) liver is performed. As additional procedures, a tissue expander filled with saline solution (from 200 to 450 mL) should be inserted underneath the right-sided (heterotopic) graft to relieve undue tension on the hilar anastomoses because the left liver graft is always too small to replace the right upper quadrant space after total hepatectomy in the recipient (Figure 57.11).

Engraftment procedures using both right and left liver grafts are a type of combination of two single-graft LDLTs using right and left liver grafts, respectively, because both grafts are positioning orthotopically. First, the right liver graft is placed into the right upper quadrant space and reconstruction of the hepatic veins is performed. The interposition graft of the MHV tributaries is anastomosed to the anterior wall of the IVC below the recipient's MHV. Second, the left liver graft is placed orthotopically and its hepatic vein and PV are reconstructed sequentially. Third, anastomosis between the recipient's right PV and the graft PV is performed, after

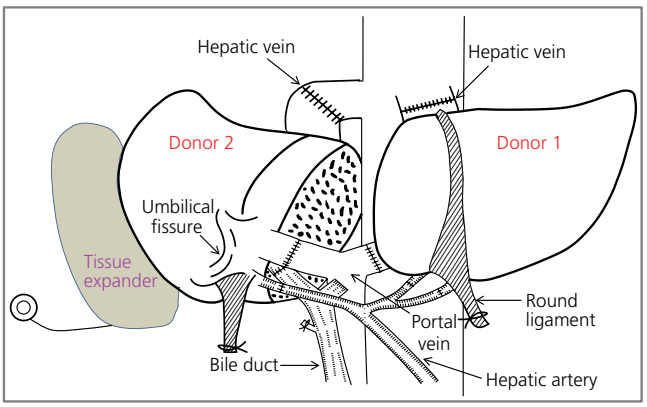

Figure 57.11. Living donor liver transplant using dual, left lobe grafts.

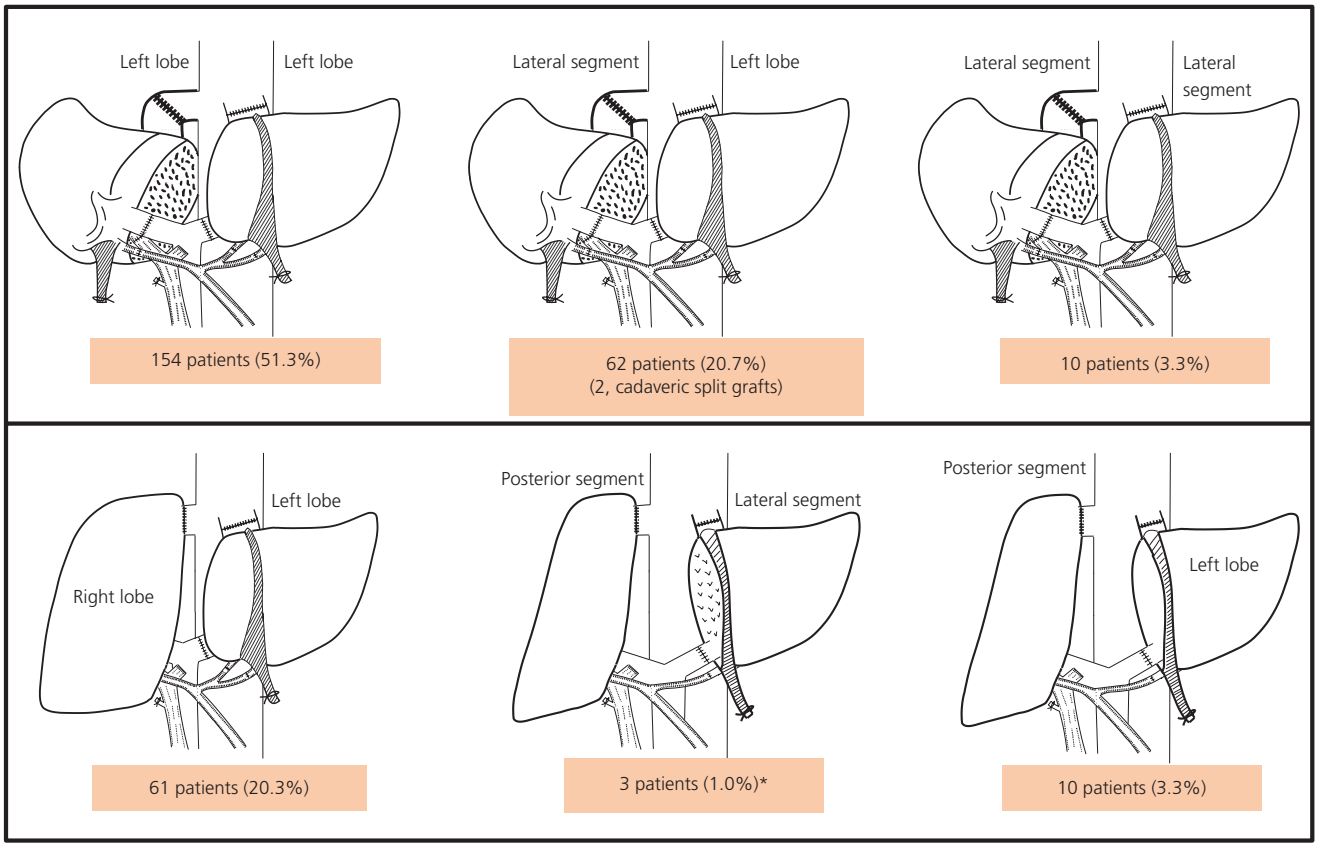

Figure 57.12. Various strategies employed for dual-graft living donor liver transplantations. Taken from an experience of 300 cases of dual graft transplantation (from a total adult living donor liver transplantation experience of 2227) performed from March 2000 to February 2011 at the Asan Medical Center.

which both liver grafts are reperfused at the same time. Fourth, after completion of the hepatic artery anastomoses, biliary reconstruction to both grafts is performed using Roux-en-Y hepaticojejunostomy only or a combination of the recipient's bile duct and Roux-en-Y hepaticojejunostomy.

If the available single largest graft cannot meet the recipient's metabolic demand, a dual-graft LDLT using left or right liver grafts from two living donors can expand the application of adult-to-adult LDLT by satisfying the GRWR of the recipient. The mean GRWR with dual left lobe LDLT (median 0.95%; range 0.59 to 1.25%) approaches that of right lobe transplant (median 0.98%; range 0.64 to 1.29%).

Most dual-graft LDLTs, particularly those using two left liver grafts, have been performed to secure the donor's safety rather than the recipient outcomes. The prevalence and the severity of donor complications were lower than those of single, right lobe graft LDLTs [92]. The most common complications in dual-graft recipients were biliary strictures (28%) and hepatic venous outflow obstruction of the heterotopic, right-sided left liver graft (15%). Hepatic vein obstruction did not occur in orthotopically positioned, both left-sided left liver and right-sided right liver grafts. This might be related to the progressive compression of the hepatic vein anastomosis by the regeneration of a heterotopically positioned left liver graft. In contrast to auxiliary, partial, orthotopic liver transplants (APOLTs), the two liver grafts in dual-graft LDLT do not enlarge competitively but do so cooperatively during the regeneration period [128].

At our medical center, of the 2227 adult LDLT recipients, 300 (13.5%) underwent dual-graft transplants from March 2000 to February 2011 (Figure 57.12). Urgent, dual-graft transplants were performed for fulminant hepatic failure in 18 patients (6.0%) and for acute-on-chronic liver failure in 44 patients (14.7%). The incidence of biopsy-proven acute rejection is similar to that in single-graft, living donor recipients (17%), three-quarters of whom developed acute rejection simultaneously in both of the grafts. The inhospital mortality rate was 7.0% (21 patients), and there was a status I and 2A patient comprise of 52% (11 patients). The overall survival rate and the incidence and severity of long-term complications between dual-graft and single-graft recipients were similar. Infrequently, unilateral graft atrophy developed in recipients of two left lobes, but this did not affect their liver function or survival.

LDLT with dual left liver grafts is technically complex and elaborate, but this procedure can help solve problems related to small-for-size grafts and can help to expand the indications for LDLT and for split-liver transplants in adult recipients.

Right posterior sector graft

A right posterior sector graft (RPS) can be a good alternative to a full right lobe graft when it satisfies the minimum volume requirement for the recipient, and which has been set at 40% of the recipient's standard liver volume [129,130] and also being larger in volume than the left lobe [131,132]. Technically, procurement of the RPS graft is the most demanding because it requires the longest time of parenchymal transection and also hilar dissection [130].

Sugawara et al. indicates that there are no exclusion criteria in RPS graft procurement, from an anatomic point of view [133]. However, considering the 45–50% biliary complication rates, including leakage and stenosis, more refined donor selection criteria for procurement of an RPS graft might be necessary in order to reduce complications in the recipients. The procurement of an RPS graft at our medical center is selectively performed so as to reduce surgery-related complications after consideration of anatomical variations including the PV, hepatic artery, and bile duct. When the left lobe volume is disproportionately small (<30% of whole liver volume) and there is type II or III PV, successful RPS graft procurement is likely [132].

In the recipient surgery, meticulous hilar dissection as high as possible should be performed in order to obtain a size-matched hepatic artery with a small caliber (1–2 mm in diameter) and/or bile duct openings for duct-to-duct anastomosis. For successful engraftment, the preparation and implantation procedures are basically the same as those for right lobe implantation. When the PV of the RPS graft has a short stump and/or a weak wall, making a fence to the graft PV using a bisected GSV can be useful in order to perform safe and wide anastomosis. When the hepatic artery of the graft has too short a stump to rotate under clamping of a metallic double micro clamp, posterior wall repair should be performed first with interrupted suturing.

Summary

Living donor liver transplantation is now applied worldwide, although it remains a technically challenging procedure to be performed only by the most experienced of teams. Donor selection is critical to insure the safety of the donor, particularly to ensure that they are left with adequate (at least 30%) hepatic volume, and careful assessments of the size of the donated hepatic lobe relative to the needs of the recipient must be undertaken preoperatively. If the volume of the right lobe in potential donors exceeds 70% of the volume of the whole liver or if a large-size recipient requires more graft volume than the expected liver graft volume from a single donor, dual-graft LDLT may be an alternative. The surgical technique for recipients is based on whole liver resection with preservation of the inferior vena cava. For technically successful LDLT, the following four conditions must be satisfied: (1) transplant a large-volume graft to avoid small-for-size, (2) good outflow to avoid congestion, (3) adequate portal inflow to enhance graft regeneration, and (4) secure bile duct anastomosis to avoid biliary leak.

CHAPTER 58

Heart Transplantation Procedure and Surgical Technique

John M. Craig,[1] Soyoung Lee,[2] Gus J. Vlahakes,[2] and Joren C. Madsen[2]

[1] Division of Cardiac Surgery, Baptist Memorial Hospital, Memphis, TN, USA

[2] Department of Surgery and Transplant Center, Massachusetts General Hospital, Boston, MA, USA

Introduction

The fundamental surgical procedures used in modern cardiac transplantation are all based on the technique of the vascular anastomosis developed by Alexis Carrel in the 1890s. At the turn of the century, Carrel first applied his anastomotic technique to organ transplantation, including cervical heterotopic heart transplants in dogs [1]. After a period of relative inactivity in the field, Vladimir Demikhov in Moscow began experimenting with intrathoracic heterotopic heart transplant and heart–lung transplantation in dogs. By the late 1940s, he had performed successful orthotopic heart transplantation in dogs, although most of his work was not published in English until the early 1960s. By that time, Lower and Shumway at Stanford had refined the techniques of orthotopic heart transplantation in dogs and reported significantly longer survival than that obtained by previous groups [2]. Utilizing the orthotopic techniques developed by the Stanford group, Christiaan Barnard performed the first successful human heart transplant on December 3, 1967 in Cape Town, South Africa [3]. Since then, the most common method of transplantation has been implanting the donor heart into the orthotopic position; however, other procedures, including heterotopic and heart–lung transplantation, have proven useful in certain situations [4]. While the most significant overall advance in heart transplantation since 1967 has been the advent of effect immunosuppression, the most notable evolution in the technique of heart transplantation has been the switch from biatrial to bicaval anastomoses of the vena cavae.

By way of a disclaimer, there are many different ways to preserve, procure, and implant human heart allografts. The techniques described below are those employed at the Massachusetts General Hospital. They have contributed to the excellent short- and long-term outcomes observed in our recipients. However, techniques can and do vary greatly between institutions with similar excellent outcomes.

Donor operation

Excellent medical care of the donor in the ICU and meticulous surgical technique during procurement are arguably the most important parts of the overall transplant procedure for the following reasons. First, to diminish the risk of early graft dysfunction, the heart must be taken in a high energy state. This can only be assured by the procuring cardiac surgeon carefully managing/optimizing the donor's blood pressure, cardiac output, volume status, metabolic parameters, and hematocrit. Second, because this period is when the donor is accepted or rejected, all patient data that bear on donor suitability must be assiduously obtained, evaluated, and incorporated into the decision-making process. Third, the procuring teams, especially the heart and lung teams, must coordinate their respective intraoperative plans so as to avoid putting any organ (and ultimately, any recipient) at risk. This requires collegial communication before surgery begins. Finally, the graft must be adequately preserved, safely explanted, and expeditiously transported to the transplanting facility to assure an optimal outcome. More general discussions on the conduct of the donor procedure are available in Chapter 21.

Preparation

The initial steps of donor–recipient matching are discussed in Chapter 39. Before leaving for the donor hospital, the heart team must ensure that all necessary items are packed. We typically carry a cooler with 2 liters of crystalloid cardioplegia (Plegisol) for use as preservation fluid. The specifics of cardiac preservation are discussed in Chapter 26. The cardioplegia is surrounded by bags of frozen saline and transported in a cooler. We also bring along items that are not universally available, such as an aortic root cannula, Prolene sutures, tourniquets, and tubing with necessary adaptors for the cardioplegia. Our local Organ Procurement Organization (OPO) provides additional cardioplegia and a sternal retractor. Upon arrival at the donor hospital, pertinent medical records, echocardiograms, chest radiographs, and angiograms are reviewed. Patient identification and ABO compatibility are verified. The medical condition of the donor is reassessed because rapid changes in physiology are not uncommon. It is important to verify proper monitoring capabilities. At a bare minimum, the donor should have a large-bore peripheral intravenous line as well as arterial and central venous monitoring lines. Goals of management in the donor operating room are maintaining a systolic arterial pressure over 100 mmHg, a central venous pressure of 8–12 mmHg, a PaO_2 of >95 mmHg and a hematocrit of ≥ 30. To minimize ventricular stimulation and energy expenditure, we avoid β agonists and

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

instead use phenylephrine as the vasopressor of choice. However, volume is usually adequate to treat transient hypotension.

The various surgical teams should become acquainted with each other and should clarify procedural steps, especially those involving competing anatomical interests. In the case of concomitant left lung retrieval, the heart and lung surgeons should work together to plan how and where to divide the pulmonary veins so as to leave adequate tissue for both implanting teams. The same holds for dividing the main pulmonary artery and to a lesser extent, discussing division of the inferior vena cava with the liver surgeon. A few minutes of collegial conversation before the operation can prevent mistakes, save time, and avoid heated arguments during the operation.

Surgical technique

After the requisite "time out," the donor is draped from neck to groins, and the multiorgan retrieval operation is begun with a generous midline incision. Strict adherence to hemostasis is important as even slow oozing from the exposed sternal surfaces can accumulate with time. To this end, the sternal marrow is completely sealed with bone wax. To avoid compromising the abdominal exposure, the sternal retractor is oriented with the crossbar toward the head. The pericardium is opened and suspended with silk stay sutures. The inferior right pericardium is divided down to the level of the inferior vena cava to improve visualization and provide for the egress of blood into the right thorax when the inferior vena cava is later vented. The heart is inspected for ventricular dysfunction, distension, coronary atherosclerosis (both by visual inspection and manual palpation), anatomic variations, evidence of trauma, and proper size match for the intended recipient. Palpation of an aortic thrill may indicate valvular pathology. The final decision on donor suitability is made and communicated back to the recipient team along with the anticipated clamp time.

Although dissection can proceed in a variety of ways, we typically proceed in clockwise fashion starting with the superior vena cava and left innominate vein, which are fully mobilized. The azygos vein is identified posteriorly and ligated distally. The preserved azygos vein takeoff can be used to enlarge the donor super vena caval orifice if necessary. If the lungs are being procured, the plane between the superior vena cava and aorta is developed and the relatively avascular pretracheal tissue is divided longitudinally between the innominate vein and pulmonary artery (see Chapters 21 and 59). The aortopulmonary window is then opened to prevent pulmonary artery injury during subsequent aortic clamping. Dissection around the aortic root is avoided to prevent injury to the coronary arteries. The inferior vena cava is circumferentially dissected.

Cannulation of the ascending aorta is delayed until all teams are nearly ready to proceed with aortic clamping. At that time, the patient is systemically heparinized (300 units/kg). The preservation solution is then removed from the cooler and hung in a pressure bag at the head of the table. For the initial flush, we use cold Plegisol. It requires the addition of 10 mL of 8.4% sodium bicarbonate solution before use. A cardioplegia catheter is placed in the ascending aorta and is secured with 4-0 Prolene as it will be retained for use during implantation. If lungs are to be procured, an additional cannula is placed through a purse-string suture in the distal main pulmonary artery at a point mutually acceptable to both heart and lung teams. All neck lines are withdrawn to above the innominate vein by the anesthesiologist. Once the preparatory steps are completed by all teams, heart procurement proceeds rapidly. The priorities for the cardiac team are adequate decompression of the right and left ventricles and optimal administration of preservation solution. The following steps are performed in a rapid but controlled sequence:

1. If the lungs are to be procured, 500 μg prostaglandin E_1 is injected into either the pulmonary artery adjacent to the cannula or into the right atrial appendage.
2. The superior vena cava is ligated at its confluence with the innominate vein.
3. If lungs are to be procured, the left atrial appendage is divided or the inferior wall of the left atrium incised to vent the left heart. If lungs are not being harvested, the left inferior pulmonary vein is divided at its pericardial reflection.
4. The intrapericardial inferior vena cava is partially transected and blood vented into the right chest.
5. Once adequate decompression is verified, the aortic cross clamp is applied as far distally as possible (preferably at the innominate artery origin).
6. One liter of cardioplegic preservation solution is infused with 100–150 mmHg pressure applied to a pressure bag surrounding the cardioplegia container.
7. Simultaneously, the pericardium is filled with cold saline slush.
8. The heart is observed for adequate aortic root pressure, prompt arrest, blanching, and the absence of ventricular distension.

After the cardioplegia infusion is completed, donor cardiectomy is performed. The posterior wall of the inferior vena cava is divided freeing the right atrium inferiorly. The superior vena cava is divided at its confluence with the innominate vein. If the lungs are not being procured, the pulmonary veins are simply transected at their pericardial reflections. If the lungs are being procured, the heart is retracted to the left, and the interatrial groove is incised and extended superiorly onto the left atrial dome and inferiorly behind the inferior vena cava. The apex is then retracted cephalad bringing both inferior pulmonary veins into view. The incision is then continued from right to left parallel to the atrioventricular groove and then anterior to the left pulmonary veins. Lastly the superior left atrial wall is divided as the heart is retracted even more cephalad and anteriorly. It is imperative that the pulmonary vein orifices be frequently reassessed during the left atrial division with supervision by both the lung and heart teams. In particular, on the left side of the left atrium, there is often a limited distance between the left pulmonary veins and the donor left atrioventricular groove. Sufficient left atrial cuff must remain to permit implantation without compromise or kinking of the circumflex coronary artery (see Chapter 59). The aortic arch branches and proximal descending aorta are divided. Finally, the main pulmonary artery is transected at its bifurcation. The donor heart is then taken to the back table for additional preservation and preparation for transport (see below).

Preparation and transportation of the allograft

Preparation at donor institution

On the back table, we infuse 500 mL of University of Wisconsin (UW) solution into the clamped aortic root and use the remaining solution as transport medium. The graft is inspected for anatomical abnormalities, including a patent foramen ovale, and/or surgical damage. The cardioplegia cannula is left in place for later use. The heart is placed into a sterile plastic bag with UW preservation solution, deaired, and tied with an umbilical tape. Ice is not placed directly in contact with the graft. This bag is placed into another

bag of saline ice, which is then placed in a plastic container that is wrapped with the final bag and put into a cooler for transport. The recipient team is notified of the cross clamp time, condition of the organ, and estimated time of arrival at the recipient hospital. See Chapter 26 for additional details on cardiac preservation.

Preparation at recipient institution

At the recipient institution, the heart is sterilely removed from the packaging and placed on the back table for final preparation. The procuring surgeon performs this as the recipient cardiectomy is being completed. ABO matching is visually confirmed. The great vessels are separated. The left atrial cuff is prepared by connecting all four pulmonary vein orifices and incising the left atrial free wall longitudinally to create a single large orifice. If a patent foramen ovale is present or the left atrial appendage was opened to vent the left heart, they are closed securely. If a biatrial anastomosis is planned, the superior vena cava is doubly ligated 1–2 cm above the sinoatrial node, and the right atrium is opened from the lateral inferior vena cava toward the base of the right atrial appendage away from the sinoatrial node. For a bicaval anastomosis, the superior vena cava cuff is trimmed at the level of the azygos vein orifice. This can later be used to enlarge the anastomosis as mentioned above. The donor aorta and pulmonary artery are not trimmed in length until later. At this point, the donor heart is brought to the operating table and perfused with cold, oxygenated, blood cardioplegia.

In an effort to expand the donor pool, some authors have reported repair techniques for a number of donor heart defects. However, the functional advantage of extensive repairs must be weighed against the expense of ischemic time. Mitral valve repair has been reported [5–7] but should be undertaken only if there is a high degree of confidence that such repair is necessary and that a durable functional result can be obtained. Aortic valve repair has been reported as well but should be performed by surgeons with experience with these repair techniques [8]. Tricuspid valve incompetence should probably be repaired by ring annuloplasty because it has been shown that recipients with even moderate tricuspid regurgitation after implantation have decreased survival [9]. Whether all donor hearts should undergo tricuspid valve annuloplasty is controversial (see below) [10]. Closure of ventricular septal defects has been reported [11] but right ventriculotomy should be avoided given the propensity for compromised right ventricular function following transplantation.

Recipient operation

Timing

Coordination of the transplant process begins before the procuring team leaves to travel to the donor site. The recipient should be brought to the operating room 2 hours in advance of the estimated start of the recipient operation and lightly sedated for insertion of monitoring lines. The procuring team communicates with the recipient team prior to aortic cross clamping to synchronize the timing of donor heart explantation and recipient cardiectomy so that the recipient team is ready in advance of the donor team arrival. This avoids increasing the ischemic time while waiting for the completion of cardiectomy. With current techniques, ischemic times should not exceed 6 hours (in adults) and should be kept to 4 hours or less if possible, particularly in high-risk transplants (i.e. suboptimal donors or recipients with increased pulmonary vascular resistance).

Preoperative preparation of the recipient

Recipients are often on warfarin or are coagulopathic from a combination of medications and hepatic congestion from long-standing heart failure. In this case, we administer vitamin K (10 mg) intramuscularly or by very slow intravenous infusion over 30–60 minutes. Given their extensive cardiac history, recipients may have had previous documentation of heparin antibodies. It is important to review previous hematology input regarding the use of heparin for cardiopulmonary bypass. It has been shown in patients with ventricular assist device (VADs) that if heparin is avoided during the bridge to transplant and preoperative antiheparin/platelet factor-4 antibody (HPF4) titers are low or absent, re-exposure during the transplant procedure is not associated with an increase in perioperative complications [12]. However, if HPF4 titers are elevated, options include use of a direct thrombin inhibitor such as bivalirudin or use of heparin with intraoperative plasmapheresis or administration of a glycoprotein II_BIII_A inhibitor [13–15]. When patients are on argatroban, we typically stop the infusion 4–6 hours before surgery. We give our patients mycophenylate mofetil (MMF) 1000–1500 mg orally on call to the operating room and high-dose intravenous corticosteroids upon induction of anesthesia [16]. Likewise, broad-spectrum prophylactic antibiotics and antifibrinolytics are administered just prior to induction of anesthesia. We routinely place a pulmonary artery catheter, arterial line, large-bore venous line, and transesophageal echocardiography probe.

Recipient operation

Preparation

Permanent pacemakers and/or implantable cardioverter-defibrillators need to be prepped in the field. After sternotomy, the patient is heparinized for bypass (initial dose of 300 IU/kg). Aortic cannulation is performed as distally as possible on the ascending aorta to provide as much length as possible for implantation. Bicaval venous cannulation is performed with right angled metal cannulas, again as far peripherally as possible. It is helpful to place the purse-string sutures such that the tourniquet is on the side of the cannula opposite the atrial suture line in order to preserve as much length as possible and minimize subsequent distortion of the anastomosis. When the procuring team arrives, cardiopulmonary bypass is initiated. Once on bypass, we systemically cool to 28°C to prevent early rewarming of the donor heart as it lies within the pericardial cavity during implantation. All central venous lines are withdrawn into the superior vena cava. Once satisfactory initiation of cardiopulmonary bypass is confirmed, the aortic cross clamp is applied, caval tourniquets are tightened, and the recipient cardiectomy is performed.

Cardiectomy

The aorta is transected at its sinotubular junction. The recipient cardiectomy then progresses in an approximately clockwise progression. First, a right atrial incision is made parallel to the atrioventricular groove through the appendage and into the dome of the left atrium. The right atrial incision is continued inferiorly toward the medial aspect of the inferior vena cava. The superior vena cava is divided just above the cavoatrial junction. Recipients often have leads traversing the superior vena cava, which are pulled toward the heart and cut as short as possible with heavy scissors. The aorta and pulmonary artery are then divided just distal to their respective semilunar valves after the aortopulmonary window is developed (if not done previously). The initial incision into the dome of the left atrium is continued in two directions. First, the interatrial septal

component is continued through the fossa ovalis and inferiorly toward the atrioventricular groove, joining the previous right atrial incision just medial to the inferior vena cava. It is then continued parallel to the atrioventricular groove just cephalad to the posterior mitral leaflet. The other component of the incision is continued over the left atrial dome, between the base of the left atrial appendage and left pulmonary veins to join the previous incision along the atrioventricular groove, thus completing the cardiectomy. As in the donor cardiectomy, great care is taken to preserve an ample cuff of left atrium near the pulmonary vein orifices. This is the ideal time to obtain hemostasis of the posterior pericardial contents, including cauterizing the free edges of the left atrium. Subsequent bleeding in this area will be difficult to correct once off bypass. Some surgeons place a vent through a right superior pulmonary vein purse-string suture to evacuate all warm pulmonary venous return.

Implantation

There is considerable variety in the sequence in which the allograft may be implanted, which allows the surgeon to tailor the strategy to the needs of each operation and to limit ischemic time as needed. Because we favor the bicaval technique, our default anastomotic sequence is as follows: (1) left atrium, (2) inferior vena cava, (3) pulmonary artery, (4) aorta (with subsequent removal of aortic cross clamp), and (5) superior vena cava. If there are concerns about an unusually prolonged ischemic time, the sequence is modified as follows: (1) left atrium, (2) aorta (with subsequent removal of aortic cross clamp), (3) pulmonary artery, (4) inferior vena cava, and (5) superior vena cava. The disadvantage of the latter sequence is that coronary venous return can partially obscure the pulmonary artery and inferior vena cava anastomoses. During the entire procedure an iced gauze covers the right ventricle and the operative field is flooded with carbon dioxide to limit the collection of intracardiac air. Note that an everting left atrial suture line is preferred to keep bare atrial muscle from being exposed inside the left atrium. In general, the pulmonary artery anastomosis is not tightened and not tied down until the end of the operation so that air can be expelled from the right heart. As with all open cardiac surgery, care must be used to ensure that the left heart has been well de-aired. Even a small air embolus down a right coronary artery during weaning from bypass can be a major issue, although usually temporary. If the cross clamp is removed early in the implant sequence, the heart should be continuously monitored to ensure that the left ventricle is not being distended.

Bicaval versus biatrial techniques

The right atrial anastomotic technique must be determined prior to implantation because this influences the cardiectomy procedure and back-table preparation. The most significant technical advance since the early era of heart transplantation is use of the bicaval method of systemic venous return. Before the turn of the century the traditional biatrial technique was used almost exclusively. A recent review of the United Network for Organ Sharing (UNOS) database showed that nearly two-thirds of transplants in 2007 utilized the bicaval technique [17]. That review of nearly 21 000 recipients over 10 years showed an increased incidence of permanent pacemaker placement in the biatrial group (odds ratio 2.6) with a significant survival disadvantage at 30 day and long-term follow-up (biatrial OR for mortality 1.17 and 1.11, respectively), which supported similar findings reported nearly 10 years previously [18]. The bicaval technique is also advantageous in that it preserves right atrial morphology as well as sinoatrial node and tricuspid valve function [19,20]. Tricuspid regurgitation is not well tolerated in the setting of right ventricular dysfunction, which is often seen after heart transplantation [21]. Additionally, the bicaval technique is associated with decreased frequency of permanent pacemaker implantation [18]. However, the caval suture lines are at risk of anastomotic stenosis, both early and late, which is not the case with the biatrial technique. The primary advantage of the biatrial technique is its relative technical simplicity, both in terms of the dissection necessary to perform the anastomoses and the anastomoses themselves. However, the biatrial anastomosis puts the sinoatrial node at risk of injury, and redundant atrial tissue may adversely impact atrial hemodynamics and contribute to an increased risk of atrial arrhythmias in the postoperative period [22–24]. The presence of two sinoatrial nodes with the biatrial technique can present difficulty in determining the pattern of sinoatrial node function and atrioventricular conduction during the postoperative period. A meta-analysis of 41 papers on this topic found significant benefits for the bicaval technique in terms of early atrial pressure, tricuspid valve regurgitation, return to sinus rhythm, and even perioperative mortality. However, long-term outcomes were less disparate between the groups [25].

Bicaval orthotopic technique

Left atrial anastomosis

Prior to implantation it is occasionally necessary to trim the donor and/or recipient left atria to prevent the creation of an excessively large cavity that may be at risk for thrombus formation [26] (Figure 58.1A). A long 3-0 polypropylene suture is started adjacent to the recipient left superior pulmonary vein and donor left atrial appendage (Figure 58.1B). The site of the recipient left atrial appendage and the donor left atrial appendage can be used to ensure the rotational orientation of the heart. The first several stitches are placed with the heart ex vivo; it is then placed within pericardium. The suture line is continued first clockwise, second counterclockwise, with forehand technique as much as possible. A running simple stitch can be used if there are deficient atrial cuffs but we favor a running vertical mattress technique, everting and excluding the thrombogenic muscle layer of atrial cuffs. In the area of the circumflex coronary artery, care is taken to avoid deep sutures. It is important to periodically reassess the position of the inferior vena cava to ensure that it is brought into proper position for subsequent bicaval anastomosis. The knot is tied near the middle on the right side of the interatrial septum.

An alternate to the traditional bicaval technique, the so-called bicaval total technique, involves two left atrial anastomoses, one to a right pulmonary vein cuff (including the superior and inferior pulmonary vein orifices) and the other to a left pulmonary vein cuff similar to those used for lung transplantation. In this case, the recipient cardiectomy would include removal of all atrial tissue except bilateral pulmonary vein cuffs. For implantation, the left pulmonary vein cuff is sewn first with the heart retracted to the right followed by the right cuff anastomosis with the heart retracted to the left [27].

Inferior vena caval anastomosis

A 4-0 polypropylene is run along the posterior onto the anterior wall (Figure 58.1C). To minimize the risk of stenosis, a portion of the recipient right atrium is retained near the inferior vena cava to allow for a patulous anastomosis. As in all our anastomoses, an interrupted stander suture is placed at the 3 and 9 o'clock positions. Deep sutures are avoided in the region of the donor coronary

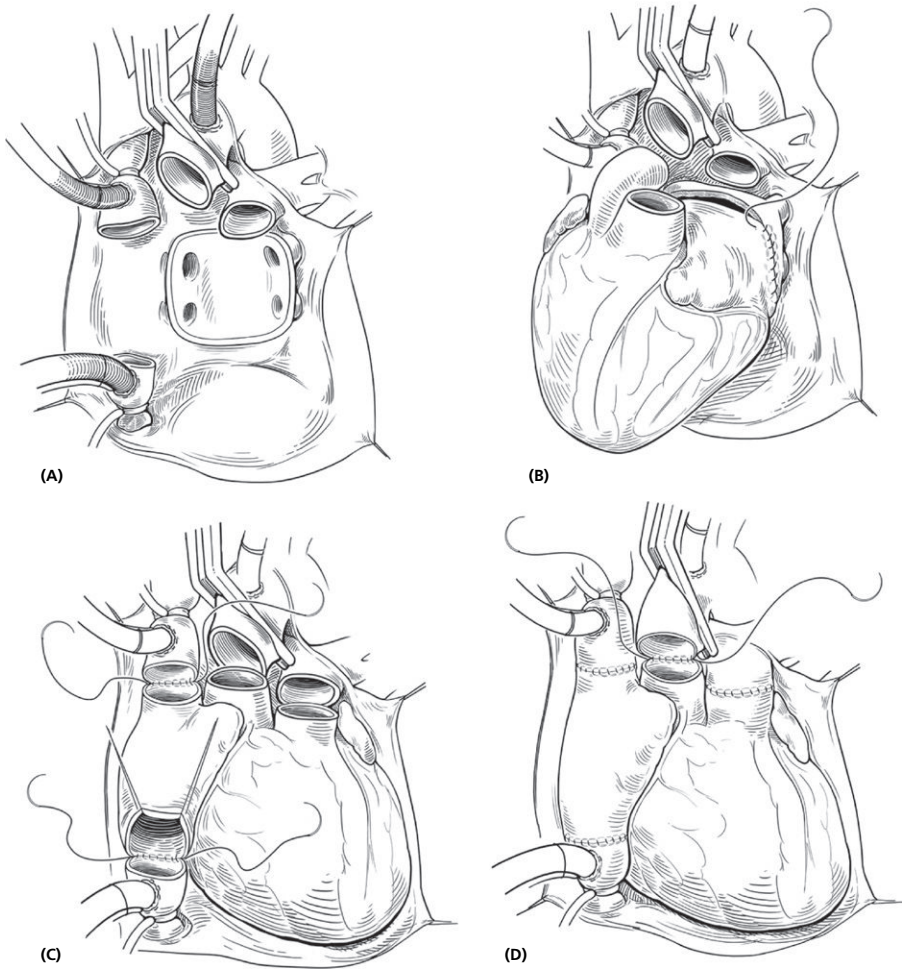

Figure 58.1. (A–D) Progressive steps detailing heart transplantation utilizing the bicaval anastomotic technique.

sinus. This anastomosis may be facilitated by femoral venous cannulation and use of vacuum assisted venous drainage with a clamped or open inferior vena cava [28]. On infrequent occasion, if the recipient has a persistent left superior vena cava draining into the coronary sinus, the recipient coronary sinus and associated tissue in the left atrioventricular groove can be preserved. When the interior vena cava anastomosis is done, the recipient side includes the interior vena cava orifice and the coronary sinus orifice. In this situation it is usually necessary to separately cannulate.

Pulmonary arterial anastomosis

Excess pulmonary artery must be trimmed aggressively because this anastomosis is particularly prone to kinking or telescoping, especially with a large donor heart. For the same reason, care must be taken to assure that the geometry of the donor and recipient pulmonary arteries are well aligned. The anastomosis is sewn with a continuous 4-0 polypropylene that is tied to interrupted stander sutures at 3 and 9 o'clock. It is advantageous to trim the donor pulmonary artery short rather than the recipient vessel as it brings the anastomosis closer and improves access if repair sutures are required. Note that excessive length of the resulting new pulmonary artery can produce invagination and a supravalvular gradient.

Aortic anastomosis

As with the pulmonary artery, the aortae are trimmed to avoid extra length with the possibility of subsequent kinking. This anastomosis is typically performed the same way as the pulmonary artery anastomosis (Figure 58.1D). Rewarming of the patient is commenced. After the suture line is completed, the heart is deaired and the aortic cross clamp is removed. Spontaneous contractions will usually commence soon after clamp removal. Continuous aortic root de-airing is performed by placing the root vent on suction.

Superior vena caval anastomosis

This anastomosis is performed with attention to fine suture technique to avoid purse-stringing. We use a running suture on the posterior wall and a simple 5-0 Prolene interrupted sutures on the anterior wall (Figure 58.1C). It is imperative to leave the recipient superior vena cava as long as possible during cardiectomy so that if the donor superior vena cava is small, the recipient superior vena cava can be sewn directly to the cavoatrial junction. If this anastomosis is performed after the removal of the cross clamp, the donor superior vena cava can be clamped to prevent blood from obscuring the field. The completed transplant is depicted in Figure 58.2, which details the anterior and posterior view of a heart transplanted using the bicaval anastomotic technique.

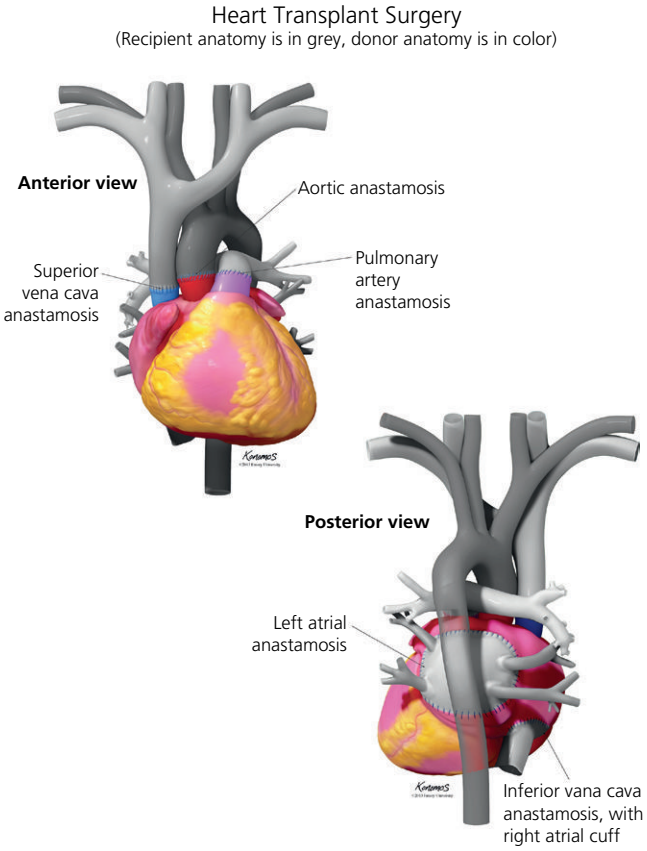

Figure 58.2. Completed anastomoses, anterior and posterior view, following performance of the bicaval anastomotic technique.

Biatrial orthotopic technique

The implantation begins with the left atrial anastomosis as in the bicaval method (Figure 58.3A,B). The right atrial anastomosis is usually performed after the left atrial anastomosis is completed; however, to decrease ischemic time, the aortic anastomosis may be performed before the right atrium. A 4-0 polypropylene suture is started near the superior end of the interatrial septum and is run clockwise around the inferior vena cava, which is the most difficult area of the anastomosis given the relatively small remnant of recipient atrium near the inferior vena cava (Figure 58.3C). Next, the superior end is sewn counterclockwise and the sutures are tied along the free wall of the right atrium. It is imperative to use caution when placing sutures near the donor sinoatrial node. The pulmonary arterial and aortic anastomoses are performed as described above (Figure 58.3D). No matter which technique is used, 1 liter of cold, oxygenated, blood cardioplegia is given antegrade after the completion of each anastomosis.

Separation from cardiopulmonary bypass

Once all anastomoses are completed, the caval tourniquets are released and high-level suction is applied to the aortic root vent. With flow through the heart, more vigorous de-airing maneuvers are performed. Gentle ventilation and massage of the heart, as well as turning the table right and left, may be used to expel air from the ventricles and great vessels. Ventricular fibrillation is promptly defibrillated during this and subsequent portions of the procedure to avoid distention of the left ventricle. The pulmonary artery catheter is then readvanced into the pulmonary artery with the surgeon's help. In cases of a prolonged ischemic time, the graft is allowed a period of reperfusion before separation from bypass. Inotropic support, usually Milrinone (0.5 μg/kg/min), is begun at this time. A heart rate above 100 beats per minute is preferred because the allograft recovering from cold ischemia is more dependant on heart rate than stroke volume to maintain cardiac output [29]. This reperfusion period is an ideal time to inspect all suture lines and place repair sutures as needed. Before separating from bypass, transesophageal echocardiography is used to evaluate for retained intracardiac air, valvular and ventricular function, gradients across the caval and pulmonary arterial anastomoses, and patency of the pulmonary veins.

Right heart dysfunction of varying degrees is a common problem following heart transplantation. Therefore, pulmonary artery pressures and right ventricular function need to be carefully and frequently assessed. The principles used to manage right heart dysfunction include: (1) minimizing right ventricular afterload, (2) optimizing RV performance, including both the free wall and the interventricular septal contributions, and (3) maximizing the systemic pressure available to perfuse the right ventricular free wall. Early right heart dysfunction is best treated by simply raising the systemic perfusion pressure. However, the threshold to institute pulmonary vasodilators should be low. The initial agents of choice include inhaled epoprostenol or nitric oxide, given their selective action. The most reliable agent to start with is inhaled nitric oxide. This should be started at an inhaled dose of 10–20 ppm. Mild hyperventilation to a P_{CO_2} in the range of 30–35 mmHg and maintenance of oxygen saturation >95% are useful adjuncts to minimize pulmonary vasoconstriction. Central venous administration of vasodilators such as prostaglandin E_1, prostacyclin, or nitroglycerin, or inotropes such as milrinone or dobutamine may be instituted as an alternative [30]. If a stenosis is suspected at the pulmonary artery suture line based on a palpable thrill or echocardiographic findings, the pressure gradient should be documented directly. A gradient of ≥10 mmHg is an indication for revision [31]. Ultimately, if right heart failure persists despite all attempts to reverse it, a mechanical assist device is indicated [32].

Particular attention is paid to the tricuspid valve after separation from cardiopulmonary bypass. Tricuspid regurgitation is encountered more frequently after biatrial technique, likely due to geometric distortion of the right atrium [33]. The severity of tricuspid regurgitation as determined intraoperatively correlates with poor late survival, even with mild regurgitation. Although tricuspid regurgitation is related to right ventricular dysfunction, these findings suggest a possible role for concomitant tricuspid valve repair at the time of transplantation [9]. A series prospectively evaluated 60 bicavally transplanted grafts randomly assigned to receive (n = 30) or not receive (n = 30) prophylactic de Vega tricuspid valve annuloplasty prior to implantation. The authors reported a short- and midterm survival benefit of tricuspid annuloplasty with significant reduction in the severity and number of patients with significant tricuspid regurgitation at 1 year. Because of these benefits and the fact it is inexpensive and quick to perform, they routinely perform this procedure during preparation of the donor heart for transplantation [34].

Once adequate rewarming has taken place, cardiopulmonary bypass is terminated and satisfactory hemodynamic and echocardiographic findings are achieved, aortic root suction (air venting) is terminated, and protamine is administered. The aortic root vent is then removed. The caval canulas are removed and the purse-string sutures snared. If there is no evidence of protamine reaction

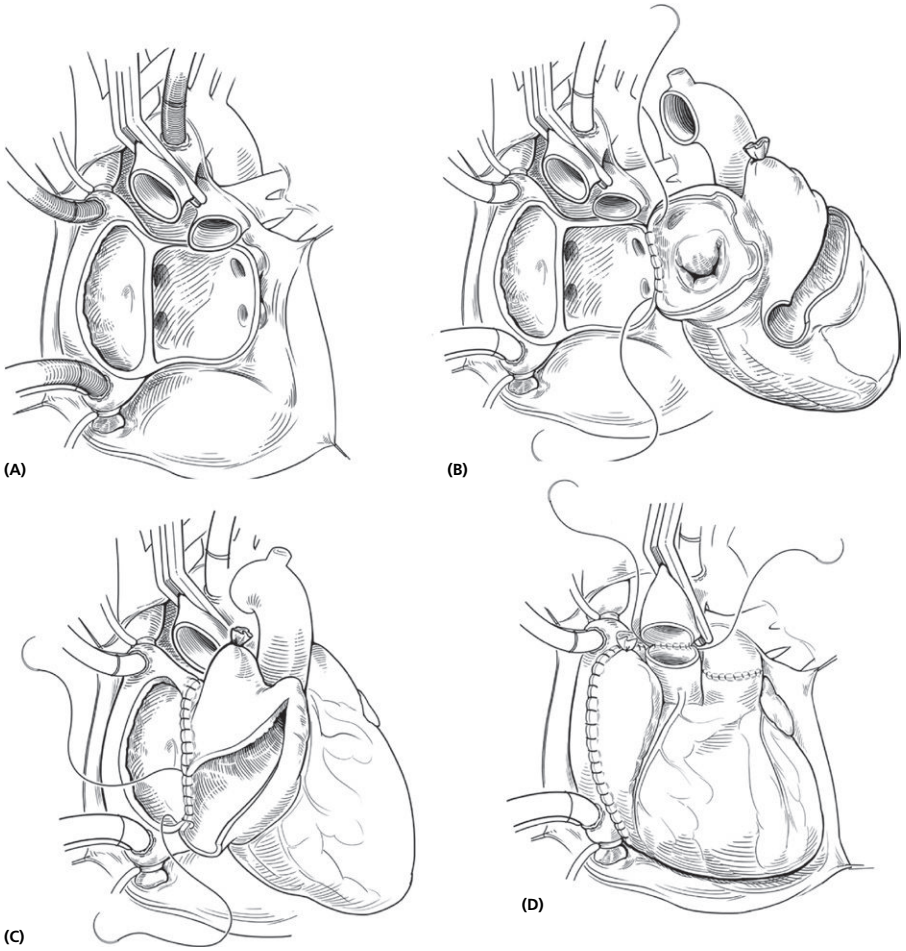

Figure 58.3. (A–D) Progressive steps detailing heart transplantation utilizing the biatrial anastomotic technique.

after 50% of the neutralizing dose is administered and all volume is returned from the pump, the aortic cannula is removed.

Drains are placed in every thoracic cavity that is opened during the procedure. There is usually a large pericardial space relative to the allograft. In addition to the usual drains, a Blake drain or similar drain is often placed in the posterior pericardium and/or VAD pocket for long-term use. Temporary atrial and ventricular epicardial pacing leads are placed. Some form of atrioventricular block occurs in approximately 10% of procedures; however, only 2% have complete heart block [35]. Use of the bicaval technique is associated with lower rates of temporary pacing postoperatively [36] and permanent pacemaker implantation [17,18,25]. For patients with a previous automatic implantable cardioverter defibrillators/permanent pacemakers, these are usually removed once coagulopathy has been corrected. Because this step is not essential at this time, it may be performed at a later date if there are concerns regarding coagulopathy or stability. The sternum and soft tissue and skin are closed in the usual manner after obtaining adequate hemostasis and hemodynamics.

Special situations

Redo sternotomy/redo heart transplant

Patients with biventricular failure and a distended right ventricle are especially at risk during redo median sternotomy. In this instance, it is prudent to place external defibrillator pads and access the central circulation for cardiopulmonary bypass through the femoral artery and vein before beginning the procedure. Once sternotomy is accomplished, care is taken to avoid injury to the right ventricle and previous bypass grafts if present. Manipulation of bypass grafts is avoided to prevent embolization and hemodynamic compromise. The priority is to expose a site for aortic cannulation, then dissect out the superior and inferior cavae for bicaval cannulation. Occasionally cardiopulmonary bypass may be required in order to decompress the heart, limit blood loss, and facilitate gaining exposure.

Given the median survival of cardiac allografts, it is anticipated that many recipients will eventually undergo retransplantation [37], especially when the primary transplant was performed at an early age as is common for congenital heart disease [38]. Although technically very similar to orthotopic heart transplantation as outlined previously, there are a few considerations unique to retransplantation. First, patients typically undergo this operation after an extended period of chronic allograft rejection. Unlike most redo cardiac surgeries involving a single inflammatory episode, redo cardiac transplantation for chronic rejection is complicated by longstanding inflammation and notoriously dense scarring and bleeding during dissection of the allograft. Dissection and exposure needed for recipient cardiectomy may require additional time, which may affect coordination with the donor operation. Every

effort is made to remove all of the previous allograft including all anastomoses, trimming back to native tissue. Outcomes for retransplantation for graft coronary disease are similar to those for primary transplantation; however, those for acute graft failure are quite poor [39].

Explanting ventricular assist device

With the number of cardiac donors being relatively constant, an increasing number of patients are bridged to transplantation with a ventricular assist device with good post-transplant survival [40–43]. This is discussed in detail in Chapter 48. Strategies to employ during assist device placement that facilitate future transplant include:

1. directing the outflow graft toward the right atrial gutter to prevent injury during sternotomy;
2. covering the outflow graft with an extra layer (usually GorTex because there is often insufficient pericardium to use for this purpose;
3. constructing the outflow anastomosis as proximal as possible on the right lateral ascending aorta thereby preserving as much aorta as possible;
4. leaving the aortopulmonary window as undisturbed as possible to facilitate dissection and exposure later;
5. placing a protective barrier over the right ventricle (i.e. GorTex, CorMatrix, etc.) to prevent injury at the time of resternotomy;
6. avoiding use of pledgets, thus avoiding associated scarring and fibrosis.

Based on these strategies, there are several considerations unique to the recipient with a ventricular assist device in place. The location of outflow graft must still be documented before resternotomy as it can shift position. Manipulation of the left ventricle needs to be minimized to decrease the risk of embolization of mural thrombus, which is more likely to form in this population. This can be assessed by transesophageal echocardiography. The device needs to be turned off and the outflow graft clamped immediately prior to institution of cardiopulmonary bypass to prevent massive functional aortic insufficiency across the device. Because the outflow graft is sewn to the ascending aorta, cannulation and clamp placement must be more distally than usual. Cannulation of the aortic arch using the Seldinger technique is useful in these cases. Alternatively, femoral or axillary arterial cannulation may be used.

Heart transplantation after congenital heart surgery

Heart transplantation after congenital heart surgery is a recognized treatment for long-term failure of corrective or palliative procedures. While patients with congenital heart disease have historically contributed relatively few patients to the adult heart transplant population, this is certain to change in the near future with the improved survival and scope of anatomy that can now be treated. There are a number of considerations that pertain to this population. First, pulmonary vascular disease is common and may necessitate heart–lung transplantation (see below). Second, patients with failing Fontan circulation are quite ill, often presenting with multiorgan insufficiency (especially renal and hepatic) and nutritional deficiency from protein-losing enteropathy. Third, finding a suitable donor may prove very difficult and, in some cases, impossible as the patients can be highly sensitized. Fourth, postoperative care can be difficult because of their predisposition to bleeding, infection, and pulmonary hypertension and the presence of aortopulmonary collaterals resulting in a significant left-to-right shunt [44].

The technical aspects of these transplants can be quite complex given the unique reconstructive needs, especially after single ventricle palliation [45–48]. As a result, the great vessels are procured in an extended fashion and are not trimmed until implantation. In some cases prosthetic material is required to complete the reconstruction. Alternatively, native tissue that might otherwise be discarded (such as the descending thoracic aorta or portions of the great vessels) may be harvested for use as a patch or other conduit. The transplanting and procuring surgeons must be familiar with the situs, vascular anatomy, and previous operations of the recipient.

Redo sternotomy can be particularly treacherous in the setting of dense adhesions, cardiomegaly, and the substernal position of the great vessels or conduits. Pre-emptive groin access or even cannulation should be considered in this population [49]. Chronic cyanosis associated with this population increases the possibility of collateral vessels, especially in the posterior mediastinum, which increases the risk for hemorrhage [50].

One of the most common scenarios is that of a failing Fontan reconstruction. Indications for transplantation in this group are protein-losing enteropathy, intractable atrial arrhythmia, and systemic ventricular dysfunction [51]. Again, ample pulmonary artery and vena caval length (including innominate vein) are procured; a segment of descending thoracic aorta may also be obtained for complex reconstructions of the pulmonary artery. During the recipient cardiectomy, the Fontan pathway is deconstructed, either by resecting the extracardiac bypass graft or the intra-atrial baffle. In either case, a generous rim of remnant superior vena cava and interior vena cava is preserved. After the Glen pathway is taken down, the pulmonary arterial circulation can be reconstructed by a variety of methods, including patching or interposition grafting [48,52]. Significant time may be required for the recipient cardiectomy and reconstruction required to establish anatomy compatible with donor heart implantation. It is of utmost importance to coordinate the cross-clamp time at the donor institution with the recipient team to account for these complexities and minimize ischemic time as much as possible. The possibilities for recipient anatomy and reconstructive techniques are numerous and beyond the scope of this chapter. Transplants for complex congenital heart disease should be deferred to surgeons with significant experience in the field of congenital heart surgery. In general, results for heart transplantation in this group are comparable to those without congenital heart disease, with 1-year survival of approximately 85% and 10-year survival of approximately 60–70% [50,53,54]. Given the young age of most of these recipients, retransplantation is likely to be needed in the future.

Heart–lung transplantation

Combined heart–lung transplantation has decreased in frequency over the last two decades as the indications for lung transplantation have broadened [55]. However, there remains a very select group of patients, many with congenital heart disease [56], who have combined pulmonary vascular disease and end-stage heart failure for which this combined transplant is the best treatment option [57]. The initial dissection and exposure of the heart–lung block is similar to those of isolated heart and lung donor procedures as described in other chapters. Briefly, in addition to typical exposure for the donor cardiectomy, the trachea is exposed by dividing the posterior pericardium between the aorta and superior vena cava. Dissection around the trachea is minimized to preserve its laterally based blood supply. Cardiectomy involves division of the superior and inferior vena cavae, placement of the aortic cross clamp, and

administration of preservation solution in the aortic root, and amputation of the tip of the left atrial appendage to prevent left heart distension by perfusate. Maximal aortic and caval procurement is paramount, particularly if a bicaval anastomosis is desired. One liter of cardiac and at least 3 liters of pulmonary preservation solutions are administered followed by division of the aorta. Next, the inferior pulmonary ligaments are divided, followed by tracheal stapling and division with the lungs partially inflated to prevent atalectasis during transport. The pericardium around the pulmonary veins is divided. The trachea is dissected free from the esophagus and posterior mediastinum with attention to meticulous hemostasis of the heart–lung block. The heart–lung block is prepared in a similar fashion to orthotopic heart transplantation. The right atrium or both cavae are prepared depending on the type of systemic venous anastomosis that is planned. Potential sources of bleeding from the mediastinum of the heart–lung block must be identified and controlled. The recipient is placed on total cardiopulmonary bypass using aortic and bicaval cannulation. The recipient cardiectomy is performed as described above. Given the size of the surgical field and considerable bleeding risk, hemostatic technique during dissection and exposure is mandatory. The right atrium and cavae are prepared as dictated by the planned type of systemic venous anastomosis. The recipient pneumonectomy follows. After the pleura are opened sufficiently to allow for removal of the lungs, the inferior pulmonary ligaments are divided and generous pericardial windows posterior to the phrenic nerves is created. The hilum of each lung is dissected out and stapled followed by removal of the lung. Next, the right pulmonary artery is removed and the carina is circumferentially exposed and divided. Hemostasis of the posterior mediastinum is meticulously ensured. Residual left atrial tissue may be oversewn. The heart–lung block is placed within the chest by inserting the lungs through the pleuropericardial windows posterior to the phrenic neurovascular bundle. The tracheal anastomosis is performed first using either a running or interrupted suture technique. Lateral tracheal stay sutures are placed to minimize tension at the level of the anastomotic sutures. Next, the right atrial anastomosis is performed as in the biatrial technique; however, a bicaval technique may be employed. The aortic anastomosis is performed last. The anastomotic sequence may be modified based on the needs of the operation. Donor ischemic time can be minimized by performing the aortic anastomosis after the tracheal anastomosis with removal of the aortic cross clamp prior to atrial anastomosis.

Summary

Improvements in heart transplant techniques have contributed to excellent 1-year survival of heart allograft recipients. However, the graft half-life for heart recipients remains a short 11 years [58]. After 5 years, cardiac allograft vasculopathy (30%) and malignancy (23%) account for most cardiac recipient deaths [58]. These sobering statistics emphasize that despite meticulous surgical technique, the limitations of chronically administered immunosuppression on long-term survival are profound, and they make clear the need for tolerance strategies that achieve long-term graft survival and prevent chronic rejection without the use of long-term immunosuppression. Similarly, as with all solid organ transplantations, the shortage of available donor organs remains the primary limitation to the greater application of heart transplantation. The development of expanded organ sources through xenotransplantation [59], heart organogenesis [60], and ex vivo perfusion systems [61] will greatly impact the future numbers of heart transplants performed. Regardless of the source of suitable donors, standardizing and implementing operative techniques as described above should provide for excellent patient outcomes.

CHAPTER 59

Lung Transplantation Procedure and Surgical Technique

R. Duane Davis and Matt Hartwig
Duke University Medical School and Medical Center, Durham, NC, USA

Introduction

To address the higher rate of rejection and mortality in lung transplantation, clinical practice has undergone remarkable changes, such as increased immunosuppression and strategies to address non-alloimmune injury, including gastroesophageal reflux (GER) [1]. These protocol changes, along with astute recipient selection, meticulous technical performance of organ procurement and implantation, and refinements in perioperative care, have led to a significant improvement in patient and graft survival over the last two decades [2]. However, new and innovative approaches to lung transplantation are still needed to further improve short- and long-term outcomes. This chapter will outline the techniques preferred at our center. Alternative techniques described in the literature, but that our center does not routinely employ, will also be presented. Details of lung procurement and preservation/resuscitation can be found in Chapters 21 and 26, respectively.

Anesthetic details

Recipient management during lung transplantation continues to be one of the most challenging endeavors for any anesthetic team [3]. Respiratory compromise and hemodynamic perturbations are frequent and require experienced, cardiothoracic-trained anesthesia staff for optimal outcomes. In addition to appropriate large-bore venous access, radial and pulmonary artery catheters are routinely placed to aid in continuous hemodynamic monitoring. Frequently, the radial artery line functions poorly due to patient positioning for bilateral anterior thoracotomies; therefore, we routinely place a small-bore femoral artery cannula as well. Other regularly utilized monitoring devices include cerebral oximetry measurements and transesophageal echocardiography (TEE). TEE allows for evaluation of cardiac function and filling during the operation, in addition to interrogation of most vascular anastomoses at the end of the case. Postoperative analgesia is typically accomplished with a thoracic epidural that is placed after transplant in the ICU, but prior to extubation.

We typically use a left-sided double-lumen endotracheal tube (ETT). Occasionally, in smaller recipients an adequate-sized double-lumen ETT cannot be placed and the operation will ensue on cardiopulmonary bypass (CPB). We prefer to avoid attempts at maintaining single lung ventilation via a single-lumen ETT due to airway compromise from tube dislodgement or occlusion. Regardless of the selected airway, flexible bronchoscopy with suction is essential. This allows for one to place the ETT correctly, as well as maintain its position and patency throughout the operation. Bronchial manipulation during the procedure will inevitably lead to tube migration with subsequent inadequate ventilation and requires intense vigilance on the part of the anesthetic team.

Effective communication among all the components of the operating room team remains an essential part of successful lung transplantation. Notifying the anesthesia team prior to cardiac retraction allows for pre-emptive administration of vasoactive drugs. This can ameliorate team angst and avoid over-reactive interventions. Minimization of intravenous fluids, coinciding with generous inotropic support (e.g. epinephrine), helps to support recipient hemodynamics during tenuous periods of the operation. This in turn contributes to fewer problems with pulmonary edema following implantation. Red blood cell volume and clotting factors should be closely monitored and replaced as needed. This remains particularly important in patients with significant bleeding, as well as those with hepatic congestion from pulmonary hypertension or right ventricular dysfunction.

Patient positioning and choice of incision

With a few notable exceptions, our center preferentially performs bilateral sequential lung transplantation via a fourth intercostal space, anterotransternal thoracotomy incision (i.e. clamshell). For this, the patient is placed in the supine position with arms slightly abducted and supported anteriorly on padded arm boards, with the elbows flexed. A thermal warming pad is placed posteriorly, while a warming blanket covers the recipient's lower body anteriorly from the umbilicus down. Groin access is not necessary as vascular access for extracorporeal support can be attained in the chest. The incision for a female patient requires placement just below the inframammary crease and typically provides for acceptable aesthetics after transplantation. This requires breast flaps to be developed bilaterally, followed by retraction of breast tissue superiorly, and then pleural space entry through the 4th intercostal space. The mammary arteries are routinely divided bilaterally between vascular clips and then the sternum transected with the sternal saw. Of note, other groups have reported a significant number of sternal complications, including malunion and override, after transecting the sternum. Although the incidence of sternal complications

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

remains low at our center, less than 5%, the procedure can be performed through sternal-sparing bilateral anterior thoracotomies in many patients without sacrificing adequate exposure. Those recipients with restrictive lung disease and small chest cavities, pulmonary hypertension, or requiring concomitant cardiac procedures typically require a clamshell incision.

Recipient explantation

Following the transverse sternotomy, division of the mediastinal pleura occurs superiorly to the level of the mammary veins and inferiorly to the pericardium. The pericardium does not require opening; however, difficulty exposing the left pulmonary veins for the anastomosis later may require opening of the pericardium and anterior retraction of the apex of the left ventricle for better visualization. Prior to extensive opening of the chest, the 4th intercostal muscles are divided just above the 5th rib in a posterior direction. The overlying serratus anterior and latissimus dorsi muscles should be mostly spared. For those patients with septic lung disease or previous thoracic procedures, a tedious lysis of adhesions may then ensue. This is oftentimes the most time-consuming portion of the operation. Electrocautery dissection can be safely used for the majority of this dissection, but extreme caution should be maintained in the vicinity of the phrenic nerve, along the mediastinum. Adhesions near the phrenic nerve should be sharply divided. Occasionally, the adhesions will be so dense near the phrenic nerve that dividing the overlying lung tissue with a stapling device is required. In patients with restrictive lung diseases and smaller chest cavities, a heavy silk figure-of-eight stitch placed in the fibrous dome of the diaphragm and retracted caudally and laterally through an inferior intercostal space enhances exposure.

After the lungs are mobilized from the pleural attachments bilaterally, attention can be directed towards the hilar dissection. Ideally, most of the hilar dissection on both sides will be carried out prior to either pneumonectomy. This will minimize the time between reperfusion of the first lung and implantation of the contralateral lung. The decision of which pneumonectomy to perform first depends on several important factors. If there is an appreciable difference in native lung function, then typically the worse lung is replaced first. However, the donor lung quality must also be taken into account, as significant unilateral contusions or consolidation may preclude single lung ventilation on the transplanted lung without CPB or extracorporeal membrane oxygenation (ECMO) support. If no appreciable difference in recipient or donor lung function is noted, then the more technically difficult side should be done first in order to decrease the time during which only one transplanted lung is being perfused. This is typically the left side.

The recipient pneumonectomy can initially be performed outside of the pericardium. An endo-GIA stapling device with vascular loads is utilized to staple and divide the pulmonary artery (PA) at, or just distal to, its first branch. Similarly, the superior and inferior pulmonary veins are taken separately prior to the confluence in the left atrium. The bronchus can also be divided with a stapling device at the level of the upper lobe take-off. The pericardium will need to be opened circumferentially and intrapericardial dissection then ensues. This includes developing Waterston's groove (interatrial groove) on the right side, as well as separating the pulmonary artery from the roof of the left atrium and the posterior left atrium from the pericardium. These maneuvers facilitate placement of the left atrial clamp. The right and left pulmonary arteries require mobilization proximally. On the right side, this involves dissection between the right main PA and the superior vena cava (SVC). On the left side, careful attention is focused on avoiding injury to the recurrent laryngeal nerve. Electrocautery dissection is minimized along the superior aspect of the left PA. The posterior hilum contains abundant lymph nodes and bronchial artery circulation that can be the source of bothersome bleeding after the lung is implanted. Attention towards hemostasis posteriorly prior to implantation is most efficient. Likewise, extensive removal of a bulky subcarinal lymph node station can optimize exposure and avoid potential future anastomotic complications. The vagus nerve runs adjacent to this area in the posterior hilum and should be avoided in order to minimize gastrointestinal motility problems post transplant.

After the intrapericardial dissection is complete, but prior to allograft implantation, the most posterolateral two figure-of-eight #1 Maxon pericostal sutures are placed in preparation for closure of the chest. Here we take advantage of optimal exposure prior to lung placement in the pleural cavity. Similarly, a large-bore thoracostomy tube is placed in the costovertebral gutter, via which a small-bore suction catheter is placed for continuous removal of excess cold slush fluid during the remainder of the case. Oftentimes a 24-french Blake drain is also placed in the inferior sulcus to assist with fluid removal.

Single versus bilateral lung transplantation

Many complications, including infection, hyperinflation, shunting, and malignancy, occur due to the native lung. Likewise, there is a well-documented long-term survival benefit of bilateral orthotopic lung transplantation (BOLT) compared to single (SOLT) [4,5]. Therefore, our center preferentially performs BOLTs for most of our recipients. However, there are subsets of patients and certain clinical situations in which a SOLT is preferred. In those situations, multiple options exist for the initial incision. For a right SOLT, our preferred incision is an anterolateral thoracotomy. This approach allows for easy access to the hilum for implantation, as well as the aorta and right atrium in the event that central cannulation is required. In left lung transplantation, the anterolateral thoracotomy can occasionally limit exposure of the left atrium for the pulmonary vein anastomosis. This can be particularly problematic in pulmonary fibrotic patients, and in this situation we will oftentimes approach via a standard muscle-sparing posterolateral thoracotomy. If concomitant cardiac procedures are required, then a median sternotomy typically provides optimal exposure for both portions of the operation.

Allograft implantation

There are very few differences between the details of left and right lung implantation. However, exposure of the left atrium for the pulmonary venous anastomosis can be challenging at times and we will discuss way to enhance that visualization in the following text. Heparin is administered prior to implantation of the first lung with a dose of 80–100 IU/kg and goal activated clotting time (ACT) can range from 200–300 seconds, depending on surgeon preference.

The hilar structures have been dissected as described above and seen in Figure 59.1. Long silk sutures are placed through the staple lines of the PA and each pulmonary vein branch and then these vascular pedicles are retracted anteriorly after a Rummel tourniquet is placed over each stitch to protect the phrenic nerve during retraction. The Rummel tourniquet can be fashioned from a simple red-rubber catheter. To aid in the exposure of the left hilum, a heavy

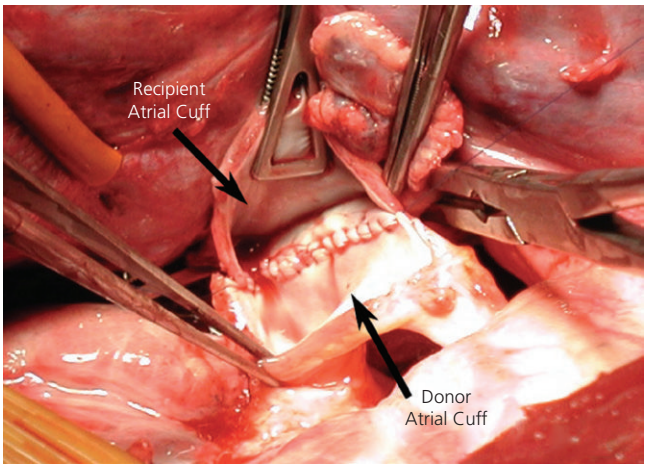

Figure 59.2. Left atrial anastomosis. A Satinsky vascular clamp is placed on the body of the recipient's left atrium while the pulmonary veins are anastomosed using a running 5-0 polypropylene suture to complete the posterior wall first, followed by the anterior wall.Source: Hartwig et al. 2004 [6]. Reproduced by permission of Wolters Kluwer Health.

silk retraction stitch is also placed inferiorly on the pericardium, posterior to the phrenic nerve, and anterior to the inferior pulmonary vein. The silk suture is similarly passed through a heavy-duty Rummel tourniquet, thus allowing the heart to be safely retracted upward and to the right to provide improved exposure during further dissection of the hilar structures and implantation of the donor lung.

The airway is the first anastomosis to be performed. The recipient mainstem bronchus is first sharply cut with a scalpel just proximal to the upper lobe bifurcation. A silk retraction stitch can then be placed several cartilaginous rings proximal to help with maneuverability of the airway. The membranous portion has a tendency to retract after transection and it should be made slightly longer than the cartilaginous side. The bronchial lumen is suctioned clear of secretions and on the left side the ETT may need to be slightly retracted. The pleural cavity should be irrigated well with antibiotic solution, followed by placement of the initial 4-0 polydioxanone suture (PDS) at one corner of the recipient membranocartilaginous junction. Iced laparotomy pads can then be placed posteriorly in the pleural cavity and the donor lung is orthotopically placed on these pads. Additional topical ice slurry maintains allograft hypothermia during implantation.

A key component to the bronchial anastomosis is preservation of the membranous-to-membranous and cartilaginous-to-cartilaginous apposition. The posterior, membranous portion of the anastomosis is performed first in a running, end-to-end fashion with the 4-0 PDS. Upon reaching the opposite membranocartilaginous junction, a transition stitch from the outside of the smaller bronchus to the inside of the larger bronchus is performed. Usually the recipient bronchus is slightly larger, and this allows a small intussusception to occur along the anterior, cartilaginous portion of the bronchus. The intussusception is typically one cartilage ring in depth and the anterior row of suture is also performed in a running fashion. During completion of the bronchial anastomosis, the anesthesiologist should be suctioning the airway clear from above and preparing to manually inflate the donor lung with room air. Following completion, the anastomosis is submerged in water and evaluated for an air leak, while the lung is gently inflated.

The PA anastomosis follows the airway. The recipient main PA is occluded proximally with a small Satinsky vascular clamp, followed by removal of the staple line. The donor PA is also trimmed to an appropriate length. Typically, this is approximately 1.5 to 2 cm proximal to the first arterial branch, but accurate measurement is often best done at this time. Poor estimation of donor and recipient PA length can lead to excessive PA tissue and kinking after completion of the anastomosis. We use a 6-0 polypropylene suture to perform the PA anastomosis. This is initiated in one corner and done in a running fashion beginning with the posterior row. Preservation of native alignment is also crucial for the vascular anastomoses, and the anterior and apical segmental branches of the donor lung can assist with proper orientation. After completing the anastomosis, a second vascular clamp is placed distally on the donor PA while slowly removing the more proximal Satinsky clamp. This tests the PA anastomosis without premature reperfusion of the donor lung. Minor bleeding is generally seen from needle holes, but additional time spent on hemostasis is unnecessary as this will eventually stop. However, larger areas of bleeding from the anastomosis should be repaired at this time.

The distal PA clamp remains on while the pulmonary vein–left atrium anastomosis is performed. A large Satinsky vascular clamp is placed on the body of the left atrium, while the previously stapled native pulmonary vein stumps are retracted laterally with Pennington clamps. The staple lines are then excised and the left atrial tissue bridge between the superior and inferior pulmonary veins orifices is transected. This creates a large common orifice for the recipient left atrial cuff. A Pennington clamp placed on the anterior edge of this cuff with anterior and medial retraction provides optimal exposure for subsequent sewing (Figure 59.2). Occasionally, the left pulmonary venous anastomotic exposure remains less than ideal in spite of the previously placed retraction stitch on the edge of the pericardium anterior to the left pulmonary veins. In that situation, the pericardium can be opened and the apex of the heart positioned anteromedially with either moistened sponges or a suction retractor designed for off-pump coronary surgery. Hemodynamic pressures may be hindered during this retraction and small bolus administration of inotropes is often necessary during this anastomosis.

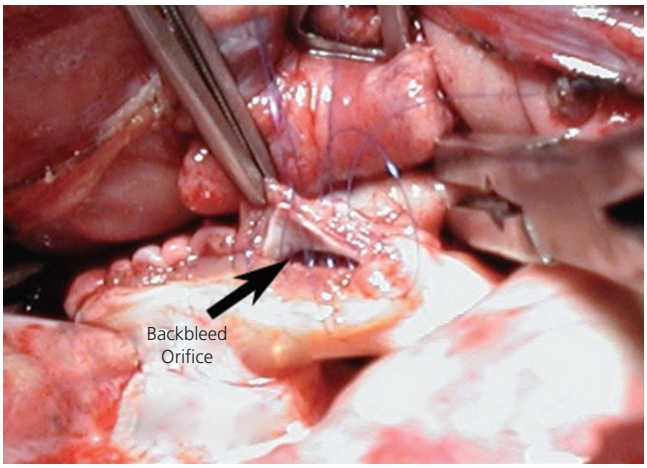

Figure 59.3. De-airing the left atrium. The last several throws of the pulmonary vein cuff anastomosis remain loose anteriorly and the vascular clamp on the PA is partially released to remove air from within the pulmonary vessels. Then the Satinsky clamp on the left atrium is loosened to force out any residual air from the left atrium. Source: Hartwig et al. 2004 [6]. Reproduced by permission of Wolters Kluwer Health.

Orientation of the superior and inferior pulmonary veins is critically important to a technically adequate anastomosis. Also, the vein cuffs should appose endothelium-to-endothelium by excluding most of the muscular tissue from the suture line, while focusing on the intimal layer. The running suture line is performed analogously to the PA, with initiation in one corner of the anastomosis and completing the posterior row of running sutures first, followed by the anterior walls. A 5-0 polypropylene suture is typically used for the pulmonary vein anastomosis, and we ask anesthesia to administer 25 grams of mannitol and 500 mg of methylprednisolone prior to completing the vascular anastomoses on each side.

Reperfusion

The period of allograft reperfusion should be carefully controlled in order to protect the graft from primary graft dysfunction (PGD). With the left atrial clamp still in place, the last several throws of the pulmonary vein cuff anastomosis remain loose anteriorly when the vascular clamp on the PA is only partially released (Figure 59.3). This allows a small amount of warm blood to flow through the donor lung in order to remove air from within the pulmonary vessels and initiate re-warming. At this time, the large Satinsky on the left atrium is then loosened to force out any residual air from the left atrium as well. After an adequate de-airing has occurred, the 5-0 suture is secured, the venous anastomosis is complete, and the left atrial clamp can be completely removed.

Low-pressure reperfusion of the allograft is achieved via incremental de-ratcheting of the PA clamp over 10 to 15 minutes. During this time, inspection of the three anastomoses, hilar dissection, and donor lung occurs with hemostatic intent. Of note, during this period of early reperfusion, hypotension is often encountered. Communication with anesthesia prior to opening of the clamp is critical. Hemodynamic perturbations at the time of reperfusion have been attributed to an autoinfusion of prostacyclin (PGI_2) or alprostadil (PGE_1) that may be residing in the graft from procurement, a redistribution of blood flow through the newly perfused graft, or an air embolus. If the hypotension is secondary to residual vasodilators within the graft or a simple redistribution phenomenon, the observed hypotension should be self-limiting. However, during this time the anesthesia team will likely need to provide temporary inotropic support and modest volume resuscitation.

Initially, the allograft should be gently inflated manually on room air. This should not occur until the lung has fully re-warmed and the airway has been cleared of residual bloody secretions. After complete removal of atelectasis with hand ventilation, the lung can be placed on the ventilator. Pressure control mode is generally preferred, with positive end-expiratory pressures of 5–8 cm of H_2O, inspiratory pressures less than 18 to 20 cm of H_2O, and minimal FiO_2—preferably less than 30%. With the pleural spaces widely open, as in the setting of a clamshell incision, inspiratory pressures tend to be lower than those needed following closure of the chest. Loop diuretics and inhaled nitric oxide are utilized if pulmonary artery pressures are elevated, early pulmonary edema is evident, or if systemic oxygenation is not adequate. PA pressures will ideally be normal by the time the PA clamp is completely removed. Abnormally elevated PA pressures at this time may indicate a technical problem, poor preservation, or early reperfusion injury and should precipitate a rapid assessment of the vascular anastomoses.

For the contralateral side, most of the preliminary dissection will have already occurred and the pneumonectomy should proceed rapidly. One may notice compromised oxygenation when single lung ventilation occurs on the newly implanted lung while the contralateral lung is deflated. This should be greatly improved once the deflated native lung creating the shunt is removed. The pericardium is opened, if it hasn't already, and the intrapericardial dissection, hilar preparation, and subsequent implantation ensue as described above. During this portion of the case, technical problems or early primary graft dysfunction may precipitate inadequate ventilation or oxygenation. In this situation, implementation of venovenous extracorporeal membrane oxygenation (VV ECMO) can be rapidly performed by dual cannulation of the right atrium [7]. Details of this are described below. Figure 59.4 depicts the final appearance from anterior and posterior views of a bilateral lung transplant.

Closure

Single lung transplant performed through a thoracotomy incision can be closed in standard fashion. Proper closure of the clamshell incision is critical to avoid subsequent incisional complications after transplant. The anterior aspect of the clamshell opening is re-approximated with three sets of #5 wires. One simple wire is placed in the midline of the sternum and then one figure-of-eight wire secured on each side of the midline with the lateral aspect placed lateral to the mammary pedicle. All three of these wires are placed through the sternum. Occasionally, there will be a significant space between the 4th and 5th ribs when the sternum is brought together. This can be avoided by removing a small transverse section of sternum with the sternal saw prior to closure. The remainder of the clamshell incision can be closed with #1 polyglyconate sutures. The most posterior of these pericostal sutures have been previously placed just after the native lung was explanted on each side.

Prior to closure, additional bilateral pleural drainage tubes are placed anteriorly. If concerns of excess drainage exist (i.e. after CPB), an additional 24-french Blake drain can be placed in the inferior sulcus. Also, we preferentially drain the submammary space in women with smaller Blake drains. The pectoral fascia,

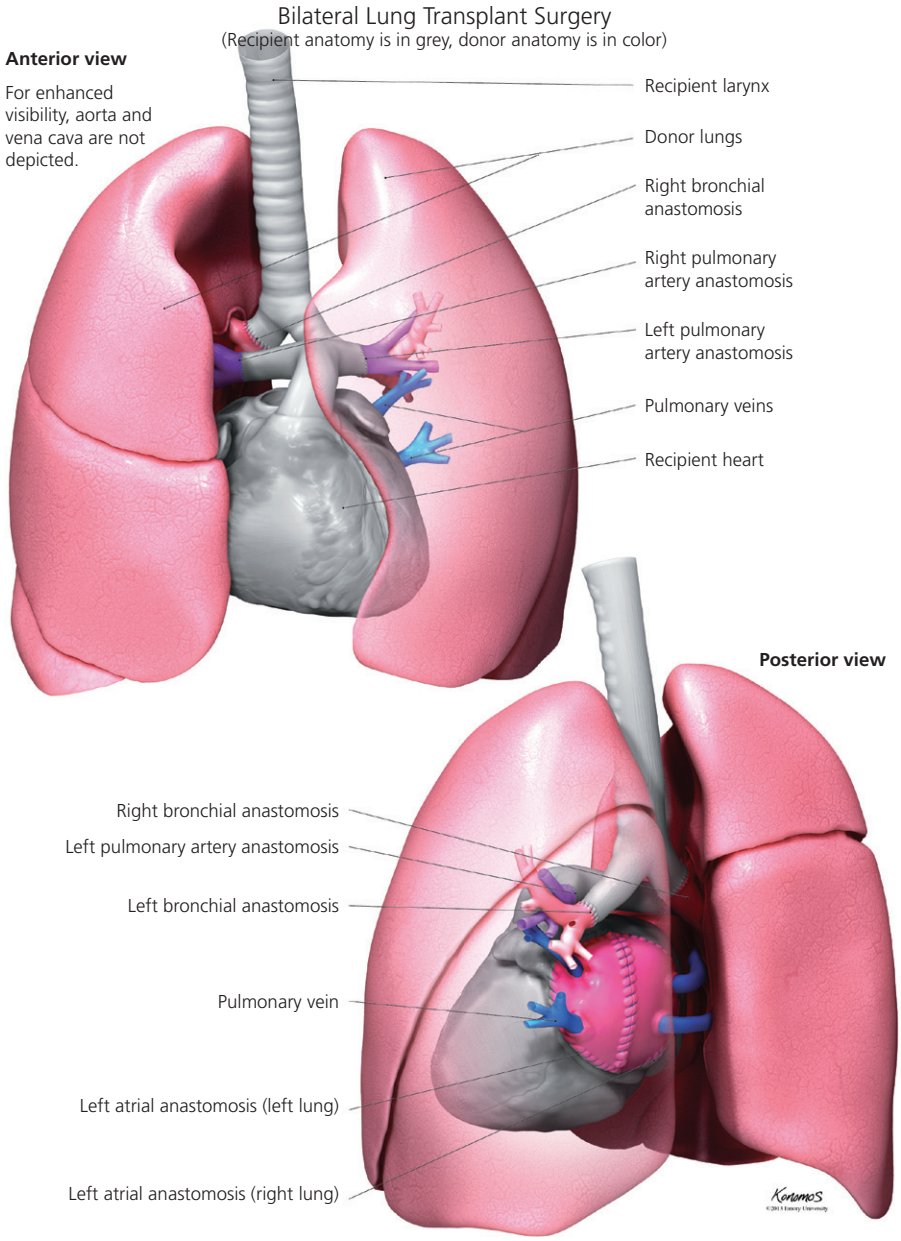

Figure 59.4. Anterior and posterior view of a completed bilateral lung transplant.

subcutaneous tissues, and dermal layers are then re-approximated with absorbable suture, followed by metallic skin clips.

The chest tubes are typically placed to suction; however, if the implanted lungs lack sufficient volume to adequately fill the pleural cavities, over-distention of the lungs may occur on suction. If this occurs, stretch injury and subsequent allograft dysfunction will develop. Marked differences in tidal volumes when the chest tubes are on and off suction will alert the surgeon to this development. After chest closure, exaggerated increases in inspiratory pressures with diminished tidal volumes may herald over-sized allografts or significant early pulmonary edema. Pneumoreduction can be performed at this time, but our preference is a priori removal of excessive lung volumes during the back-table preparation if possible. Typically, a simple right middle lobectomy and contralateral lingulectomy will be sufficient in these instances. On rare occasions, early development of pulmonary edema may require the chest to be left open.

Following the application of sterile dressings, the double lumen ETT is exchanged for a single lumen ETT. Flexible bronchoscopy is performed prior to leaving the operating room and serves multiple purposes. First of all, the bronchial anastomoses are directly inspected for patency. Torsion, or malrotation, of the airways will manifest as crescent shaped narrowing of the distal airways. Residual bloody secretions are removed and any developing PGD may be heralded by the development of frothy pulmonary edema.

Cardiopulmonary bypass

For the most part, CPB can be avoided during bilateral lung transplantation and we implant approximately 90% of our lung allografts

without the heart–lung machine. However, there will be occasion for both a priori, as well as unplanned, utility of CPB based upon recipient status and certain technical factors. Clinical scenarios typically requiring CPB include: (1) concomitant intracardiac procedures such as atrial/ventricular septal defect closures, (2) valve repair, (3) severe pulmonary hypertension, (4) small recipient airway precluding double-lumen ETT placement, (5) previous contralateral pneumonectomy, and (6) fragile or inadequate left atrial cuff tissue. In this last case, cardioplegic or fibrillatory arrest facilitates an anastomosis without the need for vascular clamps.

Cannulation strategies for performing lung transplantation on CPB vary by exposure. Standard midline, clamshell, and right thoracotomy incisions all lend themselves to central cannulation of the right atrium with a dual-stage venous cannula and the ascending aorta for the arterial return. Left single-lung transplants on bypass can typically be performed with a long 15 to 23-french femoral venous cannula and a standard aortic cannula in the descending aorta. If the groin is not easily accessible when CPB is needed, the left pulmonary artery can be cannulated proximally in the chest for venous return. However, when performing a left single-lung transplant, we will typically leave the ipsilateral groin prepped and in the sterile field in case vascular access is needed. If there is a high likelihood of needing CPB, a small-bore vascular cannula can be placed in the femoral vein and/or artery prior to initiating the procedure. Either of these can then be re-wired for a CPB cannula if necessary.

While CPB can be initiated at any time during the operation if necessary, our preference is to perform as much as the dissection as possible, including unilateral pneumonectomy, prior to going on bypass. When implantation occurs on CPB electively, both pneumonectomies are performed, and bilateral intrapericardial dissections are completed prior to beginning implantation. Following this, the posterior thoracotomy sutures and pleural drains are placed, and both lungs are implanted as described above prior to reperfusion of either allograft. The first lung that is implanted is packed in ice slush during implantation of the second lung. Methylprednisolone (1 g) and mannitol (50 g) are administrated prior to reperfusion. While the lungs are ventilated with room air, gradual reperfusion is initiated starting at 5–10 mmHg of mean PA pressure and increasing by 5 mmHg every 5 minutes until normal systemic pressures are achieved. Reperfusion of the lungs with oxygenated, hypocarbic blood may be especially advantageous to maximize pulmonary vascular recruitment and parenchymal recovery, while pulmonary artery pressures are easily controlled during reperfusion on CPB.

Extracorporeal membrane oxygenation

Extracorporeal membrane oxygenation (ECMO) is a crucial component of any lung transplant surgeon's armamentarium [8,9]. This physiologic adjunct can be used both intraoperatively when single-lung ventilation proves inadequate, as well as postoperatively in the management of severe primary graft dysfunction (PGD). The most common reason in the operating room to take advantage of ECMO is in the setting of transplantation of a severely affected pulmonary fibrotic patient in whom the native lung is not capable of fulfilling the need for single-lung ventilation. Oftentimes one can predict this prior to transplant based upon baseline oxygen requirements, chest radiographs, and nuclear pulmonary perfusion studies. In these instances, VV ECMO can be instituted percutaneously with cannulation of the right internal jugular vein with the dual-lumen ECMO cannula (Avalon™, Maquet Holding, Rastatt, Germany). An alternative cannulation strategy includes via the right femoral vein with a venous catheter (Bio-Medicus, Medtronic, Minneapolis, MN) and the left internal jugular vein with a pediatric arterial cannula (Medtronic, Minneapolis, MN). Cannulas are placed percutaneously using a modified Seldinger technique over a guide-wire following serial dilatations. The optimal placement of circuit in-flow and out-flow ports are determined by the level of recirculation noted in the system and are initially guided by TEE or fluoroscopic assistance. The venous cannula is typically near the inferior vena cava–right atrial junction, while the "arterial" return cannula is in the right atrium. The dual-lumen ECMO cannula if used should help minimize recirculation, as there are distal and proximal ports in the IVC and SVC for venous return, and an "arterial" in-flow port placed in the right atrium and directed towards the tricuspid valve. The ECMO circuit consists of a hyaluron-based heparin-coated 3/8″ tubing with a Quadrox D Poly-methylpentene (PMP) oxygenator and Jostra Rotaflow pump (Maquet Cardiopulmonary, AG, Germany).

In rare circumstances, the initial allograft may suffer immediate dysfunction and be incapable of adequate ventilation or oxygenation during implantation of the second lung. In this and other intraoperative situations, central cannulation can occur for VV ECMO, and systemic heparinization and full bypass can usually be avoided. If accessible, the right atrium can be double cannulated with the venous cannula placed near the IVC–right atrial junction and the "arterial" return cannula directed towards the tricuspid valve.

Potential pitfalls

From the beginning of the lung transplantation experience, primary graft dysfunction (PGD) has significantly impacted early survival [10]. Through the use of extracellular-based pulmonary perfusion solutions, the addition of retrograde pulmonary perfusion to lung preservation, minimizing the oxygen exposure at the time of reperfusion, controlling reperfusion pressures, and by using oxygen free-radical scavengers, the incidence of severe PGD has decreased from 15–25% to as little as 5%. PGD causes or significantly contributes to the majority of early post-transplant deaths. Unless reversible causes can be identified, treatment has primarily been supportive with optimization of ventilator parameters, inotropic support, and nitric oxide. Recently, we have shifted to a strategy of early institution of VV ECMO when recipients develop severe pulmonary edema and require a Fio_2 over 0.60. During VV ECMO support, a protective ventilatory strategy is used including minimal oxygen (Fio_2 0.30 or less) and low-pressure ventilation (*positive end-expiratory pressure* [PEEP] 10 cm of H_2O and peak inspiratory pressures less than 25 cm of H_2O). Initially, this can be done without systemic heparinization, until the surgical team is satisfied with hemostasis. Subsequent modest anticoagulation can occur with activated clotting times of 180–200 seconds typically being adequate. Weaning from VV ECMO involves discontinuing membrane gas flow and increasing ventilatory parameters as needed. No increase in anticoagulation is required for VV ECMO weaning. Using this strategy, patients are usually weaned from ECMO within 3 to 5 days of support, as pulmonary vascular resistance decreases following institution of ECMO and pulmonary capillary leak resolves. The 30-day survival in patients requiring VV ECMO at our institution approaches 90%.

Although PGD remains the most common reason for the development of severe allograft dysfunction, the development of marked hypoxia, pulmonary edema, elevated pulmonary artery pressures, and poor compliance requires immediate investigation for reversible causes. Asymmetric pulmonary edema or crescent-shaped airways on bronchoscopic evaluation may be indicative of mechanical problems. Most importantly, anastomotic or mechanical etiologies, especially venous outflow problems, need to be identified and corrected immediately. With respect to venous outflow obstruction, correction later than 4–6 hours will be unlikely to achieve reasonable allograft recovery. Interrogation of the anastomoses in the operating room includes visual inspection to assess for torsion or kinking, as well as TEE to assess for turbulent or absent pulmonary vein flow, left atrial anastomotic quality, the presence of intraluminal clot, and direct measurement of pressures across the anastomosis. TEE should provide optimal evaluation of all pulmonary veins except for the left lower, which is sometimes difficult to see with echo.

Pulmonary vein thrombosis can occur in the acute setting early after transplant and can mimic the clinical appearance of PGD. Prevention of pulmonary vein thrombosis should be emphasized by strict adherence to proper procurement techniques, a technically sound intimal-to-intimal anastomosis, and systemic anticoagulation in high-risk individuals. If discovered in the operating room, immediate revision of the anastomosis should be performed. It may be possible to treat non-occlusive thrombus with thrombolytics and/or anticoagulation, although the risk for life-threatening hemorrhage is clearly highest during the early postoperative period. Oftentimes the safest management strategy includes inspection and treatment in the operating room.

Cardiac complications can usually be identified by TEE, including left-sided valvular abnormalities, left ventricular failure, intracardiac shunts, and tamponade. However, TEE does not provide adequate assessment of the pulmonary artery anastomoses. Therefore, we routinely obtain a quantitative perfusion scan within the first few hours after the transplant. Lobar or greater perfusion defects on the perfusion scan often necessitate further assessment, most preferably by operative exploration. Computed tomography or conventional angiography can also be utilized to assess the pulmonary arterial vasculature. On rare occasions, PA kinking can be better managed endovascularly with a stent.

Uncommonly, early graft dysfunction can also be caused by humoral lung injury from circulating antidonor antibodies. These antibodies are identified via a cross-match of donor and recipient sera. Treatment of donor-specific antibodies is multimodal, including plasmapheresis or exchange, intravenous immunoglobulin (IVIG), and anti-B-cell therapies such as anti-CD20 (rituximab).

Summary

There has been encouraging progress in lung transplantation over the last two decades, with improvements in graft survival occurring with each new era. The most impressive changes have been in early outcomes, with 30-day and 1-year patient and allograft survival now comparing favorably to those of liver and cardiac transplantation [11]. Much of the enhanced patient outcomes can be attributed to astute recipient selection, meticulous technical performance of organ procurement and implantation, and refinements in perioperative care [12]. Unfortunately, as with all solid organ transplantations, the shortage of available donor organs and the development of chronic allograft injury remain the primary limitations to a greater applicability of lung transplantation. Without question, the development of expanded organ sources through xenotransplantation [13], lung organogenesis [14], and ex vivo perfusion systems [15,16] will greatly impact the future numbers of lung transplants performed. Regardless of where suitable donors are discovered, standardizing and implementing operative techniques as described above should provide for appropriate patient outcomes.

CHAPTER 60

Pancreas Transplantation Procedure and Surgical Technique

Dixon B. Kaufman, Jon S. Odorico, and Hans W. Sollinger
Division of Transplantation, University of Wisconsin School of Medicine and Public Health, Madison, WI, USA

Introduction

The prevalence of type 1 diabetes in the United States is estimated to be approximately 2 000 000 individuals, with over 35 000 new cases diagnosed each year [1,2]. Currently, there is no practical artificial endocrine pancreas (i.e. a mechanical insulin-delivery device coupled with an automated glucose-sensory apparatus) that is capable of administering insulin with the degree of control necessary to produce a near-constant euglycemic state without risk of hypoglycemia. Persons with type 1 diabetes are resigned to manually regulate blood glucose levels by various forms of exogenous insulin administration. Consequently, patients with diabetes exhibit wide excursions of plasma glucose levels from hour to hour and day to day. Since severe hypoglycemia is life-threatening, glucose control must err on the high side. Therefore, patients must live with chronic hyperglycemia and elevated hemoglobin A1c (HgbA1c).

The only treatment that reliably produces sustained euglycemia, normalizes hemoglobin A1c levels, and has been rigorously documented to influence the progression of some secondary complications include β cell replacement therapy with the immediately vascularized whole-organ pancreas transplant. Currently, islet transplantation is a very promising experimental procedure for select patients with type 1 diabetes.

A successful pancreas transplant obviates the need for exogenous insulin therapy, normalizing hemoglobin A1C levels for as long as the graft functions. Pancreas transplantation also has the added physiological properties of proinsulin and C-peptide release not possible with intensive insulin therapy [3]. Through improved metabolic control, many secondary complications of diabetes are markedly improved, or reversed. Several seminal studies have documented these benefits, including improvement in diabetic neuropathy [4], autonomic neuropathy-associated sudden death [5], diabetic nephropathy in both uremic and non-uremic patients [6,7], and stabilization of visual acuity [8]. A successful pancreas transplant significantly improves quality of life [9] and life expectancy [10,11]. This chapter will provide an overview of the critical aspects of the pancreas transplant procedure, including patient preparation, organ procurement and reconstruction, implantation, and perioperative management.

Pancreas transplantation categories

Approximately 1100 pancreas transplants are performed annually in the United States. Sixty-five to 70% involve a simultaneous pancreas and kidney (SPK) transplant for patients with type 1 diabetes and chronic renal failure. The uremic patient with diabetes is an excellent candidate for an SPK transplant from the same donor because the immunosuppressive medications that are needed are similar to those for a kidney transplant alone and the surgical risk of adding the pancreas is low. The benefits of adding a pancreas transplant to ameliorate diabetes are profound—transplantation saves lives [10,11].

The second category for pancreas transplantation consists of patients with type 1 diabetes who have received a previous kidney transplant from either a living or deceased donor. This group accounts for approximately 20% of patients receiving pancreas transplants. The important consideration is that of surgical risk, since the risk of immunosuppression has already been assumed.

The third category for pancreas transplantation is the non-uremic, non-kidney transplant patient with type 1 diabetes. In this situation one assesses the risk of immunosuppression to be less than the risk of diabetes treated with conventional exogenous insulin. Some of these patients with diabetes have extremely labile disease associated with frequent emergency room visits and inpatient hospitalizations for hypoglycemia or diabetic ketoacidosis. Other patients have significant hypoglycemic unawareness that results in unconsciousness without warning. For select patients this state can be a devastating problem that affects their employment and their ability to keep a driver's license and creates concern about lethal hypoglycemia while asleep.

More detailed discussions of pancreas transplant outcome can be found in Chapter 107.

Preparative aspects of pancreas transplant surgery

Timing

The efficient coordination of pancreas allograft allocation to a specific patient relative to the timing of actual surgical organ procurement has important implications for an efficient transplant

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

process that minimizes cold ischemia time. Effective communication between the procurement and transplant teams and the organ procurement organization is essential. Determining donor HLA typing, infectious serologic results, and HLA cross-match results will permit the ideal situation of allocating the deceased donor pancreas (plus kidney with SPK transplant) prior to operative procurement of the organs. This sequence of events has several advantages: (1) it will allow the transplant center performing the pancreas transplant the choice to also procure the pancreas; (2) it will allow patients to be admitted to the hospital and the inpatient evaluation process to begin simultaneously, rather than sequentially, to the procurement of the organs; and (3) it will minimize the cold ischemia time of the pancreas prior to implantation. Pancreas allografts do not tolerate cold ischemia as well as kidney allografts. It is ideal to revascularize the pancreas within 24 hours from the time of procurement cross-clamping. Finally, it will also allow identification of 0 antigen mismatched donor–recipient pairs to be identified prior to procurement which will minimize cold ischemia time if the organs need to be transported across country.

Preoperative transplant assessment

The pancreas transplant recipient is admitted to the hospital, re-evaluated, and a final decision made whether or not to proceed with surgery. The re-evaluation process is similar to that for kidney-alone transplant recipients, emphasizing work-up for acute medical issues that might contraindicate surgery. More detailed discussions of the initial patient evaluation and wait list management can be found in Chapters 32 and 41, respectively. There are several special considerations for the diabetic patient. Careful management of diabetes pretransplant is important for patients not allowed eat or drink prior to surgery. A bowel preparation is performed for patients that will undergo enteric drainage of the pancreas transplant.

Review of the cardiac evaluation is the most critical aspect of the preoperative evaluation. Virtually all patients will have undergone an extensive cardiac evaluation consisting of chest X ray, ECG, stress testing, and usually coronary angiography. Many patients will have been treated by coronary artery intervention to diminish the perioperative risk of the transplant procedure and to prolong the duration of life post-transplant. Patients who have experienced long waiting periods prior to pancreas transplantation should have their cardiac status carefully re-assessed.

Autonomic neuropathy is prevalent and may manifest as neurogenic bladder dysfunction, gastropathy, and orthostatic hypotension. Neurogenic bladder dysfunction is an important consideration in patients receiving a bladder-drained pancreas transplant. Inability to sense bladder fullness and to empty the bladder predisposes to urine reflux and high postvoid residuals. These problems may adversely affect renal allograft function, increase the incidence of bladder infections and pyelonephritis, and predispose to graft pancreatitis.

Impaired gastric emptying, gastroparesis, is an important consideration with significant implications in the post-transplant period. Patients with severe gastroparesis may have difficulty tolerating the oral immunosuppressive medications that are essential to prevent rejection of the transplants.

The combination of orthostatic hypotension and recumbent hypertension results from dysregulation of vascular tone. This condition has implications for blood pressure control post-transplant, especially in patients with bladder-drained pancreas transplants that are predisposed to volume depletion. Careful assessment of post-transplant antihypertensive medication is important.

Diabetic retinopathy is a nearly ubiquitous finding in patients with diabetes and end-stage renal disease. Blindness is not an absolute contraindication to transplantation since many blind patients lead very independent life styles. Although rarely a problem, it should be confirmed that a patient with significant vision loss has an adequate support system to ensure help with travel and immunosuppressive medications.

Lower-extremity peripheral vascular disease is significant in patients with diabetes. Uremic, diabetic patients are at risk for amputation of a lower extremity. These problems typically begin with a foot ulcer associated with advanced somatosensory neuropathy. The risk is further complicated by sensory and motor neuropathies in patients with longstanding diabetes. Vascular disease may have implications for the rehabilitation post-transplant and is an indicator for potential risk for injury to the feet and subsequent diabetic foot ulcers.

Mental or emotional illnesses, including neuroses and depression, are common. Diagnosis and appropriate treatment of these illnesses is important to consider because of the important implications for ensuring a high degree of medical compliance.

Donor pancreas procurement

Identification of suitable deceased organ donors for pancreas transplantation is an important and often underappreciated determinant of outcome. Table 60.1 lists the common contraindications for pancreas transplantation. Misjudging the quality of the donor organs will have significant adverse consequences post-transplant. The transplant operation begins with organ procurement.

Donor pancreas organ evaluation

The criteria determining an appropriate donor for pancreas transplantation are more stringent than for kidney or liver donors. Deceased pancreas organ donors are typically between the ages of 10 and 60. The lower age limit does not relate to the metabolic efficiency of the pediatric endocrine pancreas to regulate blood sugar control in an adult. Rather, the lower age limit of a donor pancreas reflects the anticipated small caliber of the splenic artery, which may preclude successful construction of the arterial Y-graft needed for pancreas allograft revascularization.

Regarding upper age limits, the use of pancreata from older donors has been associated with increased technical failures due to graft thrombosis, a post-transplant pancreatitis, and decreased pancreas graft survival rates [12]. The body weight of the deceased

Table 60.1. Contraindications to pancreas transplantation

1	Omission of consent for organ donation
2	Incompatible blood group
3	Donor HLA class I and/or class II antigen generating a positive immunological cross-match
4	History of type 1 or type 2 diabetes mellitus in donor
5	Donor viral infectious disease of HIV, hepatitis B, and/or C
6	Significant bacterial and/or fungal infection of the donor
7	Significant and prolonged donor hemodynamic instability
8	History of previous donor pancreatic surgery
9	Intra-abdominal trauma to the donor pancreas
10	Cancer

From [19] Kaufman DB. Chapter 47. Complications of Pancreatic Transplantation, pp. 640–655. In: Complications in Surgery, 2nd edition. Ed. M. Mulholland and G. Doherty. Lippincott Williams & Wilkins, 2011. Reprinted with permission from Wolters Kluwer.

organ donor is an important consideration. Obese donors >30 kg/m^2 body mass index (BMI) are frequently found not to be suitable pancreas donors. Obese patients may have a history of type 2 diabetes, or the pancreas may be found to be unsuitable for transplantation because of a high degree of adipose infiltration of the pancreas. Further, retrospective analyses have identified a number of donor-related factors that correlate with worse outcome following pancreas transplantation, including BMI >30 kg/m^2 [13]. Finally, a pancreas donor risk index (pDRI) has been developed to inform organ acceptance decision making, which considers ten common donor variables and one transplant factor (ischemia time) as factors associated with an increased risk of allograft failure [14].

Importantly, pancreata from relatively older donors (age 55 to 65) and obese organ donors are associated with very successful islet isolation recovery required for islet transplantation. Therefore, application of β cell replacement therapy should be considered for nearly all deceased organ donors.

Donor hemodynamic stability and need for inotropic support is an important consideration. Hemodynamic stability has more influence on the anticipated function of the kidney allograft than it does on initial endocrine function of the pancreas allograft in the case of an SPK transplant. Deceased donors who have experienced a significant period of cardiac arrest or who require high doses of prolonged inotropic support frequently exhibit slow deterioration of renal function, which may result in delayed renal allograft function in the SPK transplant recipient.

The most important determinant of suitability of the pancreas for transplantation is direct examination of the organ during surgical procurement. The experience of the procurement team is important. During procurement, this judgment regarding the degree of fibrosis, adipose tissue infiltration into the parenchyma, trauma, and specific vascular anomalies can be made. The important vascular anomaly that must be accurately evaluated during procurement is the presence of a replaced or accessory right hepatic artery originating from the superior mesenteric artery (SMA).

The use of marginal and donors with circulatory death (DCD) for pancreas transplantation has been reported [15]. If the pancreas is deemed suitable, there is the added consideration of the effect of delayed kidney graft function in a uremic SPK transplant candidate. The use of marginal and DCD donors for pancreas-alone transplantation is a decision made on a case-by-case basis.

The use of living related and unrelated pancreas donors has also been described wherein a distal pancreatectomy is performed for a segmental pancreas transplant [16]. Anecdotal cases of combined live donor partial pancreatectomy and nephrectomy for SPK transplantation have also been reported [16]. These procedures are not widely performed and are mostly of historical note. Finally, the combined use of simultaneous deceased donor pancreas and living donor kidney transplantation has been successfully applied [17].

Procurement of the pancreaticoduodenal splenic allograft

There are several standard surgical methods for procurement of the pancreas for transplantation. The general principles are similar irrespective of the specific techniques utilized. The pancreas must be procured with an intact vascular supply that does not compromise the vascularity of the liver. The pancreas is procured with the spleen and duodenum intact. The organ is perfused with preservation solution and cold stored. The donor iliac vessels are obtained for revascularization of the arterial supply and sometimes the portal vein.

There are two general methods of organ procurement. Many programs prefer to perform an en bloc removal of the liver and pancreas together and separate the two organs at the backbench. Other programs prefer to perform a more deliberate dissection of the pancreas and liver by mobilizing the relevant vasculature prior to preservation. The liver and pancreas are separated in situ. The relevant components of the in situ procurement process are briefly described.

1. long midline incision (± cruciate incision);
2. mobilization of ascending colon, control of infrarenal aorta, and identification of superior mesenteric artery;
3. control of supraceliac aorta;
4. identification of hepatic artery (ligation of gastroduodenal artery), splenic artery, portal vein, and division of common bile duct;
5. identification of replaced and/or accessory left and right hepatic arteries;
6. exposure of the anterior aspect of the pancreas for visual and manual inspection;
7. mobilization of the spleen by division of short gastric vessels and dissection of its ligamentous attachments;
8. mobilization of head, tail, and body of the pancreas;
9. NG tube positioning into the proximal duodenum and irrigation of antibiotic solution;
10. removal of NG tube and division of the proximal duodenum just distal to the pylorus;
11. heparinization of the donor and infusion of intra-aortic (± intraportal) preservation solution;
12. division of proximal jejunum, middle colic vessels, and superior mesenteric vessels distal to the pancreatic uncinate process;
13. division of celiac, SMA, splenic arteries, and portal vein;
14. procurement of liver, pancreaticoduodenosplenic allograft, and kidneys;
15. procurement of donor iliac vessels;
16. closure of incision.

Additional discussion of pancreas procurement in the context of a multiorgan procurement from a standard criteria donor or a donation after circulatory death (DCD) donor can be found in Chapters 21 and 22, respectively.

Back-table preparation of the pancreaticoduodenal allograft

The back-table preparation of the pancreaticoduoenal allograft for transplantation requires careful and meticulous surgical technique to ensure a properly revascularized pancreas with adequate duodenum and minimal extraneous fibrotic and adipose tissue (Figure 60.1). The quality of the back-table surgical procedure has the greatest impact on the immediate outcome of the transplant surgery.

The pancreaticoduodenosplenic allograft has previously been procured from the deceased donor by the procuring surgeons and placed in preservation solution and packed according to UNOS guidelines in a cold storage container for transportation to the transplantation center. The container with the allograft is brought into the operating room and the UNOS identification number and donor blood group cross referenced with the pancreas transplant recipient. A basin filled with ice is covered with a plastic wrap that is filled with fresh, cold preservation solution. The organ is then removed from the transport container and placed in the chilled preservation solution. Two surgeons typically partner to perform the back-table operative preparation.

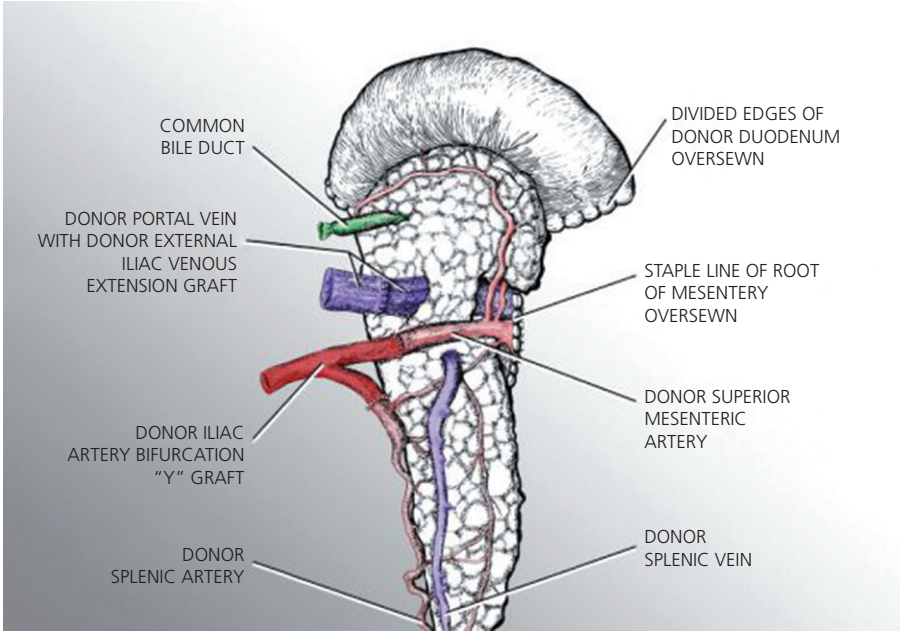

Figure 60.1. Anatomy of the pancreaticoduodenal allograft for back-table reconstruction. Illustration by Simon Kimm MD, Department of Urologic Oncology, Memorial Sloan-Kettering Cancer Center, New York, NY.

Visual inspection of the allograft is critical prior to making the final decision to proceed with transplantation. The organ should be evaluated for the degree of parenchymal adipose infiltration, fibrosis, or palpable nodular lesions Pancreata with heavy infiltration of adipose tissue are relatively intolerant of prolonged (>18 hours) cold preservation and the potential of a high degree of saponification due to reperfusion pancreatitis following revascularization. These organs may be more suitable for islet isolation.

Inspection for parenchymal, vascular, and duodenal injuries, as well as vascular anomalies, should be conducted in a disciplined fashion. The divided small bowel mesentery should be inspected to ensure that it has not been divided excessively short, encroaching on the pancreatic parenchyma and compromising the intraparenchymal vascular supply. The pancreatic portal vein must be carefully inspected to ensure that it has not been cut excessively short, damaging the joining splenic vein. This can occur when the portal vein is put on stretch during liver procurement and over aggressively divided to generate excessive length for the liver transplant team, typically when the procuring surgeons are told that the liver recipient is undergoing a re-transplant. Rescue of a short (2 mm) portal vein can be accomplished with a portal venous extension graft of donor external iliac vein.

An important vascular anomaly that must be skillfully managed during procurement and re-evaluated on the back table is the occurrence of a replaced or accessory right hepatic artery originating from the SMA. The presence of a replaced right hepatic artery is not a contraindication for the use of the pancreas for transplantation under most conditions. Experienced procurement teams will be able to successfully separate the liver and the pancreas either in situ or on the back table, without sacrificing quality of either organ for transplantation.

A few important caveats determine if this maneuver is possible. The replaced right hepatic artery must be dissected to the junction with the SMA. If the replaced right hepatic artery traverses deep into the parenchyma of the head of the pancreas, requiring extensive parenchymal dissection, this circumstance may preclude the pancreas for transplantation (however, it may be suitable for islet transplantation). In such circumstances, another alternative is to divide the replaced right hepatic artery outside the pancreatic parenchyma, not violating the pancreas. Such arteries can be safely reconstructed for the liver transplant without injuring the pancreas, but this requires experience with this specific reconstruction.

The SMA is divided distal to the origin of the replaced right hepatic artery, preserving a short length of SMA with a carrel patch for the liver graft. Occasionally, there is a large inferior pancreaticoduodenal arterial branch vascularizing the head of the pancreas that originates proximal to the origin of the replaced right hepatic artery. The inferior pancreaticoduodenal vessels are critical to vascularization of the head of the pancreas because the gastroduodenal artery is routinely ligated during the process of hepatic artery mobilization for the liver transplant. In the case of a very proximal origin of the inferior pancreaticoduodenal artery, dividing the SMA at the appropriate location for liver procurement would significantly impair vascularization of the head of the pancreas and preclude its use for transplantation.

Evaluation of the arterial vascularity of the pancreaticoduodenal allograft can be tested on the back table by several methods: (1) injection of Renografin into the SMA or Y-graft and obtaining an X ray; (2) intra-arterial injection of fluorescein, with visualization using a Wood lamp; and (3) performing a methylene blue angiogram.

The duodenum should be carefully inspected to rule out a serosal injury. Many groups will open the duodenum at the distal corner staple line, to irrigate and drain the contents into a separate container, then close the opening. Some programs routinely culture the fluid and a small piece of duodenal tissue.

The main principles of back table allograft preparation follow. First, the spleen is removed from the pancreas tail with secure ligatures on the large splenic vessels. The use of the vascular stapler is also acceptable and may be more efficient. Next, it may be useful

to cut the tie off the common bile duct (CBD) and place a cannula (5F feeding tube) temporarily to identify the location of the ampulla by manual palpation. A marking pen can be used to designate its location to accurately ensure its center position as the proximal and distal duodenum are shortened to an appropriate length (the tube is removed and the CBD re-tied). The first portion of the duodenum is dissected a couple centimeters distal to the pylorus and divided proximal to the ampulla with the stapler. The third portion of the duodenum is dissected off the mesentery until adjacent to the pancreas and stapled. Next the staple lines are inverted with 3-0 nylon or silk suture as interrupted stitches. It is important to carefully and liberally invert the corners of the duodenum to avoid its protrusion and eventual breakdown and leakage.

The mesenteric vessels protruding through the pancreas uncinate may have been stapled or individually ligated by the procurement team. The staple line on the root of the mesentery is over sewn with a running 3-0 monofilament suture for reinforcement. The middle colic vessels are secured.

The inflow arterial system is routinely reconstructed. The donor splenic artery and the SMA are identified and prepared for reconstruction by removing surrounding ganglionic tissue. The reconstruction requires use of the donor iliac arterial complex: a Y graft of common, internal, and external arteries.

The iliac arterial and venous complex is a critical inclusion. The arterial complex should be carefully inspected to determine if injury at the internal–external junction has occurred (usually by excessive retraction during procurement). The Y-graft is modified by dividing the internal and external iliac arteries to an appropriate length tailored for the end-to-end anastomoses on the splenic and superior mesenteric arteries of the pancreas allograft, respectively. Typically 7-0 monofilament suture is used as a running stitch, but interrupted stitches would be appropriate, especially if a pediatric donor pancreas is being transplanted. Conversely, if a sufficient length of splenic artery can be mobilized, it is possible to perform a direct end-to-side anastomosis to the superior mesenteric artery.

Occasionally, the pancreas allograft is obtained without a simultaneous liver procurement. In this circumstance the procurement team will return the pancreas allograft on an aortic patch with complete celiac and SMA and intact gastroduodenal artery. In these cases the Y-graft reconstructions are not necessary so long as the celiac and SMA arterial inflow are preserved. Exceptional duodenal graft perfusion will be observed following recipient graft arterial revascularization.

Some groups routinely modify the outflow portal venous vascular system as well. The portal vein is carefully mobilized to allow for appropriate length and determination if a short portal venous extension graft utilizing donor external iliac vein would be useful. A portal vein extension is easily accomplished using donor external iliac vein, aligning in the direction of blood flow using 5-0 or 6-0 monofilament suture as a running stitch.

Following vascular reconstruction, some groups infuse the pancreas Y-graft with 100–200 mL of fresh, cold, preservation solution to examine for parenchymal vascular leaks, which can be repaired prior to recipient revascularization. It is important not to use the solution in the basin for flushing since small particulate matter will be introduced into the organ and increase risk of vascular compromise and thrombosis. Finally, the preservation solution should be exchanged for fresh solution and plenty of ice resupplied in the basin underneath it. The total operative time for the back-table work can exceed 3 hours in a complicated case.

Pancreas transplantation surgery

Preparation

Optimizing the outcome of the pancreas transplant begins prior to the patient entering the operating room (OR): appropriate antibiotic prophylaxis has been ordered; DVT prophylaxis method determined; blood products are confirmed available and appropriate for the estimated blood loss; and the surgical site been marked.

Safety and efficiency in the operating room rely on good communication among the team members. Having all team members introduce themselves facilitates subsequent communication. Prior to commencing the operation several issues should be discussed: confirm correct patient and transplant procedure; the organ allograft is available including donor/recipient ABO compatibility documentation. Surgeon reviews the critical portions of the transplant procedure, its duration and estimated blood loss, including need for central venous access and direct arterial blood pressure monitoring. Surgeon and nursing staff review availability of surgical equipment, retractors, electrocautery devices, lighting, etc. Confirm that appropriate antibiotics and immunosuppression are given.

Exposure

The surgical techniques for pancreas transplantation are diverse (Figure 60.2). The principles are consistent, however, and include providing adequate arterial blood flow to the pancreas and duodenal segment, adequate venous outflow from the pancreas, and secure management of the pancreatic exocrine secretions. The native pancreas is not removed. Adequate exposure is also necessary for intra-abdominal implantation of the deceased donor kidney when an SPK transplant procedure is performed.

Proper exposure is accomplished by either a midline incision or a right lower quadrant oblique incision. Most use a long midline incision, especially if it is an SPK transplant because both organs can be implanted through the single incision. The pancreas is preferentially placed on the right-sided iliac vascular supply. After the midline incision, a modified Cattell maneuver is often used to properly expose the recipient vessels for the pancreas transplant. The right colon is reflected anteriorly and medially by dividing along white line of Toldt lateral to cecum and ascending colon. This will expose the right iliac vessels, aorta, and inferior vena cava. It is not necessary to expose the right kidney and renal vessels or 4th part of duodenum. An alternative method is to retract the small intestines cephalad without mobilizing the right colon and dissecting the iliac vessels and distal vena cava through the retroperitoneal layer. To properly expose the iliac vessels for the intra-abdominal kidney transplant, the descending colon and sigmoid are mobilized medially by dividing along white line of Toldt lateral to descending and sigmoid colon.

If a right lower quadrant incision is used, the retroperitoneal iliac vessels are dissected akin to a kidney transplant. The internal iliac veins are stick tied and divided to achieve liberal mobilization of the vein lateral to the iliac artery. The pancreas is implanted with the head caudal. The peritoneum is opened and the pancreas rotated intra-abdominally, the tail of the pancreas tacked to the anterior abdominal wall and either a duodenocystotomy or duodenoenterotomy performed.

Methods

The surgical techniques for pancreas transplantation are defined according to the methodologies of insulin venous delivery and pancreatic exocrine drainage technique. Also, for the intra-abdominally placed pancreas, it may be oriented with the duodenum cephalad

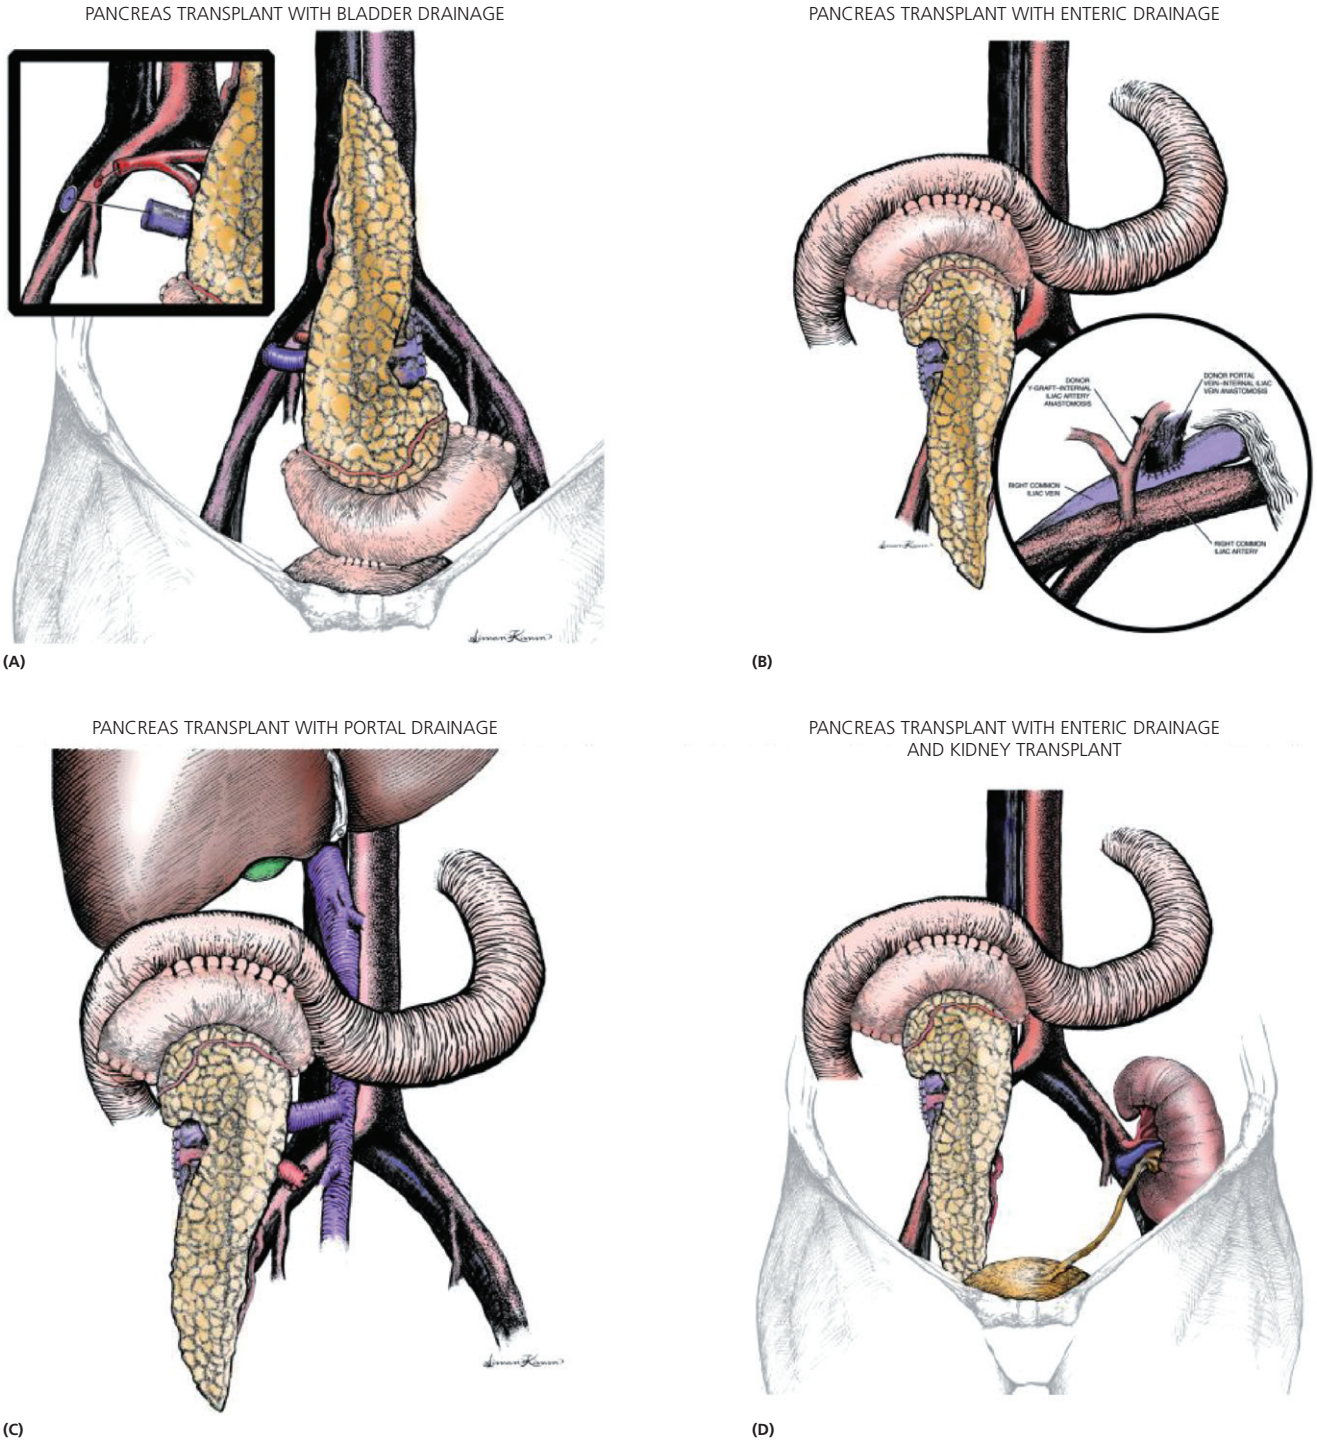

Figure 60.2. (A) Pancreaticoduodenal allograft with systemic venous insulin delivery and bladder exocrine drainage. (B) Pancreaticoduodenal allograft with systemic venous insulin delivery and enteric exocrine drainage. (C) Pancreaticoduodenal allograft with portal venous insulin delivery and enteric exocrine drainage. (D) Pancreaticoduodenal allograft with systemic venous insulin delivery and enteric exocrine drainage with kidney transplant. Reprinted with permission from [20] Stuart FP, Abecassis MM, Kaufman DB. or caudad. Systemic venous insulin delivery/enteric exocrine drainage is the most commonly applied method, usually with the pancreatic head cephalad. Occasionally, the method of portal venous insulin delivery/enteric exocrine drainage is used, but accounts for approximately 10% of cases. In this case the superior mesenteric vein is used for the venous anastomosis. This vessel is exposed at the root of the mesentery. This technique requires longer arterial length of the common iliac artery Y-graft so it can be dropped through the mesentery to the recipient right common iliac artery. It may be useful for re-transplant procedures in which difficulty of systemic venous drainage is encountered. The other common method is systemic venous/bladder exocrine drainage (portal venous drainage is not possible with exocrine bladder drainage). This technique has waned in popularity coincident with advances in immunosuppression.

Enteric drainage is performed almost uniformly in SPK transplant cases. Bladder drainage is used occasionally with solitary pancreas transplants because of opportunity to utilize urinary amylase monitoring for rejection in this category of cases because of the relatively higher rates of immunological graft losses.

Arterial reconstruction

The pancreas graft arterial revascularization is usually accomplished using the recipient right common or external iliac artery. The Y-graft of the pancreas is anastomosed end-to-side. Positioning of the head of the pancreas graft cephalad or caudad is not relevant with respect to successful arterial revascularization. The arterial anastomosis is typically performed after the venous anastomosis, except when the SMV is used for a portal drained pancreas. In that case, it may be useful to place the arterial graft first. Commonly used arterial clamps are Fogarty Hydragrip vascular clamps with inserts. They are less traumatic on vessels (often diseased) in diabetic patients. The arteriotomy is performed with an 11 blade and the vessel flushed with heparinized saline. An arterial punch can be used to expand the size of the arteriotomy to match the size of the common iliac artery of the Y-graft. The end-to-size anastomosis is performed using 6-0 monofilament suture as a running stitch.

Venous reconstruction

There are two choices for venous revascularization—systemic and portal. Systemic venous revascularization commonly involves the distal vena cava/right common iliac vein, or right external iliac vein. If portal venous drainage is used, it is necessary to dissect the superior mesenteric vein at the root of the mesentery. The pancreas portal vein is anastomosed end-to-side to a branch of the superior mesenteric vein. This anastomosis may influence the methodology of arterial revascularization and necessitates using a long Y-graft placed through a window in the mesentery to reach the right common iliac artery. Portal venous drainage of the pancreas is more physiologic with respect to immediate delivery of insulin to the recipient liver. Portal drainage results in diminished circulating insulin levels relative to those in systemic venous-drained pancreas grafts. The route of venous drainage has no documented clinically relevant differences in glycemic control.

Commonly used vascular clamps for the vein are the single Lambert–Kay or dual atraumatic straight DeBakey clamps. The former may be preferred if partial venous occlusion is sought, often if the venotomy site is the distal vena cava and a previous kidney allograft is in place. The venotomy is performed with an 11 blade or an ellipse cut with the scissors. The vessel is flushed with heparinized saline. The size of the venotomy is fashioned to match the size of the portal vein or the external iliac venous extension graft. The end-to-size anastomosis is performed using 6-0 monofilament suture as a running stitch.

Reperfusion

Following completion of the anastomoses the vascular clamps are carefully removed, venous then arterial. A well-perfused pancreas will have uniform pink color including the duodenum. The duodenum will begin filling with secretions. The revascularized pancreas bleeds more profusely than a kidney allograft. Bleeding vessels are controlled by clamps and suture stick ties. The three most common areas of bleeding are the mesenteric vessels of the pancreatic uncinate, the splenic vessels of the pancreatic tail and arterial vessels of the common bile duct. It is common for systolic pressure of the recipient to transiently decrease due to the blood loss and reperfusion effect. Excellent communication with the anesthesiology team is critical prior to revascularization to ensure adequate central venous pressure, glycemic control, and electrolyte balance of the recipient.

The pancreas is carefully positioned according to the orientation of the pancreatic head. If it is in the cephalad position, the tail is positioned inferiorly into the pouch of Douglas or lateral to the cecum in the right paracolic gutter, depending on how the intestines were previously mobilized. The pancreas is rotated so the splenic artery lies adjacent to the retroperitoneum with the mesenteric vessels oriented superiorly. Visual and manual palpation of the vessels will confirm a strong splenic arterial pulse and soft portal vein without misalignment. The intestines are repositioned around the allograft with head of the pancreas oriented cephalad and superior adjacent to the midjejunum.

Pancreatic duct management

There are several methods of managing the exocrine drainage of the pancreas. Pancreatic exocrine drainage may be handled via anastomosis of the duodenal segment to the bladder or by anastomosis to the small intestine. The bladder-drained pancreas transplant modification was introduced about 1982. This technique significantly improved the procedure's safety by minimizing the occurrence of intra-abdominal abscess from leakage of enteric-drained pancreas grafts. With the successful application of the new maintenance immunosuppressive agents and reduction in the incidence of rejection and leaks, enteric drainage of pancreas transplants has enjoyed a rebirth and largely replaced bladder drainage.

Enteric drainage of the pancreas allograft is physiologic with respect to the delivery of pancreatic enzymes and bicarbonate into the intestines for reabsorption. The enteric drained pancreas can be constructed with or without a Roux-en-Y intestinal limb. The enteric anastomosis can be made side-to-side or end-to-side with the duodenal segment of the pancreas. The anastomosis may be hand sewn or accomplished with the stapler. The former is more common. Typical is a two-layered anastomosis using 3-0 silk suture as seromuscularly placed interrupted stitches as the outer layer and 3-0 absorbable monofilament suture on the through-and-through hemostatic inner layer.

The risk of intra-abdominal abscesses is low with enteric drainage [18], and the avoidance of the bladder-drained pancreas has significant implications with respect to potential complications that include bladder infection, cystitis, urethritis, urethral injury, balanitis, hematuria, metabolic acidosis, and the requirement for enteric conversion. Currently, approximately 75% of pancreas

transplants are performed with enteric drainage, and the others with bladder drainage.

The options of enteric versus bladder drainage depend on the choice of venous drainage and the clinical scenario of the pancreas transplant. For the portal drained pancreas transplant, bladder drainage is not an option. For the recipient of an SPK transplant, enteric drainage is the technique of choice because there is no urinary monitoring benefit and the morbidities as described above are significant. In the cases of PAK and PTA, bladder drainage has two important advantages: (1) urinary monitoring for rejection and (2) placement of the graft, allowing access for percutaneous biopsy for diagnosis of rejection. In the latter situation the advantages of monitoring outweigh the morbidities associated with bladder drainage, at least in the short term, when the risk of immunologic graft loss is significant. However, many programs have had good experience with enteric drainage of the solitary pancreas transplant using other markers for rejections, such as clinical signs and symptoms of pancreas graft pancreatitis and serum amylase or lipase levels coupled with biopsy.

Closure

The fascia is closed with an absorbable or non-absorbable monofilament 0, #1, or #2 size suture. If a peritoneal dialysis catheter is present in a uremic patient, it may be removed prior to fascial closure. Closed suction drains are occasionally placed in the dependent portions of the lower abdomen adjacent to the pancreas into the pouch of Douglas. The subcutaneous adipose is approximated with 3-0 absorbable suture and the skin edges are re-approximated with surgical staples and covered with bacitracin ointment and an occlusive dressing, or as a subcuticular stitch using 4-0 absorbable suture followed by benzoin adhered steri-strips and occlusive dressing.

Conclusion

At the conclusion of the procedure the sponge, needle, and instrument counts are verified as accurate. Appropriate radiological studies are obtained. Postoperative recovery and care plan for the patient is reviewed prior to leaving the OR. Accurate descriptive documentation is completed in operative report shortly after conclusion of the procedure. Communication with patient's family members is immediately conducted in a face-to-face manner.

Summary

A remarkable amount of progress has been made in the field of pancreas transplantation since the first successful procedure in humans in 1966. Pancreas transplantation has evolved from an experimental procedure, with high morbidity and mortality, into an operative procedure with expected excellent outcomes akin to a kidney-alone transplantation. The rise of the field is due to great strides in surgical techniques, immunosuppressive protocols, donor evaluation, preoperative recipient assessment, and postoperative management. The techniques described have been in routine use at our center with excellent results and continue to evolve to make pancreas transplantation a safer and more effective treatment option for patients with diabetes.

CHAPTER 61

Islet Cell Transplantation Procedure and Surgical Technique

A.M. James Shapiro[1] and Camillo Ricordi[2]

[1] Clinical Islet Transplant Program, University of Alberta, Edmonton, AB, Canada
[2] Diabetes Research Institute, University of Miami, Miami, FL, USA

Introduction

Clinical islet transplantation (CIT) has transitioned rapidly from a rare, experimental curiosity to a reasonably routine clinical procedure in selected centers for patients with unstable forms of type 1 diabetes. Over 850 procedures have been performed worldwide [1], and, at least in expert hands, may now be considered amongst the technically safest of all the transplant procedures when compared to any other solid organ surgery. Given improving short-term outcomes (see Chapter 108), clinical islet transplantation is, in several countries, including Canada, the United Kingdom, Australia, Switzerland, Italy, France, and other parts of Europe, considered and funded as "non-research" standard clinical care. In the United States, the Food and Drug Administration (FDA) is moving rapidly towards a Biological Licensure Application (BLA) for CIT, supported by two parallel trials run through the CIT Consortium. A BLA will facilitate reimbursement through Medicare and Medicaid, and will have major bearing upon future activity in islet transplantation.

This chapter discusses the surgical techniques for pancreas procurement, islet isolation and culture, and minimally invasive techniques for intraportal delivery of islets in the recipient. Strict attention to detail throughout all aspects of the process is required in preparation of clinical Good Manufacturing Practice (cGMP) grade, highly viable islets of sufficient quantity to reverse diabetes in the recipient with minimal risk of complications.

Surgical procurement of the pancreas

The cGMP process used for clinical islet isolation, purification, and culture requires pancreas organs to be procured with utmost precision, with the goal being to ensure pancreatic capsular integrity, to maximize pancreatic oxygenated blood flow prior to aortic cross-clamp, and to minimize handling that could trigger graft pancreatitis [2]. The best islet yields are obtained from donors on minimal inotropic support, and the ideal islet donor overlaps considerably with the ideal donor used for whole pancreas transplantation [3]. The higher body mass index (BMI) donor with a more fatty pancreas tends to digest easier, but donors with underlying type 2 diabetes often have defects in insulin secretion that preclude their suitability in islet transplantation [4–7]. For this reason, donors with a hemoglobin A1C (HbA1c) elevated above 6.5% should not be used routinely for islet isolation. Up till recently, islet yield from the young ideal donor (18–30 years old) tended to be poor, in part due to the increased collagen and more fibrous nature of the younger gland [8–10]. Currently, success rates at several of the CIT Consortium centers have indicated marked improvement in islet yield from the younger pancreas and, combined with excellent clinical outcomes, this may have important bearing on future allocation of pancreas organs for whole organ versus islet utilization [11–15].

The principles behind optimal pancreas procurement are set out in Table 61.1. In general, the techniques used for pancreas procurement for islets are similar to those applied in procurement for whole pancreas transplantation, which are covered in depth in Chapters 22 and 60. The University of Wisconsin (UW) solution (Viaspan, Bristol-Myers-Squibb, New York, USA) was originally designed for optimal preservation of the pancreas [16]. UW "intracellular" solution has been used as the standard pancreas preservation solution but, more recently, perhaps more driven by economic cost saving than direct protective benefit to the pancreas, there has been a shift towards use of other solutions including histidine–tryptophan–ketoglutarate (HTK, Custodiol, Brantford, Ontario, Canada). HTK was originally developed as a cardioplegia solution in the 1970s, and is considered an "extracellular" preservation solution that is low in potassium. The use of HTK has been promoted by the liver transplant community as it avoids the risk of acute cardiac standstill with high potassium bolus previously observed with UW. There are, however, concerns that HTK may lead to inferior outcomes in whole pancreas transplantation, at least in selective centers [17,18]. The Canadian transplant programs switched from use of UW to HTK solution in 2009, and encouragingly this had little impact on the success of islet isolation, and, in fact, with use of the CIT Consortium and modification of their isolation Standard Operating Procedures (SOP), the isolation to transplant success ratio has recently risen from 40% to almost 70% (and an increase in the single donor insulin independence rates), clearly suggesting that HTK is not detrimental to clinical islet isolation success, and indeed may even be beneficial. Caballero-Corbalan et al. compared HTK and UW for human islet isolation and in vitro functionality, and found very similar outcomes provided the pancreas preservation time was kept below 10 hours [19].

Table 61.1. Surgical principles applied in the procurement of the pancreas for islet isolation

1	Selection of stable donors on minimal inotropic support
2	Absence of underlying diabetes (HbA1c < 6.5%)
3	Minimal handling of the pancreas throughout all stages of procurement
4	Maximize arterialized blood flow before cross-clamp, keeping the superior mesenteric, gastroduodenal, and splenic arteries patent
5	Avoidance of venous congestion of the pancreas during cold perfusion (ideally, complete avoidance of a mesenteric venous cannula, or, if used, maintaining a height differential of >40 cm between arterial and venous cannula)
6	Minimize warm ischemia immediately after cross-clamp by opening lesser sac, packing ice-saline slush behind and in front of the pancreas, and submersion of the pancreas after explant at 4°C in UW or HTK solution
7	Consideration of pancreatic ductal cannulation and low-volume ductal injection with 30 mL of UW, HTK, or ET-Kyoto preservation solution
8	Minimize cold ischemic transport time by use of expedited transportation where available (keep below 6 hours if possible)
9	Use the experienced procurement team from the receiving islet center when possible

HbA1c, hemoglobin A1C; UW, University of Wisconsin solution (Viaspan, Bristol-Myers-Squibb NY USA); HTK, histidine-tryptophan-ketoglutarate solution (Custodiol Inc., Brantford Ontario); ET-Kyoto, ET Kyoto Solution, Otsuka Pharmaceuticals, Tokyo Japan.

Table 61.2. Donor selection criteria[33]

Inclusion criteria	Exclusion criteria
SCD or ECD	
Multiorgan donor	Type 1 or 2 diabetes (HbA1c > 6.5%)
Male or female	Malignancy other than 1° brain tumor
Age 15–75	Untreated septicemia
Warm ischemic time <10 minutes	Viral hepatitis
Cold ischemic time <12 hours	HIV or AIDS
	Syphilis
DCD	
Controlled setting	Viral encephalitis
Warm ischemia <30 minutes	Creutzfeldt–Jacob disease
Cold ischemia <4 hours	Rabies
	Tuberculosis
	Sustained periods of hypotension
	Elevated serum creatinine (>3 × normal)
	Abnormal liver function (>3 × normal)
	Elevated serum amylase or lipase
	High-risk sexual behavior (unless NAT testing available and negative)
	History of recent i.v. drug use

SCD, standard criteria donor; ECD, expanded criteria donor; DCD, deceased circulatory death (non-heart beating); NAT, nucleic acid testing for HIV.
Data from Ponte et al. [33].

The "two-layer technique" has been promoted previously as a more optimal means to increase oxygen delivery to the pancreas during transportation. Originally developed by Kuroda and colleagues in Japan, this technique employs oxygenated perfluorocarbon (PFC) and UW solution, where the pancreas lies at the interface between the two solutions [20]. Subsequent uncontrolled studies suggested improved islet yields when the two-layer method was used [21–27]. However, more recent studies have brought these benefits into question, and, currently, in part due to complexity of widespread application and additional costs, the two-layer method is falling out of favor [28–32].

Appropriate selection of donors for islet isolation remains a critical component of isolation and transplant success [33]. Multivariate analyses have consistently shown that donor age >20 (and possibly <50), high donor BMI (in the absence of type 2 diabetes), donor normoglycemia, absence of sustained hypotension or cardiac arrest, and minimal inotropic requirements are all key variables in islet isolation success (Table 61.2) [14,34–41]. Selection of donors age

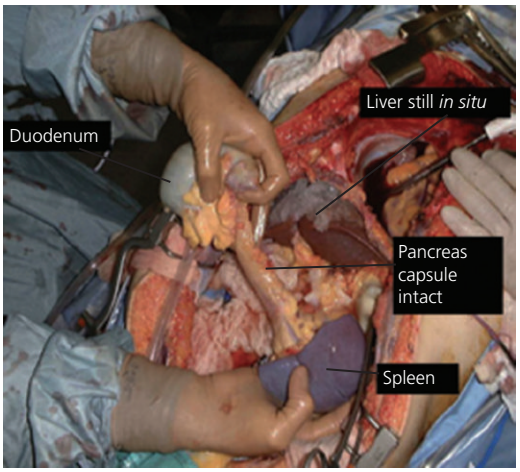

Figure 61.1. Pancreas is removed en bloc together with the first and second portion of the duodenum and spleen, with the pancreatic capsule intact.

<50 with BMI >27 kg/m^2 may have been one of the critical determinants of single donor engraftment success in the University of Minnesota series [42,43].

The surgical steps in multiorgan retrieval follow standard procedure, with minimal handling of the pancreas and minimal vascular dissection before the supraceliac aortic cross-clamp is applied. The lesser sac should be opened by separation of the omentum from the transverse mesocolon, and the anterior surface of the pancreas inspected for signs of trauma, capsular injury, pancreatitis, or mass. The duodenum should be fully mobilized by a Kocher maneuver. The duodenum should be divided distal to the pylorus, and again at the junction of the second and third portion, with two firings of a linear cutting 75 mm stapler. The splenic artery should be exposed at its origin and controlled with a vascular loop. The presence of a replaced right hepatic artery from the superior mesenteric artery is not a contraindication to pancreas retrieval either for whole pancreas or islet isolation, and especially in islet isolation there is no requirement for an SMA vascular pedicle. The gastroduodenal artery should be left patent until after cross-clamp, and may then be ligated and divided. Immediately following supraceliac aortic cross-clamp and chilled UW or HTK vascular flush, the spleen, tail, and body of the pancreas should be dissected and brought to the midline, allowing chilled saline slush solution to be placed both behind and in front of the pancreas, resulting in rapid cooling and avoidance of warm ischemic injury. Ideally, the pancreas should be the first abdominal organ removed after cross-clamping, after division of the common bile duct and portal vein (Figure 61.1). This actually facilitates the completion of the dissection of the hepatic vasculature, and optimizes visualization and protection of a replaced right hepatic artery. The pancreas is removed en bloc with the first and second portion of the duodenum, and is placed in UW or HTK solution at 4°C and triple-bagged for sterile transportation to the islet isolation center. A portion of the spleen is usually removed at this point for HLA-typing.

The Baylor islet isolation team has advocated precannulation of the pancreatic duct via the ampulla of Vater in the operating room, with flushing of the pancreatic duct with 1 mL/g pancreas of ET-Kyoto solution (Otsuka Pharm Factory Inc., Naruto, Japan), and claim that this facilitated consistent high-yield isolations [44–46]. This technique has yet to be broadly adopted, in part as it adds to

the complexity of the postretrieval preparation, and mainly because ET-Kyoto solution is not widely available. Further controlled studies are needed to clarify the utility of this promising approach.

Clinical islet isolation and culture

Restoration of endogenous islet function through intraportal transplantation of large numbers of purified human islets rests on the intricacies of the 6–8 hour islet isolation process, which extracts the 1–2% of islets contained in a 70–100 g pancreas gland that otherwise consists entirely of unwanted exocrine tissue. A series of digestive, rinse, and purification steps reduce the 60 mL digest down to an enriched islet fraction of 5 mL considered safe to infuse into the portal vein. Generally, an islet mass of 5000 IEQ per kg, based on the recipient's weight, is required for a transplant. A single donor transplant is more likely to succeed if the islet transplant mass exceeds 6000–7000 IEQ/kg. An inability to extract such large numbers of high-quality human islets represented a formidable challenge in the 1970s and 1980s and precluded success in early clinical transplant attempts. The introduction of an automated method for islet isolation by Camillo Ricordi in 1986, working in Paul Lacy's laboratory in St. Louis, enabled for the first time an increasingly reliable technique for high-yield human islet isolation, and was the cornerstone of the success of the first pilot clinical trials [47,48]. Although the process has evolved substantially in recent years, the Ricordi automated method remains pivotal, and has been adopted universally by all clinical islet isolation laboratories. More recent refinements have mainly focused on optimized collagenase enzyme blends and delivery, better purification gradients, and stringent control and record of the entire cGMP process (adoption of detailed SOPs, documentation of all steps in the process, and ultra-clean room facilities for appropriate "manufacture" of clinical grade islet product).

Centers working as part of the CIT Consortium have refined detailed SOPs relating to all steps of the clinical isolation and culture process. These protocols remain unpublished, but may be accessed through direct application to the consortium group [49].

Pancreatic ductal perfusion and digestion

The critical steps involved with the digestion and purification of human islets are illustrated in Figure 61.2. The principles involve progressive disassembly of the pancreas down to enriched, intact islets using enzymatic, mechanical, and centrifugal purification. The pancreatic duct is first cannulated (Figure 61.3), and the pancreas is distended with collagenase blend enzymatic solution. The enzyme is first delivered at 4–10 °C for 10 minutes, then warmed for 4 minutes to 37 °C, with the goal being to deliver active collagenase enzyme to the islet–acinar interface [9,50]. The pancreas is then sectioned into several large pieces (usually nine), transferred to the Ricordi chamber containing steel marbles for gentle mechanical agitation against a 500 μm screen. The enzymatic solution recirculates at 37 °C for approximately 15–30 minutes (Figure 61.2A) [51]. This process results in gradual digestion of the pancreas into fragments of decreasing size, until cell clusters containing intact islets are able to escape through the screen. Once islets begin to be released (identified by red color on dithizone staining [52]), the enzymatic digestion is halted by rapid cooling to 4 °C, diluted with multiple wash steps; human albumin solution is added to further quench enzymatic activity. Expert judgment and skill are required to determine when to halt digestion, as early or late dilution results in either inadequate fragment digestion or disintegration of intact islets, resulting in failure to yield sufficient islets for transplantation [8,53].

Collagenase enzymes

Variability in collagenase blend, lot activity, stability, and enzymatic target profile has previously created a substantial challenge to reliable large mass human islet isolation [8]. The introduction of Liberase HI (Roche Diagnostic Pharmaceuticals, Indianapolis USA) was seen as a major advance as this more standardized collagenase enzymatic blend provided more lot-to-lot stability and higher islet yields than previous collagenase types [54]. The Edmonton group found that excess collagenase class II activity was detrimental to islet isolation [55]. It subsequently became apparent that Liberase HI involved exposure to bovine growth factor extract as a feeder layer for *Clostridium histoloyticum* bacteria, with concern that clinical grade Liberase HI could potentially expose patients to a very small risk of Creutzfeld–Jacob related prion disease [56]. While the risk was judged to be exceedingly low (less than one in 100 million), this was felt to be avoidable, and alternative enzyme blends were sought for clinical islet application [56].

Serva Inc. developed a bovine-product-free GMP-grade collagenase and neutral protease designated NB 1 (Serva Electrophoresis GmbH, Heidelberg) with similar high-pressure liquid chromatography (HPLC) profile to Liberase HI [14,57,58]. The Miami group found that the pancreatic digestion times with NB 1 were longer than with Liberase HI, and that beta cell mass and viability was less optimal [59]. The Uppsala group found similar results with reduced islet yield with NB 1, but higher islet purity and glucose stimulation response [58]. The Edmonton group found that separation of the NB 1 and neutral protease components, with ductal delivery of NB 1 and neutral protease addition to the recirculating enzyme, led to less enzymatic degradation and higher and more potent islet yields [60]. In a proportion of cases, additional neutral protease was not required with NB 1 [61]. The University of California San Francisco (UCSF) group conversely found improved digestion profiles in donors age <45, with NB 1 dosing at 16 U/g of pancreas combined with neutral protease at 2 U/g of pancreas and 2.5 mL of DNAse (Pulmozyme, Genentech, San Francisco) [62]. In the UCSF experience, 9 of 12 pancreata were clinically transplanted from young donors, and high clinical functional potency was observed [12,63].

Most recently, a newer version of Liberase Mammalian Tissue Free (MTF) has been developed by Roche Diagnostics Inc. Caballero-Corbalan et al. observed reduced digestion times with reduced degradation of collagenase class I, and suggested that a two-component product with individual adjustment of thermolysin would be beneficial [64]. O'Gorman et al. found excellent digestion characteristics of MTF with similar functionality to NB 1 [14]. An alternative collagenase, called Vitacyte HA (Vitacyte LLC, Indianapolis), has been developed with controlled component activity and reduced class II degradation, and is being further evaluated in clinical islet isolation [65].

Purification

The final step in the process involves purification of the pancreatic digest using density-gradient separation, carried out on a refrigerated COBE2991 cell processor [66,67]. Typically, the purification centrifugation run takes 10 minutes. Originally, discontinuous Ficoll gradients were used, but more recently continuous gradients of iodixanol (Optiprep, Axis-Shield, Oslo), as introduced by Hering et al., have demonstrated increased purification efficiency [42]. The use of iodixanol has been associated with less inflammatory

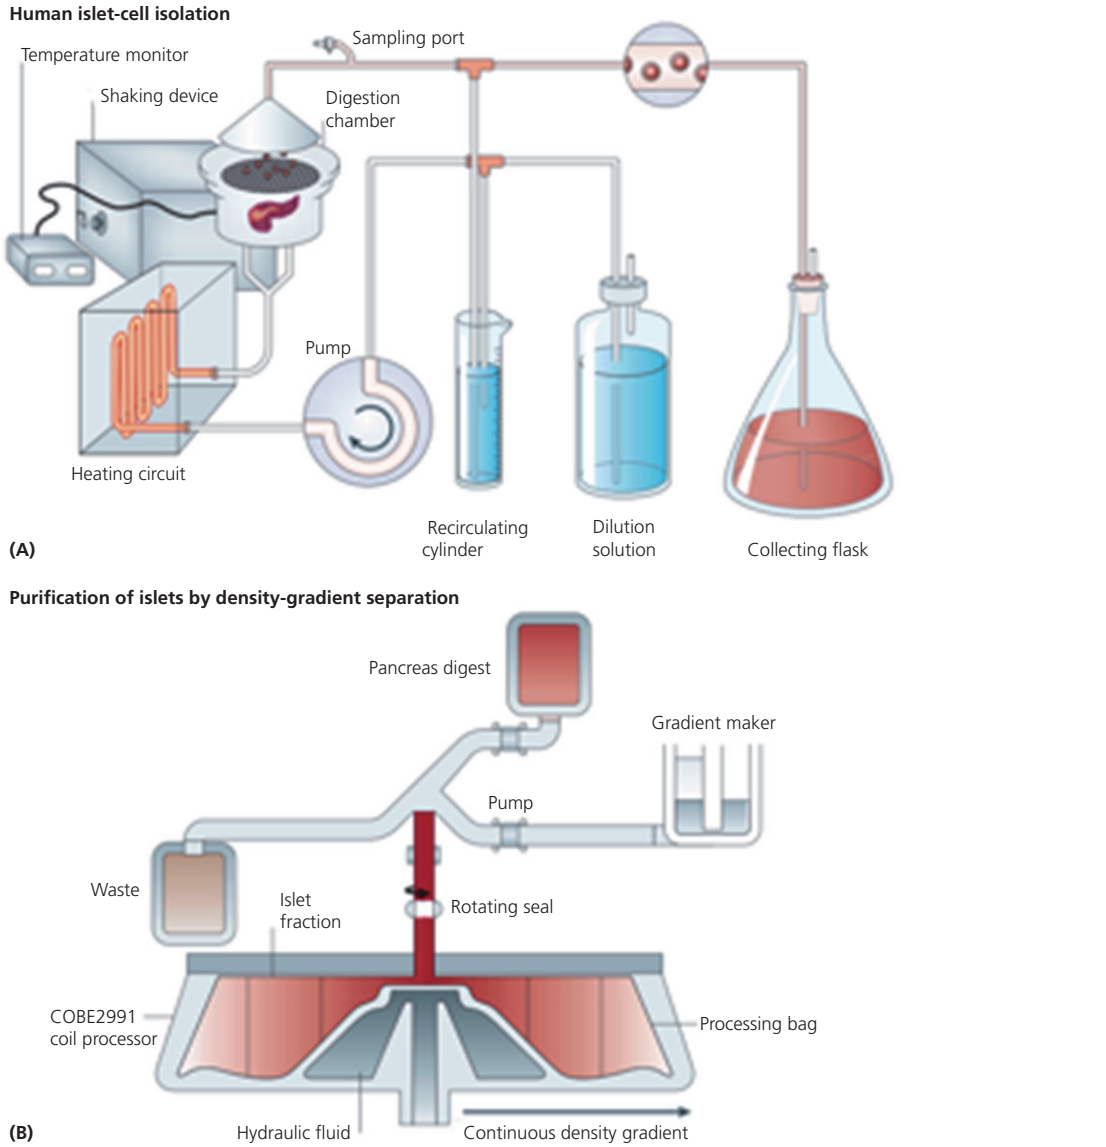

Figure 61.2. (A) Schematic diagram of the Ricordi chamber, 500-μm screen, steel marbles, and recirculating pump system used to digest the pancreas. (B) Diagrammatic representation of the COBE 2991 centrifuge cell processor used for purification of the pancreatic digest using continuous density gradient separation. Reproduced from [51] Ricordi C, Strom TB. Clinical islet transplantation: advances and immunological challenges. Nature Reviews Immunology 2004;4(4):259–268. activation compared with the previous Ficoll gradients [68]. Barbaro et al. demonstrated improved purification efficiency when iodixanol-based gradients are combined with UW solution to increase the differential density of exocrine versus islet tissue on the COBE2991 [69].

The use of rescue gradients to improve islet recovery on purification have been promoted by several groups [70–72]. The Vancouver group found that repurification of the impure tissue fractions after a further 12–36 hours of culture resulted in a 20% increase in islet yield [70]. The Miami group found that addition of a repurification step using discontinuous gradients substantially increased the rate of islet preparations suitable for clinical implantation based on islet mass, and that the additional step had no negative impact on islet functionality [72,73].

Islet culture

After further wash and recombination steps, the final islet preparation is placed in culture media and incubated for 24–72 hours before release and clinical transplantation. A period of islet culture leads to increased purification, and transplantation of islets and impurities in a less inflammatory state. Furthermore, this period facilitates patient management by allowing transportation time to the transplant center, and opportunity to administer T-depletional and other adjunctive therapies to the recipient, while avoiding exposure of newly transplanted islets to a potentially injurious cytokine storm [39,74–79]. Up to 20% of the islet mass may be lost during islet culture, with prolonged cold ischemia, lower islet purity, and higher islet index being important factors on multivariate analysis [80]. Islet culture at 24°C was previously shown by

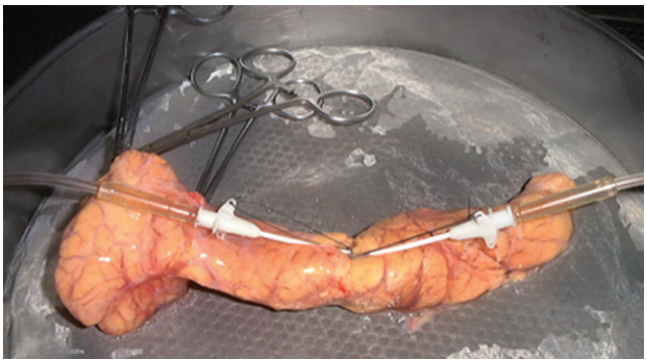

Figure 61.3. The main pancreatic duct is cannulated and a solution containing a blend of collagenase enzymes is recirculated, leading to distension of the pancreas and delivery of the enzyme to the acinar–islet interface.

Table 61.3. Islet product release criteria

Sterility
Gram stain: no bacteria
Endotoxin content: <5 EU/kg based on recipient weight
Culture: no bacteria or fungal elements (available post hoc after 14 days' culture)
Potency
Static insulin release: stimulation index >1.0
Volume
Packed tissue volume ≤5.0 mL or settled tissue volume ≤7.5 mL
Purity
≥30% (based on dithizone staining)
Viability
≥70% (based on membrane integrity staining with FDA/PI or Syto green)
Minimal islet mass (protocol dependent):
≥6000 IEQ/kg for single donor protocols
≥5000 IEQ/kg for routine initial transplants
≥4000 IEQ/kg for retransplant in multiple infusion protocols
Compatibility
ABO blood group compatibility
Negative cytotoxic cross-match (required if PRA > 10%, or depending on protocol)

FDA/PI, fluorescein diacetate/propidium iodide.

Markmann et al. to markedly reduce MHC antigen expression [81]. The addition of insulin, transferrin, zinc, selenium, and pyruvate to CMRL-based culture media as promoted by the Miami group with the addition of nicotinamide [82], and recently modified by the Little group, appears to optimize islet survival in culture [83–85]. A period of islet culture also permits islet preparations to be shipped between cGMP isolation and clinical transplant centers, concentrating skill and expertise locally and minimizing costs associated with islet isolation [73,86,87].

Islet graft assessment and product release testing

The FDA have emphasized the need for predictive islet potency assays to correlate with clinical islet efficacy, as islet transplantation moves forward to BLA. This has been a challenging area as the standard tests of islet viability using dye-exclusion based membrane integrity assays are insensitive [88], and in vitro insulin secretion in response to glucose with either static incubation or islet perifusion often fail to predict functionality in vivo. Several approaches are currently under active investigation to help better refine the sensitivity and positive predictive value of these tests. Cabrera et al. developed a combined high-throughput multiple automated islet perifusion system and kinetic flux imaging system for beta-cell potency, which may fulfill the niche required by the FDA for predictive potency testing [89]. Pappas et al. introduced an oxygen consumption rate analysis system that strongly predicts both graft function of human islets transplanted in to immunodeficient mice as well as clinical outcome after islet transplantation [90]. Novel methods designed to quantify the viability of specific islet cell subsets using flow cytometer is proving to be one promising approach. Ichii et al. have developed a multiparametric analysis of beta-cell content, viability, and cellular composition using laser scanning cytometry and mitochondrial apoptosis, and this is currently undergoing more detailed testing within the CIT centers [91].

Finally, prior to release for clinical transplantation, the cultured islet preparation must meet all product release criteria (Table 61.3). These minimal requirements reflect a need to confirm sterility and compatibility of the final islet product to prevent transmission of infection to the recipient, while providing an adequate, viable islet implant mass of sufficient purity to minimize risk of portal venous thrombosis.

Percutaneous intraportal islet transplantation in the recipient

The fact that the portal vein can be accessed through a non-surgical, minimally invasive approach by percutaneous transhepatic ultrasound and fluoroscopic guidance (Figure 61.4) distinguishes islet transplantation from whole pancreas transplantation, and makes it one of the safest, lowest risk, and attractive of all the different transplant procedures, at least in expert hands. The percutaneous approach was first described by Weimar et al. using a combination of CT and fluoroscopy [92]. The Edmonton group used a combination of ultrasound and fluoroscopic-guided percutaneous portal access for their initial series of seven patients attaining insulin independence [93]. This technique has been further refined by close collaboration between groups, for a technique that now safely allows for full therapeutic anticoagulation with heparin in the immediate peritransplant period together with effective methods to eliminate the risk of bleeding after the procedure. Effective methods that simultaneously prevent risk of portal venous thrombosis and prevent bleeding are essential if this procedure is to be carried out with the lowest morbidity.

Most interventional radiologists have considerable expertise in percutaneous transhepatic access in the setting of transhepatic cholangiography and intrahepatic biliary drainage procedures, and this technique has a proven safety track record.

The use of preliminary color duplex ultrasonography has been shown to reduce the number of liver capsular punctures, avoids inadvertent biliary punctures, and significantly reduces the procedural time [94,95]. A high-resolution fluoroscopic C-arm set up with rotational digitized imaging facilitates portal catheter placement. Access to a second or third-order portal branch, away from the central liver hilum, minimizes risk of hepatic arterial injury, and provides a better parenchymal track for subsequent ablation.

Before proceeding with the percutaneous transhepatic approach, patients must have no evidence of right-sided hepatic hemangioma, and ultrasound screening of the liver to confirm this is important before the patient is listed for the procedure. There should be no underlying coagulopathy or portal hypertension, and the underlying liver parenchyma should be non-cirrhotic. Antiplatelet agents (e.g. clopidogrel, dipyridamole) and direct thrombin or Xa

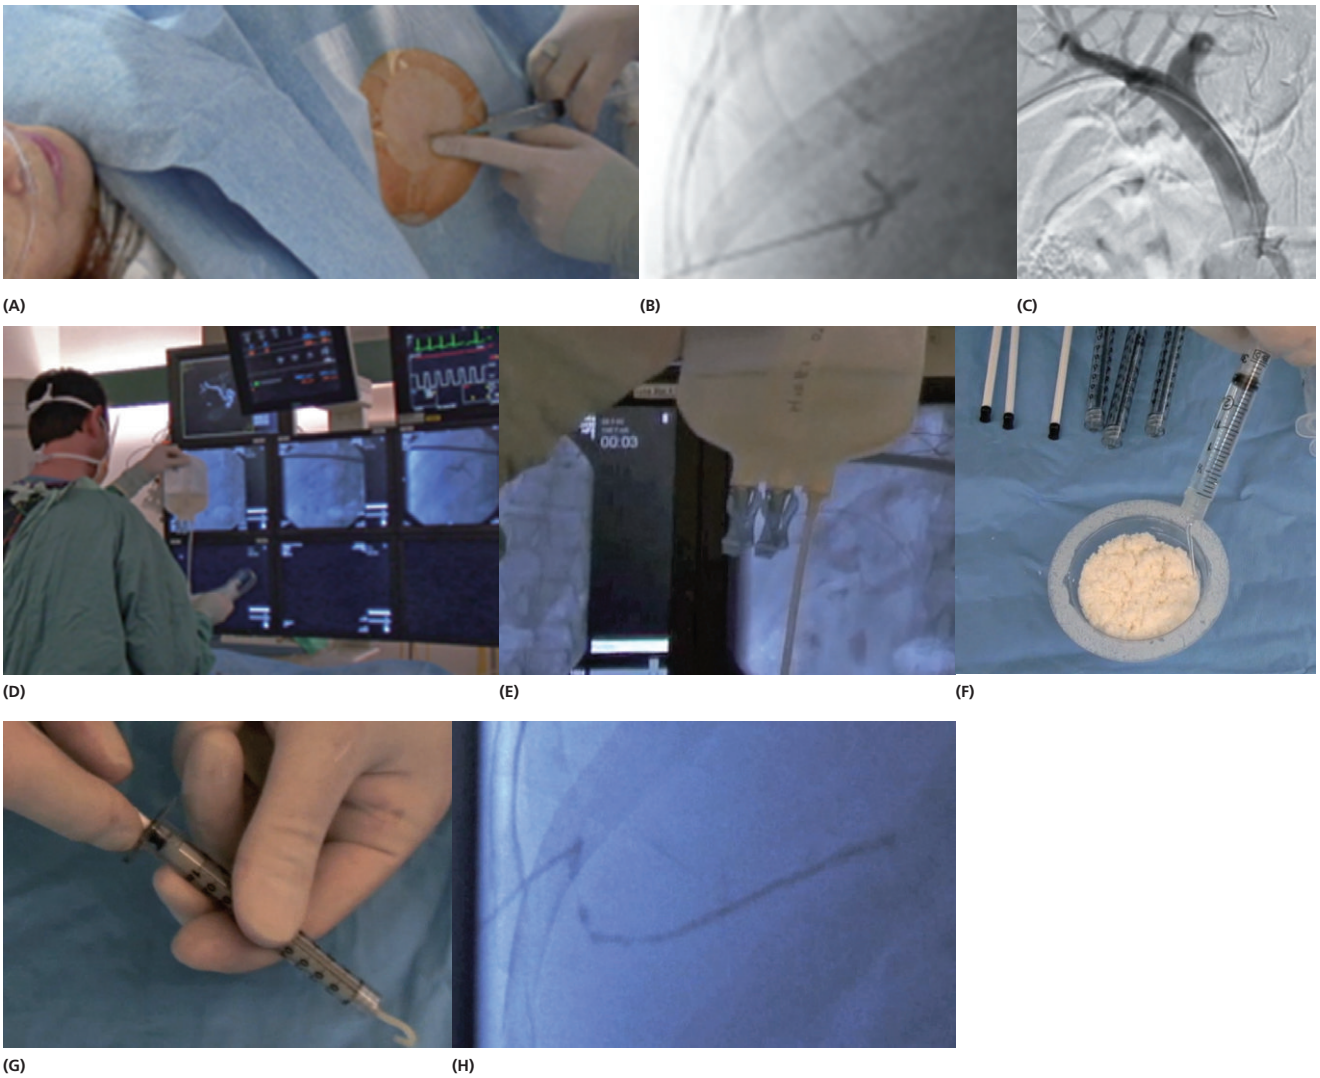

Figure 61.4. Steps involved with percutaneous islet transplantation via an ultrasound-guided fluoroscopic approach: (A) Doppler ultrasound interrogation followed by local anesthesia; (B) direct puncture of a peripheral second or third-order right-sided branch of the portal vein, with recognition of the branching pattern on fluoroscopy; (C) portal angiogram with the tip of a 4 or 5 French catheter at the portomesenteric splenic junction; (D) islet infusion under gravity after addition of 70 U/kg (based on recipient weight) heparin to the islet bag, with intermittent direct monitoring of portal pressure; (E) close-up of the i.v. tubing with transplant tissue visible; (F) making up microfibrillary collagen paste (Avitene) with 1 g powder and 3 mL saline and 3 mL radiological contrast media; (G) loading the paste in a 1-mL syringe; (H) obliteration of the catheter tract for a minimal length of 4 cm, under direct fluoroscopic visualization.

inhibitors (e.g. dabigatran, rivaroxaban) should be discontinued within 7–14 days of the procedure, which for practical purposes means that patients on the top of the transplant list should be discontinued from all such medications if safe to do so, or delisted for the procedure. Patients with a known underlying thrombophilia disorder (protein C, S, antithrombin III, factor V Leiden deficiency) should not undergo percutaneous intraportal islet transplantation [96].

The radiologic techniques used for percutaneous portal access have been described in detail by Owen et al., Gaba et al., Goss et al. and others [97–102]. In brief, after local anesthetic skin infiltration, a 22 gauge Chiba needle is advanced in to a peripheral branch of the right portal system. An 18 gauge guide wire is then advanced through the needle into the main portal vein. The guide wire is then exchanged for a single-lumen 4 or 5 French angio catheter (NEFF, Cook Canada, Stouffville, Ontario) or equivalent, with the tip directed down to just above the portomesenteric–splenic venous confluence. A portal venogram is then obtained to confirm position, and a baseline measurement of the portal venous pressure is obtained.

The final islet preparation, suspended in transplant media in a Ricordi bag, is then loaded with heparin (70 units per kg heparin based on recipient weight), and infused under gravity while the portal pressure is measured intermittently throughout the infusion [103]. If the baseline portal pressure exceeds 20 mmHg, or if the portal pressure rises above 22 mmHg during infusion, no further islets are given until the pressure normalizes, to avoid added risk of portal vein thrombosis.

Upon completion of the islet infusion, the portal catheter is slowly withdrawn through the hepatic parenchyma, while infusing

thrombostatic paste. The Miami group has used D-STAT (Vascular Solutions, Minneapolis, MN) for this purpose with success [104]. The Edmonton group has advocated use of Avitene paste (Medchem Products, Woburn, Massachusetts, USA) made up as 1 g of Avitene powder in 3 mL saline and 3 mL radiological contrast media [105]. Microfibrillary collagen made up in this way forms a thick paste that is radiographically visible by fluoroscopy, and, when deployed over a minimal track distance of at least 4 cm, has eliminated the risk of liver capsular bleeding in Edmonton, now in an accrued experience of over 360 percutaneous access islet procedures [105,106]. Alternative techniques include use of Gelfoam plugs and metal coils, but are less reliable and more easily displaced, at least in our experience.

Once the track is adequately ablated, therapeutic systemic heparinization is continued in the radiology suite at a rate of 3 units per kg per hour, and titrated to maintain a partial thromboplastin time (PTT) of 60–80 seconds once the patient is being monitored on the ward. The heparin infusion is continued for 48 hours, and this may improve single-donor islet engraftment and minimize activation of the instant blood mediated inflammatory reaction (IBMIR) [107,108]. At the time of patient discharge from hospital, low molecular weight heparin is continued (enoxaparin 30 mg s.c. twice daily for 7 days) together with aspirin 81 mg enteric coated for 14 days.

We recommend that in the rare event of inadequate track ablation, or where portal access was traumatic, that postprocedural heparin be withheld temporarily, and a repeat Doppler ultrasound be obtained at 2 hours post procedure. This will facilitate early diagnosis of potential intraperitoneal bleeding, and allow appropriate heparin management. With this combined Avitene and therapeutic heparinization approach, the risk of both bleeding and portal thrombosis has been effectively eliminated [95,105,106]. If bleeding occurs from the capsular surface, it may be dealt with by direct laparoscopic cautery, as in this rare instance of hepatic trauma the precise site is known and easily accessible by this approach [95].

Post transplant, hemoglobin and liver function should be monitored closely, and a routine Doppler ultrasound of the portal system and liver should be obtained at 24 hours and at 7 days. Complete occlusion of the entire portal tree is exceedingly rare after clinical islet transplantation (0% in 364 consecutive islet allograft procedures in Edmonton) but can have serious potential consequences [109]. Partial branch venous occlusion of a peripheral, anterior, or posterior segmental branch may occasionally occur, and while this carries very low risk of further propagation, is best managed by intravenous heparin followed by 3 months of Coumadin therapy with serial Doppler screening for evidence of resolution.

Small arteriovenous fistulas may rarely be observed after percutaneous transhepatic access (risk less than 1%), and can be safely ablated by percutaneous hepatic arterial embolization [100,110].

Open techniques for intraportal access

Where percutaneous access is not possible (e.g. large hepatic hemangioma or lack of local radiological expertise), an open surgical technique has been advocated. Fewer than 1% of procedures require an open approach in the largest clinical centers. In this case, the portal system can be accessed surgically by a minimal approach by dissection around the umbilicus and recanalization of the obliterated left umbilical vein, which provides access to the left portal system [48,111]. Alternatively, a limited laparotomy with delivery of an omental or mesenteric vein into the wound allows direct catheterization. The most effective approach is to pass a dual-lumen 9 French Broviac-type central line until the tip reaches the main portal vein, as this allows for simultaneous monitoring of portal pressure through the smaller lumen while islets are infused through the larger lumen [112].

Summary

The detailed techniques of surgical procurement of the pancreas for islet isolation, and the steps involved in cGMP human islet manufacture for clinical transplantation are reviewed in this chapter. The alternative approaches to safe portal vein access are reviewed, and the critical steps to avoid risk of portal thrombosis and bleeding are discussed in detail. Expertise in all aspects of islet preparation and clinical care are needed to avoid potential complications.

Acknowledgments

AMJS and CR are both supported through the National Institutes of Health (NIH) Clinical Islet Transplant Consortium (CIT) jointly funded through the National Institutes of Allergy, Immunology and Infectious Disease (NIAID), and the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK). AMJS holds a Canada Research Chair in Transplantation Surgery and Regenerative Medicine, and is a Senior Clinical Scholar through Alberta Innovates Healthcare Solutions (AIHS). Both AMJS and CR receive grant support through the Juvenile Diabetes Research Foundation (JDRF). The clinical islet transplant program at the University of Alberta receives support from Alberta Health Services, the Government of Alberta, and through the Diabetes Research Institute Foundation of Canada (DRIFCan). The Diabetes Research Institute (DRI) at the University of Miami receives support from the Diabetes Research Institute Foundation. Both centers in Edmonton and Miami are part of the Diabetes Research Institute Federation. AMJS and CR are members of The Cure Alliance.

CHAPTER 62

Intestinal Transplantation Procedure and Surgical Technique

Thomas Fishbein
Georgetown University School of Medicine, Washington, DC, USA

Introduction

Intestinal transplants may be performed alone or in combination with other organs. When the jejunoileum alone is transplanted, this is referred to as an **isolated intestine allograft** [1]. This allograft is based on the vascular supply from the superior mesenteric artery, with drainage through the superior mesenteric vein. However, intestinal allografts may be modified based on the co-morbidities existent in other abdominal organs of a particular patient. Some patients have undergone prior colon removal (Crohn's colitis) or stomach surgery (gastric bypass); some have developed chronic pancreatitis (associated with parenteral nutrition); while others have suffered renal failure (oxalic acid stones, repeated dehydration) or have experienced a host of other complications of intestinal failure or parenteral nutrition.

The colon may be transplanted along with the small bowel and, less commonly, the foregut may be transplanted, such that a stomach, duodenum, and pancreas are included in the graft [2,3]. Multivisceral allografts [4] including the liver are described separately in Chapter 63. Determination of the type of allograft to use is up to the individual, and anatomical or functional considerations may be addressed with a variety of approaches. Recipient characteristics also determine the most commonly employed specific implantation technique to use [5]. Preoperative considerations are addressed in Chapter 42 and postoperative management and outcomes can be found in Chapters 74 and 109, respectively.

Surgical technique

Isolated intestinal transplantation

Abdominal exposure

The most common clinical indication for isolated intestine transplantation is a patient with short bowel syndrome. Such patients have always undergone prior abdominal surgery, and the abdominal wall may contain areas of scar from enterostomy, enterocutaneous fistula, or prior gastrointestinal tubes or drains. When these complicate the abdominal wall, a midline incision is usually the most versatile for implantation of an isolated intestine allograft. Occasionally, abdominal wall reconstruction with advancement flaps, tissue loss, or skin grafts complicate the midline. In such cases a broad bilateral subcostal incision placed midway between the xiphoid and umbilicus may be preferable if it can be performed above the area of reconstruction. The choice of allograft for such transplants is critical to the outcome. Closure of the abdomen is best achieved utilizing a small graft from a donor one-third to one-half the size or weight of the recipient. Open abdomen with temporary closure is sometimes necessary, but it is associated with significant morbidity and a decreased survival rate. A variety of methods have been used to obtain coverage of the allograft [6–11]. In rare circumstances, a composite allograft of the abdominal wall has been transplanted along with the intestinal allograft.

After the incision is made, adhesiolysis is performed to clear the sidewalls of the abdominal cavity to the retroperitoneal space. The loss of domain inherent with short bowel syndrome usually requires maximizing the abdominal cavity and relaxing incisions on the lateral endoabdominal fascia or component separation to enhance laxity of the overlying abdominal wall. A self-retaining retractor is utilized for exposure. The diseased remaining small intestine or colon is a frequent cause of postoperative morbidity if not removed, so mobilization of this bowel is imperative. In cases such as Crohn's disease, areas of prior strictureplasty, enteroenteric anastomosis, fistula, or stricture are best mobilized from the pelvis and removed with a stapling device. Maintaining at least 3–5 cm of jejunum from the ligament of Treitz is helpful for restoration of proximal intestinal continuity. However, long segments of even healthy bowel may make enteroscopy for later graft surveillance more difficult. We recommend saving no more than 20 cm. Similarly, maintaining some native colon is advantageous for water absorption after closure of the stoma. If healthy distal colon is present, we attempt to salvage the left hemicolon for continuity. The remaining diseased bowel is then removed after high ligation of the mesentery.

Vascular exposure in short bowel patients

In most cases of short bowel syndrome the vascular approach will use the infrarenal abdominal aorta for inflow, with systemic outflow through the infrarenal vena cava [2]. The aortic exposure is best obtained after mobilizing the duodenum gently from the retroperitoneal attachments. Exposure of the crossing left renal vein (LRV) then demonstrates the superior extent of dissection. Ligation of lymphatics helps prevent post-transplant fluid collections or chylous ascites. Care to preserve the inferior mesenteric artery (IMA) is important, as the loss of collateral circulation from the small bowel and prior surgery sometimes leave this as the sole blood supply to the descending colon or sigmoid. A few lumbar vessels sometimes require ligation between the left renal vein and inferior mesenteric artery and then a Satinsky clamp will control the aorta (Figure 62.1A–C). Vena cava exposure is aided in some

situations by division of the right gonadal vein and, sometimes, by one or two lumbar veins. Preoperative imaging should identify a retroaortic or circumaortic left renal vein if it exists. Care must be taken not to injure either the dependent third portion of the duodenum or the renal veins during this exposure.

Exposure for functional intestinal disorder patients

In cases where the patient suffers from a primary functional disorder, such as an enterocyte or motility disease, the native intestinal tract will most commonly be in place. In such cases, total enterectomy is required. These patients usually have less or no loss of domain and, particularly in dilated motility disorders, a lax abdominal wall is common. Either midline or bilateral subcostal incision is suitable. Enterectomy proceeds along the same vascular lines as for donor enterectomy (Figure 62.2). The ligament of Treitz is mobilized, and the right colon is mobilized along the white line of Toldt with a broad Catell–Brasch maneuver to the base of the

mesenteric vessels. Division of the left transverse colon and dissection of the base of the transverse mesocolon allows the entire small bowel and right colon to be mobilized to the right lower quadrant. This move and division of the proximal jejunum define a plane along the base of the small bowel mesentery. We have found it helpful to place a laparotomy pad behind the mesentery and under the bowel to isolate the base of the mesentery (Figure 62.2A). The mesenteric fat and lymphatics are then dissected and ligated, allowing the superior mesenteric artery (SMA) and vein (SMV) to be skeletonized (Figure 62.2B). Knowledge of the anatomy of the proximal mesentery is critical here. The proximal jejunal arcade should be preserved to the residual native jejunum. The main jejunal vein then usually courses posterior to the superior mesenteric artery in most cases. Isolation of a 2-cm portion of artery and vein just below where they cross over the duodenum allows mesenteric implantation of the allograft with direct anastomosis.

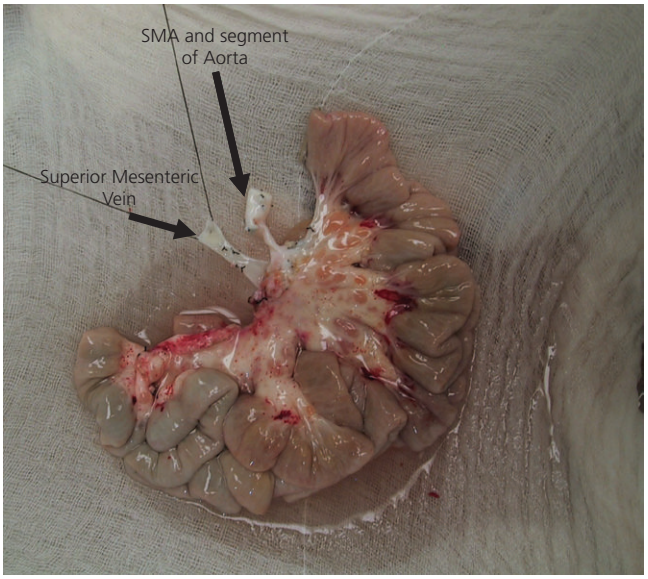
Systemic drainage graft implantation

When the allograft is being implanted, care should be taken to match vessel length to the particular recipient. In the case of systemic implantation, if no pancreas was procured from the cadaveric donor and the full SMA and SMV remain with the allograft, direct anastomosis to the aorta is preferred by some surgeons. Control of the aorta is established with a partially occluding clamp, and an anterior aortotomy is made. However, small bowel loops of the graft sometimes descend in a deep retroperitoneum, as is typical of small children. Gentle flattening of the base of the donor mesentery with upward retraction toward the point of arterial anastomosis by the assistant is critical to facilitate implantation. Here, it is important to be aware that the normal small bowel mesentery sits with an angle to the retroperitoneum, with the jejunum slightly higher in the anterior–posterior dimension, and the ileum more posterior. When the graft is implanted, the mesentery should be positioned to lie flat and parallel to the retroperitoneum. Even in systemically drained cases with a full donor artery, I prefer placing short segment interposition grafts on the aorta and vena cava prior to taking the allograft off the ice [12]. This allows easy positioning of the graft with anastomosis somewhat less recessed in the retroperitoneum.

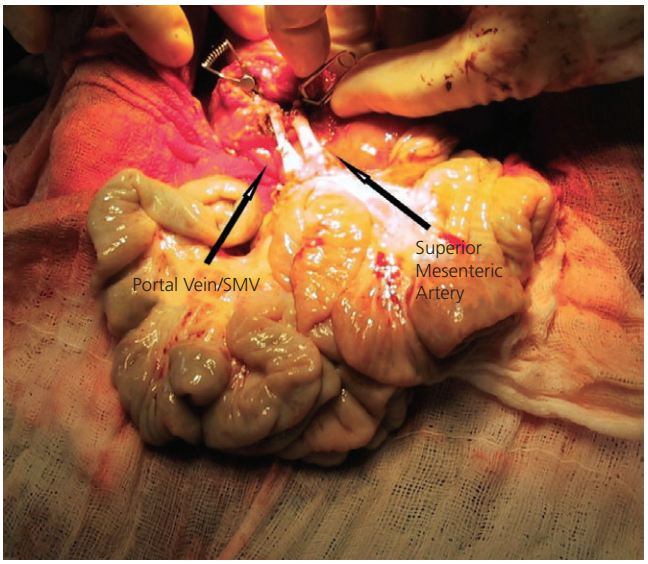
End-to-end anastomosis of the artery is performed and a growth factor is used to allow dilatation of the artery at reperfusion. The vein length is measured so that no redundancy and kinking occur. The venous anastomosis is performed as in the manner of portal vein anastomosis in liver transplantation, with a growth factor through which preservation fluid may be flushed prior to removal of the vena cava clamp. As in the case of mesocaval shunt construction, the systemically drained allograft is at risk for slight twists and shuttering of the outflow anastomosis. For this reason, a wide ellipse of anterior vein wall is always excised. Another pitfall to be avoided is vascular kinking. When no colon exists, or the size of the donor organ is significantly smaller than the native bowel, the allograft will tend to sink towards the pelvis after reperfusion. Traction on the vessels may result if they are too short, causing arterial narrowing. Thus, the interposition graft or the donor SMA should be left long enough to create an arc similar to that of the native SMA, but not long enough to kink.

Mesenteric drainage graft implantation

When the native mesenteric vessels are used for anastomosis, the proximal vessels are controlled with atraumatic bulldog clamps, and no aortic or vena cava exposure is necessary. Pre- and postimplantation orientation is shown in Figure 62.3 A and B, respectively. The mesenteric vessels should be large enough in caliber to match the size of the donor vessels. While these vessels may be isolated in some short bowel syndrome patients, they are often atretic due to the low flow state and provide insufficient flow. The length of the remaining native vessels should then be evaluated. The donor bowel will lie below the transverse duodenum, over which the native vessels course. Therefore, the weight of the allograft may produce tension on these vessels if they are of insufficient length. In this case, interposition grafts of external iliac artery and vein are often useful. The alignment of the graft usually places the jejunum slightly higher than the ileum in the right lower quadrant, such that the slight angle of the graft from higher on the left side to lower on the right side is reapproximated. The vessels are then reconstructed in the same manner as described above.



(A)



(B)

Figure 62.3. Before (A) and after (B) implantation with mesenteric drainage. The cuff of aorta has been removed and direct end-to-end anastomosis performed between native and graft mesenteric vessels.

Reperfusion

The intestinal allograft is large and capable of causing significant reperfusion-associated hemodynamic instability. For this reason, we always perform a blood flush in which the venous anastomosis is performed with a growth factor. This is left open and the distal venous outflow clamp remains in place during arterial reperfusion. The graft fills with fresh oxygenated blood, and the preservation fluid is flushed through the growth factor prior to removal of the distal clamp. The venous suture is then either tied or, if the growth factor is generous, a gating suture may be used. Volume resuscitation should be used during reperfusion, and agents causing splanchnic vasoconstriction should be avoided. Small bleeders in the hilum of the mesentery should be ligated with fine monofilament suture with care to avoid narrowing a major venous branch.

Mesenteric fixation

After reperfusion the allograft has a narrow point of fixation at the mesenteric hilum. This places it at risk of volvulus and the bowel rapidly develops a secretory state and becomes laden with mucin and heavy. The base of the mesentery must be fixed to the retroperitoneum with interrupted sutures. Care should be taken to avoid the ileocolic vessels along the cut edge of the allograft, and both sides of the mobilized mesentery should be fixed in place. Another pitfall to be avoided is ureteral injury in the patient who has undergone multiple prior operations. We liberally employ preoperatively placed ureteral stents in such patients.

Restoration of enteral continuity

After fixation of the mesentery, the proximal allograft jejunum may be reconstructed to the native jejunum in the usual hand-sewn manner. A well-preserved allograft usually holds sutures well, and the mucosa of the proximal jejunum provides information about the degree of reperfusion injury to be expected. If a gastrojejunal tube is being used to permit early jejunal feeding, this should be placed through the stomach, threaded around the duodenum, and placed across the anastomosis under direct visualization after the posterior wall has been sewn. The anastomosis is then completed. Distal reconstruction can be accomplished according to the native colon that is retained. If a significant portion of colon is not retained, an end ileostomy may be created. If left colon is retained, either an end-to-side anastomosis can be constructed with a loop ileostomy approximately 20 cm proximal, or a Santulli-type ileostomy can be constructed. It is critical in either case to both fix the base of the ileal mesentery and attempt to close the lateral defect around the ileostomy to the endoabdominal fascia.

Colonic transplantation with the isolated intestine

Patients with a functioning rectum but no appreciable colonic length to allow water reabsorption may be candidates for colonic inclusion in the allograft. In this case, the graft implantation is similar, but there is no true cut edge of the mesentery; therefore fixation of the base of the mesentery relies on the posterior leaflet instead. Usually, the right hemicolon is transplanted, and the distal transverse colon must reach to the pelvis for restoration of enteral continuity [13]. The usual orientation involves mobilization of the transverse colon such that the ascending colon lies somewhat transversely and the transverse reaches the rectum. An example of the preimplantation orientation is shown in Figure 62.4A. A proximal loop ileostomy is created, allowing proximal surveillance of the graft and distal evaluation of the colon (Figure 62.4B). Closure of the defect posterior to the mesentery to prevent herniation is important, if it is possible. Alternatively, the colon may be transplanted and an end colostomy created, for later closure to the rectum. I do not prefer this technique, as endoscopic surveillance through the ileocecal valve is required of the endoscopist to sample the ileum. Additionally, daily monitoring of the mucosal pattern of the exteriorized ileum is required, and ileostomy effluent is not available for early rejection monitoring. The colon is rarely subject to early rejection.

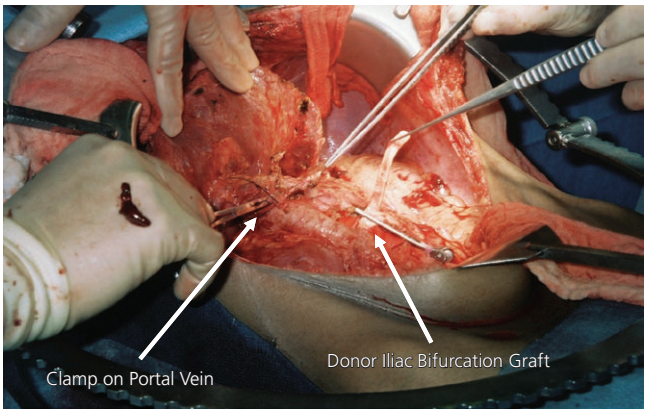
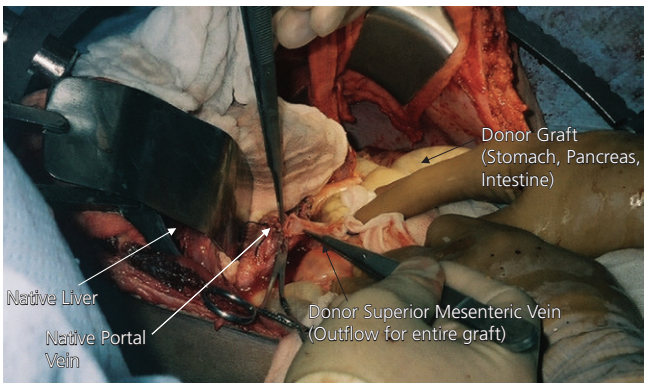
Cecum is seen to far left in inferior abdomen (B), drain and gastrojejunostomy tube in place. The patient's head is to the right.

Small bowel transplantation with the pancreas and stomach

Some patients who do not require liver transplantation with the small bowel may, nevertheless, be best served by inclusion of the pancreas and stomach with the intestinal allograft. Examples include those who have undergone prior gastrectomy or pancreatectomy, have severe motility disorders that affect the foregut and result in megaduodenum, or those for whom mesenteric tumors may encase the base of the mesenteric vessels and extend into the



(A)



(B)

Figure 62.5. The native liver with arterial inflow preserved, but portal vein clamped (top left) remains, while the foregut has been removed. An arterial bifurcation graft has been placed on the infrarenal aorta (A). The allograft sits underneath the assistant's hand, while the celiac and superior mesenteric arterial anastomoses have been completed, and the portal outflow into the liver is being constructed (B).

pancreas. Foregut exenteration maintaining the arterial supply to the liver is required, and the en bloc stomach, pancreas, and jejunoileal graft is then implanted. This has been referred to, also, as modified multivisceral transplantation [14]. In brief, the portal structures are dissected, the gastroduodenal artery ligated, and the bile duct divided low near the duodenum. A wide mobilization of the duodenum and head of the pancreas is performed to identify the SMA from the right side. The portal vein is skeletonized and the spleen and tail of the pancreas are rotated medially to the base of the SMA. The left gastric artery is ligated, and the splenic artery is identified and ligated, leaving only the celiac supplying the hepatic artery, which is intact and supplying the liver. The proximal stomach can then be divided with a stapling device. If colon is present, the right and left colon are mobilized from the lateral attachments, and rotated medially such that the entire intestinal tract is held only by the SMA. The SMA is ligated and divided and the whole foregut, with the small bowel, is now mobilized and ready for removal. When the portal vein is clamped low near the pancreatic tunnel, it can be divided and the native organs removed. Allograft implantation can then begin (Figure 62.5A,B).

Modified multivisceral implantation

To provide inflow to the allograft, a bifurcating iliac artery graft is placed on either the supraceliac or infrarenal aorta. This is placed in similar fashion to the extension graft utilized for isolated bowel implantation. The two limbs of the bifurcation graft then are reconstructed to the celiac artery (CA) and SMA of the allograft. The portal vein, emanating from above the duodenal allograft, is reconstructed end-to-end to the native portal vein, in the fashion of liver transplantation. In essence, the implantation is akin to upside-down liver transplantation. The portal vein implantation is completed with a growth factor to allow flushing of the preservation solution at reperfusion. After reperfusion of the graft, a choledochocholedochostomy may be constructed. The pylorus is denervated, so a pyloroplasty or pyloromyotomy is performed to facilitate gastric emptying. The stomach is then reconstructed to the esophagogastric junction over a nasogastric tube. A gastrojejunal feeding tube is likewise placed. The stomach is fixed to the abdominal wall and the mesentery is sutured to the retroperitoneum, as with isolated small bowel transplantation, to avoid kinking of the vessels or volvulus of the graft. The spleen is removed or may be removed on the back table, with ligation of the short gastric vessels. Distal reconstruction is performed as detailed above. Variations on this operation have evolved to allow preservation of the spleen, and/or pancreaticoduodenal complex in select circumstances [15,16].

Unusual circumstances

Short bowel syndrome and thrombosis of the infrarenal vena cava due to femoral line placements for parenteral nutrition delivery, or inferior vena cava filter

In this circumstance, we usually mobilize the inferior vena cava superior to the renal veins. Ligation of short hepatic veins from the right lobe of the liver allows a greater length of caval exposure. Sometimes, resection of the right caudate enhances exposure, particularly when mild liver disease has resulted in hepatomegaly. A common iliac vein may be used as an extension graft, and the hypogastric vein ligated. The external iliac vein lies nicely after Kocher mobilization of the duodenum, and aligns next to an infrarenal aortic conduit used for arterial inflow.

Short bowel syndrome due to aortic dissection or other severe vascular occlusive disease

If the infrarenal aorta is not usable, an iliac artery graft may be placed onto either: (1) the supraceliac aorta, (2) an aortobifemoral conduit previously placed, (3) end-to-end to the splenic artery, or (4) the right iliac artery. All have been performed, but aligning venous outflow is individualized and of critical importance.

Combined small bowel and pancreas transplantation

In the case of a type 1 diabetic with intestinal failure, the composite pancreas–intestinal allograft has been employed. The bifurcation iliac artery graft may be placed on the infrarenal aorta, and the inflow celiac and superior mesenteric arteries reconstructed to the bifurcation graft. Venous outflow requires an interposition iliac vein graft placed on the infrarenal vena cava and to the portal vein remnant of the allograft.

Isolated intestinal transplant in patients with poor gastric emptying

The isolated intestine can be transplanted into the patient in whom poor foregut function is documented. Often, gastric emptying in patients with primary motility disorder of the small bowel improves after removal of the native small bowel and transplantation. However, the isolated bowel may be transplanted and proximal

jejunojejunostomy accomplished. A loop gastrojejunostomy approximately 20 cm downstream may then be constructed. Alternatively, with megagastris and severe foregut gastric dysfunction, near-total gastrectomy may be performed. In this circumstance, the proximal graft may be reconstructed to the proximal stomach remnant, and the native jejunum brought into the side of the allograft approximately 40 cm downstream to avoid bile acid reflux. This creates a Roux-en-Y reconstruction that has proved effective in individual cases.

Summary

Intestinal transplantation remains a technically challenging procedure that requires good spatial reasoning, advanced planning, and extemporaneous adaptation to the recipient vascular, and (often) re-operative anatomy. Proper choices for the vascular reconstruction, the specific bowel components included in the reconstruction, and the means of re-establishing continuity have been increasingly standardized over the past two decades. However, numerous technical decisions remain critically important to the success of the procedure, requiring individuals practicing this transplant be experienced in the highly variable potential scenarios that present in this patient population.

CHAPTER 63

Multivisceral Transplantation Procedure and Surgical Technique

Lokesh Bathla[1] and Alan Langnas[2]

[1] Methodist Specialty and Transplant Hospital, San Antonio, TX, USA
[2] University of Nebraska Medical Center, Omaha, NE, USA

Introduction

Multivisceral transplantation (MVTx) is the en bloc transplantation of liver pancreaticoduodenal complex, and intestine [1]. This chapter will focus predominantly on the technique of MVTx. The techniques for isolated intestinal transplantation are specifically covered in Chapter 62. We usually do not incorporate stomach as a part of the multivisceral allograft; however, at other centers, stomach and/or colon may form a part of the multivisceral allograft. Patients with history of severe gastric dysmotility, extensive upper abdominal adhesions, and trauma to the stomach are potential candidates for stomach-inclusive MVTx. Not only is such a procedure orthotopic in nature, it provides for a relatively simpler vascular reconstruction as portocaval shunt is not required. Occasionally, colon may also be transplanted as a part of multivisceral allograft in patients who may eventually benefit from a coloanal pull-through, for example patients with aganglionosis of the large intestine. MVTx accounts for a quarter of all intestinal transplant operations in adult patients and nearly 13% of such operations in children [2]. MVTx is the treatment of choice for patients who suffer from irreversible intestinal failure, typically short bowel syndrome combined with intestinal failure associated liver disease (IFALD). Diseases that compromise the entire alimentary tract, such as chronic intestinal pseudo-obstruction, dense adhesions complicated by multiple enterocutaneous fistulas, severe abdominal injuries resulting in gastrointestinal tracts that cannot be otherwise reconstructed, and locally invasive malignancy such as desmoids, are the other main indications for MVTx [3,4].

MVTx can be divided into foregut-sparing and non-foregut-sparing operations, depending upon the extent of recipient organectomy. This is primarily dictated by the underlying cause of the intestinal failure. Patients with involvement of the stomach, as in severe dysmotility or hollow visceral myopathy, usually undergo non-foregut-sparing organectomy. In the foregut-sparing operation, the recipient stomach, pancreas, and duodenum (foregut) are preserved in situ. The non-foregut-sparing procedure includes excision of most of the stomach, duodenum, pancreas, and spleen in the recipient. Removal of the entire small bowel along with colon up to mid-transverse colon is common to both types of procedures. The specific reasons as to why one removes or leaves the recipient's foregut are discussed in Chapter 33. Depending on the surgical team's preference and the circumstances, the stomach and/or colon may be transplanted en bloc as part of the allograft. The basic surgical techniques and principles that apply to liver transplantation (covered in depth in Chapter 56) are generally applicable to MVTx. These include careful attention to dissection during explantation, meticulous hemostasis and vascular reconstruction, and management of coagulopathy. One of the unique aspects of MVTx is the difficulty that can be present in obtaining adequate vascular access for anesthetic management and resuscitation, as discussed in the following section.

Anesthetic considerations

An experienced anesthesiologist is critical to the success of these complex operations. An exhaustive preoperative evaluation of the patient and a thorough discussion with the surgeon about the planned procedure will serve as the foundation for a successful outcome. Besides a systemic approach to history and physical examination, accurate assessment of the patient's vascular access, coagulation status, and aberrations of nutritional, acid–base, fluid, and electrolyte balance are of prime importance.

As mentioned above, many patients who require MVTx present a challenging situation for vascular access. This is secondary to history of multiple central line placements for long-term hyperalimentation and subsequent venous thrombosis due to catheter-related complications. Experienced preparation and care is required in evaluating these patients before they arrive in the operating room so that central venous access can be obtained. Occasionally, assistance of an interventional radiologist may be required preoperatively in highly complex cases to obtain central venous access through the translumbar or the azygos route. Preoperative vein mappings, as well as intraoperative vascular ultrasounds, often times are essential for successful placement of a large-bore peripheral line or central venous catheter. If all else fails, a large-bore high-volume catheter may be inserted by the surgeon directly into the inferior vena cava in the surgical field during the early part of the operation. In addition to the standard anesthetic delivery equipment, hemodynamic monitors for continuous cardiac output and mixed-venous oxygen saturation are generally used, as well as the monitors capable of simultaneously displaying four pressure channels. In adults, we routinely use a Swan–Ganz catheter (Edward Lifesciences Corp., Irvine, CA) to monitor the pulmonary artery pressure, capillary wedge pressure, and central venous pressure. Two arterial lines is standard practice at our institution. Most of the

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

recipients of MVTx belong to the pediatric age group in whom it is difficult to place arterial lines secondary to their small size. As these patients need multiple arterial blood gas analyses as well as precise blood pressure monitoring, it is prudent to have good arterial access. The use of intraoperative transesophageal echocardiography is also standard and serves as an excellent monitor for the assessment of preload and ventricular wall motion. It is prudent to have ready access to a venovenous bypass circuit in the event of significant bleeding, hemodynamic instability, and anticipated prolonged implantation time. Close attention to electrolytes, arterial blood gases, coagulation profiles, glucose, and hematocrit are mandatory. It is not uncommon to encounter massive blood loss in these operations and the availability of blood salvage equipment and some type of rapid blood infusion device can be of great utility under such circumstances. Maintenance of a normal core body temperature is essential to prevent worsening of the patient's coagulation status. The use of upper and lower body forced airway devices, heating blankets, and fluid warmers are helpful in minimizing heat loss, and, at times, it may be necessary to raise the ambient temperature of the operating room.

From an anesthesia perspective, reperfusion of the graft can be the most challenging portion of the procedure. This phase can be marked by hypotension, hypocalcemia, hyperkalemia, metabolic acidosis, hypotension, and hypothermia. Aggressive volume infusion and prompt vasopressor support should be instituted as indicated. Additionally, the serum potassium levels should be optimized prior to reperfusion in anticipation of potassium efflux from the reperfused graft. This preunclamping optimization is achieved using the same algorithm as is used for the treatment of hyperkalemia. If hyperkalemia is noted, it should be aggressively corrected with insulin, dextrose, sodium bicarbonate, loop diuretic, and calcium. In the rare event of asystole secondary to hyperkalemia, prompt DC cardioversion should be performed. It is standard practice at our institution to prepare the entire chest in the surgical field and have sterilized shock paddles available on the operative field prior to reperfusion. The value of experience in these operations cannot be overemphasized, especially in pediatric recipients and infants.

Incision

The type of incision made on these patients is variable, based on their size, age, and prior abdominal surgeries. Most of these patients have had prior surgeries, so individualization of the incision is usually required. For many patients, a prior midline or subcostal incision can be re-used for the transplant procedure, sometimes with extensions either side to side or cephalocaudad. On rare occasion, extension of the incision may be required in a perpendicular direction to the previously placed one. However, it is important that any new incision that is made should not compromise the blood supply to the abdominal wall. At the same time, the need for generous exposure cannot be over emphasized.

Removal of abdominal organs (organectomy)

The next stage of the operation involves removal of the recipient's organs. The level of proximal transection depends on whether stomach forms a part of the allograft or not. In cases where stomach forms a part of the allograft, the proximal level of transection is either distal esophagus or proximal most stomach. Usually, a rim of stomach immediately distal to the esophagus is left in situ, as it not only makes the proximal anastomosis (gastrogastrostomy) relatively simpler, it also decreases the chances of reflux and or stricture formation at this anastomosis. In cases where stomach does not form a part of the allograft, the level of proximal transection depends on foregut-sparing versus non-foregut sparing MVTx. First, the recipient liver is mobilized in the fashion typical of a liver transplant operation. This step is common to both foregut-sparing and non-foregut-sparing techniques. Ligamentous attachments are taken down and the hilar structures are identified. Depending on the type of caval anastomosis planned (bicaval versus piggyback), complete or limited mobilization of the vena cava is performed. We usually perform bicaval liver transplant at our center and use the same technique for implantation of the liver from a multivisceral allograft. Subsequent dissection is dictated by proximal level of transection of the intestine, as is detailed below. The distal level of transection is at the level of mid-transverse colon, preserving the left colic artery.

Foregut-sparing multivisceral transplantation

In this approach, the small bowel remains in place but is mobilized cephalad to the level of the left renal vein and superior mesenteric artery. In this circumstance, the splanchnic venous drainage from the stomach, pancreas, spleen, and duodenum needs to be preserved. To this end, an end-to-side portal caval shunt is created. Following completion of the portal caval shunt, clamps are placed on the upper and lower inferior vena cava and the liver is removed.

Non-foregut-sparing multivisceral transplantation

Non-foregut-sparing organectomy for MVTx involves relatively extensive dissection. The first step is usually transection of the stomach. The stomach is completely mobilized by dividing the omentum along the greater curvature up to its mid-portion. The hepatogastric ligament is also divided to free the mid-portion of the stomach circumferentially. This mobilization of the stomach allows for the placement of a stapling device in its mid-portion for transection. Care is taken to preserve the left gastric artery as this is the main blood supply to the proximal gastric remnant. If a total gastrectomy with replacement is anticipated, the stomach and the gastroesophageal (GE) junction are mobilized circumferentially. Because the GE junction receives its blood supply from the lower esophageal branches, the left gastric artery is not preserved in this case. This step exposes the supraceliac aorta and often times exposes the origin of the celiac axis. Next, medial visceral rotation (the Mattox maneuver) is performed to mobilize the spleen and the pancreas towards the midline. The residual small bowel and the colon are mobilized from a caudal to cephalad direction by mobilizing the right colon laterally. The small bowel and the right colon are then dissected off the retroperitoneum to expose the inferior vena cava and the aorta. This dissection is taken up to the level of the left renal vein, which is an excellent landmark for the identification of the superior mesenteric artery. Kocherization of the duodenum is performed to expose the superior mesenteric artery from the right side, along with complete mobilization of the entire base of the mesentery. Next, the left or transverse colon is divided, usually with a stapling device. The left colic and the inferior mesenteric vessels are preserved because they are the only blood supply to the remaining hindgut. This dissection can be difficult and time consuming due to dense adhesions. Significant amount

of blood can be lost if one is not careful, setting up a vicious cycle of coagulopathy and bleeding.

After complete mobilization of these structures, the superior mesenteric artery (SMA) is identified and doubly ligated, typically with silk ties. The common hepatic and the splenic arteries are subsequently identified and ligated. As mentioned above, the left gastric artery is preserved if the stomach is divided at mid-body. In case the stomach is transected at the level of the GE junction, the celiac axis is ligated in a fashion similar to SMA ligation. At this time, the native foregut and midgut are attached only to the liver through the portal vein. At this juncture, a large clamp or stapling device is used to completely transect the hilum of the liver and this composite of midgut and foregut organs are removed from the abdomen. The main reason for leaving the liver in situ on the vena cava is that, despite the lack of inflow, it provides some hemodynamic stability.

There still can be considerable bleeding from the retroperitoneum due to the extensive dissection and this is a good time to obtain meticulous hemostasis. After obtaining adequate hemostasis, the crus of the diaphragm are split to identify the supraceliac aorta to expose the space between the parietal pleura superiorly and the celiac axis inferiorly for placement of the aortic conduit, which will provide the arterial inflow to the allograft.

In the previously described technique for combined liver/small bowel transplant by Grant et al., the portal vein was skeletonized but left intact, leaving it as the only structure bridging the liver and the intestinal portion of the allograft [2]. This was done primarily to avoid inflammation of the donor pancreas or the development of a pancreatic duct fistula [5]. In our initial experience, however, this technique posed several technical problems. Firstly, it made back-table dissection of the allograft technically challenging, especially in pediatric donors, including the risk of injury to the celiac trunk, superior mesenteric artery, and the portal vein. Secondly, we observed significant morbidity associated with bile leaks from the biliary–enteric anastomosis. Lastly, there was a high incidence of torsion of the portal vein during the implantation process [6].

A modified technique to resolve these technical issues was first reported in 1996 [7]. Primarily, the changes include elimination of the hilar dissection, leaving the hepatoduodenal ligament undisturbed (Figure 63.1). This not only made the back-table preparation easy, but it also avoided torsion of the allograft and eliminated the need for a biliary–enteric anastomosis. The subsequent description of the operative technique is based on our modifications as described by Sudan et al. [6].

Next, dissection is performed at the diaphragmatic hiatus and the crural fibers of the diaphragm are divided to expose the aorta in the supra celiac region. After adequate exposure has been obtained for placement of clamps, a portion of the donor aorta is brought to the operative field (the conduit). A curved occluding clamp is placed on the recipient's supraceliac aorta. The donor aorta diameter is used to estimate the size of the aortotomy on the recipient aorta. Using an 11-blade, the recipient's aortic wall is incised, followed by creation of aortotomy using an aortic punch. A 4 to 6-cm portion of the conduit is anastomosed to the recipient's aorta in an end-to-side fashion with a running suture, typically 5-0 or 6-0 polypropylene. After completion of the anastomosis, a bulldog clamp is placed across the conduit and the supraceliac aortic clamp is released to restore perfusion of the abdominal viscera and lower extremities (Figure 63.2). Subsequently, a test occlusion of the suprahepatic inferior vena cava is performed to assess whether the patient can tolerate IVC clamping for the duration of the transplant

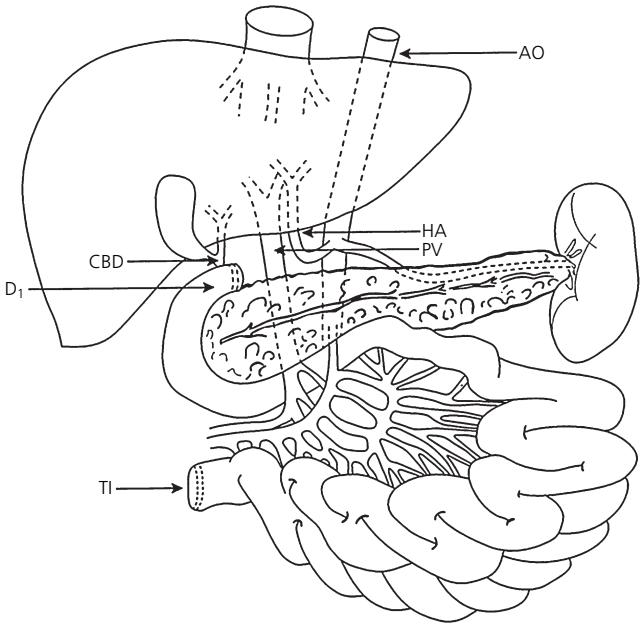

Figure 63.1. Donor operation. Note that the liver, small bowel, pancreas and spleen are procured en bloc. There is no hilar dissection and the celiac trunk and SMA are included on a long segment of aorta. procedure. If there is no hemodynamic instability, the infra and suprahepatic IVC (inferior vena cava) are clamped and divided. The liver and the retrohepatic IVC are removed. The patient may be placed on venovenous bypass at this time to prevent congestion of the kidneys and the lower extremities. At our institute, we seldom use venovenous bypass during the anhepatic phase. Over the years, we have gradually moved away from the venovenous bypass technique, which continues to be standard at many institutions.

Transplantation 2001;72(11):1846–1848 with permission from Lippincott Williams & Wilkins, Inc.

We have not seen any significant difference in overall outcome of patients who are not placed on such bypass compared to those who are.

The multiorgan allograft is then brought to the operative field. The upper caval anastomosis is performed in a fashion identical to that performed in liver transplantation (Figure 63.3). A running 3-0 polypropylene is used in adults and a 4-0 or 6-0 suture is used in children. Subsequently, the infrahepatic cava on the liver allograft is anastomosed to the recipient's infrahepatic IVC using a running 4-0 polypropylene suture. The donor aortic conduit, which had been anastomosed to the supraceliac aorta of the recipient, is anastomosed to the aorta of the composite allograft with a running 6-0 polypropylene suture (Figure 63.4).

At this point, the clamps are removed, typically beginning with the suprahepatic IVC clamp. This allows for venous back flow into the graft and early control of any major bleeding. Subsequently, the infrahepatic clamp is released. This usually helps stabilize the patient's hemodynamics as the venous return from the lower half of the body is restored. Lastly, the large bulldog clamp on the aortic conduit is released to re-establish inflow to the composite allograft. The integrity of all the major anastomosis is ensured. Small bleeding sites on the donor organs are then carefully sutured or cauterized as necessary. Once hemostasis has been obtained, continuity of the gastrointestinal tract is re-established.

If the stomach is not to be transplanted, a Roux-en-Y gastrojejunostomy is constructed between the stomach remnant and the allograft jejunum. This is typically done with a hand sewn, two-layer anastomosis. The jejunojejunostomy for the Roux-en-Y is also hand sewn in two layers. Lastly, the ileocolonic anastomosis is performed in the same two-layered fashion. Alternatively, stapling devices can be used for these gastrointestinal anastomoses, but this can sometimes results in bleeding from the staple line. It should be noted that, more commonly, the entire pancreas is left with the allograft and not resected, as depicted in Figure 63.5. Allograft cholecystectomy is performed at this time. This is followed by construction of a diverting loop ileoostomy.

We prefer to bring this ostomy out in the right lower quadrant whenever possible and mature it in "Brooke" fashion (Figure 63.6). The siting of the stoma is critical and can be very challenging because of previous incisions, prior stoma, prior stoma site hernia, large abdominal wall defect, and the extent to which the allograft mesentery can be stretched (due to donor recipient size mismatch). This may cause complications with the maturation of the ostomy and application of the stoma appliances. A poorly placed stoma

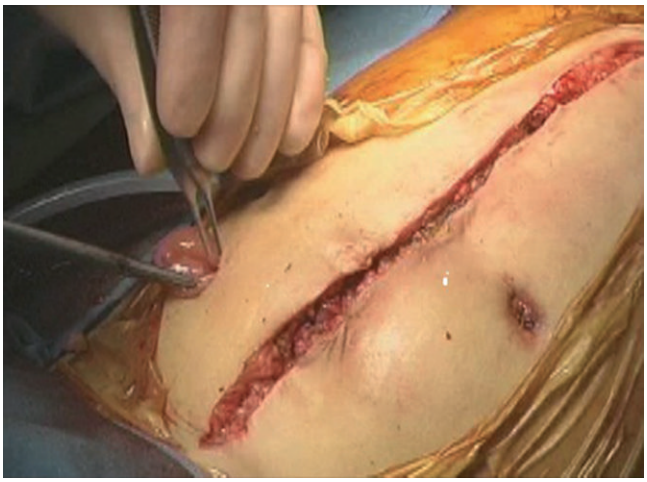

Figure 63.6. Completed multivisceral transplant followed by creation of the Brooke type of ostomy.

not only causes skin and wound complications, it also impacts the psychological and emotional well being of the patient. It is important for the patient to be evaluated preoperatively by a stoma care specialist so that the best possible site for stoma placement can be identified. During this evaluation, attention is paid to abdominal scars/contractures, posture, and mobility of the patient. Key physical considerations include abdominal folds, suture lines, waistline, iliac crest, previous stomas, and presence of hernia. Multiple stoma sites should be marked as an alternative in these complex patients, although it may not be always possible. Ideally, an area below the belt line that is visible to the patient should be chosen. Additionally, it should be placed at least 5 cm from incision lines to aid in proper appliance placement.

One of the most challenging or rather complex parts of the procedure is the closure of the abdominal wall. Primary fascial closure is the goal in all patients. The abdominal fascia is closed with heavy polypropylene suture in a running fashion, and often times the skin is left open. This goal, however, may not be achievable in all patients. It is very important to avoid closure under tension, as (1) the risk of wound dehiscence is significantly increased, (2) the perfusion in the graft may be compromised secondary to intra-abdominal hypertension, (3) the patient's respiratory status may be compromised with resultant difficulty in ventilation secondary to increased airway pressure, and (4) an abdominal compartment syndrome may occur secondary to allograft swelling and third space fluid loss. Several options are available to address this situation, including a skin-only closure, or the use of prosthetic mesh or a biologic mesh. In situations where prosthetic mesh is used, a second-look operation is performed once the swelling in the allograft has gone down (usually 48–72 hours postoperatively) to assess graft viability and attempt the fascial closure. In our experience, the best option in these cases is to achieve temporary closure of the abdominal wall with the use of biologic agents such as acellular human dermis or absorbable mesh. Over the next few days, the patient is brought to the operating room several times for washout and gradual cinching of the mesh so that a fascial closure can be accomplished. In rare circumstances, especially when there is significant amount of tissue defect, abdominal wall transplantation may be the only available option, as described below.

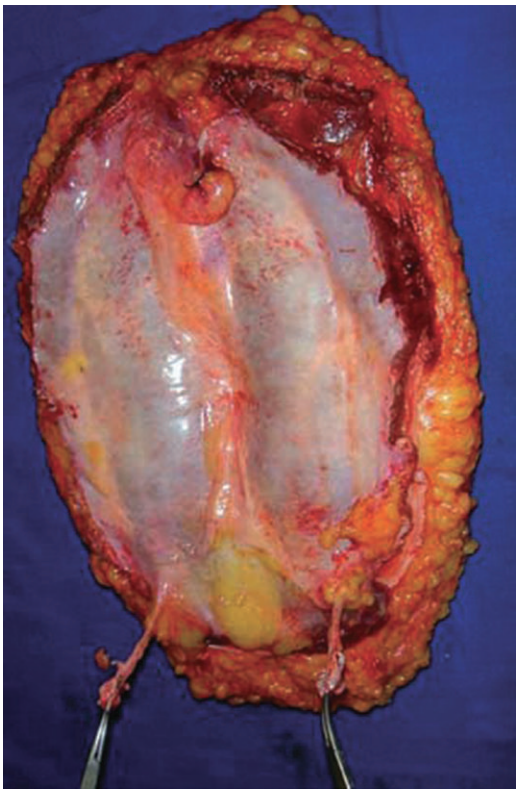

Figure 63.7. The abdominal wall allograft isolated with two epigastric pedicles. Reproduced from [8] Cipriani R, Contedini F, Santoli M, et al. Abdominal wall transplantation with microsurgical technique. American Journal of Transplantation 2007;7:1304–1307, with permission from John Wiley and Sons Ltd.

Transplantation of the abdominal wall

Patients undergoing MVTx or intestinal transplant may encounter difficulties with the closure of the abdominal wall. Due to multiple prior laparotomies, enterocutaneous fistulas, or prior stomas there is limited mobility of the musculoaponeurotic tissues in these patients. Additionally, they may also have fixed abdominal wall defects that preclude re-establishment of peritoneal domain. Also, many of these patients have had the removal of their entire midgut, which can result in an abdominal cavity that is often too small to receive the composite allograft. Additionally, the loss of peritoneal domain may necessitate the use of smaller donor organs and closing the abdominal compartment may be impossible without transplanting abdominal wall. Under these unique and limited circumstances, one has to consider abdominal wall transplantation to restore the peritoneal cavity. This abdominal wall allograft is considered a vascularized composite allotransplant (VCA) which can facilitate reconstruction and closure of the abdominal compartment, especially in patients with prior complex abdominal wall defects.

Procurement of the composite abdominal wall allograft is carried out as part of the multiorgan procurement. The allograft consists of an oval myocutaneous flap comprising of the rectus abdominis muscles, and parts of oblique muscles as well as a layer of parietal peritoneum. The vascular pedicle of this composite allograft is based on the inferior epigastric vessels, which are harvested up to their origin from the external iliac vessels (Figure 63.7) [8].

Inflow to this VCA is achieved by anastomosing either the left or right donor external iliac artery or vein to the recipient iliac artery and vein, respectively. Alternatively, under the right circumstances, a direct end-to-end anastomosis between donor/recipient epigastric vessels can be performed using 10-0 non-absorbable suture using microsurgical techniques. After successful revascularization, bleeding should be noted from the cut edges of the muscle. This myocutaneous flap is then sutured to the recipient abdominal wall musculature in two layers. The successful transplantation of the VCA helps facilitate a tension-free and biologic closure of the abdominal wall.

Reduced-size allografts

Because of the difficulty in obtaining suitably small donor organs, particularly for infants, it is often times necessary to reduce the size of the donor organs prior to transplantation. Typically, a donor that is greater than 25% larger than the intended recipient may require a size reduction of the donor organs. The size reduction is performed on the back table and these surgical techniques follow the same general guidelines outlined in the chapter on live donor liver transplantation (Chapter 57). Typically, the left lateral segment or left lobe will be transplanted. The portion of the small bowel to be removed is variable but is often times limited to one-third of the mid gut. Whether the reduced-size graft is placed in a bicaval position or a piggyback configuration is dependent on the allograft anatomy.

Summary

Multivisceral transplantation is one of the most complex surgical procedures performed in the current era. Even though our experience with MVTx has increased with time, these operations still carry high risk, especially in a patient population that is critically ill. Despite the detailed description of the operative technique, varying degrees of individualization are required depending on patient characteristics, such as age, nature of underlying disease, history of previous operations, and feasibility of vascular access. Meticulous attention to sound surgical technique and hemostasis, an earnest effort to limit allograft ischemia time, and attentive perioperative management by an experienced team are essential for a good patient and graft outcome.

CHAPTER 64

Vascularized Composite Allograft Transplantation Procedure and Surgical Technique

Gerald Brandacher, Jaimie T. Shores, Chad R. Gordon, Damon S. Cooney, and W.P. Andrew Lee
Department of Plastic and Reconstructive Surgery, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Introduction

Each year, millions of individuals sustain injuries, have tumors surgically resected, or are born with congenital defects that require complex reconstructive surgeries to repair the resulting tissue defects. However, limitations of current reconstructive procedures for such major tissue loss include poor functional and aesthetic outcomes, multiple surgical revisions, prolonged rehabilitation, donor site morbidity resulting from use of autologous tissues, and high costs of multiple surgeries and hospitalization. Transplantation of vascularized composite allografts (VCA) offers a new alternative and possibly a superior solution to the requirement for native tissue.

The idea of transplanting body parts from one individual to another dates back to the ancient times [1]; although this vision was partially realized through the first kidney transplants in the 1950s, the potential for VCA was manifest on May 23, 1962, when Ronald Malt performed the world's first arm replantation at the Massachusetts General Hospital. In doing so, he forever changed the way patients suffering from traumatic amputation and limb loss were to be treated to restore form, function, and appearance [2]. This groundbreaking surgery, combined with increasing success in microsurgical techniques, immunosuppressive drug development, and experiences in solid organ transplantation, generated renewed interest in the concept of limb and composite tissue allotransplantation in the 1980s and 1990s. The ultimate result was the first successful hand transplantation in the modern era of immunosuppression on September 23, 1998, performed by a team of surgeons in Lyon, France lead by Dr. Jean-Michel Dubernard [3].

Since then, reconstructive transplantation has become a clinical reality with over 200 procedures of different types of VCAs successfully performed around the world, including hand, forearm, arm, partial facial tissue and full face, abdominal wall, larynx, trachea, vascularized bone and joint, tongue, and even uterus and penis [4,5]. The cumulative world experience substantiates the fact that vascularized composite allotransplantation has become an important treatment option for patients suffering from complex tissue injuries with devastating tissue defects that are not amenable to conventional reconstructive approaches and techniques. However, despite the fact that the surgical procedures and functional outcomes have been largely successful and have shown highly encouraging results, the morbidity associated with chronic immunosuppression limits the broader application of these procedures and prevents them from becoming standard of care [6]. Nevertheless, with thoughtful patient selection, detailed preoperative screening and planning, meticulous surgical technique, and diligent follow-up care, excellent functional overall outcomes can be achieved [7]. This chapter will focus on the general processes of VCA, recognizing that each case is technically unique and worthy of individualized works in their own right. The chapter will complement Chapters 75, 87, and 110, which cover the treatment of VCA rejection, histology of VCA rejection, and long-term VCA outcomes, respectively.

Recipient selection, wait list management, and donor considerations

Candidate selection is critical because VCAs are not life saving, but instead are offered to improve the quality of life, and thus the individual risk–benefit assessment must justify the procedure. Given the requirement for immunosuppressive drug adherence and rigorous rehabilitation, it is arguable that selection of a properly motivated patient is the most important factor for achieving a successful outcome in reconstructive transplantation. Recipient screening and selection, therefore, must include a multistage process that entails an all-encompassing look into the patient's past medical history and pretransplant life [8]. To this end, anatomic, physiologic, psychological, and social factors must be considered and evaluated prior to determining the patient's eligibility for transplantation. Only careful and thorough evaluation of the suitability of a potential candidate will result in an outcome that is satisfactory to both patient and physician. In particular, psychological and social screening becomes critically important in assessing a candidates capacity for compliance with immunosuppressive and rehabilitative treatments. Psychosocial screening is more of an art than a science, but it continues to be refined and emphasized in the transplant literature [9]. From the world's experience with VCA we have learned that only a patient who is physically and mentally healthy, has realistic expectations, is fully capable of understanding and appreciating the complexity of the procedure, and is highly motivated to undergo at least 6 months to 1 year of intensive rehabilitation, should be considered as an appropriate candidate. Indeed, psychological stability and the capacity to comprehend all aspects of the operation and postoperative course need to be confirmed by an independent psychiatrist or psychologist who is unrelated to the

transplant team. Only when such psychosocial criteria are met can further patient screening be initiated. Depending on the type of injury and extend of tissue loss, the unique anatomical situation of each candidate, including bone, muscular, vascular, soft tissue, and neural status, is evaluated for surgical planning. This is usually done by physical exam and by using various imaging modalities such as computed tomography (CT) scan (± three-dimensional reconstruction), angiography, or CT angiography and magnetic resonance imaging (MRI). Photographs of the evaluated limb or anatomical region and the contralateral side, even if uninvolved, are compared to assist with the reconstructive procedure and in donor–recipient matching (i.e. size, skin tone). Considerations regarding the potential reconstructive options to be taken in the event of graft loss are also critically important.

To exclude any co-morbidity that would contraindicate chronic immunosuppression (e.g. malignancies or infections) or the transplant procedure itself, potential candidates undergo further transplant-specific screening, including gastroscopy, colonoscopy, and the evaluation of their renal, cardiovascular, pulmonary, hematologic nutritional, and dental status (for a summary of the screening tests see Table 64.1). Transplant-specific immunologic screening includes ABO blood typing, HLA typing, alloantibody screens, and viral serologic screens for hepatitis viruses A, B, and C, cytomegalovirus (CMV), Epstein–Barr virus (EBV), and human immunodeficiency virus (HIV). Any specific medical problem the candidate has or is encountered during screening should trigger a more specific and in-depth evaluation (Table 64.2).

The results of these tests are also provided to the Organ Procurement Organization (OPO) to initiate donor screening. Although no uniformity or standardization has been currently imposed on this process, in general the protocols developed by VCA programs adhere closely to protocols used in solid-organ procurement [10]. Explicit inclusion and exclusion criteria for potential donors are developed jointly by the VCA team and the OPO. In this regard, potential donors for VCA need to be matched not only for the usual parameters such as ABO type, age, and serologies but also for size, gender, and the color, tone, and texture of skin. Blood type must be compatible. To date, HLA matching has not found to be necessary and for practical reasons is disregarded. However, the lymphocytotoxic cross-match needs to be negative for all donor–recipient combinations. CMV matching of donors and recipients to avoid a donor positive /recipient negative combination is desirable, as the risk of CMV infection in VCA is high and complications of CMV reactivation can be significant [11–13]. It is important to note that despite "presumed consent" legislation in some countries, specialized and informed consent for donation of a VCA should be obtained. This should include a detailed explanation of the exact nature/extent of the VCA procurement and how the subsequent donor defect will be restored (e.g. alginate prostheses, facial masks, cosmetic limb prosthetic) for the comfort of the donor's family. Most importantly, coordinators must approach the families of potential VCA donors in such a way that the consent for life-saving solid organs is not derailed [10,14]. At present there are no specific listing criteria for potential VCA recipients or allocation policies and there is also no dedicated nation-wide waiting list for VCA. Thus, each case is considered individually by the transplant center and their local and regional OPO. Up to now, the number of patients awaiting reconstructive transplantation has been small and therefore competition for VCA donors is still negligible. However, as the number of VCAs increases (and the trend observed over the past several years for both face and hand transplantation clearly indicates an upward trend) it will be of utmost importance to implement respective policies and oversight to promote broad sharing of potential VCA donors. On a national level, the most appropriate governing body to oversee VCA donation will be the United Network of Organ Sharing (UNOS), which operates and acts through the Organ Procurement Transplant Network (OPTN) [15–17]. The same oversight mechanisms already established by the OPTN for solid-organ transplantation can be adapted for VCA donation to provide the same level of oversight, standardization, effectiveness, safety, and transparency (see Chapters 128 and 143 for in-depth treatments of governmental oversight in transplantation).

Since there are no standardized protocols, the surgical strategies developed for each VCA recipients have to be adapted and tailored

to that particular patient. For each patient, a precise surgical plan is generated and, in some cases, additional surgical training on a cadaver is completed in order to perfect a new reconstructive technique.

There is emerging evidence that prolonged cold and warm ischemia significantly impairs short- and long-term graft function [18]. Muscle tissue is particularly sensitive to ischemia and damage. Interstitial edema, microvascular constriction, and/or damage of myocyte membranes may result in muscle dysfunction as early as after 2.5 hours of warm ischemia [19]. Thus, allocation requiring long-distance transportation should be avoided and simultaneous preparation and dissection of the donor graft and recipient tissue in adjacent operating theaters is recommended.

Surgical technique: hand, abdominal wall

Donor surgical technique for hand procurement

Once an immunologically appropriate donor has been selected, further "matching" must take place to ensure adequate similarity of skin color, age, gender (although based on recent experiences from several centers world wide, gender mismatch may occur if skin texture, hair patterns, size, etc. are appropriate), length, circumference, and body habitus [10]. Evaluation of possible vascular injury from invasive monitoring (e.g. arterial lines), injury related to the mechanism leading to brain death, and vasopressor effect must also be performed to make sure the limb is suitable for transplantation. Radiographs evaluating injury and disease should be performed. They can also assist with size matching.

After being deemed an acceptable donor, procurement commences in concert with traditional donor organ procurement (covered in depth in Chapters 21 and 53). Given the ability to extend the limbs and isolate them from the operative field, limb procurement does not alter substantially the procurement procedure. Limb allograft retrieval may occur prior to or during procurement of the thoracic and abdominal viscera. In either case, the brachial artery and vein are exposed and placed under tourniquet control prior to aortic cross-clamping. This ensures that the required dissection can be performed in complete isolation from the systemic circulation which reduces risks of hemodynamic destabilization and prevents interference with solid organ procurement. A perfusion catheter is inserted into the brachial artery and instillation of perfusion solution commences. The authors prefer 500–1000 mL of Custodiol (HTK) solution infused with 5000 units of unfractionated heparin. The instillation continues until venous drainage is clear. The remainder of the procurement can either proceed prior to cross clamping, or occur in concert with thoracic and abdominal viscera retrieval.

A circumferential incision is made with rapid transection of flexor/extensor muscle compartments and median, radial, and ulnar nerves. It is helpful to preserve an extra length of the nerves and vessels so that they extend beyond the soft tissue envelope for ease of identification on the back table. Disarticulation through the elbow (for more distal to mid forearm transplants) is performed. Alternatively, for more proximal procurements, a humeral osteotomy is performed. In some instances, maintenance of abundant length of median, ulnar, radial, and musculocutaneous nerve is necessary. In addition, dissecting out an extended length of basilic and/or cephalic vein and extra length of deep veins and brachial artery may be desirable. The superficial veins may be reflected from proximal to distal prior to tourniquet placement. Once safely reflected, a sterile tourniquet may be placed high on the arm to facilitate proximal nerve and vascular dissection. The tourniquet is inflated until all circulation has ceased. The limb, which has been perfused with preservation solution, is then wrapped in moist gauze or towels, and placed in sterile bags on ice for transportation per standard organ preservation protocol.

Surgical technique recipient: hand transplantation

For upper extremity transplantation, the patient is prepared similarly to a liver transplant recipient. Large-bore peripheral and central venous access and arterial lines are placed away from the extremity or extremities to receive the VCA(s). The patient may be given immunologic induction therapy (e.g. thymoglobulin) per the center-specific protocols. Given the length of a VCA procedure, care should be exercised in anticipating thymoglobulin-associated cytokine release and its related hemodynamic instability. Regional block catheters (peripheral nerve catheters) may be placed but should not be dosed with long-acting anesthetic agents. Ultrasonographic evaluation and mapping of the superficial venous system is performed to assist with venous reconstruction during the revascularization period of the operation. Following induction, the patient is maintained under general anesthesia with monitoring similar to that used in liver transplant recipients. Fluid resuscitation should be performed with colloid (packed red blood cells and fresh frozen plasma) instead of crystalloid to minimize peripheral edema.

The back-table donor limb dissections and recipient site dissections are performed simultaneously and have been well described [20,21]. Of note, all donor limb dissection needs to be performed on ice, using sterile ice packs and crushed ice on the field with towels between the ice and tissue to prevent cold injury to the limb. The recipient dissection is performed under sterile tourniquet control. Skin flaps on the recipient are raised in either a volar–dorsal or radial–ulnar manner, depending upon the level of transplantation, with opposite skin flaps elevated on the donor. Extra care should be taken to preserve small veins and their branches, as they will be necessary for venous reconstruction. Extensive dissection of skin flaps and arterial pedicles should be avoided as devascularization and excessive bleeding are the likely acute result and progressive arteriopathy the potential long-term result [22]. Dissection should be limited to what is considered absolutely necessary for adequate exposure. Any scar potentially limiting functional outcome or soft tissue viability should be excised. Individual muscle–tendon units are identified using tags written with permanent ink sutured to the individual structure. The process continues until all named arteries, nerves, and muscle–tendon units have been identified. The forearm bones are exposed and only once the donor limb has been prepared, are calculations for osteotomies performed. For unilateral cases, the contralateral forearm length should be matched. For bilateral cases, both forearms should be of equal length and within normative values for the patient's height while ensuring adequate tendon, nerve, vessel, and soft tissue length. The same process is performed simultaneously on the back table for the donor limb. At this time, the tourniquets are released and compressive wrapping of the forearm performed, followed by careful bipolar and ligature-achieved hemostasis.

Once bone lengths have been determined, the radius osteotomies are performed and plated and the two separate "work stations" (back table and recipient site) are condensed to a single workstation. The donor limb should remain on ice until revascularization. The authors will frequently preplate the donor radius and ulna on the back table. Once the radius osteosynthesis is complete, the ulna cut is made. Using an oblique osteotomy may help maximize bone

contact surface area while allowing a small amount of "wiggle room" to cheat the ulna in position or length. The use of 3.5-mm locking compression plates (LCP), which are low profile, are used for rigid fixation. This enables rapid advancement of load bearing therapy in the mid and proximal forearm regions. For the distal forearm region, the authors prefer volar locking extended distal radius and distal ulna plates. For above-elbow transplants, we use a single 4.5-mm LCP placed through an anterolateral approach.

At this point, the surgical sequence may diverge from that of standard "replantation" techniques [20,21]. If the ischemia time of the limb has been relatively short, surgeons may continue to reconstruct muscle–tendon units and nerves prior to re-vascularization so that these can be performed rapidly and in a bloodless field. However, just what the time limit is for this technique is as yet unknown (see above). The authors routinely complete all extensor tendon work, most flexor tendon work, and some nerve reconstruction prior to revascularization.

Achieving tendon balance in a transplant is substantially different from that of a replant. Relative tendon balance is non-existent in such a scenario. The extensors are repaired first, placing the thumb and digits into full extension with the wrist in mild flexion so that extension may be checked with tenodesis using 20–30 degrees of wrist flexion for full thumb and digit extension. The wrist extensors are repaired next. Rapid repair of large dorsal veins may be performed at this time if possible. However, if the veins are not immediately obvious or do not lend themselves to a quick anastomosis, the authors proceed to the flexor tendon reconstruction. The flexor digitorum profundus and superficialis tendons are repaired as well as the flexor pollicis longus. The wrist flexors can be repaired following revascularization. At this point, the nerves may be repaired in a bloodless field, or revascularization may commence first. Nerve repairs are performed in a grouped fascicular manner with identification and separate repair of the anterior interosseus nerve or group (if possible) as well as motor and sensory tracts if identifiable by surface topography and level of repair to the median and ulnar nerves. The superficial radial nerve, dorsal ulnar cutaneous, and palmar cutaneous nerves should be repaired if available.

Larger veins lend themselves to a blood-free operative field and rapid anastomosis. When possible, the authors prefer to use a venous coupling device, which is reliable and saves time. Smaller veins may require anastomosis after revascularization when they are distended and more easily identified. Arteries are repaired with the least amount of dissection possible. This includes the brachial, radial, ulnar, and/or anterior interosseus arteries. When the recipient's proximal forearm is being preserved, brachial artery repairs should be performed as an end-to-side anastomosis. For transplants at the mid to distal forearm, individual end-to-end anastomoses of the radial and/or ulnar and/or anterior interosseus artery and their venae comitans (whenever possible) are performed. For above elbow transplants not preserving any distal recipient arm, spatulated end-to-end brachial artery anastomoses are performed. Beware of previously placed radial arterial lines in the ICU of the donor, as the radial artery may be thrombosed. This has been reported to propagate and lead to acute failure of the transplant, though the authors have successfully transplanted such a hand using only an ulnar artery anastomosis for arterial inflow [23]. Only at the point that clamps are removed from the arteries and in flow re-established, is the sterile ice removed from the field. Warm saline is used to irrigate and re-warm the limb. Blood is allowed to egress from uncoupled veins for several minutes until the dark coloration begins to lighten. A cell-saver may be used to recycle this intentional blood loss.

After successful reperfusion of the graft, any remaining nerves are repaired and veins are identified and hand-sewn or coupled. This is usually the most time-intensive portion of the operation. Adequate venous outflow is critically important and can be difficult to achieve. The authors prefer at least four veins per hand, but will reconstruct as many as are anatomically possible. The authors use an implantable venous Doppler probe on each transplanted limb applied to what is believed to be the most reliable vein. Once the microsurgical portion of the transplantation is complete, the superficial flexor tendon–motor units are repaired and irrigation and hemostasis are performed. The four skin flaps are interdigitated and closed over drains. Any non-viable-appearing portions of the skin flaps are excised. Skin grafting from the donor may be required if there is a skin shortage. Finally, bulky gauze dressings and a non-compressing splint are applied with the digits completely visible. Pulse-oximetry probes are placed on the thumb and small finger with saturations and waveforms compared to either the contralateral native hand or the contralateral transplanted hand and a separate reference site in the event of a bilateral transplant.

Donor surgical technique for abdominal wall procurement

The abdominal wall allograft (or alloflap) may be safely procured at the same time as the abdominal and thoracic viscerae, with some modification to the abdominal approach. The midline sternotomy incision is stopped just below the xiphoid process and bilateral subcostal incisions are performed, extending down the lateral borders of the rectus sheath to both groins. A transverse suprapubic incision is then performed [24]. The flap is circumferentially incised, leaving the deep inferior epigastric vessels intact, and then turned face down inferiorly to provide wide access to the intra-abdominal organs for procurement. Procurement proceeds per protocol until the abdominal organs have been retrieved. At this point, the vascular pedicle to the abdominal wall is isolated upon the common to external iliac system and infusion of preservation solution commenced. The alloflap is procured with a cuff of distal vena cava and aorta if desired, or may be procured anywhere along the common/external iliac vessels for large vessel anastomoses [24]. Alternatively, the flap can also be based on the deep inferior epigastric vessels taken directly off the external iliac vessels for microanastomoses [25]. The abdominal wall graft is then wrapped in moist gauze, tripled bagged, and kept on ice for transportation per standard transplant protocols.

Surgical technique recipient: abdominal wall transplantation

An abdominal wall transplant is usually indicated to follow a multivisceral abdominal transplantation or transplantation of the small bowel [26]. Following successful completion of these transplants, the recipient vessels are selected and prepared. End-to-side anastomosis of the more proximally procured vessels (distal aorta, proximal common iliac level) may be performed to the recipient common iliac artery/vein or the infrarenal aorta and inferior vena cava. Alternatively, microsurgical technique may be employed to perform end-to-end anastomosis of the more distal and smaller deep inferior epigastric vessels to the proximal take-offs of the same recipient vessels or to the circumflex iliac vessels [24–26]. It is theoretically possible to attempt superficial epigastric vessel anastomosis as well as the deep inferior epigastric system, though this is likely

unnecessary. Motor nerve coaptations have not been necessary in previously reported series [26].

After ensuring adequate arterial inflow and venous outflow into the abdominal wall, fascia-to-fascia repair is preformed and subcutaneous and skin closure is then performed. The abdominal wall graft may be monitored by implantable Doppler probe, external hand held Doppler probe, and by clinical evaluation of skin color, capillary refill, edema, and turgor.

An additional technique incorporates a vascularized abdominal wall/fascial component in continuity with a liver allograft. The posterior abdominal wall fascia connected and vascularized via the falciform ligament has been performed successfully in pediatric liver transplant recipients and provides additional fascial tissue for closure, though the recipient's skin has been closed primarily in each presented case. This composite allograft has been termed the posterior rectus sheath (PORSH)-liver composite vascularized allograft [27,28].

Surgical technique: face

Pretransplant anatomical review

Each face transplant candidate should be assessed in the same orthognathic fashion as other patients undergoing facial skeletal surgery [29]. It is important that the surgical team documents each individual's facial skeletal deficit based on three regions: (1) upper third (scalp/skull), (2) middle third, and (3) lower third. With this in mind, the face transplant team should plan an individualized approach for each candidate [30]. The relevant anatomy and function of each missing facial subunit should be assessed, thereby allowing the team to foresee reconstruction in an ideal setting using customized free-tissue transfer. All pre-existing vascular inflow/outflow aberrancies must be documented during the candidate's pretransplant head/neck surgical screening phase [31]. Detailed preoperative radiological analysis includes three-dimensional CT scan reconstruction and angiography (Figure 64.1). Of note, one needs to be aware of both the donor and recipient surgical/medical history and distinct skeletal anatomy surrounding the facial organ, since both the alloflap recovery and recipient preparation dissections can be equally challenging.

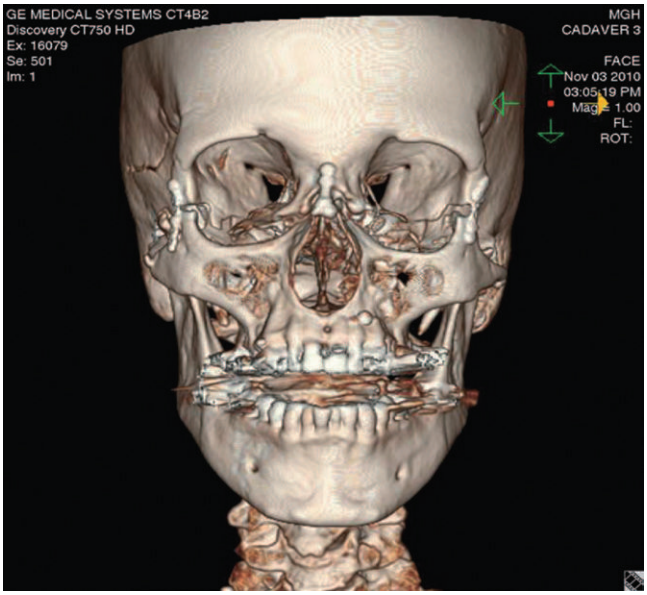

Figure 64.1. Three-dimensional computed tomographic scans (frontal view) depicting an optimized hybrid skeleton in the recipient.

Transplant procedure: timing and logistics

Timing and coordination of both the donor and recipient operation are based on the complexities of the recipient's pretransplant anatomy. In our program at Johns Hopkins, we employ a multidisciplinary approach combining plastic/reconstructive surgery, craniomaxillofacial surgery, microsurgery, and facial plastic surgery/head and neck surgery. For those transplants necessitating complex facial skeletal osteotomies, we prefer to transport the donor to our home institution and use two neighboring operating rooms. This allows us to use and coordinate two teams, one based on craniomaxillofacial expertise and the other based on head/neck surgery–microsurgery expertise. If both rooms are available side-by-side, we aim to start the donor operation (VCA recovery) and recipient operation (preparation) in similar fashion. However, if the recipient contains a large amount of facial scar tissue and complex microanatomy, we choose to delay the donor operation until progress has been made on the recipient procedure [32]. Ideally, the alloflaps are dissected to completion at the same time with all target vessels and nerves labeled. If the recipient's dissection is delayed, the donor's alloflap is fully islandized until ready for transplant so as to minimize alloflap ischemia. However, this may not be possible if the facial alloflap needs to be recovered at an outside institution. In this situation, the alloflaps are perfused, wrapped in moist gauze and kept on ice, according to solid organ transplant standards.

Donor surgical technique for face allograft procurement

A prerecovery, elective tracheostomy (percutaneous or open) should be performed to allow safe access to the face/neck and to assure donor stability. In some instances, the patient may already have a pre-existing tracheostomy in place. Given the central nature of the facial donor site, some special logistical arrangements are required to facilitate facial procurement without impeding the progress of the procurement of the thoracic organs. These are nicely discussed by Brazio et al. [33] and displayed in Figure 64.2. Skin and soft tissue incisions are dissected in the mirror image of the necessary size limits based on the recipient's deficit and with respect to aesthetic unit boundaries. For the purpose of graft monitoring, some groups, including ours, choose to leave a redundant portion of skin at the inferior edge of the facial flap so that protocol skin biopsies can be performed in an inconspicuous region. Others perform a second alloflap (sentinel skin flap) for this purpose. The authors believe that preserving redundant tissue is better than adding a sentinel flap, because facial skin rejects differently in different anatomical locations [34]. The donor facial vessels should be dissected with utmost care from the proximal level extending superiorly. An operating microscope is often necessary for microneurovascular reconstruction. If there is a vasovagal reaction due to carotid bulb stimulation, 1% plain lidocaine should be injected into the carotid bulb. In certain cases, exposure of the facial vessels may require a mandibular osteotomy. One should determine pretransplant which facial vessels are most appropriate given the exact deficit being reconstructed based on angiography. This includes considering superficial temporal vessels for the upper third, transverse facial/superficial temporal vessels for middle third (facial) defects, and ipsilateral neck vasculature for the lower third.

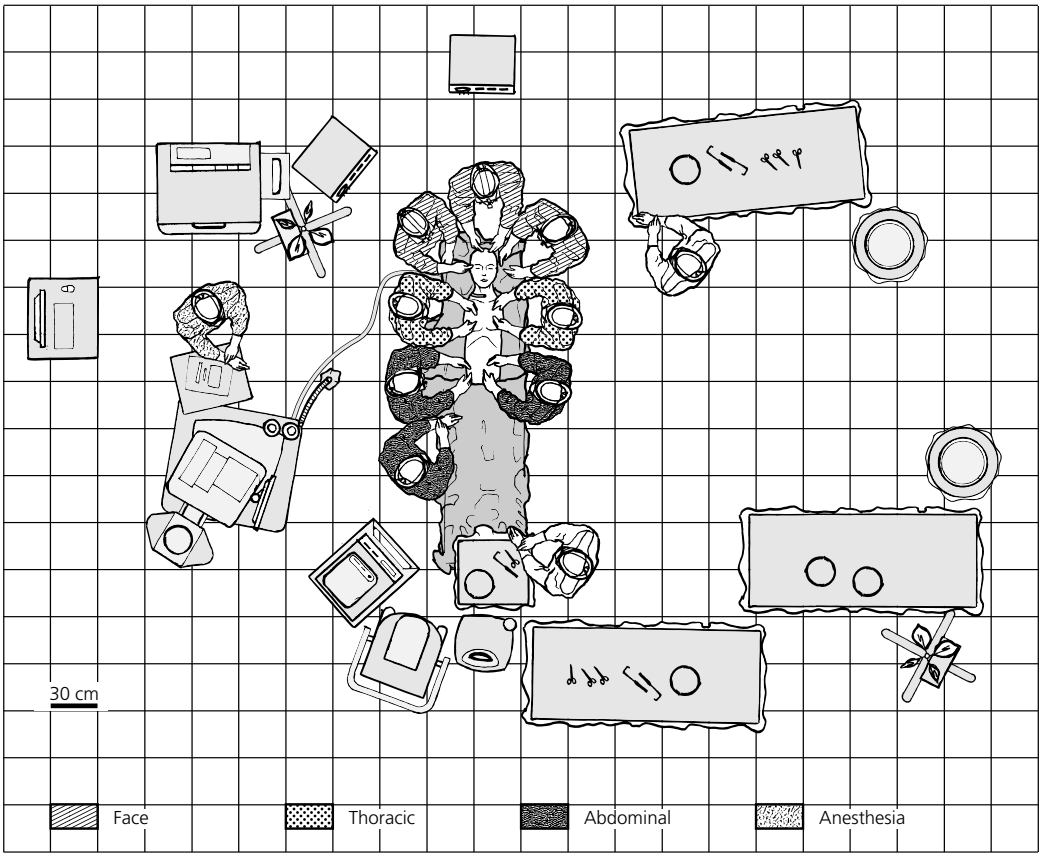

Figure 64.2. Donor operating room set up for multiorgan procurement including a face allograft. The arrangement allows face, thoracic, and abdominal teams to work concurrently with the sole exception of sternotomy. In addition to standard anesthesia and monitoring equipment, there were two OR lights, two monopolar and one bipolar electrocauteries, three suction assemblies, and two head lamp light sources. The operating table was complemented by one back table at each end for face and solid organ teams, respectively, and a back bench for organ preparation. From Brazio et al. 2013 [33], with permission.

When the optimum vessels are not available, one can use alternative vessels, such as adjacent small vessels in the neck branching from the external carotid and/or internal jugular vein systems. Due to the common zone of injury for those with severe facial injuries, having to identify an alternative vessel is a common situation. This may prolong operative time and therefore should be considered in advance by all teams. Pretransplant imaging (e.g. Doppler ultrasound, angiography) provides the microsurgical team with important information about target vessel patency, which saves time and helps prevent technical failures. Again, depending on which facial tissue types (soft tissue with or without skeletal components) are included in the facial alloflap, the vascular supply may vary. The Cleveland experience demonstrated that the majority of facial skin, glandular tissue, muscular, and a modified Le Fort-III maxillofacial structure can all be adequately supplied by the bilateral facial artery system [35]. Studies have also shown that the periosteal blood supply to the facial bones provides significant perfusion [36]. For a flap transplanted with lateral cheek tissues, ear, scalp, and forehead, one should consider including the superficial temporal, internal maxillary, and/or facial branches during recovery. In addition, the craniofacial dissection should strive to preserve all of the overlying periosteum for the sake of viability. Regardless of the vessels chosen, one should dissect to the most proximal level where the caliber is greatest to reduce the risk of technical failure. However, one should avoid recovering the carotid artery proximal to its bifurcation as inhibiting blood flow in the internal carotid artery could result in acute cerebral edema. Following the arterial/venous dissection, the facial nerve branches are defined bilaterally. Most often, the main venous drainage is based on the external jugular venous system. The facial nerve dissection at the area of the stylomastoid foremen allows one to raise the flap at the donor's main trunk level. In contrast, the Boston group recommends an inset with distal neurorraphies so as to prevent synkinesis [37].

If applicable, the Le Fort-based osteotomies are best left to the final stage, prior to final flap recovery, so as to minimize bone bleeding. These bone cuts should be tailored to the recipient's needs and are best performed once the soft tissue envelope has been dissected and labeled. The craniofacial team should request relative hypotensive anesthesia and reverse Trendelenburg positioning during the Le Fort recovery to prevent iatrogenic bleeding. Another surgical consideration in maxillofacial alloflap recovery is the adequate exposure of the lower orbital floors in preparation for a Le Fort-type osteotomy. One should consider using a small vibrating saw (Sonopet and Nakagawa Serrated Knife, Stryker, Inc., Kalamazoo, MI) with constant irrigation to protect the donor globe for possible cornea donation. If the recipient's maxillary defect is primarily anterior, thereby restricting the inset of a full maxilla, it may be reasonable to employ a "veneer approach." This "maxillary onlay" technique entails harvesting the anterior, medial, and lateral maxillary walls, leaving behind the rest of the maxilla so as to not

disrupt the pertinent soft tissue bony attachments and retaining ligaments.

The face transplant team should talk with their solid organ transplant colleagues before commencing surgery to coordinate certain maneuvers such as vessel cannulation and cross-clamping so as to not jeopardize the procurement of life-saving solid organs. It is imperative that all parties be aware of each other's surgical plan and specific techniques, which could be altered or abandoned in the setting of donor instability. We prefer to recover the facial alloflap and place a customized on-lay mask prior to the solid organ team beginning their operation. The goal is to prevent any major disturbance to the solid organ recovery process, while at the same time protecting the identity of the donor when they are transported from the operating room to the morgue. To avoid any donor disfigurement, it is recommended that a facial prosthesis is placed on all donors following facial tissue recovery irrespective of cremation or open-casket burial.

Surgical technique recipient: face transplantation

As the donor team is recovering the face, the recipient team simultaneously dissects and prepares the patient's head/neck in order to minimize total ischemia time. Great care is taken to identify and label viable nerve and vessel endpoints, excising excess scar, and creating skin flaps for closure. All pertinent endpoints are dissected to predetermined lengths and mobilized accordingly. Prior to implantation, all UW fluid should be flushed from the alloflap and replaced with cool lactated ringers (LR) solution.

Similar to an extremity replantation, a face transplant including bone begins with partial osteosynthesis to provide necessary stability for neurovascular reconstruction. Cranial osteosynthesis may involve the maxilla, orbital rim, mandible, zygomatic–maxillary complex, and/or cranial vault, depending on the recipient's extent of alloreconstruction. The hard tissue component of the alloflaps is rigidly fixated with multiple titanium plates and screws. In certain cases, the width of the donor facial bones may be wider or narrower compared to the recipient's, and if this is the case, the donor's bizygomatic distance will be modified using surgical techniques (e.g. greenstick fracturing) to allow adequate apposition with the recipient's zygomatic arch [29,30]. Careful attention is needed to make sure the X-, Y-, and Z-axis is accurately positioned for facial width and projection, in addition to appropriate dental occlusion and orbital volumes. We employ a novel approach using a "HYBRID splint" and pretransplant cephalometrics to predict the ideal Le Fort inset position. Of note, this portion of the transplant can be challenging if the donor and/or recipient has poor dental hygiene and periodontal disease. Before face–jaw transplantation, preoperative dental preparation and intraoperative tooth extraction may be necessary if caries are present. This will diminish the risk of infectious complications after the recipient is placed on lifelong immunotherapy. If dental extraction is necessary for the donor's maxilla or mandible, a modified Gunning splint will allow proper vertical spacing for ideal maxilla–mandibular relation.

One should be also cautious in aligning the frontonasal sinus tracts during Le Fort-III type alloreconstruction because the donor-to-recipient junction can be a potential drainage obstruction, leading to future problems such as infections and/or mucoceles. For this reason, it may be prudent to burr down the donor's frontal sinus mucosa using a high-speed burr, with possible obliteration depending on the team's comfort level. A single nasofrontal osteosynthesis permits the microsurgical team to complete unilateral vascular reconstruction, which allows contralateral perfusion and minimizes ischemia time. Total ischemia time from alloflap division to first artery and vein repair should be considered most critical and be monitored. Once the perfusion of all facial tissues has been completed, the craniofacial team can then complete the remaining osteosynthesis, depending on the recipient's stable skeleton. The goal is to create the most optimized hybrid skeleton using many well-tested maneuvers, as described above (Figures 64.1 and 64.3).

After osteosyntheses and vascular perfusion has been secured, facial nerve and sensory nerve repairs are completed if possible. Donor nerve cable grafts can be utilized for such repairs, including the likes of spinal accessory, sural, vagus, greater auricular, and hypoglossal nerves. The authors prefer to replace motor nerve defects with motor grafts, and sensory nerve defects with sensory grafts. Ideal nerve diameter is accounted for as well. Depending on the patient's mechanism of injury, it may be challenging and/or impossible to reconstruct all sensory branches. However, if possible, all trigeminal nerve branches should be repaired. Also, if the facial nerve trunk is scarred, a mastoidectomy releasing the facial nerve from its canal may also be necessary. The ultimate goal is to perform a tension-free neurorraphy to the donor's facial nerves

Figure 64.3. Frontal and lateral photographs of cadaver face transplantation (edentulous technique), demonstrating class I skeletal profile.

bilaterally. The authors avoid a donor parotid dissection and leave the overlying facial tissue intact so as to prevent possible alloflaps vascular compromise and/or iatrogenic injury to smaller facial nerve branches. This results in the recipient having excessive lower-face bulkiness for a short time post-transplant. However, redundant tissue provides an added benefit for tissue biopsies. At a later stage, all extraneous tissue can be excised during a soft tissue staged revision for optimal aesthetics.

For those recipients with inadequate sensory nerve length, osteotomies to the orbital floors can be used to increase the length of infraorbital nerves for reconstruction. The need for this procedure only becomes apparent when the recipient's anatomy has been fully characterized. Interestingly, the Cleveland patient gained optimal two-point discrimination even though she was unable to undergo infraorbital nerve reconstruction at the time of transplantation due to her close-range ballistic injury [38].

Finally, the soft tissue should be inset using multilayered closure. Closed suction drains are placed strategically and sewn in place. Skin incisions made at the start of the transplant should be designed to assure a tension-free closure of donor–recipient skin edges. More importantly, they should be made within aesthetic unit junctions and fall within aesthetic lines (e.g. nasolabial folds). If incomplete skin coverage is obtained, donor skin grafts may be needed for closure. The face transplant incisions should be dressed with antibiotic ointment and semipermeable gauze, thereby allowing physiotherapy to commence within 1 week. It is difficult to minimize unwanted motion after this type of surgery. As such, it is beneficial to have a patent airway via tracheostomy and gastrostomy for nutritional feeds.

Particular considerations for craniomaxillofacial transplantation

In a recent cadaver study, Gordon and colleagues [34] evaluated the value of orthognathic planning for face transplants that include underlying skeletal components. Key principles and practice, such as dental splint fabrication and cephalometrics, were shown to improve the final facial skeletal results. This, in turn, (1) optimized "hybrid occlusion" between the donor and recipient, (2) provided the team surgical with guidance for aesthetic facial–skeletal harmony during flap inset/rigid fixation, and (3) enhanced the ability to predict and plan for intraoperative and post-transplant hard tissue discrepancies between donor and recipient. With this approach, all face transplant patients should receive a much-improved hybrid occlusion and facial–skeletal relation.

In a setting where the facial alloflap includes an accompanying jaw (e.g. maxillofacial transplant), all efforts should be made to improve the recipient's hybrid occlusion (the dental relation of the two jaws). To begin, one should place the donor maxilla and recipient mandible into ideal "hybrid" occlusion during the transplant by way of a "hybrid occlusal splint" (donor impression on one side, and recipient impression on the other side). Next, the team should perform rigid fixation of the orbital segments while assessing the recipient's orbital volumes, malar projection, and nasofrontal junction. These findings help to determine how much under- or over-rotation of the recipient mandible is needed to obtain an orthognathic profile (e.g. Class I skeletal relation). For instance, if the recipient has a steep mandibular plane angle and prominent maxilla (e.g. Class II relation), one should rotate the face and jaw alloflap in the counter-clockwise direction (as viewed from the right) to allow for close bone-to-bone distance at the nasofrontal junction. This allows for some dis-impaction from the recipient bone posterolaterally at the zygomaticofrontal regions and improves the sagittal projection of the midface and mandible. With these movements, one can improve the overall facial–skeletal form of the recipient (as compared to pretransplant) and preserve ideal orbital volume without compromising ideal occlusion (Figure 64.4). However, this may come at the cost of creating a few millimeters of posterior vertical maxillary excess, as well as interbony gaps between the upper bony segments. In this instance, posterior vertical maxillary excess may manifest clinically as an anterior open bite. This potential problem can be anticipated preoperatively and dealt with by leaving a small, anterior open bite with the condyles in centric relation, which maintains ideal facial–skeletal projection and optimizes midfacial convexity and orbital volume. An open bite could be corrected in the post-transplant phase without resorting to osteotomies of the alloflap (both challenging techniques in the setting of impaired wound healing, questionable vascularity for maxillary osteotomies, and mandated immunosuppression). There are two potential options for post-transplant open bite correction. For small anterior open bites, correction can be accomplished with non-surgical methods, including occlusal grinding of posterior teeth, molar intrusion, or with the assistance of minianchorage devices. Alternatively, a delayed bilateral sagittal split osteotomy (BSSO) may be used and can be combined with secondary aesthetic procedures at a later date [39]. The second option is less ideal, as it is subject to the same challenges of wound healing and immunosuppression as mentioned previously; however, vascularity of the virgin mandible may not be as concerning. For example, a patient with a Class II skeletal pattern and excessive overjet could be treated at 6–12 months postoperatively, with BSSOs and mandibular advancement/setback, as indicated, in combination with bilateral donor parotidectomies and skin tailoring (i.e. face and neck lifting).

Figure 64.4. A best-fit occlusion with optimal intercuspation is shown for donor maxilla and recipient mandible models.

Surgical strategies in the event of a technical failure

As with any microsurgical procedure, there is always a risk of arterial and/or venous complications in the immediate postoperative period. If this happens, the facial alloflap requires emergent vascular revision in the operating room. As such, the facial alloflap should be monitored closely in an ICU setting for at least 48 hours postoperatively using frequent observation and continuous skin oxygen level monitoring. When the diagnosis of vascular insufficiency is made early, the flap is often salvageable. However, there is always a chance that the transplant or salvage surgery fails, requiring removal of the alloflap. As such, it is imperative that each institution conduct these surgeries under an institutional review board (IRB) protocol. Within the protocol, a full description of techniques for salvage should be provided. In many cases, this will most likely include a combination of skin grafts and/or autologous free tissue transfer. Notably, one should consider a parascapular–scapular free flap due to its large surface area and its usual availability in patients with severe facial deformities for salvage procedures.

Surgical technique: larynx, trachea

Anatomical considerations for laryngeal transplantation

Vascularized laryngeal allotransplantation is one of the less common VCA procedures performed. To date, only two such transplant cases are known to have been performed in the United States and only one, performed by Dr. Marshall Strome at the Cleveland Clinic in 1998, has been published in any detail in the scientific literature [40].

Although the reported outcomes (including a functional voice, protective cough sensation, and swallowing function without significant aspiration) were relatively good, there are only a few programs capable of laryngeal transplantation. Due to the paucity of published information, the surgical details discussed below pertain to this single case. There are of course alternative methods and surgical techniques that could be used and, indeed, are used in animal models of laryngeal allotransplantation. The exact surgical procedure to be used in future larynx allotransplantation has yet to be determined [41].

The surgical details of laryngeal transplantation are dictated by the anatomical intricacies of the larynx itself. The larynx consists of the airway, the vocal cords and their musculature, and a cartilaginous framework to provide support. However, these structures lie in intimate relationship with the epiglottis superiorly, the trachea interiorly, the lobes of the thyroid laterally, and the hypopharynx and esophagus posteriorly. The intimate relationship of these structures with the larynx and their frequent partial or total resection at the time of laryngectomy mean that they must be considered when planning a laryngeal transplant procedure. Additionally, the blood supply of the larynx comes from a combination of the superior and inferior laryngeal arteries, which are branches of the descending superior thyroid artery and inferior thyroid artery, respectively. Additional small arteries penetrate the larynx from the surrounding tissue of the pharynx and esophagus, and its blood supply is intimately connected with that of both thyroid and anterior pharynx and esophagus. These factors make it difficult, though certainly not impossible, to design a vascularized laryngeal graft and must be considered carefully during the planning for the procedure.

Another critical factor to consider when regarding the surgical details of larynx transplantation is the nerve supply to the larynx. All of the necessary functions of the larynx require successful recovery of both sensory and motor component re-innervation of the vocal cords. The superior laryngeal nerve provides the majority of protective sensation that prevents aspiration. The superior laryngeal nerve also supplies the cricothyroid muscle, which, by varying tension on the cords, allows variation in voice pitch. The function of this muscle alone is insufficient, however, to lateralize the cords for adequate respiration. This function relies on the recurrent laryngeal nerve, which supplies the remaining muscles of the larynx. Unfortunately, repair of the recurrent laryngeal nerve, even as an isolated injury, frequently results in synkinesis. The inability to predictably re-innervate the abductors of the vocal cords is one of the reasons that patients treated with this technique have continued to require tracheostomy and why the overall utility of larynx allotransplantation is limited [42].

Donor operation (procurement)

Potential laryngeal donors are identified having proper consent and no history of airway trauma, surgery, or neoplasm. Prior thyroid surgery, laryngeal nerve injury, or neuromuscular disease would be an absolute contraindication to donation. Heavy smoking history must be considered as a relative contraindication. The entire pharyngolaryngeal complex, including the larynx the thyroid/parathyroid glands, the anterior surface of the pharynx, and a portion of the superior trachea, are resected en bloc. This can be done before or after cross-clamping and thoracic organ harvest provided the donor has a tracheostomy below the level of planned tracheal en bloc resection. Standard nerve detection techniques can be utilized, if necessary, to identify the nerves; however, it is important to remember that motor function will degrade rapidly once the graft is no longer perfused. The vascular supply can be harvested with the internal jugular veins. Arterial supply can be harvested at the level of the superior thyroid and inferior thyroid artery or the carotid or thyrocervical trunk can be harvested if additional vascular pedicle is necessary. Following harvest, the donor graft is perfused on the back table and stored in University of Wisconsin solution until revascularization. Ischemia time in the first transplant was approximately 10 hours.

Recipient operation (transplantation)

During the recipient operation, careful planning is required to guarantee the safety of the airway at all times. If not already present, the patient undergoes tracheostomy at the beginning of the surgery. The level of the ostomy should be at the level of planned tracheal repair. Only once the graft is available for transplant, the recipient dissection is carried out. The patient's native remaining laryngeal structures are exposed and dissected free of surrounding tissue and scar. Every attempt is made to identify all four nerves (although in the first case the left recurrent laryngeal nerve could not be identified). Recipient vessels are identified and the graft re-perfused using microsurgical anastomosis with standard techniques. Any available arteries and veins may be utilized. In the case of the first transplant patient, the superior thyroid artery was anastomosed to the recipient superior thyroid artery and the internal jugular vein and anastomosed to the right facial vein. Laryngectomy was then performed leaving the thyroid gland intact and lateralized. The graft was then rotated into position. The contralateral superior thyroid artery was then reconnected and the left middle thyroid vein was anastomosed end-to-side into the recipient's left internal jugular vein. The thyroid

cartilage was secured to the hyoid superiorly. Posteriorly, approximately 75% of the donor's pharynx was utilized. Inferiorly, the trachea was repaired at the level of the tracheostomy [43]. These final details may by modified to fit the particular circumstances of each patient's anatomy but the success of the transplant done in such a way demonstrates that this particular sequence can result in a viable and functional graft.

Anatomical considerations for tracheal transplantation

Surgical reconstruction of the trachea continues to be a daunting surgical challenge and one for which an ideal solution has not yet been found. Despite the wide variety of different techniques for surgical reconstruction of the trachea with autologous, alloplastic, and allogenic materials that have been proposed and performed over the years, no single technique has resulted in consistent and reliable long-term results [44]. This provides the opportunity for reconstructive transplantation to play an important role in advancing the field. However, tracheal reconstruction presents significant challenges. In particular, the arterial and venous supply to the trachea makes it difficult to design a robust vascularized flap that can be transplanted in a single surgical procedure. The majority of the trachea is supplied by branches from the inferior thyroid arteries that course through the gland before giving very small branches to the trachea. The inferior third of the trachea is supplied by arterial branches from the bronchial arteries and the posterior, membranous portion of the trachea is supplied in part by perforating branches from the immediately adjacent esophagus. Several animal models have been designed using various vascular pedicles and containing composite structures, including the thyroid gland and in some cases the esophagus. Although these models do allow transfer or transplant of the trachea as a vascularized graft in a single stage, use of similar techniques in humans has not been published. Several groups have used living tracheal allografts in the human by utilizing revascularization of the isolated tracheal graft in a recipient vascular bed [45,46]. This can be either the sternocleidomastoid muscle, the omentum, or a radial forearm flap. This can be performed immediately and in situ; however, most cases utilize heterotopic placement during the revascularization phase followed by a second-stage relocation into the orthotopic position using free tissue transfer. The most recent and promising studies have come from the Leuven Tracheal Transplant group in Belgium and their technique is outlined below [46,47].

Donor operation (procurement)

Following harvest of the thoracic organs, an 8 cm long tracheal segment is harvested from immediately below the cricoid cartilage to the point of transaction of the trachea for double lung transplant. Care is taken to remove the thyroid gland and esophagus without damaging the adventitial structures of the trachea itself. The graft is stored in University of Wisconsin solution on ice during transport. Cold ischemia time may be up to 10 hours. A full-thickness skin graft is also harvested from the donor and stored in identical manner.

Recipient operation (transplantation)

The recipient bed is prepared for first-stage heterotopic placement by elevation of the skin overlying the vascular territory of the radial forearm flap. The radial artery and underlying fascia serve as a bed for revascularization of the tracheal allograft. The graft is placed longitudinally in this bed with the superior portion facing proximally in the arm for proper orientation of the cilia once the graft is transferred to the neck. During initial surgeries, it was found that the membranous portion the trachea necrosed prior to revascularization. It is therefore removed during implantation in the arm. Full-thickness buccal mucosal grafts may be harvested and inserted in place of the membranous portion. The radial forearm skin is then closed over the trachea and the tracheal ends left open to facilitate drainage and observation. The donor skin graft is sutured behind the patient's ear for immunological monitoring. The graph is maintained heterotopically for 4 months, at which point the immunosuppression may be tapered. Once the skin graft behind the ear has fully rejected and the tracheal graft remains viable, orthotopic transfer may be performed. At this stage the graft is raised with the radial artery and the forearm fascia as a free flap. The skin may be taken with the flap if it is needed for coverage in the neck or for a monitoring sentinel flap. Otherwise skin flaps are elevated prior to raising the flap and the forearm skin left in place on the arm. The flap is then transferred to the orthotopic position after removal of the damaged segment of airway. Oral tracheal incubation is maintained while the graft is positioned and suited in place. The radial vessels are then anastomosed to adequate recipient vessels in the neck in standard microvascular fashion. It is recommended that a small flap of skin or fascia be externalized in order to monitor the microvascular status of the transplant. This may be excised when the patient leaves the hospital or soon thereafter. The patient can be extubated once they no longer require mechanical ventilation and a stent may be placed in the early postoperative period if necessary.

Summary

Despite initial skepticism and debate, reconstructive transplantation is now a clinical reality. As illustrated in this chapter the technical surgical aspects of VCA transplantation are reasonably well established and are no longer the factors that limit the widespread and routine application of this therapy. Nevertheless, microsurgical challenges will remain the Achilles' heel of any type of reconstructive transplantation. Excellent results require meticulous technique, in combination with intelligent immunosuppressive therapy, a high degree of patient compliance, and close follow-up. As our experience increases, the safety, efficacy, and applicability of these life-changing reconstructive modalities will continue to improve dramatically to the benefit of our patients.

SECTION 6

Post-transplant Management

CHAPTER 65

Induction Immunosuppressive Therapy

Introduction

The introduction and improvement of immunomodulatory medications have paved the way for organ transplantation to become the treatment of choice for most causes of organ failure. Over the decades, the immunomodulatory regimens used for organ transplantation have evolved into three general classifications: induction, maintenance, or rescue therapy. Induction therapy is intense, prophylactic treatment that is used at the time of transplantation when the recipient's immune system is exposed for the first time to the donor organ. It can include medications that are specific to the induction indication, medications used at high dose during induction that are used chronically at lower dose, and other immunomodulatory maneuvers (e.g. donor-specific transfusions) to facilitate the initial acceptance of an allograft. Its use has emerged from the empiric observation that the early requirements for immunomodulation exceed those late after transplantation. Over time, the biological basis for this observation has become increasingly apparent and related to numerous mechanisms of immune activation.

In general, the intensity of induction regimens is such that prolonged exposure is prohibitively toxic, leading to infectious morbidity and impaired wound healing. Nevertheless, when used appropriately, induction therapy can reduce the incidence of early acute rejection and avoid immune injury at a newly transplanted organ's most vulnerable time: its recovery from the ischemic consequences of the transplant procedure. This avoidance of early rejection simplifies the early immune management of transplant recipients; whether it improves the long-term outcome post transplant remains a matter of continued investigative interest. Regardless, the use of induction therapy is increasingly commonplace, as reflected in the 2010 Scientific Registry of Transplant Recipients. In 2010, more than 80% of kidney transplant patients received some form of induction immunotherapy beyond the ubiquitous bolus methylprednisolone that serves as the base regimen for most induction approaches. More specifically, 58% of kidney transplant patients received a T-cell depleting antibody, 21% received an IL-2RA (interleukin-2 receptor antibody), and 4% received both a T-cell depletional therapy and an IL-2RA (Table 65.1, Figure 65.1).

As the need for immunomodulation decreases, induction therapy is replaced by maintenance therapy—medications of lesser potency and improved tolerability for chronic use. Should acute rejection emerge during maintenance therapy, rescue therapy is deployed. Rescue therapy is similar to induction therapy in that it is intense and used for a short period of time. This chapter will cover the emerging biological basis for induction therapy and review the specialized induction agents currently available for clinical use. The general clinical rationale and composition of maintenance and rescue therapies will be covered in Chapters 66 and 67, as well as in the section Clinical Allograft Rejection Syndromes: Diagnosis and Management, which contains organ-specific chapters on the clinical diagnosis and treatment of acute rejection.

The biologic basis for induction therapy

A recipient of a transplanted organ first encounters that organ handicapped by two non-physiological circumstances that favor a pathological immune response. The first is the recipient's thymic and hematopoietic selection has selected a lymphocyte repertoire that is appropriate for them, in that it has a relatively low precursory frequency of autoreactive cells (cells responding to self-MHC and/or with self-peptides). Those cells that have autoreactive potential are generally of such affinity that their activation is dependent on accessory signals (discussed below) for activation. The second non-physiologic factor driving a graft-specific immune response is related to the ischemia, reperfusion, and related tissue injury that inevitably result from the process of transplantation (Figure 65.2). These factors alter mechanisms of antigen presentation, change the activation threshold of T and B cells, and alter cell trafficking so as to favor an alloimmune response (Table 65.2). Thus, the processes leading to alloimmunity derive from physiological immune processes encountering an organ under non-physiological conditions (injury within a high allospecific precursor frequency). This forms the basis for alloimmunity and as such serves as an appropriate conceptual framework for the initial immunomodulatory approach for avoiding alloimmune rejection. Additional detail regarding these concepts can be found in Chapter 11. In this section, we will relate the immunologic basis that necessitates induction therapy to the therapeutic maneuvers used at the time of transplantation. Current clinically common induction regimens are focused on T-cell-mediated rejection (largely based on the available agents, not to discount the importance of alloantibody development post transplant).

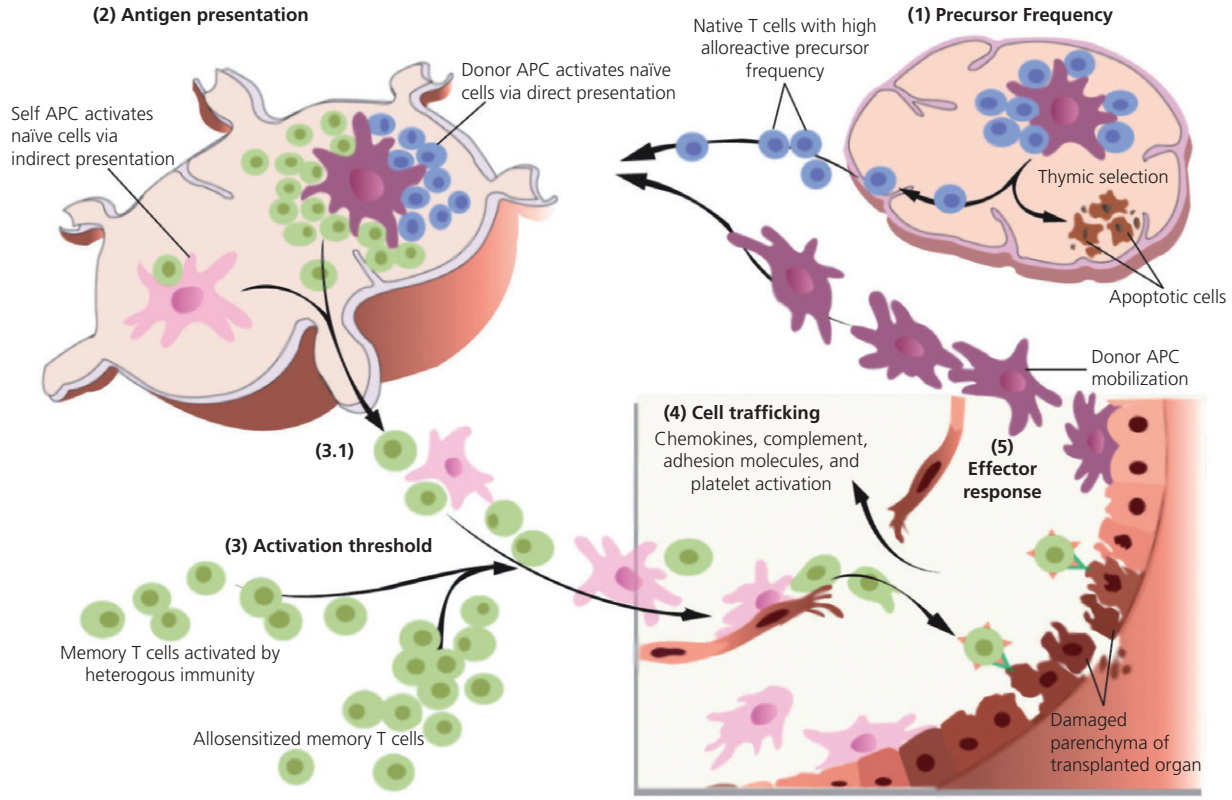

Figure 65.2. Factors necessitating induction therapy.

(1) Precursor frequency. The absence of alloantigens in the native thymus at the time of thymic selection leads to the release of T cells without regard for allo-MHC and, as such, leads to a non-physiologically high precursor frequency in the naïve T-cell pool generated. This is influenced by MHC mismatching and can be manipulated, in theory, by the introduction of donor antigen into the recipient thymus.

(2) Antigen presentation. Allospecific antigen presentation (direct through migration of donor APCs to the nodes/spleen and indirect through autologous APC antigen uptake and presentation) occurs in the secondary lymphoid tissues (e.g. peripheral lymph nodes and the spleen). It can be manipulated by costimulation blockade (e.g. belatacept), T-cell depletion, steroids, and anti-IL-2R antibodies. Strategies that alter T-cell activation threshold (CNI, mTORs) or cell division (antimetabolites) also affect a T cell's receptivity to antigen presentation.

(3) Activation threshold. T cells can be activated in the lymph nodes (3.1) or locally adjacent to the graft. Memory T cells bypass the need for nodal presentation.

(4) Cell trafficking. Recipient APCs and activated T cells are attracted by chemokines and adhesion molecules to the recently injured graft. Reperfusion injury promotes donor APCs migration to the nodes for direct presentation.

(5) Effector response. Reinforced by a milieu enriched in T-cell-derived cytokines (IL-2), donor-specific CTLs damage the transplanted organ through direct effects of the cells and indirect effects of proinflammatory cytokines.

Immunologic concepts relevant to the need for induction therapy

Several basic concepts conspire to determine a recipient's initial capacity for an alloimmune response. As induction immunosuppression is predicated on blocking the initial response, and its risk–benefit assessment is based on using this potent immunosuppressive approach only when required by the conditions of the recipient, it is useful to understand, in general terms, the factors that determine the veracity and effect of that response. These factors can be loosely defined through an understanding of the general factors determining a recipient's T-cell activation threshold, their allospecific precursory frequency, the degree to which the T-cell repertoire is in a memory as opposed to a naïve state, the amount of injury accompanying the antigen exposure, and the overall susceptibility of the organ being transplanted. These factors will be briefly summarized.

Table 65.2. The biologic basis of induction therapy

	Precursor frequency	Antigen presentation	Activation threshold	Cell trafficking
Biologic factors	MHC mismatch	IRI, APC activation	Sensitization, homeostasis	IRI, endothelial injury
Therapeutic interventions	OKT3, ATG, alemtuzumab, DST, mTOR	Steroids, belatacept	mTOR, CNI, MMF, steroids, anti-IL2R, ATG	Steroids

IRI, ischemic reperfusion injury; DST, donor-specific transfusions; mTOR, molecular target of rapamycin; CNI, calcineurin inhibitors; MMF, mycophenolate mofetil; ATG, antithymocyte globulin.

Threshold of activation: the three-signal model of the immune response

The three-signal model of immune activation is conceptually useful for understanding T-cell activation (Figure 65.3). Indeed, most commonly used immunosuppressive agents target specific pathways that fall within this framework.

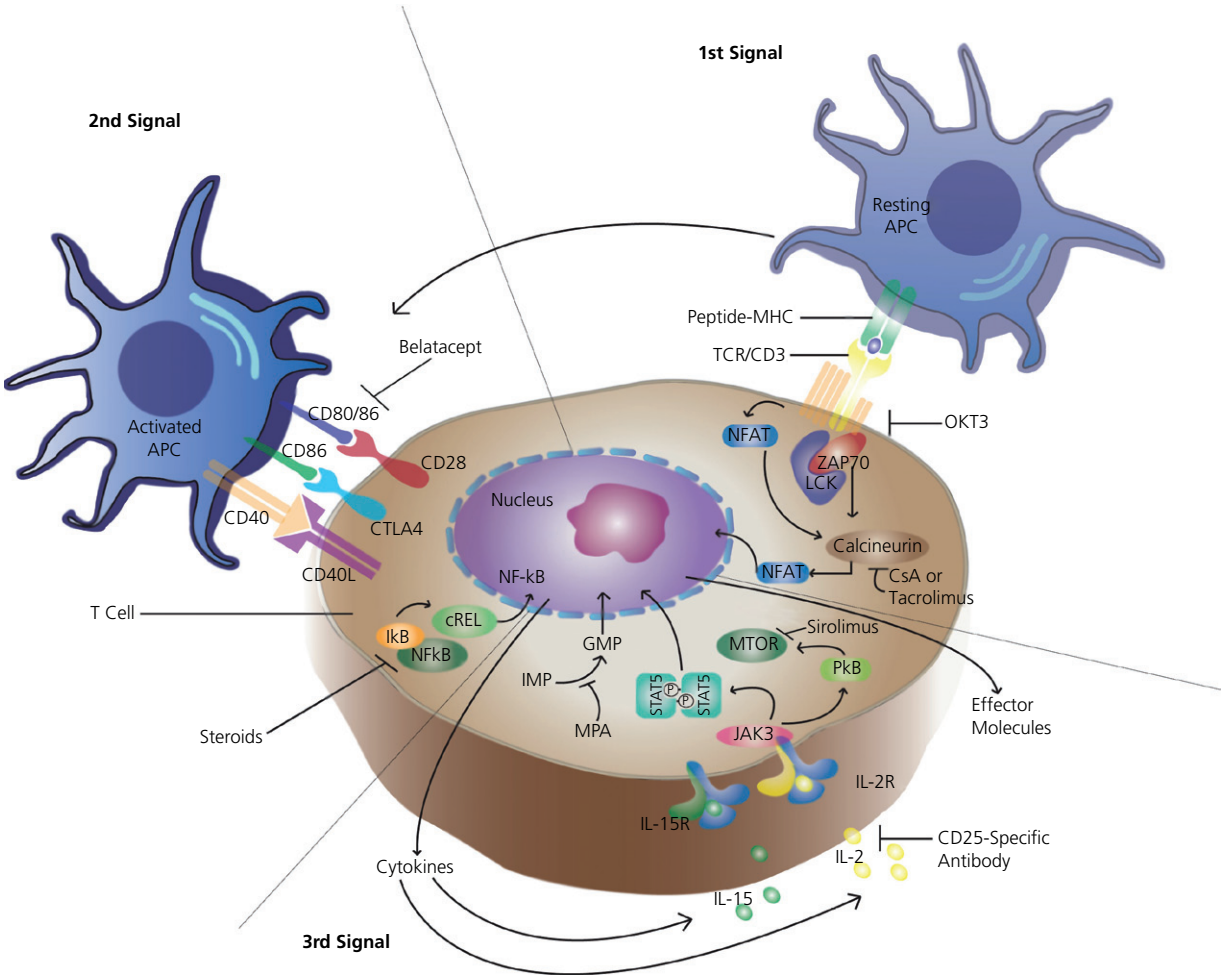

Figure 65.3. The three-signals model for T-cell activation. Signal 1 is the antigen-specific signal conferred by the TCR. Signal 2 is received by costimulatory molecules, and signal 3 is derived from postactivation cytokines. OKT3, CsA, and tacrolimus act on signal 1; belatacept and steroids act on signal 2 (and to some extent on signal 1 by limiting MHC expression); CD25-specific mAbs and sirolimus block signal 3. APC, antigen-presenting cell; CTLA-4, cytotoxic T lymphocyte antigen 4; GMP, guanosine monophosphate; IκB, inhibitory κB; IMP, inosine monophosphate; JAK3, Janus kinase 3; L, ligand; mTOR, mammalian target of rapamycin; NFAT, nuclear factor of activated T cells; NF-κB, nuclear factor κB; PKB, protein kinase B; R, receptor; STAT5, signal transducer and activator of transcription 5; TCR, T-cell receptor; TLR4, Toll-like receptor 4; ZAP70, zeta-chain-associated protein 70.

Alloantigen-stimulated activation is largely a process that occurs in secondary lymphoid tissues. Donor dendritic cells are activated at the time of transplantation and are mobilized to move to T-cell areas of secondary lymphoid organs (Figure 65.1). The chemotactic signals derived from a recently reperfused organ also attract recipient-type dendritic cells and other cells with mobile antigen-presentation capabilities (e.g. monocytes and macrophages) to the graft where donor antigen uptake can occur. These cells also migrate to the secondary lymphoid tissues. The resulting condition is one in which donor antigen is richly represented in the secondary lymphoid tissues and available for presentation to allospecific T cells. In this location, antigen-bearing dendritic cells engage naïve and central memory T cells in non-physiologically high numbers.

"Signal 1" is transmitted when an antigen on the surface of antigen presenting cells (APC) triggers T cells with the appropriate receptors through the CD3 complex. This process is labeled as direct antigen presentation when T cells are responding to donor-derived antigen-presenting cells; it is referred to as indirect antigen presentation when T cells are responding to recipient-derived antigen-presenting cells (Figure 65.4). Furthermore, antigen-presenting cells provide costimulation, also known as "signal 2", when CD28 present on T cells is engaged with CD80 and CD86 on the surface of dendritic cells. There are numerous costimulatory pathways, many of which (e.g. CD152, also known as CTLA-4) provide down-regulatory signals. Thus, the combination of signal 1 and signal 2 can lead either to antigen-specific activation or antigen-specific anergy. The details of this are outlined in Chapter 5. At the time of transplantation, generally CD28-derived activating costimulation signals tend to dominate. Thus, signals 1 and 2 activate three signal transduction pathways in the T cell: the calcium–calmodulin calcineurin pathway, the RAS-MAP kinase pathway, and the nuclear factor kappa-B (NFκB) pathway. These pathways lead to the expression of many new molecules, including IL-2, CD154, and CD25. Ultimately, IL-2, IL-15, and other cytokines activate the target of rapamycin (TOR) pathway via JAK-STAT dependent signaling through the common gamma chain of IL-2 and IL-15 (and others) cytokine receptors leading to "signal 3", the trigger for recruitment of additional cells and enhanced cell proliferation, which leads to a large number of effector T cells [1].

Of note, B cells also are activated when antigen engages their antigen receptors in lymphoid follicles or extrafollicular sites, like the red pulp of the spleen, or even the transplanted organ. Specific therapeutic manipulation of this pathway, though important, is not, in general, clinically available. Consequently, within a short period of time the unrestrained immune response can mobilize effector T cells and alloantibody.

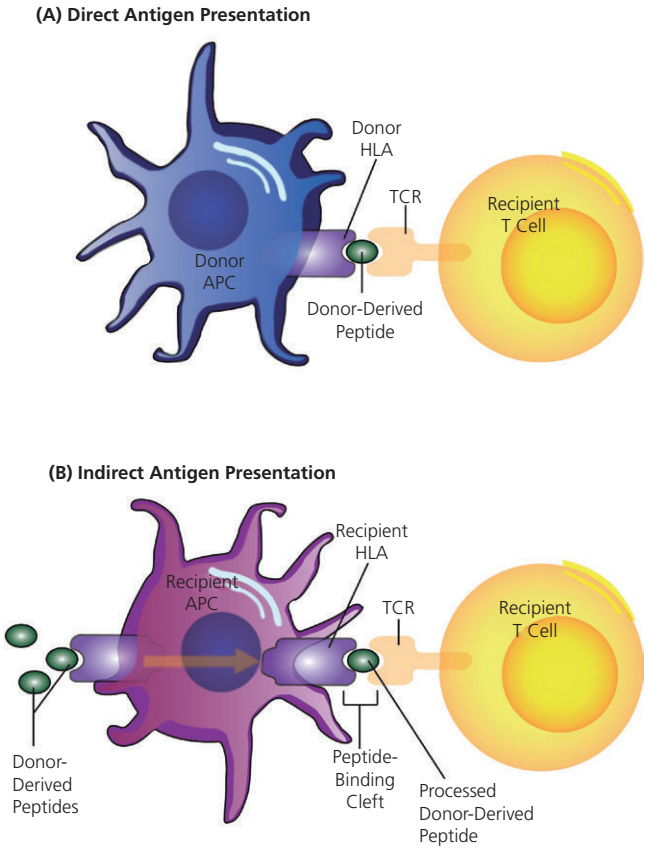

Figure 65.4. (A) Direct allorecognition. T cells responding to direct antigen presentation by donor-derived antigen-presenting cells (APCs) recognize determinants on the allogeneic HLA molecule as well as structures found on the bound peptide. (B) Indirect allorecognition. Indirect recognition requires antigen processing and presentation by recipient-derived APCs. HLA, human leukocyte antigen; TCR, T-cell receptor.

Precursor frequency

The allospecific T-cell precursor frequency is the number of T cells in the host immune repertoire that are able to respond to donor alloantigen, either through direct or indirect means. Unfortunately for transplant clinicians, in most recipients this donor-specific precursor frequency can be many logs-fold higher than the precursor frequency to any nominal antigen presented on a self-MHC. In other words, the number of T cells that are available in a recipient to respond to donor antigen is much higher than the number of T cells that can respond in a physiologic manner to a typical viral infection. Keeping in mind that immune responses are exponential in nature, a slight change in the initial donor-specific precursor frequency can pose a tremendous change in the immune response as a whole, and present rapidly escalating immunity that exceeds the regulatory controls that have evolved for much more conscribed responses. Figure 65.5 portrays the concept of precursor frequency in more detail and illustrates the effect of precursor frequency on clinical immune responses [2].

The effective precursor frequency differs widely among recipients and is mostly affected by the degree of MHC mismatch between donor and recipient. Matching the MHC, in effect, matches the recipient's thymic selection more closely to the MHC of the donor and, in doing so, assures a more appropriate T-cell precursor frequency for the incoming organ. Other factors that influence the recipients' precursor frequency are prior immune history and MHC sensitization (Figure 65.6). Up to 10% of the recipients' immune repertoire can be alloresponsive to a given donor. As such, the processes of activation that occur in the secondary lymphoid tissues are greatly (and non-physiologically) facilitated, making the chance for a productive APC–T cell interaction inevitable and much less likely to succumb to homeostatic regulatory pressure.

Memory T cells

Immunological memory is one of the characteristic features of the mammalian adaptive immune response and, in general, it makes secondary responses much more efficient than primary ones.

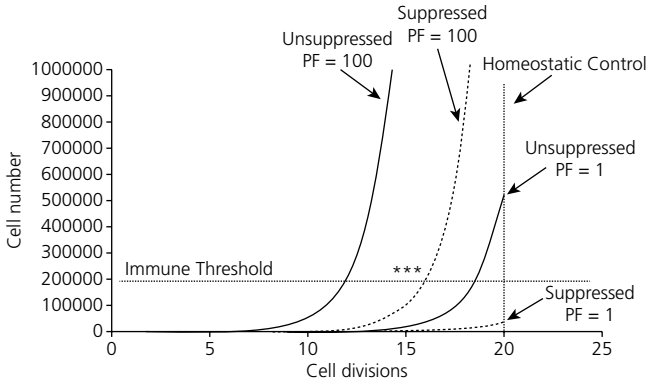

Figure 65.5. The effect of precursor frequency on clinically relevant immune responses. An efficient (or unsuppressed) immune response starting at a low precursor frequency (PF) can be surpassed by an inefficient (suppressed) immune response starting at a high precursor frequency. To mount an effective adaptive immune response, T cells must reach an "immune threshold" (theoretically a certain number or activity level), without exceeding the homeostatic control. During an optimal immune response under normal physiologic conditions (precursor frequency of 1 and no immunosuppression), T cells divide and proliferate (approximately 20 cell divisions; cell doubling at y = 0.5e0.69x) to reach the immune threshold and mount the immune response. The homeostatic control bar marks the end of T cell proliferation. When T cells are deprived of their costimulation (suppressed; and PF = 1; cell doubling at y = 0.03e69x), the homeostatic control point will be reached before the activation threshold, and this immune activity fails to register as an immune phenotype. On the other hand, raising the precursor frequency to 100 (unsuppressed cell doubling at y = 50e0.69x) will tremendously assist the immune activity reach the immune threshold to mount an immune response, way before the homeostatic control point. Even when suppressed, those cells at a precursor frequency of 100 will still reach the threshold of activation more efficiently than unsuppressed cells at a PF of 1.

Memory T cells pose a significant barrier to tolerance induction (Figure 65.7). They are the product of prior antigen exposure delivered in the setting of sufficient costimulation to induce cell division, and persist and survive as a pool of long-lived antigen-specific cells [3]. Memory T cells are characterized, based on surface phenotype, into central memory (Tcm) and effector memory (Tem). Central memory cells (Tcm) migrate to secondary lymphoid organs (lymph nodes, spleen) and, from those locations, generate bursts of new effector T cells upon recall. Effector memory cells (Tem) migrate to peripheral non-lymphoid sites and provide immediate effector function to foreign antigen (for example, alloantigen following organ transplantation) [3]. The common characteristic of both is an ability to reactivate with substantially less need for costimulation and fewer repetitions of MHC-TCR binding. As such, therapies that work well for naïve cells may fall short when directed against memory cells. Of note, memory cells tend to have reduced capacity for proliferation and reduced survival once reactivated. As such, this barrier, though substantial, can be attenuated with brief therapies targeted toward transient elimination, a principle of induction.

The influence on memory is manifest experimentally in considering the effects of costimulation blockade. In rodent models, depriving T cells from costimulation at the time of antigen presentation induces transplantation tolerance successfully [4]. However, this approach is less successful in outbred models (e.g. humans) and memory T cells are thought to be largely to blame. Specifically, memory T cells in young laboratory mice raised in specific pathogen-free conditions represent only 5–10% of the total T-cell compartment. On the other hand, over 50% of the T-cell compartment in humans and non-human primates is composed of memory T cells. This discrepancy can be explained by the difference in the environmental exposure and the resultant immune history. Thus, humans and socially housed non-human primates possess an armamentarium of potent memory T cells that is in a sense on standby to mount a barrier to transplantation tolerance induction [3].

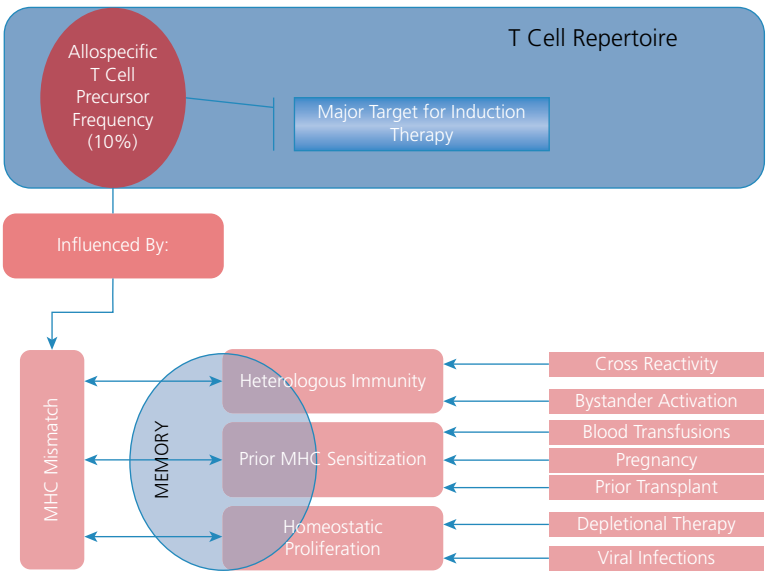

Figure 65.6. Allospecific precursor frequency is a major target for induction immunosuppression.

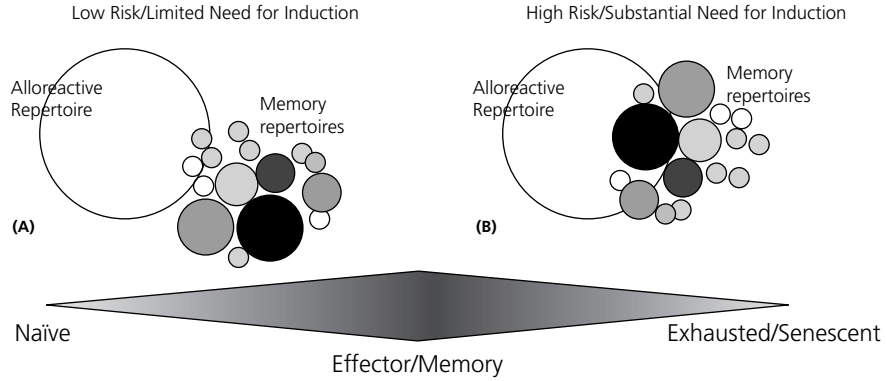

Figure 65.7. Conceptual scheme for induction. The spectrum of naïve T cells through expanded activated effector memory states, moving to senescent phase, is shown at the bottom of the figure. Looking at the allorepertoire and multiple viral reactive repertoires at variable stages of maturation, we would hypothesize that individuals with a very low degree of heterologous cross reactivity (A) will be at low risk for rejection, and individuals who have a high degree of cross reactivity (B) (with large expanded activated populations that are in fact incorporated in the alloimmune repertoire, represented by black circles) would be at a very high risk of rejection. So, if we can distinguish between A individuals and B individuals we might be able to tailor our immune management such that we would avoid complications and unnecessary risks.

In addition to their prevalence in adult humans, memory T cells exhibit an increased resistance to depletional therapy and are also less inhibited by the activity of regulatory T cells than naïve T cells. This large pool of memory T cells in adult humans stochastically contains a high frequency of donor reactive memory T cells, which imposes a major factor in determining the relative success of tolerance induction protocols during transplantation [5].

When developing a tolerance induction strategy for human patients, one must consider both the naïve component of the alloimmune response and the memory counterpart. This is important regardless of the pathway that generated those memory cells. In fact, several mechanisms have been described to explain the generation of donor-reactive memory T cells. These include heterologous immunity, homeostatic proliferation, prior MHC sensitization, and T cells with dual receptors. The relationship between memory and alloimmunity is described briefly below, but covered in depth in Chapter 9.

Heterologous immunity. Previous immunological exposures can influence the course of future responses to completely unrelated stimuli. At least two mechanisms can explain this phenomenon: T-cell cross reactivity and bystander activation [6]. A normal immune response to a pathogen, like a virus, occurs when APCs process the viral proteins and present antigenic peptides complexed to self-MHC molecules in secondary lymphoid organs. Molecular mimicry, leading to T-cell cross-reactivity, occurs when this viral antigen–self-MHC complex imitates a foreign MHC molecule containing self-peptide. Alternatively, a heterologous response could occur through bystander activation, when viral-specific T cells release growth factors, cytokines, and inflammatory mediators, thus activating bystander alloreactive T cells in a non-specific manner [6] (Figure 65.8).

Homeostatic proliferation. T cells can extensively proliferate under conditions of lymphopenia, a process named homeostatic proliferation. This process shows high resistance to costimulation blockade and generates alloreactive memory T cells that show resistance to tolerance induction. Clinically, lymphopenia can be induced by a viral pathogen or by therapeutic depletion of T cells for the treatment of autoimmune disease or organ transplantation. The residual T cells undergo rapid division and acquire a memory phenotype, hence posing a strong barrier to transplantation tolerance [7].

MHC sensitization and other mechanisms. Prior exposure to antigens can occur through pregnancy, blood transfusions, and transplantation. Recently, it has become apparent that other mechanisms exist by which donor reactive memory T cells might be generated. Memory T cells specific for a pathogen-derived epitope have in some cases been shown to express a second T-cell receptor that can be alloreactive [8].

Tissue injury mechanisms necessitating induction therapy

Injury and immunity are intimately associated in that injury leads to exposure to pathogens, and pathogens themselves ultimately cause tissue destruction—a vicious circle. Types of injury include endothelial damage, complement activation, ischemia and reperfusion, surgical wounding in the recipient, donor injury, and brain death, and all impact the intensity of the immune response. These factors propel immunity by increasing the effectiveness of antigen presentation, and the trafficking of cells to the transplanted organ and its draining lymph nodes [9]. Recognition of, and response to, injury is typically viewed as a role of the innate immune system, which is covered in depth in Chapter 7.

Several other aspects of injury conspire to promote alloimmunity. For example, complement deposited within a reperfused transplanted organ can facilitate naïve T-cell activation. Ischemia and reperfusion have been shown to increase costimulatory molecule expression, thus leading to increased efficiency of both resident and migratory APCs, and also improving the response of engaged T cells. Furthermore, the cytokine milieu created right after reperfusion strongly favors activation and differs markedly from that seen months after engraftment [9]. Damaged endothelium and parenchyma secrete chemokines that attract effector cells to the organ; at the same time, reperfusion injury initiates APC mobilization to the lymph nodes and spleen. Both of these events increase the possibility of a specific T cell meeting its suitable APC or target antigen, thus creating a locally enhanced T-cell precursor frequency [9].

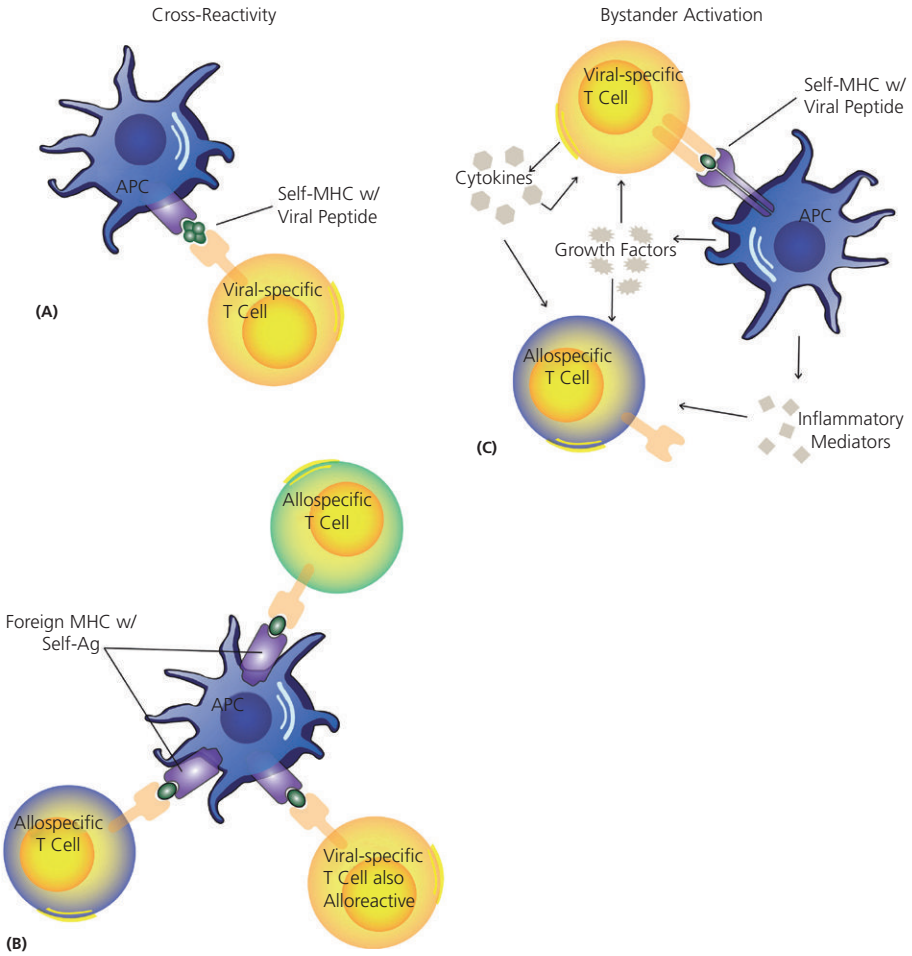

Figure 65.8. Heterologous immune response: (A) normal immune response. APCs process a viral protein and present the antigenic peptides complexed to self MHC; (B) cross-reactivity through "molecular mimicry"; (C) bystander activation.

Organ susceptibility as a variable in the need for induction therapy

It is important to keep in mind that transplanted organs markedly differ with regard to their susceptibility to injury. For example, a heart needs to function immediately and continuously and is dependent on the electrical activity of the conduction system (a small volume of tissue); it also is susceptible to the negative inotropic effect of local cytokines. Contrast this to a kidney, which can fail for several weeks and still regenerate its tubules and function even after a marked injury, or a liver, which can regenerate over half its mass in response to injury. Furthermore, the need to avoid immunity is greater in older organs with pre-existing injury. Thus, the magnitude of an acceptable immune insult varies widely not solely based on the size of the response, but also on the ability of the organ to withstand the response and still recover in sufficient time to be of use. In summary, a survivable alloimmune response varies not only from patient to patient, but also from organ to organ and donor to donor. Consequently, the perioperative immunosuppression required to obtain a good outcome also varies [9].

Linking the above factors to a clinical scenario is complex and has yet to be achieved in a prospective quantitative approach. Still, one can, in a very broad sense, identify that there are various considerations at play. Factors like age, prior pregnancies, EBV status, prior organ transplantation, MHC match, donor clinical condition, and ischemia time are to be taken into consideration. Ideally, induction therapy would be tailored to the specific characteristics of the recipient and donor [9]. In practice, however, a finely tuned means of assessing the myriad circumstances at play in a quantitatively proportional way has not been developed. As such, general approaches are taken to address common themes of early immune activation, and induction agents are used based on broad institutional or demographically based guidelines.

Targeting specific elements of an initial immune response

The term immunosuppression has a very broad meaning and gives no specific information about a patient's risk of rejection. Since each patient receiving an organ has a unique immune history and each graft has its unique vulnerabilities, induction therapies should then vary in their required intensities, duration, and target. The most reasonable approach is to look at those variable factors that warrant induction therapy and choose medications that address specifically those factors (Table 65.3).

Targeting precursor frequency

Depletional induction agents can non-specifically reduce precursor frequency. Depletional agents include polyclonal anti-T lymphocyte/thymocyte preparations (thymoglobulin, ATGAM,

Table 65.3. Immunosuppressive medications that can lower T-cell activation threshold

Immunosuppressive Drug	Mechanism of Action
Calcineurin inhbitors	Decrease signal transduction
Anti-TCR antibodies	Limit efficiency of TCR binding
mTOR inhibitors	Limit the effect of activating cytokines
IL-2R antagonists	Limit the effect of activating cytokines
Glucocorticoids	Change nuclear proteins avaliable to TCR
Costimulation antagonists	Block CD28 engagement

ATG-Fresenius), and monoclonal preparations specific for common lymphocyte determinants like CD3 (OKT3) and CD52 (alemtuzumab). These agents mediate rapid T-cell depletion with varying degrees of durability and tolerability. In doing so, they reduce the number of cells available to harm the graft and, ideally, reduce the allospecific T-cell frequency to more closely approximate that of a physiologic immune response. An important observation is that not all T cells are depleted equally. T cells with a memory phenotype are less susceptible (still susceptible but proportionately less so) to antibody-mediated depletion than are naïve T cells (likely a reason they are tolerated despite markedly reducing the T-cell count). It is also important to note that following partial T-cell depletion, the remaining T cells undergo homeostatic proliferation, thus creating a population of T cells with a memory-like phenotype. This considerably lowers the threshold of activation of each cell, leaving remnant cells that are relatively more active and potent. Thus, following depletion, patients are capable of rejecting with very few T cells. As such, depletion always requires additional immunosuppression as the recipient emerges from the depletional therapy. Clinical trials using aggressive depletion with OKT3, alemtuzumab, or thymoglobulin have all been performed without additional maintenance immunosuppression and shown rejection as soon as T-cell repopulation begins, even with T-cell counts of less than 10 cells/μl.

One theoretical way of avoiding the bulk activating effects of post-depletional homeostatic activation is to target specifically activated T cells. IL-2R (CD25)-specific monoclonal antibodies (daclizumab and basiliximab) were designed with this in mind. Although designed with hopes of selective depletion, their clinical effect has been modest with little or no depletional capacity.

Donor-specific transfusions (blood or marrow) have been shown to facilitate allospecific T-cell depletion when combined with agents that promote activation-induced cell death (AICD). Theoretically, providing donor antigen to activate a cell while at the same time depriving it of signal 3, the cytokines required to promote its division, leads to apoptosis. Among these agents are the mTOR inhibitors (sirolimus and everolimus). The possible mechanisms by which donor-specific transfusion works include clonal deletion, activation of regulatory T cells, anergy, and chimerism. Regardless, the effects of this, though evident in experimental models, have not been shown to be practically operative in general clinical situations.

Targeting antigen presentation

As mentioned earlier in this chapter, two different dynasties of APCs are available after organ transplantation to initiate rejection: those derived from the donor (involved in direct presentation) and those of the recipient (involved in indirect presentation) (Figure 65.4). Both can lead to rejection; however, donor-derived APCs likely influence the initial risk of rejection most as they tap into the bulk of the alloreactive T-cell repertoire.

Numerous steps can be taken to limit APC mobilization, beginning with good preservation technique and expedient transplantation. This limits factors such as oxidative stress that have been shown to influence APC activation and function. From a therapeutic medication standpoint, methylprednisolone is used almost without exception at the time of organ reperfusion, and is known to decrease APC trafficking. While it is common to dismiss bolus steroid use as not "truly" being induction, in fact it is one of the more effective induction strategies, and has been accepted as such to be considered just part of the transplant procedure rather than a specific induction approach.

Polyclonal antibody preparations have antiadhesion effects. Therefore they potentially block APC activation and trafficking, and this might differentiate polyclonal preparations from monoclonal preparations in that the former have a mechanistic reach extending beyond mere depletion. Deoxyspergualin (DSG) has also been found experimentally to block APC activation, and has been used anecdotally on this basis without substantial effect [10]. Costimulatory molecules are crucial in APC function. Most prominent are the B7 molecules, CD80 and CD86. Biologic agents have been specifically designed to block this pathway, the most advanced of which is belatacept [11]. Belatacept has been studied as a maintenance drug, but may have some effect on the initial APC function. Data do not support it as having substantial efficacy over and above general maintenance agents, even when used at the time of transplantation.

Targeting the threshold of activation

Many factors are involved in T-cell activation. T cells reach an activation threshold as a result of marked antigen affinity, excessive antigen presentation, or weak antigen presentation supplemented by optimal costimulation, or even abundance of stimulatory cytokines in the T-cell immediate environment. Given that T cells are crucial for organ rejection, most commercially available immunosuppressive drugs alter the T-cell activation sequence of events (Table 65.3). These effects are covered in depth in Chapter 17. With regard to the use of standard immunosuppressive drugs with induction in mind, most clinicians view achievement of therapeutic drug levels early post transplant to be an important goal. As such, aggressive dosing of calcineurin inhibitors, antimetabolites, and mTOR inhibitors all have been explored. In general, the tolerable doses of these drugs are limited by toxicities and, as such, high "induction dose" use of drugs altering T-cell activation is limited. Alternatively, glucocorticoids can induce a change in the nuclear binding proteins available for a signal transmitted through the T-cell receptor, and likely influence this mechanism, adding to its efficacy as an induction agent.

Targeting cell trafficking

Ischemia and reperfusion promote cell trafficking toward the transplanted organ through a multifactorial process, which includes adhesion receptor up-regulation, endothelial retraction or damage, and chemotactic cytokine release [12]. This phase of the alloimmune response is gaining wide recognition as worthy of specific targeting. In general, glucocorticoids limit adhesion molecules expression and polyclonal antilymphocyte medications also have antiadhesion molecule effects. As such, this mechanism has been cited as being in part responsible for the rationale of methylprednisolone and/or polyclonal antibodies during the induction phase. However, numerous investigational agents are being considered based on the importance of trafficking at the time of reperfusion.

Integrins play a vital role in leukocyte activation and trafficking to sites of inflammation. Found on a variety of immune cells, including T cells, B cells, neutrophils, and macrophages, integrins are heterodimeric cell surface receptors that mediate adhesion between these cells and other cells in their immediate environment. In particular, leukocyte function-associated antigen-1 (LFA-1) and very late antigen-4 (VLA-4) are the most studied integrins. LFA-1 plays a vital role in the formation of the immune synapse between T cells and antigen-presenting cells, while both LFA-1 and VLA-4 have been shown to play a role in the arrest of rolling lymphocytes at sites of inflammation and the migration of T cells into sites of inflammation. Integrin antagonists are discussed later.

One class of agents specifically targets the chemokine pathways that are essential in cell homing and trafficking. In particular, sphingosine-1-phosphate (S1P) is a critical element in the regulation of chemokine sensitivity and theoretically represents an interesting target for blockade. Fingolimod (FTY720) was designed to bind to S1P and leads to internalization of this molecule, thus inhibiting lymphocyte migration from the secondary lymphoid organs. It has been shown to reduce the rate of relapses in relapsing–remitting multiple sclerosis. Unfortunately, fingolimod has been found to have a first-dose bradycardia effect that has limited its development in transplantation.

Clinical results with specialized induction agents

Many agents are clinically available to target the components of alloimmunity that are amplified shortly after transplantation. Several of these agents have been studied in clinical trials in combination with standard maintenance regimens and shown to be efficacious, but few prospective studies have compared the prominent agents and no agent has distinguished itself as clearly superior in all situations. Most trials have used the surrogate endpoint of early acute rejection rather than a more definitive endpoint of patient or graft survival. Almost all trials have layered "specialized" induction agents on an induction base of bolus methylprednisolone.

When compared to a standard bolus of methylprednisolone induction, specific induction agents considered as a whole have been shown to reduce the incidence of early biopsy-proven acute rejection (BPAR) in kidney recipients, particularly those who are allosensitized and on the historical standard of cyclosporine (CsA), azathioprine (AZA), and prednisone [13,14]. Induction in simultaneous kidney–pancreas transplantation offers a modest trend toward reduction of rejection [15,16], and its efficacy in heart transplantation remains controversial [17]. Induction has not been shown to benefit liver transplantation. Long-term analysis has failed to show a measureable effect in kidney transplantation after 5 years [13], likely because the effects of maintenance therapy and recipient co-morbidities become dominant over time.

As with all forms of aggressive immunosuppression, induction therapies have been associated with increased incidences of infectious and malignant complications. The benefits of induction do not come at the cost of higher technical complications [18]. However, several induction strategies measurably increase the risk of post-transplant lymphoproliferative disease (PTLD) and death from malignancy when combined with conventional maintenance immunosuppression [19,20]. Specifically, the expected PTLD rate is 0.5% in patients who do not receive specialized induction, or who receive CD25-specific therapy. OKT3 induction increases the risk to 0.85% as does polyclonal depletion at 0.81%, particularly in recipients newly exposed to the Epstein–Barr virus at transplantation. Given this trade off, it remains unclear whether long-term outcomes are improved by induction therapies. Regardless, the reduction in early rejection does ease the early management of a transplant recipient, and this has led to a general increase in induction therapy use. Table 65.4 summarizes the monoclonal and polyclonal antibodies used in induction.

Table 65.4. Monoclonal and polyclonal antibodies

Name	Form	Source	Target
AntiThymocyte Globulin (ATGAM)	Polyclonal	Horse	Anti-CD2, CD3, CD4, CD8, CD11a, CD18, CD25, CD44, CD45, HLA-DR1
AntiThymocyte Globulin (Thymoglobulin)	Polyclonal	Rabbit	
Muromonab (OKT3)*	Monoclonal	Mouse	Anti-CD3
Basiliximab (Simulect)	Monoclonal	Recombinant (chimeric)	Anti-CD25
Daclizumab (Zenapax)#	Monoclonal	Recombinant (humanized)	Anti-CD25
Alemtuzumab (Campath)	Monoclonal	Recombinant (humanized)	Anti-CD52

*Withdrawn from global market in 2009; #Withdrawn from US in 2009

Muromonab-OKT3

OKT3 (muromonab-CD3; Orthoclone OKT3, Janssen-Cilag) is a mouse IgG2a antihuman CD3 antibody which was the first monoclonal antibody approved for induction therapy. OKT3 binds at the epsilon chain of the CD3 protein, resulting in the transient activation of circulating T cells and their release of cytokines (IL-2, -3, -6, IFN-γ); eventually, opsonized T cells undergo massive lysis and disappear from the circulation [21].

Muromonab was first introduced in the early 1980s and quickly shown to be efficacious in treating acute rejection. Despite its clinical success, its adverse side-effect profile was challenging, most secondary to the immense cytokine release from T cells inducing a clinical cytokine release syndrome which included hypotension, fever, nausea, vomiting, and pulmonary edema. Rarely, OKT3 caused aseptic meningitis or intragraft thrombosis. Furthermore, being a mouse antibody, patients developed antimurine antibodies that limited OKT3's usefulness after the first dose. Other major side effects of OKT3 were PTLD, fungal infections, and CMV infection. As a result, OKT3 was removed from the market and is mentioned here for historical purposes [21]. A number of humanized OKT3 Fc variants have been developed with attempts to achieve the antirejection effects without cytokine release; however, none have been shown to be useful in the setting of transplant induction.

Anti-CD25 antibodies

The side effects of the pandepleting muromonab was substantial incentive for the development of better-tolerated induction immunosuppression. As the cytokine IL-2 was well recognized as a prominent T-cell growth factor, basiliximab and daclizumab, both mABs targeted to the alpha subunit of the IL-2 receptor (CD25), were developed. Both competitively inhibit IL-2 binding and preventing T-cell expansion [21]. Most importantly, the serum sickness and expedited drug clearance associated with horse, mice, and rabbit

protein-derived mABs are absent with basiliximab (chimerized) and daclizumab (humanized). A theoretical advantage lies in the fact that these mABs target a receptor that is uniquely expressed by activated T cells.

Daclizumab and kidney transplantation. Daclizumab is a humanized IgG1 monoclonal antibody, introduced in 1998 after it was proven to be safe and efficacious in kidney transplantation in a prospective placebo-controlled trial [22]. On a background of triple therapy (AZA, CsA, steroids) or double therapy (CsA, steroids), daclizumab has been shown to modestly reduce BPAR at 6 months [23]. In other studies, daclizumab-treated patients, when compared to placebo, had a better graft function, a similar post-transplant lymphoproliferative disease incidence, and decreased infections with CMV [24–26]. Importantly, treatment with daclizumab did not induce a systemic inflammatory response syndrome (SIRS) or its associated symptoms.

Induction with daclizumab in the setting of triple therapy but with a lower dose of CsA was shown to be roughly equivalent to a standard CsA dose; unfortunately, weaning off CsA completely was associated with a significant increase in BPAR [27–29]. A regimen of daclizumab induction on the background of a triple therapy with mycophenolate mofetil (MMF), corticosteroids, and low-dose tacrolimus (TAC) was advantageous in terms of renal function, graft survival, and acute rejection episodes, when compared to regimens containing daclizumab induction with low-dose CsA or low-dose sirolimus, or standard CsA alone [30].

For high-risk patients, defined as patients who had lost a previous graft or had alloantibody (not donor specific), induction with the depletional agent rabbit antithymocyte globulin (RATG) on a background of triple therapy (MMF, TAC, steroids) was significantly more effective than induction with daclizumab in terms of steroid-resistant rejection and BPAR [31].

Daclizumab with other solid organs. Daclizumab has also been studied in liver, heart, and lung transplantation. In liver transplantation, daclizumab in a two-dose regimen had a similar effect to that observed in kidney transplantation [32]. Several studies showed lower acute rejection episodes with daclizumab when added to conventional MMF and TAC regimens and, more recently, several studies revealed that corticosteroids could be safely eliminated from this regimen [33–35].

In heart transplant patients, the standard five-dose regimen of daclizumab reduced the frequency of acute rejection episodes when compared to conventional immunosuppression. Eventually, a two-dose regimen of daclizumab was shown to be as effective as a five-dose regimen in heart transplant patients [36–39]. As for lung transplant patients, daclizumab was slightly superior to RATG in two controlled studies [40,41].

Although daclizumab was on the market for approximately 10 years, its use was discontinued in September 2009. This was largely related to market share competition with its contemporary, basiliximab, rather than for biological differences. The most prominent difference between daclizumab and basiliximab is the number of doses recommended for induction (five versus two, respectively) and this difference has swayed in favor of basiliximab.

Basiliximab in kidney transplantation. In a 1997 randomized, prospective trial of basiliximab induction on a background of CsA and steroids, compared to placebo, patients who received basiliximab had a lower 6-month BPAR, a lower incidence of steroid-resistant rejection, no evidence of the cytokine release syndrome, and a similar rate of infections and PTLD [42]. These results were again verified in three other trials at different institutions; induction with basiliximab in the setting of a triple background therapy (CsA, AZA, and prednisone) also showed a lower 6-month acute rejection rate [43–46]. Trials looking at single-dose basiliximab versus double doses showed that single-dose regimens (40 mg on post operative day 1) had a slightly better BPAR and acute rejection rates [47–49]. Most importantly, several trials have shown that in the setting of induction with basiliximab, calcineurin inhibitor-sparing regimens were well tolerated [50–52].

Furthermore, another study compared RATG plus delayed CsA to basiliximab plus CsA induction on a background of MMF and steroids. Graft survival rate, patient survival, and BPAR rates were comparable in both groups [53].

Basiliximab with other solid organ transplants. A two-dose basiliximab induction in liver transplant patients was well tolerated in clinical trials and effective at reducing BPAR rates (though to a lesser extent in HCV-positive patients) [54–56]. Interestingly, basiliximab allowed for a delayed TAC administration and a better renal function in liver transplant patients [57]. Most importantly, in HCV-positive patients, induction therapy with basiliximab with a steroid-free background showed a higher BPAR rates (39.4% basiliximab minus steroids vs. 24.3% basiliximab plus steroids) but better patient survival (84.3% without steroids vs. 61.0% with steroids). In addition, HCV recurrence was lower in the steroid-free regimen with basiliximab induction [58–60].

The jury is still out on the efficacy of basiliximab in heart transplant patients. In one trial, basiliximab induction was used to facilitate delayed CsA administration, thereby decreasing renal toxicities in post-heart transplant recipients [61]. Even comparative studies with RATG are still controversial [62,63]. A recent meta-analysis of several smaller studies has found little evidence that IL-2R-specific therapy improves outcome [64].

In lung transplantation, a recent analysis of the International Society of Heart and Lung Transplant Registry data have shown IL-2R-specific therapy to be beneficial in single and double lung transplant recipients [65].

Alemtuzumab

CD52 is a membrane glycoprotein with an unknown function. It is present on T cells, B cells, macrophages, monocytes, eosinophils, and cells of the male reproductive system. Alemtuzumab is a humanized IgG2b specific for human CD52, which has been used for induction and rescue therapy [66–69]. Its administration leads to rapid and effective T and B-cell depletion, and some degree of monocyte depletion. It is indicated for the treatment of lymphogenous malignancies, and is being developed as a therapy for multiple sclerosis. Although not specifically indicated for transplant induction, it has long been used off-label for this indication, and is now used in approximately 10% of kidney transplants performed in the USA. See Chapter 101 for an in-depth discussion of off-label drug use.

Alemtuzumab gained the attention of the transplant community following its use to facilitate low-dose CsA monotherapy in kidney transplantation [67]. Subsequent investigations explored its use as a tolerogen [68], clearly demonstrating that despite profound depletion, alemtuzumab did not induce tolerance, but rather facilitated low-dose maintenance therapy. Subsequent studies, combining it with more conventional immunosuppressive approaches, have

guided this agent into reasonably routine use [69–71], showing that it is effective in reducing the rate of BPAR, and provides a window of several months where maintenance immunosuppressive needs can be reduced, although in the absence of sufficient maintenance immunosuppression late BPAR is seen.

Comparative studies. Few well-controlled comparative studies have been performed using alemtuzumab, and this reflects its lack of a specific indication in transplantation and the fiscal implications this has on trial conduct. In an early trial using a historical control group, alemtuzumab was compared to basiliximab on a background of MMF and TAC. In this large single-center study, alemtuzumab-treated patients had a lower rejection rate at 3 months, but similar rejections rates at 1 year [70]. Other small studies followed, suggesting benefits of alemtuzumab induction with short-term follow-up [71,72].

The single most important study investigating alemtuzumab as an induction agent was a multicenter, randomized, controlled trial that stratified patients based on perceived rejection risk (defined by repeat transplant, a peak value of panel-reactive antibodies above 20%, or Black race) compared with low-risk patients randomized between basiliximab and alemtuzumab, and high-risk patients randomized between RATG and alemtuzumab [73]. The rate of BPAR was significantly lower in the alemtuzumab groups at both 6 (3% vs. 15%, $P < 0.001$) and 12 months (5% vs. 17%, $P < 0.001$). At 3 years, the rate of BPAR in low-risk patients was lower with alemtuzumab than with basiliximab (10% vs. 22%, $P = 0.003$), but among high-risk patients, no significant difference was seen between alemtuzumab and RATG (18% vs. 15%, $P = 0.63$). Adverse-event rates were similar among all groups. This study has done the most to establish alemtuzumab as a viable option for induction therapy, but has not convinced its maker, Sanofi, to seek an indication in transplantation.

Alemtuzumab has not been systematically or extensively studied in extrarenal organs. One study compared alemtuzumab and low-dose TAC to conventional TAC and steroids in liver transplant recipients. Alemtuzumab-treated patients needed less steroids for maintenance, had less renal toxicity, and, most importantly, the incidence of acute rejection at 1 year was lower with a longer median time to rejection [74]. Lung transplant patients suffering from refractory acute rejection or bronchiolitis obliterans syndrome received alemtuzumab. The histological rejection scores in rejection did improve, as did freedom from broncholitis at 2-year follow up [75]. These liver and lung studies show that alemtuzumab might have some benefits in organs other than the kidney.

Polyclonal antibodies

Several polyclonal antibody preparations have been explored, beginning in the earliest days of transplantation. Polyclonal antibodies are heterologous antibody preparations that are produced by whole-cell immunization of a variety of animals, with the clinical preparations being derived from either rabbits (RATG) or horses (ATGAM). Rabbit preparations are overall noted to be the most effective in multidrug renal transplant immunosuppression protocols [76,77]. Polyclonal antibodies contain antibodies that exhibit binding specificities to a variety of cellular antigens, including TCR cell-surface markers involved in antigen recognition, T-cell adhesion, and costimulation (e.g. CD2, CD3, CD4, CD8, CD11a, CD18, CD25, CD44, CD45), as well as MHC molecules and non-T-cell molecules.

The affinity spectrums for polyclonal antibody preparations are diverse and variable. Even the clinically approved RATG and ATGAM agents designed to contain only IgG remains diverse, highly immunogenic and consequently associated with a vast array of undesired adverse effects, including pancytopenia [78,79]. Currently, three preparations are used clinically: antithymocyte immunoglobulin-R (ATG-R or RATG), antithymocyte globulin-Frensius (ATG-F), and ATGAM (horse prepared). While all are used to some extent, by far the most commonly used is RATG, the result of comparative trials showing its higher efficacy in kidney transplantation [80]. The dominant mechanism of action of polyclonal preparations is currently unknown but has been inferred to be related to a combination of precursor frequency reduction, inhibition of leukocyte adhesion, and blockade of accessory molecule signals required for lymphocyte activation.

The side-effect profile of polyclonal antibody induction is well documented. Cytokine release syndrome tends to be the most common adverse effect observed with therapy, affecting up to an estimated 20% of all treatment recipients. This physiologic phenomenon is thought to be caused by a similar means to that discussed above for muromonab, but in general is substantially less severe. Additionally, these drugs generally require administration via central venous access to minimize the risk of thrombophlebitis. Other concerning adverse effects relate to their potent immunosuppressive effects and include PTLD, opportunistic infections, and reactivation of latent herpesviruses. Dose-limited side effects include leukopenia and thrombocytopenia, serum sickness, and anaphylaxis.

Polyclonal antibodies in kidney transplantation. Polyclonal antibody preparations are used for induction for approximately 50% of all kidney transplant recipients in the USA. The rates are lower in Europe and elsewhere in the world. To date, most trials have been designed to evaluate polyclonal antibodies added to an otherwise rigorous maintenance regimen, and, as would be anticipated, this intense approach has both reduced acute rejection rates and increased infectious morbidity [81,82]. Given that polyclonal antibodies target many of the mechanisms compelling induction and have lasting effects both in terms of CD4 depletion and cell surface molecule modulation, recent trials have been designed to reduce the need for maintenance therapy. Two pilot studies have demonstrated that RATG facilitates monotherapy maintenance immunosuppression in selected patients with graft and patient survival comparable to the current standard [83,84]. Longer follow-up has suggested that upon lymphocyte repopulation, late rejections can be seen, and, as such, the advisability of this approach remains a matter of debate.

Trials dating back to the pre-CsA era have shown that RATG induction delays early acute rejections [76]. More contemporary trials have shown RATG to be more efficacious and better tolerated in most situations compared to ATGAM [85,86]. As modern concerns have turned toward cost analysis, evidence has suggested that the modest long-term benefits of polyclonal induction may not warrant the additional cost associated with their purchase and administration [87].

The most robust evidence defining the proper use of polyclonal induction has been provided in the form of a randomized, prospective trial comparing RATG to basiliximab in patients deemed at high risk for acute rejection or delayed graft function [88]. In this study, 278 patients were randomized to RTG or basiliximab. The RATG group had less BPAR (15.6% vs. 25.5%, $P = 0.02$) and less

steroid resistant rejection (1.4% vs. 8.0%, $P = 0.005$), but no differences in the incidences of graft loss (9.2% and 10.2%, respectively), delayed graft function (40.4% and 44.5%), and death (4.3% and 4.4%). The incidences of adverse events, serious adverse events, and cancers did not differ but those patients receiving RATG had higher rates of infection (85.8% vs. 75.2%, $P = 0.03$) but, paradoxically, less cytomegalovirus disease (7.8% vs. 17.5%, $P = 0.02$). Thus, polyclonal induction has a role in the management of high-risk patients in that it reduces the BPAR rate, but it does not alter the rate of delayed graft function or improve long-term outcomes.

Extrarenal use of polyclonal antibodies. Both ATG-R and ATG-F have been prospectively demonstrated to be superior to OKT3 in heart transplantation with respect to reducing the rate and consequences of acute rejection [89,90]. When compared to each other, their results have been equivalent in heart transplantation [91]. Induction appears to be most beneficial for patients with the highest risk of rejection (African Americans, allosensitized patients, patients dependent on a ventricular assist device); otherwise, induction therapy with polyclonal antibodies in heart transplant patients is associated with a higher incidence of infectious complications and malignancies [21]. Polyclonal induction agents have not been shown to be of use in liver transplantation [92], although induction with RATG can be employed to delay calcineurin inhibitor introduction in patients with a pre-existing renal failure [93].

In lung transplantation, RATG on a background of triple therapy was found to reduce the rejection episodes with no effect on the incidence of bronchiolitis obliterans syndrome [94]. Analysis of the International Society of Heart and Lung Transplant Registry indicates that a benefit to induction with RATG is evident in recipients of double lung transplants [65].

Investigational agents of note

Antiadhesion drugs. Given the clear role of adhesion molecules in the trafficking of lymphocytes to the graft and the draining secondary lymphoid organs, the blockade of the adhesion has long been conceptually attractive as an induction strategy. Several approaches have been explored and remain of potential importance.

LFA-1 (leukocyte function-associated antigen 1), a B2 integrin, is present mainly on the surface of T cells, and has two distinct functions: (1) cell arrest and migration on surfaces that express an LFA-1 ligand (intracellular adhesion molecule-1, ICAM-1); and (2) contact with APCs and stabilization of an immunological synapse. LFA-1 helps T cells withstand the shearing force of blood flow, and helps T cells create a firm adhesion and transmigration into the site of injury [95].

Efalizumab (Raptiva; Genentech) is a humanized LFA-1 IgG1 antibody that was initially approved for psoriasis treatment in 2003. Vincenti et al. studied efalizumab induction in 38 kidney transplant patients receiving standard triple maintenance immunosuppression [96]. The study suggested efficacy in that the rate of rejection was low, but the immunosuppressive potential added to an already effective regimen was excessive, leading to several cases of PTLD. Subsequent use in islet transplantation demonstrated remarkable tolerability and efficacy in two pilot studies [97,98]. These studies inspired a resurgence of interest, which was unfortunately halted by efalizumab's removal from the psoriasis market in 2009. As the drug's only indication was psoriasis, off-label use in transplantation has stopped.

Alefacept (Amevive; Astellas) is an LFA-3/IgG1 fusion protein that, like efalizumab, was indicated for psoriasis. Preclinical data in primates was promising in showing that alefacept provided a depletion of memory T cells and as such facilitated costimulation-blockade based immunosuppression [99]. While its logical use would be in this setting, the development of alefacept moved to the clinic as an agent added to a TAC-based regimen, and, in this setting, no efficacy was demonstrated. Regardless, like efalizumab, alefacept has been withdrawn from the psoriasis market, making it unavailable for off-label investigation in transplantation.

TNF inhibitors. TNF blockade, with the TNF-specific mAb infliximab, or more recently with the TNF receptor antagonist etanercept, is commonly used in inflammatory bowel disease, where its efficacy has been clearly demonstrated. In transplantation, TNF-specific therapy has been used as an induction agent in islet cell transplantation. Although it has been shown to be effective in rodent models [100], its use in islets has been based on uncontrolled common usage.

Etanercept was used in the induction phase along with antithymocyte globulin and daclizumab in eight human recipients of single-donor marginal-dose islet transplantation. All recipients achieved insulin independence and freedom from hypoglycemia [101]. Etanercept also was studied in patients receiving supplemental islet transplantation (those are patients who received allogeneic islet cell transplantation with progressive graft dysfunction). Despite the small sample size and lack of randomization, the results suggested an improvement in engraftment, long-term survival, and function [102]. More recently, etanercept was used in 17 patients with graft dysfunction receiving supplemental islet infusions. Induction therapy consisting of etanercept and thymoglobulin was used in 13 patients, while four patients received daclizumab induction. Maintenance consisted of sirolimus and TAC or TAC plus MMF. There was no difference in the insulin independence rates or durations between the two induction regimens used [103].

Summary

Induction therapy is now a common practice in most transplant surgery programs in the United States (in all if bolus methylprednisolone is considered). As detailed in this chapter, precursor frequency, innate immunity, tissue injury during transplantation, and ischemia reperfusion injury are the main factors compelling the use of induction therapy. Its benefits are centered on the decrease in the rate of early acute rejection episodes and a general simplification of the early perioperative immune management of patients, compensating for early low drug levels, and reducing the likelihood of rejection when non-rejection related causes of dysfunction are more common (e.g. reperfusion injury, technical issues). Thereafter, the benefits of induction remain less well defined, but may include incremental reductions in rejection balanced by an increased risk of infections (viral and fungal) and malignancies (virally induced cancers, PTLD). As such, the use of induction therapy should be considered based on the individual risks of the patient and their particular organ, and chosen to match the biological factors most likely to influence those risks.

CHAPTER 66

Maintenance Immunosuppressive Therapy

Introduction

Advances in immunosuppressive strategies over the past decades have led to significant improvements in the field of solid organ transplantation. Cyclosporine revolutionized transplant practice by lowering acute rejection rates and improving *short-term* graft survival in the 1980s (see Chapter 1). In the 1990s, post-transplant outcomes improved with tacrolimus and mycophenolic acid. Despite these advances, clear evidence for a beneficial effect on *long-term* graft survival is lacking, especially in the field of renal transplantation. Additionally, significant improvements in early graft survival have come at the expense of associated adverse side-effects, including metabolic side-effects that increase the risk of cardiovascular and cerebrovascular disease. The use of newer immunosuppressive agents, including the mammalian target of rapamycin (mTOR) inhibitors and belatacept, are being incorporated into evolving strategies that aspire to minimize lifelong exposure to calcineurin inhibitors and corticosteroids and improve long-term survival rates.

In an effort to improve outcomes, clinicians have used several general maintenance immunosuppression strategies that are applicable regardless of the organ transplanted. One approach involves assessing patient risk factors for rejection. Patients at higher risk for rejection may receive more potent immunosuppression—either higher doses or longer duration of therapy—while patients at low risk for rejection may receive less potent immunosuppression. Immunosuppression may also be adjusted based on the time after transplant. Immediate postoperative needs are different from long-term maintenance therapy needs. Other management strategies involve monitoring viral infections, which appear to be a sign of excessive immunosuppression and may guide immunosuppressive adjustment and reduction. Likewise, maintenance immunosuppression adjustment may be beneficial in patients with malignancy or recurrent disease.

An ideal immunosuppressive regimen limits toxicity and prolongs the functional life of the graft. This chapter will review maintenance immunosuppressive strategies and provide an overview of the pivotal trials in kidney, pancreas, lung, liver, heart, and intestinal transplant.

Trends and types of maintenance therapy

Immunosuppression regimens for transplant recipients change over time and vary by center. Currently, the five drug classes that comprise maintenance regimens include calcineurin inhibitors (cyclosporine and tacrolimus), mTOR inhibitors (sirolimus and everolimus), antiproliferative agents (azathioprine and mycophenolic acid), costimulatory blockers (belatacept), and corticosteroids (Tables 66.1 and 66.2). The mechanisms of these drugs are covered in detail in Chapter 17, and their approved indications are covered in detail in Chapter 98. In the past two decades, tacrolimus has been substituted for cyclosporine, and mycophenolic acid has been substituted for azathioprine as primary therapy in most US transplant centers, making tacrolimus plus mycophenolate mofetil/mycophenolate sodium, with corticosteroids the most common maintenance immunosuppressive regimen (Figure 66.1A–F). When considering data from the US Scientific Registry for Transplant Recipients (SRTR), there are few deviations among the commonly transplanted solid organs (Figure 66.2). Currently, a majority of lung transplant recipients receive tacrolimus and mycophenolate, but 20% of patients are discharged on a combination of tacrolimus and azathioprine [1]. Secondly, most intestine transplant recipients receive tacrolimus without mycophenolic acid, most likely due to the gastrointestinal side-effects of mycophenolate [1]. Lastly, approximately 20% of heart transplant recipients receive cyclosporine, while the majority receive tacrolimus [1].

Maintenance immunosuppressive therapy can be classified as quadruple, triple, dual, or monotherapy. Quadruple therapy consists of an induction agent at the time of transplant, followed by triple maintenance therapy. Triple therapy, a three-drug regimen, is the most commonly used maintenance regimen because it targets various sites of the immune response, and drug synergies allow minimization of drug toxicity. Historically, the main goal of immunosuppressive therapy was to prevent acute rejection and allograft loss. The relative achievement of these goals has shifted the focus to strategies that minimize immunosuppressive therapy and associated infection and toxicity without compromising efficacy. Therefore, some centers use corticosteroid- or calcineurin inhibitor-sparing regimens in the hope of attaining these goals. There are two principal steroid-sparing strategies: (1) steroid withdrawal/ avoidance and (2) steroid free. These regimens consist of corticosteroids for a short period after transplant or no corticosteroids at all, respectively. According to current data, there has been a movement to withdrawal of corticosteroids in renal, liver, and pancreas transplants, while most heart, intestine, and lung transplant recipients still receive corticosteroids (Figure 66.3) [1]. Many of these regimens consist of two maintenance medications or dual maintenance

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Table 66.1. FDA approved immunosuppressive medications used for transplantation

Drug	Dose	Side-effects
Prednisone	Maintenance: 2.5–10 mg/day Rejection: 250–1000 mg/day × 3 days i.v.	Mood disturbances, psychosis, cataracts, hypertension, fluid retention, peptic ulcers, osteoporosis, muscle weakness, impaired wound healing, glucose intolerance, weight gain
Cyclosporine	4–5 mg/kg p.o. twice daily	Neurotoxicity, gingival hyperplasia, hirsutism, hypertension, hyperlipidemia, glucose intolerance, nephrotoxicity, electrolyte disturbances
Tacrolimus	0.05–0.075 mg/kg p.o. twice daily	Neurotoxicity, alopecia, hypertension, hyperlipidemia, glucose intolerance, nephrotoxicity, electrolyte disturbances
Sirolimus	2–10 mg/day p.o. daily	Hypertriglyceridemia, anemia, thrombocytopenia, mouth sores, hypercholesterolemia, gastrointestinal disturbances, bone marrow suppression, poor wound healing, edema, pleural effusions, pericardial effusions
Everolimus	0.75–1.5 mg p.o. twice daily	Hypertriglyceridemia, anemia, thrombocytopenia, mouth sores, hypercholesterolemia, gastrointestinal disturbances, bone marrow suppression, poor wound healing, edema, pleural effusions, pericardial effusions
Azathioprine	1–2.5 mg/kg/day p.o. daily	Leukopenia, thrombocytopenia, gastrointestinal disturbances, pancreatitis, hepatotoxicity
Mycophenolate mofetil	500–1500 mg p.o. twice daily	Leukopenia, thrombocytopenia, gastrointestinal disturbances
Mycophenolate sodium	360–1080 mg p.o. twice daily	Leukopenia, thrombocytopenia, gastrointestinal disturbances
Belatacept	10 mg/kg administered, prior to implantation, on day 5, and at the end of weeks 2, 4, 8, and 12, then 5 mg/kg every 4 weeks (plus or minus 3 days)	Increased acute rejection, post-transplant lymphoproliferative disorder, progressive multifocal leukoencephalopathy, tuberculosis

p.o., by mouth; i.v., intravenously.

Table 66.2. Classification of immunosuppressive agents

Classification	Drug (generic)	Drug (trade)	Generic	Dosage form
Corticosteroids	Methylprednisolone	Solumedrol® (Pfizer, New York, NY)	Yes	Injection, oral
	Prednisone	Deltasone® (Pfizer, New York, NY)	Yes	Oral
	Prednisolone			Oral
Calcineurin inhibitors	Cyclosporine, CsA	Sandimmune® (Novartis, East Hanover, NJ)	Yes	Injection, oral
	Cyclosporine microemulsion	Neoral® (Novartis, East Hanover, NJ) GenGraf® (AbbVie, Chicago, IL)	Yes	Injection, oral
	Tacrolimus, FK506	Prograf® (Astellas, Northbrook, IL)	Yes	Oral
	Astragraf (Astellas)	Hecoria® (Novartis, East Hanover, NJ)		
mTOR inhibitors	Sirolimus, rapamycin	Rapamune® (Pfizer, New York, NY)	No	Oral
	Everolimus	Zortress® (Novartis, East Hanover, NJ) Certican ® (Novartis, East Hanover, NJ)	No	Oral
Antiproliferative	Azathioprine, AZA	Imuran® (GlaxoSmithKline, Mississauga, Ontario, Canada)	Yes	Injection, oral
	Mycophenolate mofetil, MMF	Cellcept® (Genentech, San Francisco, CA)	Yes	Injection, oral
	Mycophenolate sodium, EC-MPS	Myfortic® (Novartis, East Hanover, NJ)	No	Oral
Costimulation blockade	Belatacept	Nulojix® (Bristol-Myers Squibb, New York, NY)	No	Injection

therapy. Calcineurin inhibitor sparing/ avoidance therapy is being investigated, but is not commonly used. The last type of maintenance therapy is monotherapy, which is rarely used outside of clinical trial settings [2,3]. Candidates for monotherapy or dual therapy include patients with transplanted organs that are perceived to have less immunogenic potential and perceived to be at less immunological risk. Both groups have been defined primarily upon epidemiological data and not on clearly defined immunologic data such as human leukocyte antigen (HLA) matching (see Chapter 36), which—although used in kidney transplantation—is uncommonly used or ascertained in other solid organ transplantation [4–7].

Risk factors and maintenance immunosuppression

Patients perceived to be at increased risk for acute rejection may receive more intense maintenance immunosuppressive regimens. These perceived risks have had variable degrees of utility but, in general, no clear metric for one's need for immunosuppressive therapy has been validated. Immunologic, donor, and recipient risk factors are discussed below.

Immunologic risk factors

Multiple tests may be performed prior to transplant to assess a patient's risk for acute rejection, including panel-reactive antibodies, an immunologic cross-match, HLA matching, and blood/ tissue typing. The methods and basis for these tests are covered in depth in Chapter 36. Highly sensitized patients, those with alloantibodies directed against HLA antigens of the donor, are at higher risk for acute rejection. Circulating antibodies to the donor's antigens may be a result of prior transplantation, pregnancy, or multiple blood transfusions. As the panel-reactive antibody level rises, the chance of a positive B or T cell cross-match and an immunologically incompatible transplant is increased. In a study of the effect of sensitization on graft survival in haploidentical living related transplants, patients with greater than 50% panel-reactive antibody titers had a significantly shorter time to graft failure [8]. A positive T-cell cytotoxicity cross-match is a contraindication to kidney transplant without effective "desensitization" because of the associated risk for hyperacute rejection and graft loss. Patients with positive B-cell cross-match are known to be at risk for accelerated acute rejection, and more potent immunosuppressive regimens are used, although this practice has not been well studied. While not a

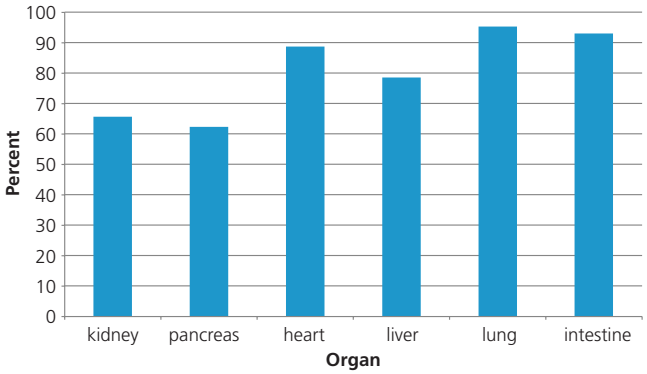

Figure 66.3. Corticosteroid use at transplant discharge by organ type.

contraindication to transplant, a positive flow cross-match is also associated with poorer graft outcomes and may warrant augmented immunosuppression or more intensive post-transplant monitoring [9]. In general, donor specificity is the fundamental characteristic of antibodies conferring high risk, with the risk of non-donor specific alloantibodies less well established.

Human leukocyte antigen matching

In kidney transplant, HLA antigens are important in determining the risk of rejection, especially when potent immunosuppressive agents are not used. The greater the number of antigen mismatches between the donor and recipient, the higher the chance of the recipient having a rejection episode. Numerous studies have shown that better HLA matching leads to better graft survival [10,11]. Despite this, a study of the United States Renal Data System (USRDS) database analyzing 23 443 patients transplanted between 1995 and 2002 revealed a mere 4–8% lower use of immunosuppression with mycophenolate mofetil and tacrolimus at 6 months in the "No HLA ABDR mismatched group" compared to the DR mismatched group. Thus, adjustment of immunosuppression based on HLA matching represents a possible opportunity for "tailoring" of immunosuppression based on immunologic rather than epidemiologic risk of rejection that appears under-utilized.

Studies have suggested that HLA mismatching is associated with rejection and graft outcomes in non-renal transplantation as well. HLA mismatching impacts acute rejection rates in liver transplant but does not impact 1-year graft survival [12]. In lung transplant, HLA mismatching is associated with acute rejection as well the development of bronchiolitis obliterans syndrome (BOS) and decreased patient survival [13,14]. Studies examining the effect of HLA matching in cardiac transplantation have been conflicting, with recent larger single-center studies demonstrating no impact on survival [15]. For non-renal solid organ transplant, considerations such as matching the size of the organ to the size of the recipient and the constraints of cold ischemia time have overshadowed routine use of HLA matching, but with the new calculated panel-reactive antibody (cPRA) using pretransplant single-bead anti-HLA antibody assessment, HLA matching may become useful across all organs to guide maintenance immunosuppressive therapy.

Other immunologic assessment

Additional assays and markers have been investigated to identify preformed T-cell memory, enabling additional assessment of pre-transplant risk or for post-transplant monitoring. These are covered in more detail in Chapters 89, 90, and 91. Ideally, this would provide information enabling individualized treatment, with patients at greater immunologic risk of rejection treated with augmented immunosuppression and those with lower risk considered for drug minimization [16]. The interferon (IFN)-γ ELISpot assay is a technique to detect alloantigen-specific memory T cells. Evidence suggests that high frequencies of donor-reactive memory T cells are associated with poorer graft outcomes [17] and that panel-reactive memory T-cell reactivity is independent of PRA [18]. Markers that reflect general immune activation have also been examined, such as soluble CD30, which is generated by the proteolytic cleavage of membrane-bound CD30 in activated T cells [19]. Although sCD30 levels have been used to predict post-transplant development of donor-specific antibodies [20], high levels do not necessarily correlate with rejection [21]. The ImmuKnow assay (Cylex, Inc., Columbia, MD), which measures ATP released in vitro (iATP) from isolated, polyclonally stimulated $CD4^+$ T cells, has also been examined as a method to discriminate between under- and over-immunosuppression. A meta-analysis suggests that this assay has poor predictive capability for either rejection or infection, and its use to directly manage patients is generally discouraged [22]. Overall, further prospective information regarding the clinical utility of these tests in various patient cohorts and immunosuppression regimens is warranted before any can be recommended for routine clinical use to guide immunosuppressive therapy.

Donor and recipient characteristics

Donor risk factors for acute rejection include the duration of cold ischemia and delayed graft function [23–26]. Cold ischemia time and delayed graft function also influence outcomes. In a multicenter analysis, cold ischemia was reported to be strongly associated with delayed graft function, with a 23% increase in the risk of delayed graft function for every 6 hours of cold ischemia. Acute rejection occurred more frequently in grafts with delayed graft function, which was independently predictive of 5-year graft loss [27]. Delayed graft function has been associated with a significant reduction in renal allograft survival before and after the cyclosporine era [28]. Use of potent immunosuppression in patients with delayed graft function is common in clinical practice, although this practice has not been well studied. Sirolimus, through its inhibiting effect on cell proliferation, may prolong delayed graft function [29].

Recipient characteristics that place a patient at risk for rejection include age, pretransplant dialysis, and re-transplantation. Aging is associated with a reduction in immunoresponsiveness due to the generalized decrease in T-cell production and response [30,31].

However, the Belatacept Evaluation of Nephroprotection and Efficacy as First-Line Immunoprotection Trial (BENEFIT-EXT) showed that rejection was more common in older recipients of expanded criteria donor kidneys [32]. Since an expanded criteria donor has more histologic damage, this may represent "priming" for rejection or reflect that older donor organs have histologic changes that mimic acute rejection. Randomized clinical trials addressing the management of immunosuppression in older patients are needed. Longer waiting time on dialysis and repeat transplant status also have been reported to impact post-transplant patient and graft survival negatively [33]. Historically, re-transplantation was unsuccessful. However, more recently, success has improved with potent immunosuppressive regimens [1]. Although the use of more potent immunosuppressive agents in patients with these risk factors is common, this practice has not been well studied.

Race

Historically, differences in renal transplant outcomes have existed between African-American and Caucasian recipients [34–37]. African Americans are at higher risk for rejection, even among living related two haplotype matched recipients [38], and may benefit from more aggressive immunosuppressive strategies [39]. Despite overall improvements in 1-year graft survival rates in the cyclosporine era, survival rates remained lower in African-American compared to Caucasian patients [40–43] and although cyclosporine-based quadruple immunosuppression has been reported to improve short-term graft survival rates in African-American as well as Caucasian recipients, long-term outcomes in African-American patients have not been affected [44,45]. Outcomes with tacrolimus and mycophenolic acid have shown more promise. Tacrolimus-based immunosuppression with antibody induction has reduced the occurrence and severity of acute rejection at 1 year post-transplant when compared to cyclosporine, especially in African-American recipients [46]. Beneficial results have also been reported with mycophenolate mofetil, although African Americans may require a higher dose than Caucasian kidney transplant recipients. An analysis that compared azathioprine and mycophenolate mofetil reported that acute rejection was reduced in African-American kidney transplant recipients on mycophenolate mofetil when compared to azathioprine, and that acute rejection was similar in African-American recipients given mycophenolate at a dose of 3 g/day and Caucasian recipients given 2 g/day [39]. This study also showed that there was no dose effect in non-African Americans, and that in non-African Americans the combination endpoint of biopsy-proven acute rejection and treatment failure at 6 months was not significantly different between azathioprine and mycophenolate.

Adherence

Non-compliance is associated with rejection, graft failure, and poor outcomes after transplantation, particularly in adolescents [47–50]. This is covered in considerable depth in Chapter 120. Newer immunosuppressive therapy may provide alternative treatments to patients known to be non-adherent. Sirolimus has a long half-life that affords convenient once-daily dosing. Belatacept may prove useful in patients with adherence difficulties due to increased patient compliance with less frequent (monthly) administration as compared to other daily and twice daily oral regimens. Alternatively, it may be perceived as a barrier to patients without social support, those who have difficult intravenous access, or those for whom an infusion center is not readily available.

Pregnancy

Pregnancy may increase the risk of acute rejection and allograft loss. The effects of pregnancy on transplant outcome are covered in Chapter 97. To minimize this risk, careful immunosuppressive selection and drug monitoring is needed. Mycophenolic acid, sirolimus, and everolimus may be harmful to a fetus, and should be avoided. Although listed as category D in pregnancy, azathioprine has been used safely in pregnant transplant patients since the 1950s. Pharmacokinetics, such as volume of distribution and metabolism of immunosuppressives, are also altered with pregnancy and require monitoring and adjustment.

Summary

Given toxicities of immunosuppressive agents, different maintenance regimens are being explored to minimize adverse short- and long-term effects. However, these strategies remain strongly guided by perceived immunologic risk rather than rigorously validated objective metrics. Patients at risk for rejection may require more potent immunosuppressive medication, more medications, and higher doses. Patient at lower risk for rejection may need less potent medications, lower drug concentrations and dosages, or mono- or dual therapy. At present, strong evidence exists only for risk stratification based on HLA mismatching and preformed alloantibody rather than epidemiological risks.

Infection and maintenance immunosuppression

Newer immunosuppressive regimens have revolutionized transplantation, lowering rejection rates and improving graft survival, but at the cost of higher infection risk. Viruses utilize target host cell machinery to replicate, and an effective antiviral immune response depends on both innate (e.g. natural killer cells) and adaptive (e.g. T cells) responses. In suppressing the host immune system to preserve the allograft, the risk of viral infection is increased. The infectious disease risks inherent in transplantation are covered in depth in Chapters 92, 93, and 94. This section will relate viral infection to immunosuppressive management. In general, viral replication is indicative of robust, and perhaps overly heavy, immunosuppression and should prompt consideration for reducing maintenance immunosuppression.

Highly seroprevalent viruses that are relatively benign in the general population can threaten the immunosuppressed transplant recipient, resulting in allograft damage and malignancy. Viruses that pose the greatest clinical threat include human herpesviruses (HHV) 1 and 2, varicella zoster virus (VZV), Epstein–Barr virus (EBV), cytomegalovirus (CMV), HHV6, 7, and 8, hepatitis C virus (HCV), hepatitis B virus (HBV), BK virus (BKV), human immunodeficiency virus (HIV), human papillomavirus (HPV), and parvovirus. Although many immunosuppressants have demonstrated antiviral effects in vitro, clinical observations may differ (Table 66.3). Strategies for the management of maintenance immunosuppression in the patient at risk or diagnosed with viral infection post-transplant are discussed; with focus on BK, CMV, Hepatitis B and C, and EBV.

BK virus

BK virus is the most common human polyomavirus activated after solid organ transplant. Seroprevalence of BKV is 82% in healthy blood donors; the virus establishes latency in the renal cortex, medulla, and uroepithelial cells. Despite decreased BKV-specific

T-cell responses caused by immunosuppression [51], BK nephropathy (BKVN) rarely occurs in the native kidneys of non-renal solid organ transplant recipients as BKVN results primarily from reactivation of latent BK in the transplanted organ [52]. Thus, BKVN is primarily observed in renal transplant recipients (1–10%). Clinical manifestations include asymptomatic viral shedding, cystitis, tubulointerstitial nephritis, nephropathy, ureteral stenosis, and allograft failure.

A correlation exists between BKV infection and the overall degree of immunosuppression. Antirejection treatment and cumulative steroid exposure are risk factors for BKVN. Several studies have demonstrated that tacrolimus-based regimens are associated with higher risk of BKVN [53–55]. However, no specific induction or maintenance immunosuppressive agent or combination is exclusively associated with development of BKVN.

Eighty per cent of patients developing BK viremia do so within the first 3 months post-transplant [56]. Fortunately, BKV can be detected in plasma prior to development of nephropathy [57]. Therefore, consensus recommendations are to screen recipients for viremia every 1–3 months initially post-transplant [58]. As viremia represents imbalance between BKV reactivation and BKV-specific cellular immunity and effective antiviral agents are lacking, immunosuppression reduction remains the cornerstone of therapy to allow for development of BKV-specific immunity. Immunosuppression reduction in those with viremia (>10 000 copies/mL) can avoid progression to histological and functional renal impairment. Outcomes with screening and preemptive strategies are likely superior to treatment of established nephropathy, although comparative trials have not been performed.

Two approaches to immunosuppression reduction after detection of viremia have been described. In the first approach, the calcineurin inhibitor is decreased by 25–50% followed by reduction in antiproliferative agent [59,60]. The alternative approach is first to decrease or eliminate the antimetabolite followed by subsequent calcineurin inhibitor reduction, if necessary to achieve clearance of viremia [54]. Direct comparison of these two strategies has not been done. One single-center study in which BK viremia was treated with cessation of the antimetabolite followed by calcineurin inhibitor reduction reported long-term outcomes. In 200 patients, viruria and viremia occurred in 35% and 12%, respectively by 1 year. Resolution of viremia was observed in 95% of patients after immunosuppression reduction. Overall 5-year patient survival was 91% and graft survival was 84%. Development of BK viremia did not influence patient or graft survival [61].

In patients with allograft dysfunction, allograft biopsy should be performed to direct therapy. As BKVN is associated with inflammation on biopsy, BK nephropathy may masquerade as rejection or occur concurrently with rejection. The presence of endarteritis, fibrinoid vascular wall necrosis, glomerulitis, or peritubular capillary C4d positivity support diagnosis of concurrent rejection [62]. Staining for SV40 can confirm the presence of BKV nephropathy. Treatment of concurrent BKVN and rejection is controversial; one strategy is the institution of antirejection therapy followed by decreased maintenance therapy. As intravenous immune globulin (IVIG) has also been used for the treatment of rejection, the use of IVIG may be particularly beneficial in patients in whom BK nephropathy and rejection are difficult to distinguish. In patients with acute rejection occurring following clearance of BK viremia by immunosuppression reduction, conventional antirejection therapy should be administered with careful monitoring for recurrent BK viremia every two weeks following treatment. In diagnosed BKVN, alternative maintenance immunosuppressive strategies have been described; for example the substitution of cyclosporine for tacrolimus, which has the additional effect of lowering mycophenolic acid levels [57]. The conversion of a calcineurin inhibitor to an mTOR inhibitor can be considered [63], although this strategy would be useful only in those with preserved renal function lacking proteinuria. Although in vitro and initial small studies suggested that leflunomide, a malononitrile amide, inhibits BKV replication [64,65], a systematic review failed to identify any benefit of the addition of leflunomide on graft survival following development of BKVN [66]. Additionally, a study in kidney transplant recipients with BKVN treated with FK778, a leflunomide derivative, failed to demonstrate a benefit [67].

Re-transplantation can be successfully achieved in transplant candidates with prior graft loss due to BKVN [68]. General consensus is to delay re-transplantation until clearance of viremia is achieved, although there are case reports of transplantation with active viremia. In an Organ Procurement and Transplantation Network (OPTN) database analysis, 126 kidney transplant patients with prior graft loss due to BKVN who were re-transplanted were identified. Induction was utilized in 80% of re-transplants and tacrolimus plus mycophenolate was the most common maintenance regimen (57%). Of these patients, treatment for BKV was reported in 17.5% although only one graft loss due to BKVN occurred and 1-year graft survival rate was 98.5% [68].

Cytomegalovirus

As opposed to BKV, CMV can cause significant morbidity and mortality in all solid organ transplant recipients [69]. Manifestations of CMV can range from asymptomatic viremia to infection (fever, arthralgias, leukopenia, thrombocytopenia) to organ-invasive disease (pneumonitis, gastroenteritis, colitis, hepatitis, encephalitis). Seroprevalence is approximately 60% in those above age 20, and after infection the virus establishes life-long latency. Therefore, CMV infection or disease after transplant can represent reactivation of host-latent virus or primary infection from the donor organ. In addition to donor and recipient CMV serostatus, innate host immunity and net state of immunosuppression are major risk factors for infection; thus risk of disease is greatest after immunosuppression for the prevention and treatment of acute rejection. As CMV infection occurs in over 50% of solid organ transplant recipients without prevention, strategies have been employed which have significantly lowered the incidence of CMV disease. Prophylaxis, or the administration of antiviral agents to recipients during greatest perceived risk, and pre-emptive therapy or initiation of therapy after detection of CMV antigenemia both have been successfully utilized [69,70].

While no single immunosuppressive agent is consistently associated with CMV infection, the use of lymphocyte-depleting agents [71,72] and calcineurin inhibitors (particularly cyclosporine) [73,74] appear to correlate with increased risk, while the use of the mTOR inhibitors sirolimus and everolimus may be protective [75–78]. Clinical studies regarding incidence of CMV with mycophenolic acid versus azathioprine have been conflicting [79], with some but not all demonstrating higher incidence and severity of disease with mycophenolate mofetil. Differences between these studies may reflect variable mycophenolate mofetil and azathioprine dosing used. Additionally, many earlier studies were performed before routine use of ganciclovir prophylaxis. Overall, given the efficacy of antiviral agents for the prevention and treatment of CMV, there is insufficient evidence at present to support the use of any individual maintenance immunosuppressive agent or combination for CMV prevention. Conversion to a mTOR inhibitor may be considered in patients with recurrent or intractable CMV disease [80].

Reduction in the overall degree of immunosuppression should be considered as adjunctive therapy to the use of antiviral agents in the treatment of CMV infection and disease particularly with documented organ involvement. Commonly this is achieved through reduction or discontinuation of the antimetabolite (mycophenolate or azathioprine) although reduction of the calcineurin inhibitor may additionally be required in severe cases [81]. In a trial comparing valganciclovir and intravenous ganciclovir for the treatment of CMV, greater eradication of CMV viremia at 21 days was observed in patients on dual versus triple therapy maintenance regimens and was also observed in patients with low versus high calcineurin inhibitor levels. However, the rates of long-term eradication and risk of recurrent disease was comparable between groups [82]. It remains unclear whether the antimetabolite should be restarted after successful CMV treatment and may be best guided by the perceived immunologic risk.

Hepatitis C

Prevalence of hepatitis C varies considerably between solid organ transplant groups, with a higher prevalence among liver and kidney transplant populations. HCV-induced cirrhosis remains one of the principal indications for liver transplantation [83]. Additionally, the prevalence of HCV among kidney transplant recipients is 5–46% with geographic variances. Viral recurrence following transplantation is nearly universal, leading to accelerated hepatic fibrosis, and decreased graft and patient survival primarily due to cirrhosis and hepatic cancer [84].

Accelerated development of fibrosis, increased incidence of cirrhosis, and fibrosing cholestatic hepatitis occurring in immunosuppressed patients establishes that immunosuppression contributes to disease progression [85]. Extensive in vitro evidence has suggested that cyclosporine possesses anti-HCV activity [86,87], with non-immunosuppressive cyclosporine analogs under investigation as therapeutic agents for HCV [88]. However, clinical studies have not demonstrated a clear benefit of cyclosporine compared with tacrolimus in recurrence rates, or response to antiviral therapy. A meta-analysis examining mortality, graft survival, and incidence of fibrosing cholestatic hepatitis after liver transplantation demonstrated no significant difference comparing cyclosporine and tacrolimus-based regimens [89]. Similarly, a randomized controlled trial demonstrated no difference in survival and severe HCV recurrence in liver transplant recipients randomized to cyclosporine or tacrolimus regimens [90]. However, the mean time to histologic recurrence was longer in the cyclosporine arm. Retrospective studies have suggested that cyclosporine may enhance efficacy of antiviral therapy and improve sustained virologic response rates [85]; confirmatory prospective data is needed.

The effect of corticosteroid use on HCV recurrence and response to antiviral therapy is also controversial. Steroid boluses are generally perceived as deleterious. Steroid withdrawal and steroid-free protocols have not been associated with improved survival or slower fibrosis progression to date [91,92]. Both the antimetabolites azathioprine and mycophenolate have anti-HCV effects in vitro [93]. Clinical studies have, overall, failed to demonstrate a consistent benefit using antimetabolite-based regimens in terms of HCV recurrence, although a systematic review in liver transplant recipients suggests reduced severity of HCV recurrence with azathioprine compared to mycophenolate [94]. Data on the utility of mTOR inhibitors in HCV-positive liver transplant recipients has been limited and conflicting. In one study, time to and severity of recurrence was similar in those patients receiving or not receiving sirolimus [95], while in another study, the use of sirolimus was an independent predictor of minimal fibrosis at 1 and 2 years [96].

Hepatitis B

HBV replication may occur after solid organ transplant due to immunosuppressive therapy. Reactivation of replication is more likely in recipients who were HBeAg positive or had detectable HBV DNA prior to transplant, with minimal reactivation observed in HBcAb-positive, HBsAg-negative patients [97]. Similar to CMV prevention, the two approaches to prevent post-transplant HBV reactivation are prophylaxis (administration of antivirals during period of greatest reactivation risk) and a pre-emptive strategy involving post-transplant monitoring for viremia. HBV reactivation following liver transplant was nearly universal until the development of antiviral therapies, including lamivudine and hepatitis B immune globulin [98].

Although immunosuppression may contribute to HBV replication, a paucity of information exists to guide maintenance immunosuppressive management in the present era with the availability and effectiveness of antiviral agents. Present recommendations support minimization of the immunosuppressive regimen based on individual immunologic risk assessment. For example, in the HBsAg-positive liver transplant recipient steroid withdrawal may be considered as corticosteroid use has been shown to increase HBV DNA synthesis in vitro [99]. Although in vitro studies suggested an inhibitory effect of mycophenolate on HBV replication, the use of mycophenolate did not improve outcomes after reactivation of lamivudine-resistant HBV in a small study of liver transplant recipients [100]. Chronic hepatitis may increase the risk of hepatotoxicity of azathioprine or cyclosporine.

Epstein–Barr virus

Clinically, the most important manifestation of EBV infection after solid organ transplant is the uncontrolled proliferation of EBV-infected B cells contributing to the spectrum of post-transplant lymphoproliferative disease (PTLD). The incidence of PTLD is bimodal. Cases occurring within the first year of transplantation often are in EBV-seronegative recipients receiving an organ from an EBV-seropositive donor, with the vast majority represented by B-cell lymphoma expressing CD20. The risk of PTLD depends on the organ transplanted, with heart–lung recipients at greatest risk (Figure 66.4) [101], and differences between organ type may reflect intensity of immunosuppression used, degree of organ antigenicity, and amount of lymphoid tissue within the graft [102]. The use of

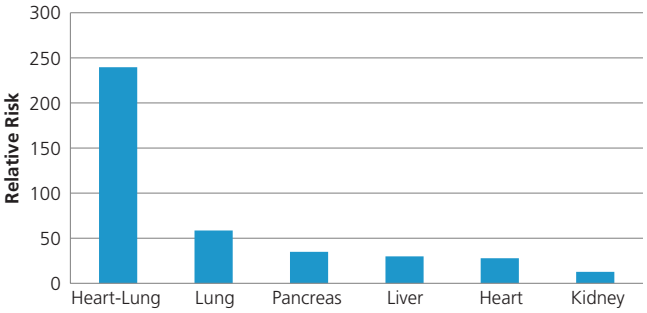

Figure 66.4. Relative risk of post-transplant lymphoproliferative disease (PTLD) by organ type by 5 years post-transplant.

depleting antibody therapy for induction and/or treatment of rejection is clearly associated with increased risk of PTLD development, particularly early post transplant [101,103]. However, use of maintenance immunosuppressive agents and overall degree of immunosuppression also increases PTLD risk by inhibiting EBV-specific T-cell responses. The risk of lymphoma returns to pretransplant levels upon weaning immunosuppression after transplant failure [104]. Patients on quadruple versus dual or triple immunosuppressive agents are at highest risk [103].

Registry analyses have demonstrated increased risk of PTLD in patients on calcineurin-based regimens, particularly in those on tacrolimus [101,103]. However, this increased risk has been observed primarily in patients not receiving induction therapy [103,105], suggesting that the strong immunosuppressive effect of induction initially surpasses any difference in calcineurin inhibitor effect. Rather, the use of a calcineurin inhibitor may impact incidence of late PTLD [104]. Any difference in risk with tacrolimus may be due to the higher level of immunosuppression the drug affords relative to cyclosporine. In contrast to the calcineurin inhibitors, the use of the antimetabolites has not been associated with PTLD, with some studies suggesting slightly decreased risk. Mycophenolic acid inhibits human B-cell lymphoma proliferation in vitro [106]. In registry analyses [104], case–control [107], and prospective cohort studies [108], mycophenolate mofetil was not associated with increased PTLD risk with a trend towards lower risk of malignancy and increased time to malignancy. In a large registry analysis, there was no difference in PTLD comparing mycophenolate and azathioprine; however, the percentage of patients on azathioprine was low [105].

The effect of the mTOR inhibitors sirolimus and everolimus on PTLD is unclear. Use of mTOR inhibitors has been associated with decreased incidence of overall de novo malignancy post-transplant [109]. These agents have been found to inhibit the growth of EBV-positive B-lymphoma cells [110]. Analysis of over 25 000 Medicare transplant recipients did not show an association between PTLD development and sirolimus use [103]; however, only 665 patients of this group were treated with sirolimus. In the ELITE-Symphony trial in renal transplant recipients, which was a randomized controlled trial comparing low-dose tacrolimus, low-dose cyclosporine, standard-dose cyclosporine, and sirolimus-based maintenance immunosuppression, all the cases of PTLD and non-Hodgkin's lymphoma occurred in the sirolimus arm. The rates of acute rejection, however, were also greatest in the sirolimus group; thus the use of T-cell depleting agents may have contributed to higher lymphoma rates [74].

The novel agent, belatacept, a fusion protein that selectively blocks T-cell costimulation, was associated with greater risk of PTLD compared with a standard cyclosporine regimen in phase III studies, especially among those recipients who were EBV-seronegative recipients of an EBV-positive donor [111,112]. Interestingly, rates of rejection were also greater in the belatacept arm, challenging the concept that higher degree of immunosuppression is the sole contributor to increased PTLD risk using maintenance agents. Restricting use of belatacept to EBV-seropositive patients is currently recommended.

Treatments for PTLD may include immunosuppression reduction, antiviral therapy (EBV-associated), chemotherapy, radiation, and local excision. Immunosuppression reduction alone, by 25–50% of baseline level, may be effective in treating limited, polymorphic PTLD. Extensive cases may warrant more aggressive immunosuppression reduction; however, the risk of rejection and allograft loss has to be carefully considered [113]. One analysis pooled 19 renal transplant patients from European centers converted to sirolimus or everolimus with minimization or discontinuation of the calcineurin inhibitor following the development of PTLD [114]. Fifteen patients had remission of PTLD; however, six patients were concomitantly treated with rituximab and another six patients received CHOP (cyclophosphamide, doxorubicin, vincristin, and prednisone), making the contribution of the mTOR inhibitor difficult to discern. Recently, there is increasing interest in strategies to reconstitute EBV-specific immunity through infusion of autologous cytotoxic T lymphocytes [115].

Cancer and maintenance immunosuppression

The use of immunosuppressive agents after transplantation increases the long-term risk of malignancy after solid organ transplant. This risk is covered in depth in Chapter 95. In a large cohort study using linked data from the US Scientific Registry of Transplant Recipients and 13 state and local registries, the frequency of malignancy in over 175 000 patients transplanted between 1987 and 2008 (kidney, liver, heart, and lung) was determined. Over the study period, 10 656 cases of malignancy were reported, correlating to a standardized incidence ratio of 2.1 compared with the general population. Cancers with an increased risk of fivefold or greater compared to the general population were Kaposi's sarcoma, non-Hodgkin lymphoma, skin, lip, vulvar, anal, and liver cancer, illustrating the oncogenic potential of particular viral infections. Cancers commonly screened for in the general population, including cervical, breast, and prostate, were not significantly increased in transplant recipients [116].

Depleting antibody therapy has clearly been associated with increasing the risk of PTLD, commonly associated with EBV infection (discussed above). Beyond this, there is no conclusive evidence that a particular immunosuppressive agent is associated with development of a specific malignancy. Rather, the overall degree of immunosuppression correlates with risk. Several observations support this. The risk of malignancy differs among solid organ transplant recipients, with those receiving more intensive immunosuppressive therapy (e.g. heart–lung) at greatest risk for cancer [101]. Additionally, the risk of certain cancers (e.g. PTLD) is greatest during the first year post-transplant during heightened immunosuppression [101]. Episodes of rejection increase risk of malignancy, perhaps due to treatment with depleting antibodies and/or increased maintenance immunosuppression [117]. The number of immunosuppressive agents correlates with cancer risk

[103]. Certain malignancies (e.g. Kaposi's sarcoma, polymorphic PTLD) may regress completely with decreased immunosuppression [113]. Finally, risk of malignancy dramatically falls after graft failure and weaning of immunosuppression [104]. Mechanisms by which immunosuppression may contribute to malignancy development include impairment of immune activity against oncogenic viruses, decrease in neoplastic cell immunosurveillance, direct DNA damage and disruption of DNA repair mechanisms, and up-regulation of cytokines that promote tumor formation [118].

Malignancy potential for individual immunosuppressive agents, independent of their immunosuppressive effect, is controversial. Studies to date are limited by insufficient power, particularly given the low incidence of some malignancies. Additionally, data on immunosuppressant use may reflect agents used at time of transplant and not capture changes in long-term management. Furthermore, the degree of immunosuppression may vary despite use of similar regimens depending on drug levels achieved [119]. However, certain experimental and clinical findings warrant further discussion. Cyclosporine and tacrolimus may promote cancer progression via the production of transforming growth factor-beta (TGF-β), vascular endothelial growth factor (VEGF), and interleukin-6 (IL-6) [120,121]. Lower calcineurin inhibitor levels correlate with lower risk of cancer [122]. Among kidney transplant patients, increased de novo tumors, including PTLD, were observed in patients on tacrolimus versus cyclosporine; however, this observation was limited to those who did not receive induction therapy [105]. Azathioprine has been associated with increased risk of squamous cell carcinoma of the skin [123] and lip [124], perhaps via photosensitization to ultraviolet A radiation [125]. Conversely, mycophenolate does not appear to be associated with increased malignancy risk [108,123]. Evidence for an antitumor effect of sirolimus in animal models is increasing; mechanisms by which sirolimus may suppress tumor growth include inhibition of p70 S6 kinase (inhibit cell proliferation), IL-10 (Jak/STATs activity), cyclins (block cell cycle activity), and VEGF signaling (impede lymphangiogenesis) [120,126]. In the Rapamune Maintenance Regimen Study, renal transplant patients randomized to maintenance prednisone plus cyclosporine plus sirolimus versus sirolimus alone, the risk of malignancy was nearly twofold lower in the cyclosporine withdrawal group [127]. In the CONVERT trial, patients converted to sirolimus therapy had lower rates of non-melanoma skin carcinomas compared to patients in a calcineurin inhibitor continuation group [128].

Although reduction of immunosuppression may be useful in treatment of diagnosed malignancy, this approach is useful primarily for renal transplant recipients as graft loss due to rejection is non-fatal. Immunosuppression reduction may be particularly effective in treatment of lymphoma, skin cancer, and Kaposi's sarcoma [129]. Substitution of sirolimus for cyclosporine in renal transplant patients has been associated with complete regression of Kaposi's sarcoma [130,131]. In patients with malignancy, either in remission or under treatment, conversion to a sirolimus-based regimen warrants consideration. However, use of sirolimus in patients with or without a history of malignancy is associated with a more than twofold increased risk of all cause mortality [132]. In patients undergoing chemotherapy, minimization or discontinuation of maintenance agents may be indicated until completion of therapy; azathioprine in particular can increase severity of myelosuppression. Cyclosporine is a potent inhibitor of the efflux p-glycoprotein encoded by the ATP-binding cassette subfamily B member 1 gene (*ABCB1*), also known as multidrug resistance gene 1 (*MDR1*), and may affect or be affected by various chemotherapeutic agents that interact with p-glycoprotein [133].

Maintenance immunosuppression by time after transplant

Immediate postoperative period

Optimizing immunosuppressive management in the early post-transplant period is important for attaining long-term graft function and survival. The practice of using induction agents and/or higher doses of maintenance agents in the early post-transplant period evolved after the early transplant experiences illustrated the heightened risk for acute rejection during the first post-transplant months [134]. Specific induction therapies are covered in depth in Chapter 65. The introduction of cyclosporine revolutionized transplantation, with dramatic improvements in the acute rejection and 1-year graft survival rates. Cyclosporine was initially envisioned as an agent that would prevent rejection and allow for steroid avoidance. However, monotherapy with cyclosporine proved problematic, as the high doses needed for rejection prophylaxis caused significant toxicity, particularly nephrotoxicity [135]. Triple therapy, or the combined use of a calcineurin inhibitor, prednisone, and azathioprine, thus emerged as a strategy to maximize immunosuppressive effect while minimizing toxicity. Although tacrolimus and mycophenolic acid have largely replaced cyclosporine and azathioprine as initial maintenance agents, triple therapy is still the predominant approach after solid organ transplant [1]. Since the risk for acute rejection is highest in the first 3 months after transplantation, higher doses are used during this period, and then reduced thereafter in stable patients to minimize toxicity.

There remains interest in minimization of immunosuppression even in the early post-transplant period. Since the introduction of the calcineurin inhibitors, target levels have been lowered, which has decreased nephrotoxic effects while maintaining acceptable acute rejection rates. Calcineurin-free regimens are uncommonly used given high acute rejection rates, particularly in more immunogenic solid organ transplants. Interest remains in steroid minimization and avoidance. However, the higher rejection rates observed with these protocols [136] despite concurrent use of calcineurin inhibitors have prevented widespread adoption of these strategies.

Particular issues with regards to the use of maintenance agents in the immediate postoperative period warrant further review. In kidney transplant, the mTOR inhibitors sirolimus and everolimus are associated with delayed graft function; thus the Kidney Disease: Improving Global Outcomes (KDIGO) Clinical Practice Guidelines recommend that if an mTOR inhibitor is used, it should not be started until graft function is established and surgical wounds are healed [58]. Although sirolimus has a relatively low risk of traditional afferent arteriolar vasoconstrictive nephrotoxicity, concomitant use of angiotensin converting enzyme inhibitors (ACEI) may cause acute renal failure [137] or anaphylaxis [138]. Sirolimus is uncommonly used early after lung transplant due to associated risk of anastomotic bronchial dehiscence [139,140]. It has also been associated with hepatic artery thrombosis following liver transplant [141].

Medium to long-term management

Medium to long-term management of transplant focuses on preventing chronic rejection and minimizing drug toxicity. A summary of drug toxicities and management options are listed in Table 66.4.

Table 66.4. Tailoring immunosuppressive regimens on adverse events

Condition	Immunosuppressive cause	Immunosuppressive change
New-onset diabetes after transplantation (NODAT)	Corticosteroid, tacrolimus, cyclosporine, mTORS	Avoidance, dose reduction,
Dyslipidemia	Corticosteroids, cyclosporine sirolimus, everolimus	Avoidance, dose reduction, tacrolimus
Hypertension	Corticosteroid, cyclosporine, tacrolimus, mTORS	Avoidance, dose reduction
Osteoporosis	Corticosteroids	Avoidance, dose reduction, vitamin D
Bone marrow suppression	Mycophenolic acid, azathioprine, sirolimus, everolimus, tacrolimus	Dose reduction
Delayed wound healing	Sirolimus, everolimus	Avoidance
Gastrointestinal side-effects	Mycophenolate mofetil, tacrolimus, sirolimus	Enteric-coated mycophenolic sodium, dose reduction, azathioprine
Proteinuria	Sirolimus, everolimus	Avoidance
Nephrotoxicity	Cyclosporine, tacrolimus, sirolimus	Avoidance, dose reduction, belatacept

Based on data from [58].

Calcineurin inhibitors are associated with numerous toxicities that are often dose dependent. Hirsutism, gingival hypertrophy, hypertension, and hyperlipidemia are more commonly encountered with cyclosporine treatment than with tacrolimus, whereas neurotoxicity, alopecia, and potentially post-transplant diabetes are more commonly encountered with tacrolimus treatment than with cyclosporine.

One concern with tacrolimus is the possible relative increase in the incidence of diabetes, which has been noted in recipients of kidney allografts alone [142]. Several studies have not reported an increase in diabetes with tacrolimus in pancreas transplant recipients [143–146]. Low-dose tacrolimus minimizes the risk of new-onset diabetes after transplantation (NODAT) compared to higher doses of tacrolimus [147]. Calcineurin inhibitors may also cause nephrotoxicity. Calcineurin sparing/ avoidance protocols are discussed in the organ sections below. However, even patients who have never been treated with a calcineurin inhibitor may have histological changes on kidney biopsy consistent with calcineurin inhibitor toxicity [148].

Corticosteroids are associated with side-effects including hypertension, dyslipidemia, glucose intolerance, and osteoporosis. Many new protocols have attempted to withdraw corticosteroids in order to circumvent these adverse effects. These protocols are discussed in corticosteroid withdrawal by organ type in the sections below.

Antimetabolite agents are associated with bone marrow suppression and gastrointestinal side-effects. Close monitoring of complete blood counts is necessary post-transplant. Gastrointestinal side-effects are discussed in antimetabolite section relating to kidney transplant below.

Sirolimus and everolimus may be associated with a number of adverse effects, including leukopenia, thrombocytopenia, anemia, mucositis, hypercholesterolemia, hypertriglyceridemia, pleural effusions, pericardial effusion, ovarian cysts, and edema. De novo use of sirolimus has been associated with delayed wound healing, lymphocele formation, and prolonged delayed graft function.

Failing allograft

The appropriate immunosuppression for the failing allograft is unknown. This is complicated in solid organ transplant recipients where there is no available supportive therapy and re-transplantation is the only option. However, increasing use of, and efficacy of, left ventricular assist devices makes re-transplantation for heart transplant recipients a potential viable option. In kidney transplantation, many physicians will lower the calcineurin inhibitor or replace it with an mTOR inhibitor. The CONVERT study, however, showed that it is unsafe to replace a calcineurin inhibitor with sirolimus when the estimated glomerular filtration rate is less than 40 mL/min, and ineffective and dangerous when the estimated glomerular filtration rate is greater than 40 mL/min when there is more than 100 mg/day of urinary protein, limiting its usefulness in this setting [149]. The appropriate immunosuppression after a patient has returned to dialysis is also unknown. After a patient returns to dialysis, an elevation of the serum creatinine is no longer useful as a marker to identify rejection and calcineurin inhibitors reduce the common signs and symptoms of acute rejection. Some centers withdraw the antimetabolite to reduce the risk of infection, and reduce the calcineurin inhibitor and the prednisone to 5 mg/day as long as the patient is making more than 500 milliliters of urine daily [150]. When the patient becomes anuric, the risk of continued immunosuppression is unwarranted and the calcineurin inhibitor is withdrawn and prednisone tapered slowly. If the patient develops signs and symptoms consistent with acute rejection, treatment may include steroids and possible transplant nephrectomy. An exception to the practice of weaning immunosuppression after graft failure is when a subsequent transplant (i.e. a living donor kidney transplant) is imminent. In this case, maintenance immunosuppression may be beneficial to avoid increased alloantibody levels. Relatively non-toxic immunosuppressive strategies to avoid allosensitization after graft loss are clearly needed given the increasing number of patients returning to dialysis and seeking a new transplant.

Recurrent disease

Disease recurrence is one factor known to adversely affect allograft survival. However, the impact of various immunosuppressive strategies on the occurrence, severity, and progression of disease recurrence is often poorly understood. In general, patients with immune-mediated primary diseases (i.e. autoimmune hepatitis and lupus nephritis) are treated with higher doses of immunosuppression, including corticosteroids, while patients with infection issues (such as HCV) might benefit from less aggressive immunosuppressive regimens. This will be discussed in detail by organ type elsewhere in this textbook (see Chapters 77–80).

Generic immunosuppressants

Cost may be an important factor when choosing maintenance immunosuppression. Cyclosporine, tacrolimus, prednisone, mycophenolate mofetil, mycophenolate sodium, and azathioprine are available as generic products. In order for the FDA to approve a generic product it must contain the same active ingredient, be an identical strength, dosage form and route of administration, have the same use indications, be bioequivalent, and meet the same batch requirements for identity, strength purity, and quality as the brand drug. Generic medications do not need to be proven efficacious and safe in the treated populations, for example transplant recipients. In general, generic drugs are being used with increasing

frequency in all sectors of transplantation, and it is likely that they will become the predominantly used form of maintenance immunosuppression in the coming decade. Minor variations in drug performance surely exist, but are unlikely to be systematically defined.

Maintenance therapy for kidney transplant recipients

In the current era of kidney transplantation, graft survival rates that exceed 90% at 1 year [1] have been achieved with calcineurin inhibitors, antimetabolites, and corticosteroids. Additional discussions on drug mechanism and usage are available in Chapters 17 and 98, respectively.

Calcineurin inhibitors

Over the last two decades, calcineurin inhibitors have been extensively used in post-transplant immunosuppressive regimens and have secured a vital place in today's solid organ post-transplant care for prevention of acute rejection and improved graft survival. Several landmark trials have compared the available calcineurin inhibitors, cyclosporine, and tacrolimus. The first two multicenter studies that compared microemulsion cyclosporine to tacrolimus using the combination of calcineurin inhibitors, azathioprine, and corticosteroids demonstrated a significant decrease in acute rejection with tacrolimus, but there was no difference in patient or graft survival post transplantation [151,152]. A subsequent study randomized first deceased donor recipients to one of three immunosuppressive regimens (all included corticosteroids): (1) tacrolimus with azathioprine; (2) tacrolimus with mycophenolate mofetil; and (3) microemulsion cyclosporine and mycophenolate mofetil [153]. Acute rejection rates were similar in each group (<20%) but the incidence of corticosteroid-resistant rejection was lower in the tacrolimus arms. Three-year follow-up found no statistically significant difference in renal function, patient or overall graft survival, but improved graft survival in recipients with delayed graft function in the tacrolimus arms [153]. In agreement with these data, a meta-analysis reported that for every 100 patients treated with tacrolimus rather than cyclosporine for the first year, 12 would be prevented from having acute rejection, two would be prevented from having graft failure, but five would develop new-onset diabetes after transplantation [154]. More recently, the ELITE Symphony trial demonstrated that a low-dose cyclosporine regimen was not as effective as a low-dose tacrolimus regimen [74]. As a result of these trials, the KDIGO Clinical Practice Guidelines suggest that tacrolimus should be the first-line calcineurin inhibitor for renal transplant recipients [58].

Corticosteroids

Corticosteroids are a key component of most immunosuppressive protocols. However, they are associated with side-effects including hyperlipidemia, glucose intolerance, and osteoporosis. Trials investigating the avoidance or withdrawal of corticosteroids with the hopes of minimizing adverse events and improving graft survival have shown variable results. In the first double-blinded, randomized, placebo-controlled, multicenter, 5-year trial comparing early steroid withdrawal (7 days post-transplant) with steroid maintenance therapy, investigators reported higher rates of acute rejection in the corticosteroid-free arm. Patients with immediate graft function were included in the trial and immunosuppression consisted of induction per the local transplant center, tacrolimus and mycophenolate mofetil. Most patients received antilymphocyte induction with rabbit antithymocyte globulin. At the end of the trial, patients with rapid corticosteroid discontinuation had lower serum triglycerides, less weight gain, and a lower incidence of new-onset diabetes after transplantation requiring use of insulin. There were no differences observed with respect to high-density lipoprotein, low-density lipoprotein, blood pressure, or diabetes [136]. The rate of biopsy-proven acute rejection and chronic allograft nephropathy was twice as high in the rapid corticosteroid discontinuation arm. In contrast, a meta-analysis did show a significant reduction in these cardiovascular risk factors in patients in whom corticosteroids are avoided or withdrawn [155]. Three pooled studies of corticosteroid withdrawal have shown that, despite the increased incidence of acute rejection in the withdrawal arms, short-term results demonstrated comparable patient and graft survival [156–158].

Low-immunologic-risk patients who are at risk for corticosteroid complications may be the best candidates for corticosteroid withdrawal if they receive antilymphocyte induction therapy. High-risk recipients, like African-Americans, may not be the best candidates for corticosteroid withdrawal, although this is controversial [159,160]. Another factor to consider is the timing of corticosteroid withdrawal. Chronic corticosteroid use can lead to dependence and therefore late withdrawal may be associated with an increased risk of rejection. If prednisone is being used beyond the first week after transplantation, it should be continued rather than withdrawn. Given the lack of long-term data defining the optimal timing of corticosteroid withdrawal, the appropriate maintenance agents to continue, and the patient population in which this may be an acceptable practice, the ideal use of long-term corticosteroids remains to be determined.

Antimetabolite agents

Antimetabolite agents are usually considered the "third agent" in triple immunosuppressive regimens, providing additive effects, but less essential than the calcineurin inhibitor or the corticosteroid component. Azathioprine and mycophenolic acid are the commonly used agents in this category. Currently, there are two forms of mycophenolic acid available on the market, mycophenolate mofetil and enteric-coated mycophenolic sodium. The efficacy of mycophenolate mofetil in renal transplantation has been reported in several well-designed trials [161–163]. Mycophenolate mofetil treatment groups demonstrated a reduced incidence and severity of early rejection episodes as compared to low-dose azathioprine-treated patients in treatment regimens consisting of tacrolimus plus corticosteroid as well as cyclosporine plus corticosteroid [161]. Three-year follow-up of these studies found that the decreased incidence of early rejection in the mycophenolate mofetil arm had not translated into a significant improvement in graft function or survival [162,163]. An Italian trial of deceased donor renal transplant recipients using cyclosporine microemulsion and corticosteroids also demonstrated no benefit of mycophenolate mofetil compared to azathioprine [164,165]. Although it may be controversial, as a result of the summative evidence from these trials, the KDIGO Clinical Practice Guidelines suggest that mycophenolate be the first-line antiproliferative agent [58].

Mycophenolate mofetil is often associated with upper and lower gastrointestinal side-effects that are dose related. Enteric-coated mycophenolate sodium has been developed to help circumvent the upper gastrointestinal side-effects by facilitating release in the small

intestine [166]. Two major clinical trials demonstrated that enteric-coated mycophenolate sodium is therapeutically equivalent to mycophenolic mofetil, and that both drugs have a similar incidence and severity of side-effects [167,168]. These trials did not demonstrate a statistically significant difference in overall gastrointestinal symptoms when patients were given equivalent doses of mycophenolate mofetil or enteric-coated mycophenolate sodium. Postmarketing studies have attempted to explore the gastrointestinal profiles of the two formulations of mycophenolic acid [169–181]. Many trials have proven a beneficial effect of enteric-coated mycophenolate sodium [169–177] while others have not reported a difference in gastrointestinal-related adverse effects [178–181]. In the myTIME, Progris, and myGAIN [171,180,181] studies, patients reported improvement in their perception of change in gastrointestinal symptom burden after conversion to enteric-coated mycophenolate sodium using the self-administered Gastrointestinal Symptom Rating Scale questionnaire, Overall Treatment Effect (OTE) scale for gastrointestinal symptoms, and OTE scale for health-related quality of life questionnaires.

It is possible that gastrointestinal events are multifactorial (infectious etiology, related to gastroparesis or other concomitant medications) and enteric-coated mycophenolate sodium may offer benefit to specific populations. If a patient fails mycophenolate mofetil because of the gastrointestinal side-effects, then the patient may benefit if switched to enteric-coated mycophenolate sodium. Also, if the patient is predisposed to gastrointestinal disorders, then enteric-coated mycophenolate sodium may be a better initial choice for the patient. However, enteric coating is unlikely to influence the systemic effects of the drug including effects on enterocyte proliferation and viral infection that may be responsible for gastrointestinal side-effects.

Drug interactions may also occur with the concurrent use of proton pump inhibitors and mycophenolate mofetil. Studies suggest that the combination of mycophenolate mofetil with pantoprazole or omeprazole results in reduced dissolution of mycophenolate mofetil in the stomach, leading to reduced bioavailability and lower systemic mycophenolic acid exposure. In contrast, the enteric-coated formulation of mycophenolic acid passes the acidic environment of the stomach and dissolves after reaching the neutral pH environment of the small intestine [182].

mTOR inhibitors

Excellent rejection rates have been achieved through a regimen consisting of a calcineurin inhibitor, corticosteroids, and an antimetabolite. Although calcineurin inhibitors have significantly lowered acute rejection rates, they are direct nephrotoxins and cause several other side-effects. Historically, preventing acute rejection was the main goal of transplantation. Currently, chronic allograft nephropathy is the most common reason for graft loss and this has become a major concern for clinicians. Calcineurin sparing regimens are an attractive immunosuppressive option to potentially minimize the risk of long-term graft loss while maintaining low rates of acute rejection. An alternative to the calcineurin inhibitor-based regimens use mTOR inhibitors. Two agents, sirolimus and everolimus, have been developed and FDA-approved in the hope of achieving this goal.

Sirolimus may have a favorable role in calcineurin inhibitor-free maintenance therapy [183,184], but caution is warranted in calcineurin inhibitor sparing regimens, as nephrotoxicity and rejection are still concerns. In the Spare-the-Nephron trial, a calcineurin-free regimen of sirolimus and mycophenolate mofetil was compared to cyclosporine and mycophenolate mofetil. At 2 years of follow-up, renal function was not different [185]. ORION (Optimizing Renal Transplant Immunosuppression to Overcome Nephrotoxicity), another calcineurin-sparing trial, was recently halted because of high acute rejection rates in the tacrolimus elimination arm. The trial [186] was a three-arm study of 450 de novo patients evaluating a sirolimus/ mycophenolate mofetil/ corticosteroids combination, sirolimus/ tacrolimus-elimination at 12 weeks/ corticosteroid versus a standard regimen consisting of tacrolimus/ mycophenolate/ corticosteroids. All patients in this study received daclizumab induction therapy. At 2 years, patient and graft survival and glomerular filtration rate were not different between groups and the urinary proteinuria to creatinine ratio was significantly higher in both sirolimus-containing arms when compared with the tacrolimus group. Everolimus has also been studied in calcineurin-sparing regimens.

Everolimus 1.5 versus 3 mg/day with corticosteroids and low-exposure cyclosporine without induction (n = 237) or with induction (basiliximab, n = 256) has been studied in a calcineurin-sparing protocol [187]. In this study, the use of an induction agent eliminated the need for high-dose everolimus. Six-month biopsy-proven acute rejection occurred in 25.0% and 15.2% of patients in the 1.5 and 3 mg/day groups without induction, and 13.7% and 15.1% in the study groups with induction. Calculated glomerular filtration rates (62–67 mL/min) and adverse events were similar in all arms.

Conversion of a calcineurin inhibitor to sirolimus has met with limited success. The CONVERT trial studied 830 renal allograft recipients who were receiving cyclosporine or tacrolimus from 6 to 120 months post-transplant. The participants were randomly assigned to continue calcineurin inhibitor (n = 275) or convert from calcineurin inhibitor to sirolimus (n = 555) [149]. Success with sirolimus was only observed in a subgroup of patients with a baseline glomerular filtration rate more than 40 mL/min and urine protein to urine creatinine ratio less than or equal to 0.11. Early elimination of calcineurin inhibitor by use of everolimus-based immunosuppression may improve renal function while maintaining efficacy and safety outcomes in selected patients. In a later study, everolimus replaced calcineurin inhibitors at 4–5 months after transplantation in patients with mean glomerular filtration rates above 60 mL/min [188]. In this multicenter, European, open-label study (ZEUS), 300 low- to moderate-risk renal transplant patients initially received basiliximab induction, cyclosporine, enteric-coated mycophenolate sodium, and corticosteroids. At 12 months, the everolimus regimen was associated with a significant improvement in glomerular filtration rate in comparison to the cyclosporine regimen (mean difference +9.8 mL/min). Rates of biopsy-proven acute rejection were statistically higher in the everolimus group than in the cyclosporine group after randomization (10% vs. 3%), but similar at the end of the study period (15% vs. 15%). Compared with the cyclosporine regimen there were higher mean lipid concentrations, slightly increased urinary protein excretion, and lower hemoglobin concentrations noted with the everolimus regimen; thrombocytopenia, aphthous stomatitis, and diarrhea also occurred more often in the everolimus group.

Everolimus has also been used as a substitute for mycophenolate mofetil in combination with cyclosporine and corticosteroids in a recent trial (n = 583) [189]. Everolimus (1.5 or 3 mg/day) was as efficacious as mycophenolate mofetil, although the side-effect profile featured increased adverse events. Discontinuation of therapy due to adverse events (hemolytic uremic syndrome,

lymphoproliferative disease, and proteinuria, and higher serum creatinine) was more frequent in the everolimus arm compared to the mycophenolate mofetil arm.

In summary, the de novo use of sirolimus has been proven to be comparable to a calcineurin inhibitor, while it has been associated with early post-transplant adverse events including lymphoceles, prolonged delayed graft function, and poor wound healing [183,184]. Likewise de novo use of everolimus in combination with induction has produced acceptable rates of acute rejection, although adverse events were common [187,189]. It appears that sirolimus conversion is only successful in a subgroup of patients with a baseline glomerular filtration rate more than 40 mL/min and urine protein to urine creatinine ratio less than or equal to 0.11 [149]. Likewise, the ZEUS study demonstrated the everolimus conversion is possible in low- to moderate-risk patients with normal renal function, although this may come at the expense of a higher acute rejection rate. The best evidence for calcineurin withdrawal with mTOR inhibitors is in selected patients. Close monitoring of drug concentration levels and adverse events is warranted. Whether or not calcineurin inhibitor-free/ sparing regimens using mTOR inhibitor maintenance therapy is efficacious in the long term remains unknown. Therefore, at this time, the KDIGO Clinical Practice Guidelines suggest that calcineurin inhibitors be continued rather than withdrawn [58].

Belatacept

Belatacept is the first immunosuppressive to demonstrate a renal benefit over a calcineurin inhibitor-based regimen. It is a second-generation costimulation blocker that received FDA approval for use in kidney transplantation in June of 2011. In the first partially blinded, parallel group, phase 2 study, more intensive belatacept, less intensive belatacept, and cyclosporine administrations were compared [190]. All patients received basiliximab, mycophenolate mofetil, and corticosteroids (n = 218). Similar rates of acute rejection and graft loss occurred in each arm at 6 months, while the glomerular filtration was statistically higher in each of the belatacept arms. The belatacept groups had less chronic allograft nephropathy, diabetes, hypertension, and hyperlipidemia.

Subsequently, two 3-year, phase 3, randomized, multicenter studies—Belatacept Evaluation of Nephroprotection and Efficacy as First-Line Immunoprotection Trial (BENEFIT) and BENEFIT Extended Criteria Donor (BENEFIT-EXT)—tested the efficacy and safety of belatacept in adult de novo kidney transplant patients [32,190,191]. In both trials, patients were randomized into three groups: more intensive belatacept, less intensive belatacept, and cyclosporine in conjunction with basiliximab, mycophenolate, and corticosteroids. BENEFIT-EXT was designed similarly to the BENEFIT trial with the inclusion of expanded-criteria donors. In the BENEFIT trial, despite the higher incidence of acute rejection in the belatacept arm, at the end of the first year renal function was statistically superior in the belatacept arms (more intensive 65 mL/min, less intensive 63 mL/min, and cyclosporine 50 mL/min). In contrast, in the BENEFIT-EXT trial, acute rejection rates were similar and renal function was statistically superior in the more intensive belatacept group, but not the less intensive group (more intensive 18%, less intensive 18%, and cyclosporine 14%) [191]. Three-year follow-up of these trials demonstrated persistent improvement in renal function (mean change +21 mL/min in the BENEFIT and +10 mL/min in the BENEFIT-EXT) [112]. A major concern that arose from these trials was the high incidence of post-transplant lymphoproliferative disease in the belatacept-treated Epstein–Barr virus seronegative recipient arms. Therefore the drug is contraindicated in patients who are Epstein–Barr virus seronegative.

One limitation of the BENEFIT and BENEFIT-EXT trials was that cyclosporine, a less contemporary immunosuppressive, was utilized and at high doses and concentrations. More recently, a trial was reported that incorporated a more contemporary immunosuppressive regimen. In a phase 2, 1-year randomized study, belatacept/ mycophenolate mofetil, belatacept/ sirolimus and tacrolimus/ mycophenolate mofetil, in combination with rabbit antithymocyte globulin and without corticosteroids were compared (n = 89) [192]. Acute rejection was highest in the belatacept/ mycophenolate mofetil arm, graft loss was lowest in the tacrolimus/ mycophenolate arm, and renal function was better in the belatacept arms.

A conversion trial was recently conducted to test the hypothesis that belatacept-based regimens may provide a treatment option for calcineurin-based maintenance immunosuppression. Patients who were more than 6 months but less than 36 months after transplantation with stable graft function (calculated glomerular filtration rate $\geq$35 mL/min and $\leq$75 mL/min) were randomized to switch to belatacept (n = 84) or continue calcineurin inhibitor treatment (n = 89) [193]. At month 12, the mean change in calculated glomerular filtration rate from baseline was higher in the belatacept group versus the calcineurin inhibitor group. Six patients in the belatacept group had acute rejection episodes, all of them within the first 6 months after conversion; all cases were resolved with no allograft loss. At month 24, mean calculated glomerular filtration rate was 62.0 mL/min in the belatacept arm versus 55.4 mL/min in the calcineurin inhibitor arm [194]. The mean change in calculated glomerular filtration rate from baseline was +8.8 mL/min in the belatacept arm and +0.3 mL/min in the calcineurin inhibitor arm. The relative renal benefit of belatacept was observed in patients switched from either cyclosporine (+7.8 mL/min) or tacrolimus (+8.9 mL/min), and was observed regardless of baseline renal function. Patient survival, graft survival, and the overall safety profile were similar between groups.

Belatacept's demonstration of an improvement in glomerular filtration rate over a calcineurin inhibitor-based regimen is the first by an immunosuppressive agent. The chronic intravenous administration and drug cost may influence prescribing patterns and patient compliance. Another special consideration for belatacept is that it has a relatively long half-life and cannot be discontinued in cases of severe infection. Further trials are needed to explore the long-term outcomes, the impact of Epstein–Barr virus on post-transplant lymphoproliferative disease, and development of chronic allograft nephropathy with belatacept use. These trials should include more current immunosuppressive regimens.

Summary

The KDIGO Clinical Practice Guidelines recommend using a combination of immunosuppressive medications as maintenance therapy, including a calcineurin inhibitor and an antiproliferative agent, with or without corticosteroids [58]. They suggest that tacrolimus be the first-line calcineurin inhibitor used and that mycophenolate be the first-line antiproliferative agent. In patients who are at low immunological risk and who receive induction therapy, corticosteroids could be discontinued during the first week after transplantation.

Maintenance therapy for pancreas transplant recipients

In clinical practice, a maintenance immunosuppressive regimen containing a calcineurin inhibitor, mycophenolic acid, and corticosteroids is the preferred regimen for pancreas transplant recipients. Evidence-based medicine has supported the transition from cyclosporine to tacrolimus and azathioprine to mycophenolic acid over the past 15–20 years. A multicenter, randomized trial (n = 205) has proven that tacrolimus reduces the incidence of acute rejection (moderate to severe; 3% tacrolimus vs. 28% cyclosporine) and results in superior pancreas allograft survival (89.2% vs. 72.4%) [145,195]. Likewise, mycophenolate mofetil has also been shown to improve early outcomes after pancreas transplant. In an open-label, randomized, multicenter study, patients received mycophenolate mofetil 1.5 g twice daily (n = 74) or azathioprine 1–3 mg/kg daily (n = 76) for 1 year after transplantation [196]. At 6 months, there was no difference between survival or rejection rates, but the time to rejection or treatment failure was significantly longer with mycophenolate mofetil compared with azathioprine. One-year acute rejection rates for mycophenolate mofetil versus azathioprine patients were similar (35% vs. 47%, respectively).

There is less evidence supporting the use of corticosteroid withdrawal and mTOR inhibitors in pancreas transplantation. According to SRTR data, 38% of pancreas transplant recipients undergo corticosteroid withdrawal [1]. Several non-randomized studies [197–205] and one randomized, single-center study [206] have investigated corticosteroid withdrawal in pancreas transplant recipients. In the randomized study, 50 simultaneous kidney–pancreas recipients received either no corticosteroids or corticosteroid withdrawal at 3 months in conjunction with rabbit antithymocyte globulin, cyclosporine, and mycophenolate mofetil. Acute rejection (4% in both groups), patient survival, and graft survival rates were similar, but the serum creatinine levels were significantly higher after 1 year of follow-up in the complete corticosteroid avoidance group (1.50 vs. 1.30 mg/dL). In summary, early steroid withdrawal with a potent induction agent, a calcineurin inhibitor, and mycophenolic acid may be safe in pancreas transplant recipients, but long-term follow-up is needed. The metabolic benefits of corticosteroid withdrawal may be limited to simultaneous kidney–pancreas patients as pancreas after kidney recipients did not have improved lipid levels in one study [207]. Little is known about the use of mTOR inhibitors in pancreas transplant recipients. Sirolimus appears to prevent rejection in pancreas transplant recipients, but only a few small, non-randomized studies have been published [156,157,208–212].

Maintenance therapy for lung transplant recipients

For the past two to three decades, the most commonly used regimen in lung transplant recipients has consisted of a calcineurin inhibitor plus an antimetabolite, and corticosteroids [1], specifically cyclosporine, azathioprine, and prednisone. There is less evidence supporting the use of tacrolimus in lung transplantation and therefore the switch from cyclosporine to tacrolimus has been delayed when compared to other transplanted organs (Figure 66.3). Currently based on SRTR statistics, 86% of new lung transplants are prescribed tacrolimus at the time of discharge [1]. Many of the trials of tacrolimus in lung transplantation are limited by single-center, non-randomized designs. Most of the studies that compared tacrolimus to cyclosporine revealed a lower incidence of acute rejection episodes/100 patient days in patients treated with tacrolimus [213–216], while one trial did not demonstrate a difference in the incidence of acute rejection [217]. Similarly, many lung transplant centers have not switched from azathioprine to mycophenolic acid. Based on current SRTR data, 55% of lung transplant recipients are given mycophenolic acid at the time of transplant and 30% of lung transplant recipients are given azathioprine [1], perhaps because the published literature suggests an increased incidence of infection and gastrointestinal toxicity with mycophenolate mofetil [217–220]. Two non-randomized studies that compared azathioprine versus mycophenolate mofetil in combination with cyclosporine and prednisone have demonstrated a reduced incidence of rejection in mycophenolate mofetil treated patients [218,221], and less decline in FEV_1 at 1 year of follow-up [218], while randomized trials with similar immunosuppressive regimens have shown no difference in acute rejection rates [219,220]. Additionally, in one study there was no difference in the number of patients who were bronchiolitis obliterans-free at 3 years (75% vs. 73%) [220]. Lastly, nearly all lung transplant recipients are maintained on corticosteroid therapy [1]. One small, non-randomized trial that used potent induction agents has shown promise for corticosteroid avoidance in lung transplant recipients [222].

Sirolimus in not commonly used or FDA approved for use in lung transplantation because it has been associated with several fatal cases of anastomotic bronchial dehiscence when used in the early post-transplantation period [139,140] as well as interstitial pneumonitis [223,224]. In contrast, everolimus has been studied in lung transplantation with more success. In a randomized double-blind trial, 213 lung transplantation recipients were assigned to receive everolimus or azathioprine in combination with cyclosporine and corticosteroids [225]. While everolimus treatment resulted in fewer episodes of acute rejection and less deterioration of FEV_1 in the first year, only the incidence of acute rejection remained significantly less after 2 years. Unfortunately, everolimus treatment resulted in more serious adverse events and elevated serum creatinine levels. Converting lung transplant recipients (greater than 1 year after transplant) to everolimus with low-exposure calcineurin inhibitors has resulted in a renal benefit (+3.2 vs. −2.4 mL/min) that has been sustained at 2 years post conversion [226].

Maintenance therapy for liver transplant recipients

According to the United Network for Organ Sharing (UNOS) registry data, current 1- and 5-year patient survival rates following orthotopic liver transplantation are 88% and 74%, respectively, with graft survival rates of 83% and 67% [1]. These results are due in part to recent advances in immunosuppressive agents. For liver transplant recipients, the regimen that is most commonly used at the time of transplant is tacrolimus plus mycophenolic acid, and corticosteroids, although corticosteroid withdrawal is becoming more common [1]. Although many patients receive triple immunosuppressive therapy at the time of transplant, agents are eventually weaned and dual and single therapy is commonplace after the initial post-transplant period.

Tacrolimus therapy has been associated with less rejection than cyclosporine in two landmark, randomized, multicenter trials (US trial n = 529 and European trial n = 545) of patients receiving a first liver transplant [227]. Tacrolimus was associated

with significantly fewer episodes of acute or refractory rejection, but substantially more adverse events requiring discontinuation of the drug. These studies used Sandimmune®, which requires bile for absorption, and many programs historically used a bile drainage tube at the time of liver transplant. However, similar results have also been reported with the microemulsion formulation of cyclosporine (cyclosporine USP modified) whose absorption is not as bile- dependent. In a randomized trial of 606 liver transplant recipients in the United Kingdom and Ireland, the primary outcome (combined frequency of death, re-transplantation, or treatment failure for immunological reasons) was statistically lower in tacrolimus-treated patients (21% tacrolimus vs. 32% cyclosporine microemulsion) [228]. Three-year follow up of the composite primary endpoint was similar; however, freedom from death or re-transplantation no longer achieved statistical significance [229]. A recent meta-analysis has confirmed these findings [230]. It concluded that treating 100 recipients with tacrolimus instead of cyclosporine would avoid rejection and corticosteroid-resistant rejection in nine and seven patients respectively, graft loss and death in five and two patients respectively, but four additional patients would develop diabetes after liver transplantation [230].

Although mycophenolic acid acts similarly to azathioprine, it is a more effective immunosuppressant with fewer side-effects, including less hepatotoxicity, translating to sparse use of azathioprine in liver transplantation. Mycophenolate mofetil has also been shown to lower the incidence of acute rejection in liver transplant recipients [231]. In a randomized, double-blind comparative study, liver transplant recipients were treated with either mycophenolate mofetil or azathioprine, both in combination with cyclosporine and corticosteroids [232]. The 1-year incidence of acute rejection (68% mycophenolate mofetil vs. 76% azathioprine) and steroid resistant rejection (19% mycophenolate mofetil vs. 36% azathioprine) was statistically lower at 6 months while patient and graft survival rates were similar.

The use of corticosteroids varies between liver transplant programs. Corticosteroid withdrawal or avoidance has been attempted in liver transplant recipients in an effort to reduce adverse events and minimize the consequences of HCV recurrence [233,234]. Three meta-analyses have concluded that when corticosteroids were replaced by other agents, the incidence of acute rejection was reduced [92,235,236] and that corticosteroid-free regimens are beneficial in lowering cholesterol [92,235], cytomegalovirus infection [92,235], hypertension [92], and new-onset diabetes mellitus [209,235].

Side-effects of sirolimus in the postoperative period include hepatic artery thrombosis, delayed wound healing, and incisional hernias, while chronic use has been associated with hyperlipidemia, bone marrow suppression, mouth ulcers, skin rashes, albuminuria, and pneumonia. In 2002, the FDA alerted the transplant community to two studies of sirolimus in liver transplant recipients [237]. In one study of de novo liver transplant patients, sirolimus was associated with excess mortality and graft loss (22% in combination vs. 9% on tacrolimus alone). In this study and another study, de novo sirolimus was associated with an increase in hepatic artery thrombosis (7% in combination vs. 2% in the control arm); most cases of hepatic artery thrombosis occurred within 30 days post-transplantation and led to graft loss or death. In June 2009, the United States Food and Drug Administration issued another alert based on an unpublished study that found increased mortality in stable liver transplant patients after conversion from a calcineurin inhibitor-based immunosuppressive regimen to sirolimus [237]. In this study of stable liver transplant patients at least 6 months post-liver transplantation, an increased number of deaths was observed in the group converted to a sirolimus-based regimen compared to the group who was continued on a calcineurin inhibitor-based regimen, although the difference was not statistically significant (3.8% vs. 1.4%). These warnings have led to sparse use of sirolimus in liver transplant recipients although several studies have explored its use. A systematic published review that included 11 studies found a small non-significant increase in glomerular filtration rate (3.4 mL/min), after 1 year of sirolimus use in liver transplant patients who received sirolimus as primary immunosuppression due to renal insufficiency or who were switched to sirolimus from another regimen due to nephrotoxicity [238]. However, sirolimus use was associated with higher rates of infection, rash, ulcers, and discontinuation of therapy.

Everolimus has also been studied in liver transplant recipients. In a few small, non-randomized studies of liver transplant patients converted to everolimus for renal dysfunction, the creatinine level and glomerular filtration rate improved significantly [239]. A retrospective 15-month study that followed 240 patients who were converted to everolimus for maintenance therapy following liver transplantation found low rates of rejection among patients on everolimus [239]. Because of adverse events, everolimus was discontinued in 47 patients (20%) and the dose was decreased in 59 (25%).

Maintenance therapy for heart transplant recipients

Since the first heart transplant was performed in 1967, immunosuppression has changed dramatically. Since 2000 there has been a steady increase in tacrolimus use [1]. Currently, tacrolimus is the most widely used calcineurin inhibitor (75%), mycophenolic is the predominant antimetabolite agent (88% of patients), and the use of sirolimus and everolimus remains low. Most patients (89%) remain on low-dose glucocorticoids at 1 year post-transplantation.

Multiple single-center and multicenter randomized comparisons between de novo use of tacrolimus and cyclosporine after heart transplantation have been reported [240,241]. These trials have shown similar patient survival and a more favorable side-effect profile with tacrolimus. In the largest trial (n = 314), de novo heart transplant recipients were randomized to either tacrolimus or microemulsion-based cyclosporine in combination with azathioprine, glucocorticoids, and induction therapy [240]. At 6 months, there was a lower incidence of moderate to severe acute cellular rejection (28% tacrolimus vs. 42% cyclosporine, $P = 0.013$), less hypertension (66% vs. 78%), and dyslipidemia (29% vs. 40%), yet more new-onset diabetes mellitus (20% vs. 11%) with tacrolimus.

Substitution of mycophenolate mofetil for azathioprine may reduce mortality and rejection in the first year after cardiac transplantation. In a double-blind, active-controlled trial, 28 centers randomized 650 patients undergoing their first heart transplant to receive mycophenolate mofetil (3000 mg/day) or azathioprine (1.5–3 mg/kg/day), in addition to cyclosporine and corticosteroids. Although survival and rejection were similar in enrolled patients, treated patients had a significant reduction in mortality at 1 year (6.2% vs. 11.4%) and a significant reduction in the requirement for rejection treatment (65.7% vs. 73.7%). Opportunistic infections, mostly herpes simplex, were more common in the mycophenolic

mofetil group (53.3% vs. 43.6%). Enteric-coated mycophenolic sodium and mycophenolate mofetil appear to be similar except that significantly fewer enteric-coated mycophenolic sodium patients required dose reductions during treatment [175,242].

The mTOR inhibitors are typically used in patients with cardiac allograft vasculopathy (CAV) or renal insufficiency because of their inhibitory effects on smooth muscle proliferation and absence of intrinsic nephrotoxicity [226,243]. The high incidence of adverse effects, including lower extremity edema and poor wound healing, may limit the universal use of these agents.

Of the two available mTOR inhibitors, everolimus has the most evidence supporting use in cardiac transplant. In a randomized, double-blind trial of 634 de novo heart transplant recipients, the use of two concentrations of everolimus (1.5 mg/day and 3.0 mg/day) was compared to azathioprine. All patients received cyclosporine and corticosteroids. At 6 months post-transplantation, significantly fewer patients in the 1.5 mg everolimus group (36% vs. 47%) and 3.0 mg everolimus group (27% vs. 47%, $P < 0.001$) reached the primary efficacy composite endpoint of death, graft loss or retransplantation, loss to follow-up, biopsy-proven moderate to severe acute cellular rejection, or rejection with hemodynamic compromise, compared to the azathioprine group. The difference in efficacy between the groups was almost entirely due to a decreased incidence of acute cellular rejection in the everolimus groups. In this study, everolimus therapy was associated with a significant increase in serum creatinine concentration compared to azathioprine, an effect that was likely due to the potentiation of the nephrotoxic effects of cyclosporine by everolimus [244]. The effects of everolimus on rejection rates, allograft vasculopathy, and renal function were sustained at 24 months [245].

In the Nordic Certican Trial in Heart and Lung Transplantation substudy, 111 maintenance heart transplant recipients were randomized to everolimus plus reduced calcineurin inhibitor or standard calcineurin inhibitor [246]. No significant difference in CAV progression was evident between the treatment groups. However, other immunosuppressive therapy is important as azathioprine plus everolimus patients demonstrated attenuated CAV progression and a decline in inflammatory markers, whereas the opposite pattern was seen with everolimus plus mycophenolate mofetil.

Corticosteroids are used in most heart transplant recipients at relatively high doses in the early postoperative period then tapered to low doses or discontinued altogether in the first transplant year [247,248]. Low-risk patients may tolerate earlier (within 1–2 months post-transplantation) corticosteroid withdrawal without long-term adverse consequences [249,250]. An Australian study randomized 112 patients to induction with rabbit antithymocyte globulin, cyclosporine, and azathioprine with or without corticosteroids [251]. The 3-month rejection rate and the number of patients experiencing corticosteroid-resistant rejection were higher in the corticosteroid-withdrawal group. The number of antihypertensive agents and cholesterol levels at 3 years was significantly higher in the maintenance corticosteroid group. Of note, 47% of patients in the steroid withdrawal group required the addition of maintenance corticosteroids during follow-up, largely owing to the increased incidence of rejection.

Maintenance therapy for intestine transplant recipients

Intestinal transplant recipients have the highest rejection rates and the lowest graft survival rates due to the high immunogenicity of the bowel. Newer immunosuppressive drugs have played a significant role in the success with the procedure since the mid-1990s. Currently, most intestinal transplant recipients receive tacrolimus and corticosteroids as maintenance immunosuppression. Fewer than 200 intestine transplants are performed yearly and therefore the clinical trials of immunosuppression are few in number [252].

Summary

In the past 10–20 years tacrolimus and mycophenolic acid have become the cornerstones of immunosuppressive regimens. While awaiting further advances in the immunosuppressive armamentarium, we should be able to improve the functional life of most allografts by tailoring available agents for induction and maintenance therapy. Maintaining the effectiveness of immunosuppressive therapy requires shifting our therapeutic approach from "one-size-fits-all" to a tailored or individualized strategy. Tailored immunosuppression should prevent both under-immunosuppression (rejection) and over-immunosuppression (associated infections and cancer). As such, ongoing vigilant monitoring of transplant patients should be combined with a willingness to respond to rejection or infection with alterations in maintenance immunosuppressive therapy. The information gained through further study in these complex regimens should provide innovative strategies and new immunosuppressive agents that will serve to extend the functional life of allografts without toxicity or infection.

CHAPTER 67

Rescue Immunosuppressive Therapy

Mark D. Stegall and Patrick G. Dean
Division of Transplant Surgery, Mayo Clinic, Rochester, MN, USA

Introduction

"Rescue therapy" is defined here as any therapeutic intervention designed to address a specific alloimmune-mediated post-transplant process that causes acute or chronic allograft injury. It is of sufficient potency to reverse an emerging acute process, but is prohibitively immunosuppressive to be tolerated for a prolonged period of time. The classic rescue therapy is the treatment of clinically significant acute cellular rejection (ACR). Historically, the management of early ACR was one of the central problems of transplant therapeutics. The development of more effective immunosuppressive regimens has largely solved this once insurmountable problem; however, its management is still important and we discuss this below.

Over the past decade, the role of acute antibody-mediated rejection (AMR) in acute allograft injury has become increasingly appreciated. Mediated by donor-specific alloantibody (DSA), AMR can occur in combination with ACR or can occur in a more pure form—especially in sensitized recipients. Management approaches to these clinical situations are discussed in detail.

With improvements in early post-transplant management, long-term allograft loss has emerged as the major problem facing allograft recipients. In fact, the rate of graft loss beyond 1 year after kidney transplantation has remained relatively constant for decades [1]. We have advocated that the path forward to improving long-term allograft survival is that of detailed patient follow-up to identify specific causes of late renal allograft loss and the development of new therapies designed to address these problems before allograft damage becomes irreversible [2]. We will discuss clinical situations in which chronic allograft damage is encountered and address the connection between subclinical inflammation and chronic injury—specifically within the context of rescue therapy.

Organ-specific guidelines on the clinical diagnosis and treatment of rejection also are presented in Chapters 69–76, and the histopathological criteria defining the various forms of rejection by organ are presented in detail in Chapters 81–87. This chapter will provide an overview of common principles shaping organ-specific therapies, and will serve the reader as a suitable introduction to the treatment of rejection in general.

Before embarking on a discussion of these topics, it is important to note that much of the data does not reach Level I evidence of efficacy, with most widely used practices based on only Level III evidence [3]. This is especially true regarding chronic injury in which there is still controversy on the predominant mechanisms (of which there are likely many) and no consensus exists regarding what therapy may be indicated, if any.

Acute renal allograft dysfunction

While the definition of acute allograft dysfunction is not standardized, a good working definition might be one similar to that used for other forms of acute renal injury: an abrupt (within 48 h) reduction in kidney function (currently defined as an absolute increase in serum creatinine of $\geq$0.3 mg/dL [$\geq$26.4 mmol/L]), a $\geq$50% increase in serum creatinine from baseline, or a reduction in urine output (documented oliguria of less than 0.5 mL/kg/h for more than 6 h) [4]. The differential diagnosis of acute renal allograft dysfunction early after transplantation is broad and, similar to acute kidney injury of native kidneys, includes prerenal, intrinsic renal, and postrenal etiologies (Table 67.1). The majority of this chapter will focus on immunologic causes of graft dysfunction; however, transplant providers also should be familiar with and be able to recognize the non-immunologic causes.

The evaluation of a transplant recipient with acute allograft dysfunction should include the following: a detailed history and physical examination to assess blood pressure and volume status; a urinalysis (paying particular attention to the presence of proteinuria or a nephritic sediment) and urine culture if pyuria is detected; measurement of plasma calcineurin inhibitor (CNI) concentrations (for patients receiving a CNI); measurement of plasma polyoma virus copy number; an allograft ultrasound to detect renal artery stenosis, urine leak, lymphocele, or urinary tract obstruction; measurement of serum alloantibody levels by single antigen bead assay; and placement of a bladder catheter if bladder dysfunction or outlet obstruction are suspected. If no definitive cause of allograft dysfunction is identified from the above interventions, a renal allograft biopsy should be performed. This biopsy should be subjected to routine light microscopic investigations as well as immunofluorescence for IgG, IgA, IgM, C3, albumin, and fibrin. Immunoperoxidase studies should be performed if polyoma virus nephropathy or post-transplant lymphoproliferative disease is suspected. Electron microscopy should be added if de novo or recurrent glomerular disease is suspected. Renal allograft biopsies currently are graded and scored according to the Banff '07 Classification of Renal Allograft Pathology, a consensus-based diagnostic system that is discussed in detail in Chapter 81 [5].

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Table 67.1. Differential diagnosis of acute and chronic kidney allograft dysfunction/ injury

Acute renal allograft dysfunction/ injury
Prerenal
Allograft thrombosis
Atheroemboli
Intravascular volume depletion
Hypotension
Intrinsic renal
Acute cellular rejection
Acute antibody mediated (humoral) rejection
Recurrence of primary renal disease
Polyoma virus nephropathy
Acute calcineurin inhibitor toxicity
Allograft pyelonephritis
Post-transplant lymphoproliferative disease
Postrenal
Ureteral obstruction
Urinary bladder dysfunction
Bladder outlet obstruction
Chronic renal allograft dysfunction/ injury
Chronic antibody mediated rejection
Chronic cellular inflammation
Recurrence of primary renal disease
Chronic drug toxicity (e.g. calcineurin inhibitors)
Polyoma virus nephropathy

Acute cellular rejection

Acute cellular rejection episodes can be described as either clinical or subclinical depending on whether or not allograft dysfunction accompanies the episode. This section will focus on the evidence supporting the treatment of clinically evident acute cellular rejection and subclinical inflammation will be discussed later in this chapter.

In the first three decades of clinical kidney transplantation, ACR was seen in as many as 80% of recipients and was a frequent cause of early allograft dysfunction [6]. Furthermore, a single episode of ACR was found to be predictive of long-term allograft survival [7–10]. More recently, the incidence of ACR within the first 6 months after transplant has decreased significantly from approximately 40% in 1995 to less than 15%, but this decrease has not resulted in a significant increase in long-term graft survival, suggesting that the link between early ACR and long-term outcome may not be as strong as previously suggested [1,11]. Similar to previous reports [12,13], these analyses of registry data show that if complete functional recovery is achieved after treatment of ACR, there appears to be no deleterious effect on long-term outcome. However, those recipients whose graft function (estimated by Cockroft-Gault) did not return to within 75% of baseline after treatment of ACR had a fivefold increased risk of graft loss at 6 years compared to those whose function returned to baseline [10]. Although ACR occurs less frequency than in prior eras and is less consequential, this does not imply that ACR is benign, but rather that its recognition and prompt treatment has become routine practice in transplant centers. Indeed, the progress realized in mollifying the effects of ACR underscores the importance of prompt and properly treating ACR when it is diagnosed. The following sections will discuss the rationale and evidence for the two most commonly used therapeutic agents for the treatment of ACR—steroids and antibodies directed against lymphocytes. The discussion will proceed from a kidney-centric point of view as historically, the management of ACR was initially established in kidney transplantation and largely adapted to other organs as they became more commonly transplanted. Organ-specific considerations follow later in this chapter.

Steroid therapy

Since the early years of clinical transplantation, corticosteroids have been used both as maintenance therapy and as adjuncts to treat ACR [14,15]. Due in part to the rapidly evolving nature of the field of kidney transplantation during these years, as well as to the severe repercussions of not treating established ACR, a randomized trial comparing the use of steroids to treat ACR versus not treating ACR has not been performed. As a result, the consensus regarding the efficacy of these agents in treating ACR has been generated solely from Level III data. Nonetheless, this "experience-based" approach did result in the widespread use of steroids to treat ACR, a practice that continues to the present day. Most current protocols for the treatment of clinically evident, biopsy-proven ACR calls for the use of bolus methylprednisolone therapy for recipients with borderline changes, Banff 1A or Banff 1B scores on biopsy (Figure 67.1). It should be noted that glucocorticosteroids and not mineralocorticosteroids are indicated for the treatment of rejection as they exert a substantial and broad immunosuppressive effect. An ideal dose of methylprednisolone has not been established and varies considerably by transplant center from 100 mg to 1000 mg per dose (or up to 15 mg/kg) for durations that vary similarly by center from 3 days to several weeks, with or without tapering doses. The duration and intensity is often varied by the histopathological grade, although there are no data supporting specific variation.

Steroid-resistant rejection is defined by a failure to clinically respond to steroid therapy, but its precise definition has varied considerably. Most trials have required three full days of bolus methylprednisolone without clinical improvement to meet the definition.

Antilymphocyte therapies

In contrast to the use of corticosteroids to treat ACR, randomized clinical trials (Level I evidence) have been performed using monoclonal and polyclonal antibody preparations directed against lymphocytes. These trials examined the effects of several different antibody preparations [16–36], and reported the effects of a variety of antilymphocyte preparations generated in mice, rabbits, or horses on either the first episode of ACR or in the treatment of steroid-resistant ACR. The nature, results, and limitations of these 21 trials (involving 1394 participants) have been described at length in a Cochrane review [37]. The sum of the data would suggest that antibody therapy is better than steroid therapy at reversing a first episode of rejection and no one antibody preparation is clearly statistically more effective at reversing steroid-resistant rejection.

While it is encouraging to see that these trials were performed, many of them contain limitations that must give the reader pause when interpreting the results. These deficiencies are nicely outlined in the aforementioned Cochrane review [37], but relate mostly to the criteria used to diagnose rejection and define "reversal" of the rejection episode. In the majority of these studies, rejection was diagnosed based upon clinical, laboratory, and imaging criteria without the requirement for an allograft biopsy. In none of the studies was a repeat biopsy performed to verify resolution of the inflammatory process and definitively show reversal of rejection. Lastly, none of the studies examined the effects of these agents in a cohort of patients receiving more contemporary immunosuppressive therapy (e.g. tacrolimus and mycophenolate mofetil ± steroids ± induction therapy). As a result, the true efficacy of these agents

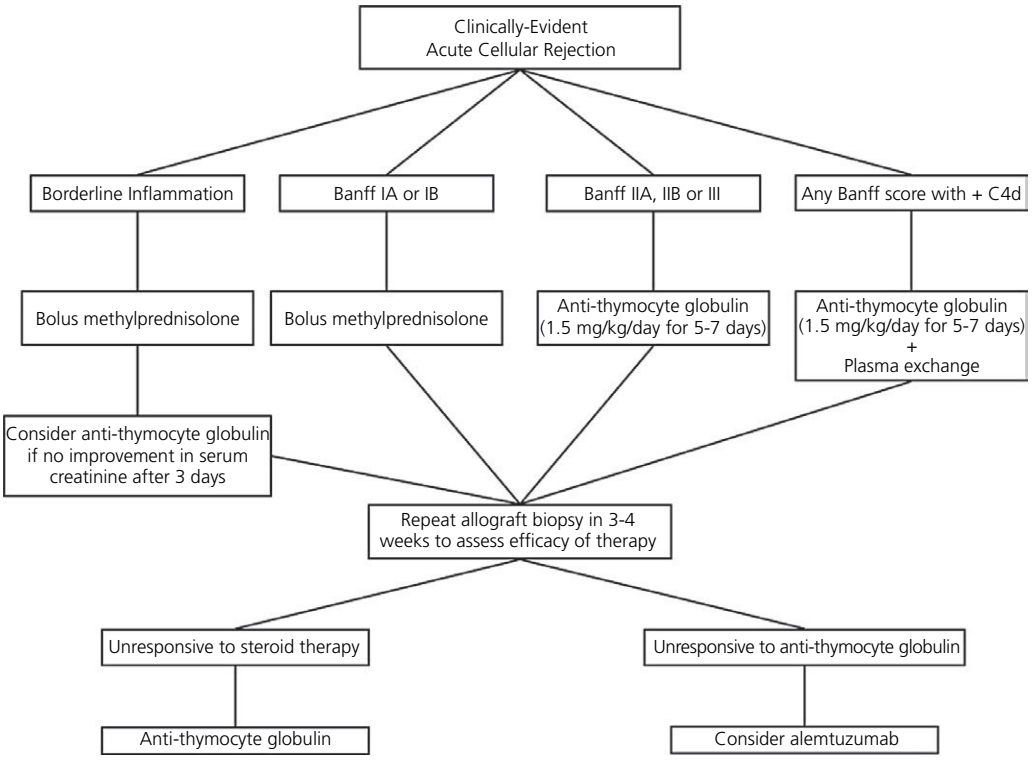

Figure 67.1. Algorithm for the treatment of clinically evident acute cellular-mediated kidney allograft rejection.

in treating ACR in the current immunosuppressive era can be extrapolated from prior results but is, at the current time, unknown. These limitations speak to the need for well-designed clinical trials that include strict inclusion criteria, carefully defined endpoints, and comprehensive follow-up (including repeat allograft biopsies) if the true effects of immunosuppressive agents on rejection episodes and long-term outcome are to be ascertained. Given these caveats, however, our approach is to use antilymphocyte globulin (specifically, antithymocyte globulin [Thymoglobulin®, Genzyme, Cambridge, MA]) for the treatment of a Banff IIA, Banff IIB, or Banff III clinically evident acute rejection episode or in conjunction with plasma exchange for those recipients with "mixed" acute cellular and acute antibody-mediated rejection (Figure 67.1). As with the use of steroids, the use of antibody preparations remains largely center-specific with regard to deployment as a first-line therapy, use in the setting of steroid resistance, and duration of therapy. These policies are driven both by efficacy and cost considerations, noting that antibody preparations are typically costly.

Acute antibody-mediated rejection

Over the past decade, the role of alloantibody in acute renal allograft injury has become increasingly appreciated. The diagnostic criteria for acute AMR according to the Banff classification are: (1) DSA detected in serum; (2) C4d staining in peritubular capillaries; and (3) morphologic evidence of acute tissue injury, including glomerular microthrombi, mesangiolysis, and glomerulitis and/or capillaritis involving neutrophils, macrophages and lymphocytes [38]. Again, acute graft dysfunction differentiates the clinical from the subclinical form. The presence of duplication of the glomerular basement membrane (transplant glomerulopathy) suggests more chronic changes (see below). Early AMR may be seen in association with features of acute cellular rejection (combined ACR and AMR) or may occur alone ("pure" AMR). While the de novo development of alloantibody is likely T-cell dependent and thus implies T-cell activation at some level, but this is not always manifest in the allograft for reasons that remain unclear. The role of T cells in antibody responses in sensitized patients also is unclear.

Pure antibody-mediated rejection

In kidney transplant recipients with high levels of DSA prior to transplantation that are sufficient to cause a positive cross-match (+XMKTx; see Chapter 36 for a complete discussion of DSA detection), the reported incidence of clinical AMR in the first 3 months is high—ranging from 10 to 43% [39]. In many such cases, AMR is a "pure" form and does not involve the histologic features of acute cellular rejection. The diagnosis of AMR in this setting is relatively easy given the presence of DSA, the typical biopsy findings, and the commonly severe graft dysfunction. In our experience at Mayo Clinic, Rochester, we use plasma exchange (PE) and low-dose (100 mg/kg) intravenous immunoglobulin (IVIG) dosed after PE for desensitization; the mean time to acute AMR after +XMKTx was 10 days and all episodes occurred within 3 months of transplantation [40]. This study suggested that the incidence of early AMR correlated best with the level of DSA present at the time of AMR rather than the baseline DSA level. Thus, patients who develop high levels of DSA (either persistent DSA or a "memory" response) develop AMR and those in whom DSA remains low after transplantation do not experience AMR. The onset of AMR in this setting is quite rapid and can lead to graft loss if not aggressively treated. A complete discussion of desensitization protocols is found in Chapter 68.

Table 67.2. Treatment options for acute antibody mediated rejection*

Agents that impact antibody levels
Plasma exchange
High-dose IVIG
Bortezomib
Rituximab
Agents that ameliorate graft damage
Eculizumab (terminal complement blockade)
Corticosteroids
Splenectomy for refractory or severe AMR

*The current Mayo Clinic protocol for acute antibody-mediated rejection (AMR) involves eculizumab and corticosteroids to ameliorate ongoing damage plus plasma exchange and low-dose IVIG to reduce donor specific alloantibody levels. Bortezomib (1.5 mg/kg × 4 doses) is added when DSA levels are very high (e.g. B flow cytometric cross-match channel shift >400 or mean fluorescence index on single antigen beads >10 000).

Surprisingly, acute AMR is usually amenable to therapy and few grafts are lost during the actual AMR episode using current therapy. Because most clinically available immunosuppressive drugs target T cells, they are ineffective in the treatment of AMR. Currently, the treatment of acute AMR may include methods thought to impact antibody levels (PE, IVIG, bortezomib, and rituximab) and/or agents that ameliorate allograft damage via blockade of terminal complement activation (eculizumab or corticosteroids). We discuss these various treatments below with the caveat that this area of rescue therapy is likely to continue to evolve quickly. In addition, the reversal of AMR as an endpoint of a study is sometimes difficult to assess. The studies discussed below fall outside the realm of FDA-approved drug indications and have been termed "off-label" uses. Their use is supported by emerging data that are limited by small numbers of subjects, non-randomized design, and the use of multiple treatment modalities in combination making it difficult to assess the impact of any one agent. An in-depth discussion of off-label drug use in transplantation can be found in Chapter 101.

The mainstay of treatment of AMR is either multiple PE treatments in combination with low-dose IVIG or high-dose (1–2 g/kg) IVIG alone (Table 67.2). In more severe cases such as those with increasing DSA and profound graft dysfunction despite frequent plasma exchanges, splenectomy has been used [41]. Rituximab has been suggested in some reports [42]. The Cedars-Sinai group has reported a two-level protocol using high-dose IVIG as primary therapy and reserving PE for resistant episodes [43]. Both PE and high-dose IVIG based protocols appear to result in the resolution of AMR in >90% of cases [40]. A recent retrospective analysis suggested that treatment of acute AMR with a combination of PE, low-dose IVIG, and rituximab was superior to high-dose IVIG in that DSA levels were lower at 3 months and graft survival at 36 months was higher (91.7% versus 50%, respectively, $P = 0.02$) [44].

Terminal complement inhibition with eculizumab has been shown to ameliorate antibody-mediated damage even when DSA levels are very high after transplantation [45]. Eculizumab also has been used for the treatment of AMR [46]. The advantage of using eculizumab during an early severe AMR episode is that it will significantly block ongoing complement activation and likely ameliorate further damage. The disadvantage is that since it is a humanized monoclonal antibody, it will be removed during PE along with alloantibody and needs to be replaced after each PE treatment. Acute AMR can occur despite treatment with eculizumab, suggesting the existence of C5-independent mechanisms of AMR, but these responded well to PE [45]. Our current protocol for the treatment of acute AMR involves eculizumab (600 mg/dose) and bolus corticosteroids in combination with daily PE and low-dose IVIG. While no controlled studies exist regarding this treatment, this regimen does offer a combination of graft protection while treatment is initiated to reduce DSA levels.

The proteasome inhibitor, bortezomib, also has been used for the treatment of acute AMR—mostly in combination with PE [47–50]. The rationale for bortezomib use is its possible ability to deplete antibody-secreting cells from the bone marrow in vitro [47] and in vivo [50]. It may have additional effects on newly activated lymphoid cells. One of the possible drawbacks of bortezomib is its low bioavailability that likely necessitates multiple doses for efficacy. Studies of bortezomib monotherapy in acute AMR are rare and its contribution to the treatment of AMR remains unclear. Walsh et al. reported that 87% patients with early AMR responded to a combination of bortezomib, rituximab and PE [51].

Combined acute cellular rejection and antibody-mediated rejection

In conventional kidney transplants with a negative cross-match at the time of transplantation, the most common form of AMR is that which occurs in combination with ACR [48]. In contrast to acute pure AMR seen in +XMKTx, this combined AMR and ACR tends to occur months to years after transplantation and has been associated with non-adherence to medical therapy.

Given its late presentation, this form of ACR and AMR is commonly seen in grafts that already have chronic injury. Treatment should address both the cellular and humoral components of the immunologic processes. Thus, bolus corticosteroids and/or anti-T-cell antibodies should be given to treat the T-cell component. PE and/or bortezomib may be considered in order to treat the humoral component. The duration of PE and/or bortezomib has not been clearly defined, but published reports have used one four-dose bortezomib "cycle" [48]. Regardless of the treatment deployed, the long-term prognosis for combined ACR and AMR occurring late after transplantation appears to be quite poor with more than half of the grafts developing chronic injury or graft loss within 4 years of treatment.

Subclinical inflammation and chronic injury

The above discussions have focused on the clinical scenario of early graft dysfunction that is found in association with a biopsy showing features of cellular and/or humoral alloreactivity. Data regarding the management of these entities is now emerging, and outcomes can be followed at least in part by acute improvements in graft function. Subclinical inflammation, that occurring on biopsy but not obviously manifest by graft dysfunction, remains a vexing scenario.

However, over the past decade, it has become clear that the major unsolved problem in transplantation is that of chronic allograft loss and the question arises whether or not rescue therapy might be applied to prevent chronic injury. Recommendations specific to this question require the introduction of two important issues: (1) how chronic injury is defined or diagnosed; and (2) to what degree chronic inflammation (usually present early in a well-functioning organ, i.e. subclinical inflammation) is etiologically linked to chronic injury and graft deterioration. While a detailed discussion of the pathogenesis of chronic injury is beyond the scope of this chapter, a brief summary is warranted in order to understand the theoretical basis for possible future rescue therapy in this clinical scenario.

Chronic injury is usually defined either functionally or histologically. A functional definition usually involves declaring a certain creatinine or glomerular filtration rate (GFR) as a chronically injured allograft. Since allografts tend to have functions across a wide spectrum, it would seem that a decline in renal function in a previously well-functioning allograft also might be a useful metric. Interestingly, very few studies have used declining function to study chronic injury. Defining chronic injury histologically is by far the most common approach. The presence of interstitial fibrosis, usually in combination with poor function, is an accepted definition of chronic injury [52]. Chronic antibody-mediated injury is commonly defined by the presence of transplant glomerulopathy [53].

The association between ACR and interstitial fibrosis was noted in the early years of transplantation. However, Rush et al. definitively showed the connection between subclinical rejection and subsequent interstitial fibrosis [52]. In a randomized trial, they showed that the treatment of subclinical rejection with corticosteroids increased graft survival and likely led to less fibrosis. This early study was from the cyclosporine–azathioprine era of transplantation and subclinical ACR rates were 30%. Tacrolimus-based regimens appear to have much lower rates of subclinical ACR and no randomized trial of treatment in the current era of immunosuppression has been performed. Several transplant programs, including our own, routinely perform surveillance biopsies in well-functioning renal allografts. We continue to find an association between subclinical inflammation at 1 year and lower subsequent graft function and survival (Figure 67.2) [53]. Most of the inflammation found on protocol biopsies is "borderline" in that it is insufficient to meet criteria for ACR. The significance of borderline changes is unclear and has recently been challenged [54]. We and others performing surveillance biopsies tend to treat subclinical inflammation meeting Banff criteria of ACR with bolus corticosteroids. However, the impact of treatment on subsequent outcome in well-functioning grafts is unclear, and the potential infectious risks of additional immunosuppression need to be considered in addition to changes in graft function.

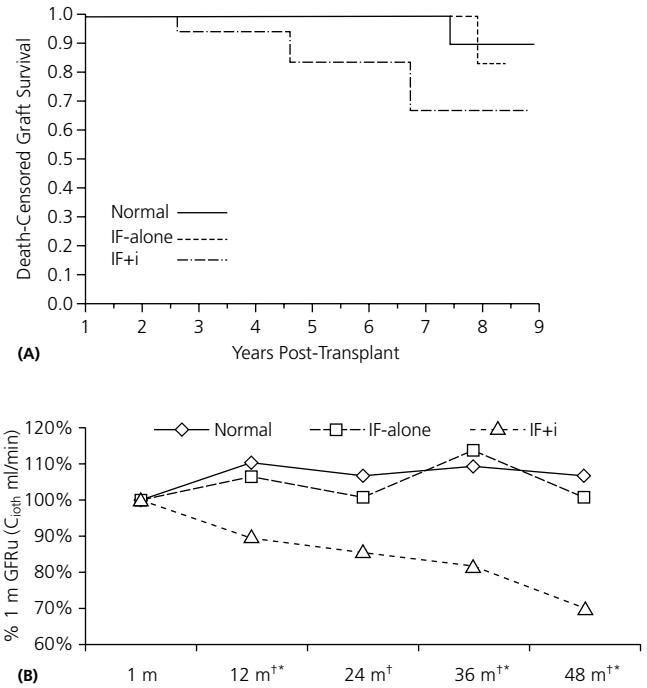

Figure 67.2. (A) Decreased death censored graft survival in patients whose 1-year protocol biopsy showed interstitial fibrosis plus subclinical inflammation (IF+i) compared to normal biopsies and biopsies with fibrosis alone (IF alone). (B) Decreased glomerular filtration (GFR) over time in patients with IF+i (†$P \leq 0.05$ for normal versus IF+I; *$P \leq 0.05$ for IF alone versus IF+i.) Reprinted with permission from the American Society of Nephrology, from [53] Park WD, Griffin MD, Cornell LD, Cosio FG, Stegall MD. Fibrosis with inflammation at one year predicts transplant functional decline. J Am Soc Nephrol 2010; 21: 1987–1997.

Approach to the graft with declining function

A common clinical scenario is that of an allograft with gradually declining renal function—for example the glomerular filtration rate has declined from 60 mL/min at 1 year post-transplant to 40 mL/min at 5 years after transplantation. The rate of decline in GFR may be so slow that the clinician may not consider the event an acute change. The role of therapeutic interventions in these patients is unclear, but a general clinical approach can be outlined.

First, to rule out non-immunologic causes (e.g. partial ureteral obstruction, polyoma virus nephropathy, etc.), the same detailed evaluation should be performed on these failing allografts as those performed on allografts with acute dysfunction (Table 67.1). In addition, assessment for DSA using solid-phase single-antigen beads would be indicated. An allograft biopsy then would be the next logical step in management. Possible findings of the biopsy might include recurrence of the primary renal disease and chronic histologic damage with or without evidence of active inflammation.

However, as described above, a biopsy in this setting also might show cellular infiltration of the interstitium with lymphocytes meeting the Banff criteria for acute cellular rejection. While there is an emerging consensus that subclinical rejection is associated with chronic injury, there is no consensus regarding its treatment. Our treatment protocol involves bolus methylprednisolone similar to the treatment of clinical acute cellular rejection; however, there is no evidence that this or any other treatment prevents the progression of chronic injury. In some instances, when the findings of subclinical rejection accompany recent decreases in immunosuppression (whether prescribed or otherwise), it is likely prudent to attempt to resume the prior drug regimen and levels. Similar to the situation with ACR, there is even less consensus regarding what is an appropriate endpoint to establish the success of treatment of subclinical rejection. Our approach is to repeat the kidney biopsy 1 month after treatment to demonstrate improvement in the severity of the infiltrate.

A second common histologic finding is that suggestive of chronic antibody-mediated injury. The histologic lesion most closely associated with chronic antibody mediated injury is that of transplant glomerulopathy (TG). However, TG also may represent recurrent native renal disease [55]. Chronic active antibody-mediated injury also is suggested by glomerulitis and/or peritubular capillaritis [56,57]. The cellular infiltrate is different from that of cellular rejection, not only in location but also in the fact that macrophages and neutrophils are much more common. In contrast to acute antibody-mediated rejection, the peritubular capillaries commonly do not stain positive for C4d in chronic AMR. The presence of new DSA is further circumstantial evidence that the glomerular lesion is likely due to chronic AMR.

The prognosis of TG appears to be poor, with more than 50% of allografts failing within 5 years of diagnosis [58,59]. Unfortunately,

there are no proven therapies for chronic AMR and few anecdotal reports. We have used multiple PEs to reduce DSA levels, but DSA returns soon after the treatment finishes. High-dose IVIG, rituximab, and/or bortezomib also may be considered, but none have been shown to decrease the progression of TG. Given that chronic AMR may account for more than half of late graft losses [60], more controlled trials are needed to develop effective rescue therapies for this clinical entity.

Calcineurin inhibitor avoidance or cessation as rescue therapy

The past few years have seen increased interest in the avoidance of CNIs using newer agents [61–66]. The major goal of these regimens appears to be avoidance of long-term nephrotoxicity. However, the bulk of the data developed over the past decade have not demonstrated chronic CNI toxicity as a major cause of late renal allograft loss [55]. A major endpoint of CNI-free protocols has been an improvement in renal function at 1 or 2 years after transplantation. However, data demonstrating that improving renal function in the overall renal transplant population will prevent graft loss in the subset of patients destined to fail are lacking. Even the surrogate endpoint of early, improved renal function with CNI-free protocols has been difficult to demonstrate, especially when compared to tacrolimus-based immunosuppression [61]. A recent 10-year renal biopsy study similarly showed the difficulties of using histology to attribute late injury to CNIs [67,68].

When a graft has developed chronic injury, conversion from CNIs to a CNI-free regimen may improve the GFR, but it is unclear if this actually increases graft survival [69–71]. Simply improving the serum creatinine may prolong graft survival marginally, but given the underlying pathology is most likely not due to CNIs, the fate of the allograft may be unaltered.

The end-stage kidney allograft

The role of rescue therapy in the setting of very poor allograft function (e.g. GFR <25 mL/min) and severe, irreversible histologic changes is likely marginal. Most clinicians attempt to maximize medical management by controlling blood pressure and optimizing intravascular volume status. Changes in immunosuppressive regimens also have been suggested, including decreasing the target level of CNIs or discontinuing CNIs with conversion to sirolimus. If there is active inflammation meeting the criteria of ACR, the decision to treat with corticosteroids may be considered; however, the presence of severe (Banff ci3) fibrosis suggests that no treatment will affect the outcome of this transplant. Patients with advanced graft injury should be assessed for retransplantation.

Novel methods of assessing allografts

While renal function and histology have been the cornerstones of allograft assessment for decades, novel methods are being tried to provide a less invasive and/or more detailed profile of intragraft events. Assays for urinary cytokines and other inflammatory markers are being tested for the early detection of ACR [72–74]. These assays are less invasive than biopsies and can be performed more often. In addition, the genomic profile of either the peripheral blood or an allograft biopsy is beginning to help to differentiate different types of inflammation [53,75–79]. In the future, gene expression profiles might be used to decide which grafts need treatment and also could be used as a surrogate marker for the efficacy of treatment. Thus, in the future, "rescue therapy" might be based on the results of urinary assays and/or gene expression profiles.

Rescue therapy for other solid organ allografts

In general, the treatment of ACR and AMR in non-renal solid organ transplantation has evolved along the same lines as in kidney transplantation and, similar to kidney transplantation, the majority of treatment regimens have been adopted without Level I evidence to support their use. However, the implications and treatment of acute and chronic allograft injury in both heart and liver transplantation are unique. Given the life-supporting nature of these organs, the management of alloimmune-mediated allograft injury in these types of transplants deserves attention.

Liver transplantation

The incidence of ACR in liver transplantation varies from approximately 24 to 80% [80,81]. Treatment of ACR with bolus corticosteroid therapy and augmentation of baseline immunosuppression intensity (particularly tacrolimus) typically results in resolution (at least biochemically) of the allograft injury. For those cases that are steroid-resistant, monoclonal or, more commonly in this era, polyclonal antilymphocyte preparations are administered [82,83]. The resilience of the liver greatly exceeds that of the kidney in that livers have a substantial regenerative capacity, making rapid reversal of ACR less pressing. However, a particularly difficult situation arises in the management of ACR in recipients infected with hepatitis C virus (HCV). While a mild episode of ACR does not seem to be associated with an increased risk of graft loss or mortality in non-HCV infected recipients, treatment of ACR in HCV-infected recipients does lead to increased risks of HCV recurrence, graft loss, and mortality [84–89]. At the current time, no consensus exists regarding the most appropriate course of treatment for ACR in the setting of HCV, suggesting the need for prospective trials in this area [90]. As a result, the most appropriate "rescue therapy" for HCV-infected liver transplant recipients may be little or no therapy at all.

Heart transplantation

As with liver transplantation, the implications of graft failure due to allograft injury in heart transplantation are profound. The intensity of treatment of either ACR or AMR generally is determined by the hemodynamic status of the recipient and can vary from increased doses of maintenance immunosuppression or bolus corticosteroid therapy for asymptomatic (subclinical) ACR to plasma exchange $\pm$ bortezomib combined with hemodynamic support for severe episodes of AMR causing cardiogenic shock [91,92].

Similar to kidney transplantation, there are increasing data regarding the role of alloantibody in both acute and chronic heart allograft injury. More specifically, there is emerging evidence supporting the linkage between early allograft injury and the development of cardiac allograft vasculopathy (CAV), a lesion of the epicardial coronary vessels characterized by infiltration of the endothelium, proliferation of vascular smooth muscle cells and subsequent luminal narrowing [93]. Specific management of CAV is discussed in detail in Chapter 79. Patients experiencing either ACR or AMR of the cardiac allograft are more likely to develop CAV [94–96]. Until recently, while percutaneous stenting

and optimizing medical therapy could temporize the condition, the only definitive treatment of severe CAV was retransplantation [93].

The poor prognosis and survival implications of CAV have led to investigations into both preventive and rescue strategies. The most promising immunosuppressive agents in this area appear to be the proliferation inhibitors, everolimus and sirolimus. While the exact mechanisms of action are not completely understood, conversion to or de novo treatment with a proliferation inhibitor has been shown to decrease the incidence and severity of allograft vasculopathy [97–100]. The use of such regimens may have a significant impact on improving the long-term survival related to chronic cardiac allograft damage.

The future role of "rescue therapy" in improving long-term allograft survival

Our ability to manage acute immunologic complications such as ACR and even AMR has made kidney transplantation an almost routine procedure. However, it is has become clear that while early graft loss has almost disappeared, late renal allograft survival has improved little over the past two decades.

We contend that the path toward improved long-term allograft survival will involve detailed patient follow-up to identify specific causes of late renal allograft loss and the development of new therapy designed to address these problems before allograft damage becomes irreversible. Unfortunately, there is a paucity of data regarding the causes of late renal allograft loss and this hampers our ability to devise rational approaches to improve outcomes. Our most recent protocol biopsy study suggests that renal allografts from the era of 1998–2004 demonstrate fewer and less progressive histologic changes in the first 5 years after transplantation than reported in earlier eras [101,102]. For example, the prevalence of moderate to severe fibrosis was only 17% (60/343) at 5 years after transplantation and when mild fibrosis was present on a 1-year biopsy, it progressed to more severe forms at 5 years only 23% of the time. Indeed, two-thirds of all allografts at 5 years showed Banff scores of 0 (none) or 1 (mild) for chronic histologic changes (cg, ci, ct, cv, and ah).

Based upon these data, we have suggested a new path forward to improving long-term graft survival [2]. We recommend that protocols for follow-up be optimized and recent studies into the causes of late graft loss need to be validated. A combination of serum tests (DSA levels and polyoma virus testing) and protocol biopsies might be the best approach. The intensive follow-up aims to identify patients with specific problems at a time point when the graft is still functioning well. Biopsies for cause are likely too late to allow successful intervention.

Thus, we believe that rescue therapy will play an important role in improving long-term graft survival if it is able to move from a reaction to clinical changes to pre-emptive treatment. For example, surveillance for the appearance of de novo DSA might enable "rescue therapy" to be instituted prior to the development of chronic antibody-mediated injury. Similarly, surveillance renal allograft biopsies using either conventional light microscopy or gene expression analyses could be used to identify allografts at risk for chronic injury.

Summary

The concept of rescue therapy is deeply ingrained in transplantation. Therapies for ACR are well established. Treatment protocols for acute AMR, either alone or in combination with ACR, are likely to continue to evolve as new therapies are tried. The role of rescue therapy for subclinical processes remains unclear, but we contend that these will become the most important new areas for intervention as we begin to understand the pathogenesis of chronic allograft injury.

CHAPTER 68

Desensitization Protocols for Organ Transplantation

Carmen Lefaucheur and Denis Glotz
Department of Nephrology and Kidney Transplantation and INSERM U940, Hopital Saint Louis, Paris, France

Introduction

Desensitization can be defined as preconditioning treatment aimed at reducing alloantibodies in an allosensitized patient before transplantation. Allosensitization refers to the presence of alloantibody directed toward another genetically distinct individual. Although patients can be B-cell or T-cell allosensitized, in general, the term is typically interpreted as referring to B-cell allosensitization and inferring the presence of alloantibodies against a given donor. The goal of a desensitization procedure is to eliminate donor-directed alloantibody as defined by attainment of a negative or sufficiently low cross-match and, in doing so, allow transplantation to proceed between a previously incompatible donor–recipient pair. Specifics regarding interpretation of a positive cross-match can be found in Chapter 36. At present, the vast majority of data regarding desensitization arise from the kidney transplant literature. As such, this chapter will be solely focused on desensitization prior to kidney transplantation.

Desensitization in the current context of kidney transplantation

The success of desensitization protocols is closely related to the global success of kidney transplantation as a therapy for end-stage renal disease (ESRD). Transplantation provides mechanisms to expand access and reduce cost for successful treatment of ESRD and surpasses dialysis treatments for quality and quantity of life and for cost effectiveness [1–3]. The current major restriction on kidney transplantation rates is the shortage of donated organs. The crisis in organ availability is related to the fact that patients who require a kidney transplant exceed the organs available, with a ratio between donors and potential recipients lower than 1:3 in most high-income countries [4,5]. Worldwide the number of potential candidates for renal replacement therapy is growing rapidly and, in almost all countries, transplantation meets only 10% of global needs [6].

Recent developments have led to an increase in the pool of donors based on excellent results from ABO-blood-group-incompatible transplants and progress made in transplantation of sensitized patients. High titers of donor-specific HLA antibodies also have limited individuals' prospects for transplantation, although better desensitization protocols and paired kidney exchange programs now afford real opportunities for those previously deemed unsuitable for a transplant.

Desensitization protocols for renal transplantation across HLA antibody barriers

Intentionally crossing the HLA barrier is a relatively recent phenomenon related to the development of methods for detecting and characterizing anti-HLA antibodies and to the availability of potentially effective therapies. The field of desensitization has made great gains over the last decade. Although the expanded practice of desensitization has fostered concerns about feasibility, clinical efficacy, durability of allograft function, and patient safety associated with their use [7–12], nevertheless, significant survival benefit for transplant patients after desensitization compared with waiting for a compatible organ has been suggested by recent studies [12]. As such, these therapies are increasingly being considered as valuable strategies to increase the access to transplant for many allosensitized patients.

Desensitization strategy in response to sensitization to HLA: a serious public health problem

Patients who are HLA sensitized are disadvantaged by prolonged wait times or otherwise limited access to transplantation. This is especially true for patients for whom matching is difficult and/or those considered to be highly HLA sensitized [4,5,13]. Thus, these patients with insufficient flow of potential matched donors are destined to remain on the waiting list for extended periods of time while undergoing dialysis, an additional risk factor for death and graft loss [8,12].

HLA-specific antibodies arise through previous blood transfusion, pregnancy, and previous transplants; the last is currently considered the leading cause of sensitization for renal transplant candidates. The growing utilization of solid-phase tests to detect anti-HLA antibodies using both single HLA phenotypes and single HLA antigens has made possible the establishment of calculated panel-reactive antibody (CPRA) as a new method for assessing sensitization to HLA antigens. The details of this procedure are found in Chapter 36. The CPRA is defined as the percentage of potential donors expected to have one or more of the unacceptable HLA antigens indicated on the waiting list for the candidate. CPRA represents a fundamental change in allocation policies, replacing PRA among French transplant candidates in July 2009 and US transplant candidates in October 2009 [14–16]. It provides a more consistent and accountable measure of sensitization among kidney transplant candidates. Prior to the implementation of

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Box 68.1. Key points: sensitization and kidney transplantation

- The introduction of HLA antibody characterization based on solid-phase assays has improved detection and quantification of donor-specific antibodies (DSA).
- The new measure of sensitization for transplant candidates is the calculated panel-reactive antibody (CPRA), which is based upon unacceptable HLA antigens listed on the waiting list.
- Over the last decade, the percentage of very broadly sensitized patients increased (>80% CPRA) while their rate of transplantation fell.
- Depletion of donor-specific anti-HLA antibodies and pretransplant conditioning improve rates of transplantation.
- Transplantation after desensitization provided a significant survival benefit for patients with HLA sensitization as compared to waiting for a compatible organ.

CPRA, transplant centers and laboratories could report a PRA value based on any of a variety of tests with widely differing sensitivities and specificities. Today, the CPRA policy requires laboratories to enter the specific acceptable HLA identified for their transplant candidates on the national computer system.

The introduction of CPRA has increased the efficiency of organ allocation in sensitized patients [15]. However, the CPRA does not solve all issues of transplantation of highly sensitized patients. Furthermore, it has led to new issues, such as the increasing number of hypersensitized patients on waiting lists and their increased difficulty in gaining access to transplants. Currently, between 35% and 50% of the registrants on our active waiting list have evidence of sensitization [15,16]. About one-quarter of transplant candidates are broadly sensitized: 15.8% of registrants on the Organ Procurement and Transplantation Network (OPTN) and 23% on the French National List had >80% PRA/CPRA and this percentage could be increased by the widespread use of single antigen assays. Nearly all of that increase was among registrants with >95% PRA/CPRA. The percentage of registrants who had >95% of PRA/CPRA doubled between 2009 (5.3%) and 2010 (10.2%) . Therefore, we might see a decline as the patients with very high CPRA values accumulate and do not receive any offers. The rate of transplantation in >95% PRA/CPRA fell from 97 to 69 transplants per 1000 patient years [15]. Few options for transplantation currently exist for these patients who are broadly sensitized to HLA.

The access of sensitized patients to transplants can be increased by specific strategies to reduce HLA-specific antibody levels and improve transplantation rates. Desensitization protocols increase the percentage of patients getting a transplant to 80% (16 of 20 patients who underwent desensitization with intravenous immunoglobulin (IVIG) and rituximab received a renal transplant within a mean of 12 months) [11] or higher (98% in a cohort of live-donor kidney transplantation after desensitization) [12]. Thus, desensitization regimens have the potential to greatly increase access to transplant for this disproportionately disadvantaged population of transplant candidates (Box 68.1).

Treatment options for desensitization programs

High-dose intravenous immunoglobulin is the backbone of desensitization therapies

Intravenous immunoglobulin (IVIG) products are known to have powerful immunomodulatory effects [17]. They are, with or without association with plasmapheresis, the backbone of desensitization regimens. IVIG refers to commercial preparations of normal, polyclonal, polyspecific Ig, consisting mainly of IgG isotype antibodies made from plasma pools derived from thousands of healthy donors. IVIG is composed of more than 97% IgG molecules, with a ratio of the IgG1, IgG2, IgG3, and IgG4 isotypes comparable to human sera. The preparations contain antibodies to foreign (non-self) antigens, to self-antigens (natural autoantibodies), and to other antibodies (idiotypic antibodies).

Several non-mutually exclusive mechanisms have been proposed to explain the beneficial effects of IVIG in patients. None has been definitively shown to be operative in all settings, and it is likely that all play some role in IVIGs salutary effects.

1 Provision of anti-idiotypic antibodies [17,18]. Anti-idiotypic antibodies are antibodies with specificity for the antigen binding portion of another antibody. When bound, these antibodies inhibit the effectiveness of their targeted antibody.
2 Impact of IVIG on the cell function. Some of the beneficial effects of administered IgG extend beyond its half-life, suggesting that these effects are not due merely to passive clearance or competition with pathogenic antibodies. These observations raise the possibility that IVIG therapy results in significant alterations in the cellular compartment of the immune system [17,19,20]. Several recent observations have emphasized the effects of IVIG therapy on dendritic cells, the monocyte/ macrophage system, granulocytes, natural killer cells, and various subsets of T cells, in particular the regulatory T-cell (Treg) subset and B cells.
3 Scavenging of complement fragments. Binding of IgG molecules to potentially harmful complement fragments (C3b, C4b, C2a, and C5a) blocks deposition of these fragments onto their targets and prevents subsequent immune damage [21–24].
4 Immunomodulation by sialylated IgG. One such process, proposed by Ravetch et al. [25], is that the beneficial effect of IVIG is mediated mainly by a fraction of antibodies with terminal sialic acid at the glycan linked to asparagine at position 297 (Asn 297) of the constant Fc chain of IgG. The fraction of IVIG rich in these sialic acid-containing antibodies showed an anti-inflammatory effect by enhancing the expression of the inhibitory IgG Fc receptor IIB, and the enzymatic removal of the sialic acid residues abrogated this anti-inflammatory effect. Recent data demonstrate that the anti-inflammatory properties of IVIG can be recapitulated with a fully recombinant preparation of appropriately sialylated IgG Fc fragments [26]. These and other similar mechanisms may be involved in the means by which general immunoglobulin homeostasis is maintained.

These findings demonstrate the considerable progress that has been made in understanding the mechanisms of action of IVIGs and may influence future perspectives in the field of Ig therapy in organ transplantation.

Plasmapheresis and immunoadsorption

Plasmapheresis (PP) and immunoadsorption (IA) are techniques used to remove plasma proteins and specific proteins like alloantibodies, respectively. The end point of these therapies is the elimination of HLA donor-specific antibody either before or after the transplant. PP is not specific for Ig removal and results in lowering of all plasma proteins, including clotting factors, and requires replacement with fresh frozen plasma and albumin. IA includes a sepharose-bound staphylococcal protein A column with a high affinity for binding all IgGs, not just alloantibodies. Anti-HLA antibody titers rebound and return to baseline levels after the completion of PP or IA [27]. This relates to the general homeostatic mechanisms used to regulate physiologic Ig levels such that

physiologically low Ig levels may actually promote antibody production. Thus, these techniques do not result in a durable reduction in HLA antibodies, unless the patient undergoes transplantation within several days after the last treatment.

Some studies showed that immediate pretransplant IA might convert a positive to negative complement-dependent cytotoxic cross-match in sensitized deceased-donor kidney allograft recipients and thus allow transplantation. However, this experience still remains very limited. The first study using IA immediately before transplantation was presented in 1996 by Higgins et al. on 12 cytotoxic or flow cytometry cross-match-positive patients. The rate of rejection was high (13 rejection episodes in nine patients) as was the rate of graft loss (53.8% at 26 months) [28]. Better results were reported more recently by Lorenz et al. on the outcome of 40 deceased-donor kidney transplant recipients, including nine patients with positive cross-matches rendered negative by a single pretransplant IA. Three-year graft survival (78% vs. 71%), acute rejection (11% vs. 20%), and C4d-positive graft dysfunction (33% vs. 32%) were comparable in cross-match-positive and cross-match-negative patients [29].

The rituximab debate

The renewed interest in B cells and antibodies in organ transplantation has stimulated the search for new drugs. Rituximab is a chimeric murine/ human monoclonal antibody that reacts with the CD20 antigen and selectively depletes B cells [30]. The surface protein CD20 is expressed on naïve and memory B cells, is rapidly down-regulated on activated B cells, and is absent on pro-B cells and plasma cells [31,32]. As such, there is no direct influence of rituximab on antibody-secreting cells.

The drug was originally approved by the FDA for the treatment of refractory or relapsed B-cell lymphomas, and has since become widely used in solid organ transplantation for ABO-incompatible transplant [33,34], treatment of rejection [35,36], rejection prevention [37], and desensitization protocols [10,38–40]. Unfortunately, studies describing rituximab use in transplant are small, and generally uncontrolled. This is a critical point and the value of adding rituximab in desensitization regimens is still questioned.

There are two potential means by which rituximab might function in desensitization regimens [41]:

1 Rituximab might deplete specific antidonor antibody, although the mechanism by which this would occur is unknown. The data for this effect is sparse. In a small phase 1 study of nine sensitized dialysis patients treated with single doses of rituximab, only one patient converted a living kidney donor-specific cross-match to negative and underwent a successful kidney transplantation [39]. There were no significant reductions in panel-reactive antibody levels or antibody specificity in most of the patients. In a more detailed analysis using single-antigen beads, Pescovitz found that specificities with lower titers were more likely to fall after rituximab treatment [38]. Other investigations have demonstrated that rituximab treatment for antibody-mediated rejection (ABMR) in combination with multiple other therapies results in the reduction or elimination of donor-specific antibody [36,42]. Use of rituximab has been anecdotally reported to lead to interference with both flow-cytometric cross-match and complement-dependent cytotoxic cross-match for B cells [11].
2 Rituximab may act by eliminating B cells and in doing so interrupt non-antibody secreting functions of B cells such as antigen presentation. Supporting the direct role of B cells in rejection is the conclusion of Sarwal et al., who showed that CD20 gene expression, and $CD20^+$ infiltrates were associated with poor prognosis [43]. Subjects with CD20-positive rejection had worse long-term graft survival [44]. Treatment of these patients with rituximab was successful [45].

There are problems with both of these concepts. First, anti-CD20 activity has no effect on long-lived $CD138^+$ plasma cells, which are the primary source of acute antibody production [46,47]. Second, rituximab has no immediate or powerful effect on circulating antibody levels. These problems might explain the difficulty of assessing the efficacy of rituximab when used as sole treatment. However, the combination with other treatments including IVIG and/or polyclonal rabbit antithymocyte globulin might constitute an improved approach for the management of allosensitization. These combination protocols can reduce both antibody secretion by, and the number of, long-lived plasma cells. Rituximab is likely to reduce or eliminate the silent cohort of resting naïve and memory alloreactive B cells, as well as the short-lived $CD20^+$ activated plasmoblasts of an early anamnestic response.

The new agents

Two new drugs are under consideration for pretransplant conditioning in highly sensitized patients. Both are used off-label (see Chapter 101), and thus neither has been shown to be efficacious in properly powered randomized trials.

Bortezomib is a proteasome inhibitor that targets all cells with high-level protein turn over, including plasma cells. The drug is FDA approved for use in multiple myeloma patients and anecdotal evidence suggests efficacy in transplant patients [48] through many mechanisms. The immune-modulating effects of bortezomib include activity against normal plasma cells, as shown in animal models [49–51], and induction of apoptosis of normal human plasma cells preventing alloantibody production [52]. In addition, proteasome inhibitors have been shown to suppress T-cell functions [53] and to inhibit function of antigen-presenting cells [54,55].

In the setting of transplantation, bortezomib has been used as primary treatment [56] or as a rescue strategy for acute ABMR [48]. Bortezomib has also been used to abrogate HLA-specific antibodies outside of acute rejection in an attempt to improve long-term allograft survival [57]. All these clinical experiences highlight bortezomib's capacity to promptly and rapidly reduce antibody levels as measured by Luminex assays. In these proteasome inhibitor-based therapies, bortezomib is associated with PP. Inclusion of PP provided the advantage of removing previously screened antibody, thereby causing circulating antibody levels to be a more accurate reflection of current production rates by the residual plasma cells population, rather than a reflection of pre-bortezomib antibody production rates [56]. These considerations have led to proposals for prospective clinical trials to evaluate the efficacy of bortezomib in desensitization programs, as proposed by Woodle and colleagues (University of Cincinnati, OH). The frequency of serious side-effects of bortezomib, most notably neurological, also has to be explored in a meaningful number of pretransplant patients.

Eculizumab, a humanized monoclonal antibody directed against the complement protein C5, is another drug under investigation. By targeting terminal components of the complement cascade, eculizumab works on secondary effects of deposited antibody, and thus is not dependent on antibody clearance, per se. In a presensitized murine model of acute ABMR, C5 blockade in combination with conventional immunosuppression was shown to prevent antibody-mediated allograft injury, resulting in prolonged graft survival [58]. As presented by the Mayo Clinic team, the terminal complement

activation is critical for the development of ABMR. Eculizumab decreases the risk of early acute ABMR in sensitized transplant recipients. The incidence of acute ABMR fell from 41.2% in the control group of 51 sensitized patients treated with plasma exchange-based protocol without eculizumab to 7.7% in the 26 patients of the eculizumab group [59].

Inclusion criteria for and success of desensitization protocols

The inclusion criteria for desensitization protocols, as well as the criteria for accepting a donor after completion of the desensitization protocols, are heterogeneous. This reflects the development of the concept of appraisal of the immunologic risk prior to transplant. Today, the techniques that are used to define this risk vary from the classic complement-dependent cytotoxic cross-match and T-cell antiglobulin enhanced complement-dependent cytotoxicity, to more sensitive techniques of solid-phase assays, of which the Luminex-based assays are the most frequently used (discussed in detail in Chapter 36). While the more advanced of these assays have the potential to be quantitative, at present they are approved only as qualitative assays, and this substantially limits the ability of clinicians to make objective determination of a patient's risk for ABMR.

In the first experiences of desensitization protocols in deceased donors, the inclusion and success criteria were exclusively based on cytotoxic tests: cytotoxic PRA >50% or 80% as inclusion criteria and a negative cross-match was required for patients to be eligible to receive a kidney transplant [7,8]. For living donors, the goal of desensitization treatment was the conversion to a negative cross-match before transplantation [9].

In recent years, the policies of graft acceptance have progressed and the strength of cross-matching for donor HLA-specific antibody plateaued at lower levels of reactivity: titer <1:8 on the complement cytotoxicity assay [12] or a T-cell donor-specific flow cytometric cross-match <250 mean flow-channel shifts [11]. This concept is clearly revealed by Johns Hopkins' experience on live-donor renal transplantation. In this study, the definition of HLA incompatibility included three non-overlapping categories of antibody strength: positive complement-dependent cytotoxic or flow-cytometric cross-matching or only detectable donor-specific anti-HLA antibody on Luminex assays. A survival benefit was associated with desensitization in all three categories of HLA incompatibility. This study also suggested that an increase in the donor-specific level was a predictor of reduced graft survival: patients with positive results on the bead assay had the shortest follow-up, with rate survival of 90.8% at 48 months; rates of survival were 92.2% at 1 year, 85.5% at 3 years, and 79.8% at 8 years in desensitized patients with a positive flow-cytometric cross-match; and, respectively, 87.7%, 82%, and 78% in desensitized patients who had positive cross-match on the complement-dependent cytotoxicity assay [12]. Other studies showed a strong correlation between the risk of acute ABMR and the levels of donor-specific antibodies postdesensitization, as defined by mean flow-channel shift on flow-cytometric cross-matching and mean fluorescence intensity on Luminex assays [60,61].

Specific desensitization protocols

There are currently three desensitization protocols for which clinical efficacy has been demonstrated: (1) high-dose IVIG; (2) rituximab and high-dose IVIG (R/IVIG), and (3) plasmapheresis (or immunoadsorption) with low-dose IVIG (PP/IVIG). As of today, there have been no randomized prospective studies comparing their clinical efficacy. Moreover, data from various studies to date are difficult to interpret or compare because of heterogeneity among inclusion and success criteria of desensitization protocols, histocompatibility testing techniques, donor-specific anti-HLA antibody levels, and demographic and clinical characteristic of donor and recipient populations (Table 68.1).

The choice of desensitization regimen relies, for largely logistical reasons, on the origin of the donor, that is living or deceased. In living donor situations, where transplantation can be performed as soon as the projected reduction in antibody level has been achieved, the combination of PP/IVIG is the treatment of choice, with or without the addition of rituximab. When one has to wait for an unknown period of time for a deceased donor, use of high-dose of IVIG, alone or associated with rituximab, is preferred because the decrease in antibody level is far more prolonged, and therefore compatible with the wait for the organ.

High-dose IVIG regimen

High-dose IVIG regimen is a protocol used for both live and deceased donor transplants, but the major advantage of this approach is its applicability in deceased donor kidney transplant candidates. It consists of monthly courses of 2 g/kg body weight of IVIG until either the cross-match is deemed safe or totally negative [7,8,18].

The efficacy of high-dose IVIG protocol was demonstrated in a randomized, multicenter, placebo-controlled trial conducted by the NIH (NIH IG02 study) from 1997 to 2000 [8]. This study, which is the only controlled clinical trial of a desensitization therapy, was designed to determine whether IVIG could reduce PRA levels and improve rates of transplantation without concomitantly increasing the risk for graft loss in this difficult-to-transplant group. IVIG was superior to placebo in reducing HLA-specific antibody levels and improving rates of transplantation (Figure 68.1). The 3-year follow-up showed that the predicted mean time to transplantation was 4.8 years in the IVIG group versus 10.3 years in the placebo group ($P = 0.02$). With a median follow-up of 2 years after transplantation, the viable transplants functioned with a mean serum creatinine of 1.68 ± 0.28 (IVIG) versus 1.28 ± 0.13 mg/dL for placebo ($P = 0.29$). Allograft survival also was superior in the IVIG group at 3 years. From this multicenter, double-blinded, placebo-controlled trial, we concluded that IVIG was superior to placebo in reducing HLA-specific antibody levels and improving transplantation rates in highly sensitized patients with end-stage renal disease.

The rate of acute rejection in desensitized patients was still high (35% to 50%). Although more acute ABMR episodes were seen (20% to 38%), the 3-year allograft survival was satisfactory: 78% in the French experience and 80% in the NIH IG02 study [7,8]. The authors did not report the specificity and the strength of donor-specific HLA-specific antibodies.

Induction treatment in high-dose IVIG protocols was complemented by antithymocyte globulin [7] or daclizumab [18], with similar results. The impact of induction treatment was nonsignificant as shown by Cedar-Sinai Center experience, in which the induction treatment was switched from daclizumab to antithymocyte globulin [62]. The 2-year graft survival was 84% in the daclizumab group (58 patients) and 90% in the antithymocyte group (39 patients), whereas the acute rejection rate was 36% (22% ABMR) and 31% (21% ABMR), respectively.

Table 68.1. Summary of reported desensitization protocols and their clinical outcomes

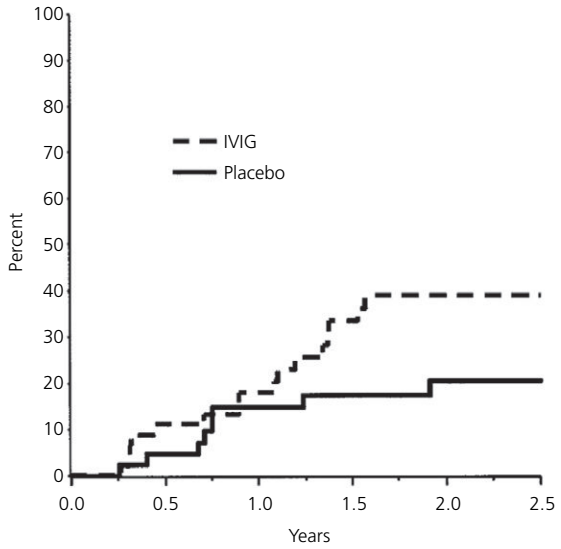

Figure 68.1. The cumulative time to transplantation. Intravenous immunoglobulin (IVIG) significantly ($P < 0.05$) decreased the time to transplantation compared with placebo. The rates of transplantation in the IVIG group were double those in the placebo group and were greater for retransplant patients. Source: Jordan et al. 2004 [8]. Reproduced with permission of Massachusetts Medical Society.

Rituximab and high-dose IVIG regimen

The Cedars-Sinai Medical Center group added rituximab given twice (1 g on days 7 and 22) to a monthly IVIG regimen (2 g/kg body weight on day 0 and 30) and achieved 80% transplant rate among 20 patients with 100% and 94% 1-year patients and graft survival rate [11]. However, the acute rejection rate was very high (50%), and 31% of these episodes were ABMR.

The reduction in PRA was similar to the NIH IG02 study and it remains unclear whether rituximab added any efficacy to the IVIG regimen (Figure 68.2).

Plasmapheresis and low-dose IVIG regimen

This protocol produces a rapid reduction in anti-HLA titers that allows for transplantation after three to five PP treatments, depending of the strength of HLA-specific antibodies before transplantation. The addition of low-dose IVIG adds an immunomodulatory effector mechanism that might be beneficial in keeping the antibody titers low.

The PP/low-dose IVIG protocol was first utilized in 1998 at Johns Hopkins Hospital in cross-match incompatible living-donor kidney transplant candidates [9]. Patients received PP and IVIG at 100 mg/kg after each PP along with tacrolimus and mycophenolate mofetil treatment starting 2 to 3 weeks before transplantation. The treatment plan is individualized on the basis of an assessment of the patient's risk of ABMR [9]. Montgomery et al. reported their 11-year experience in a large cohort of 211 live-donor recipients. They clearly demonstrated that live-donor transplantation after desensitization provided a significant survival benefit for patients with HLA sensitization, as compared with waiting for a compatible

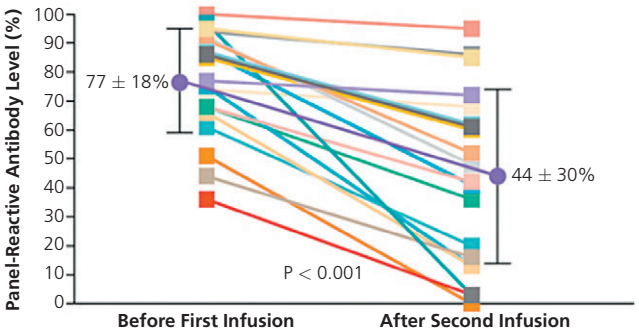

Figure 68.2. Panel-reactive antibody levels. Individual data are shown for patients before the first infusion of intravenous immune globulin and after the second infusion. The pretreatment and post-treatment means are also shown, as determined with the T-cell complement-dependent cytotoxicity panel-reactive antibody assay. The means were significantly different ($P < 0.001$). Bars denote standard deviations. Source: Vo et al. 2008 [11]. Reproduced with permission of the Massachusetts Medical Society.

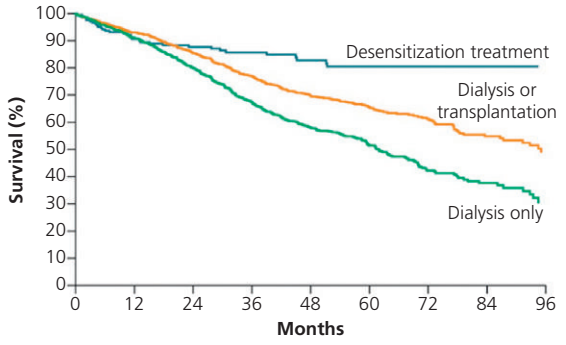

No. at Risk

Figure 68.3. Survival in HLA-incompatible kidney recipients. Kaplan–Meier estimates of patient survival are shown for patients who underwent desensitization treatment before kidney transplantation (treatment group), as compared with two matched control groups of patients on a kidney waiting list who continued to receive dialysis (dialysis-only group) or who either continued to undergo dialysis or underwent HLA-compatible transplantation (dialysis or transplantation, or dual therapy, group). Source: Montgomery et al. 2011 [12]. Reproduced with permission of Massachusetts Medical Society.

organ. By 8 years, the survival advantage more than doubled (80.6% vs. 30.5% for patients in the dialysis-only group) [12] (Figure 68.3).

Similar PP/low-dose IVIG-based desensitization regimens were used by several other teams [63–67]. In these studies the induction therapies were very heterogeneous, including daclizumab [68], OKT3 [63], or antithymocyte globulin/ basiliximab and rituximab [65,66], or antithymocyte associated with rituximab and splenectomy [64]. Despite these modifications, the rates of rejection remained high (between 33% and 100%) with good short-term graft survivals, ranging from 78% to 100% in the first 2 years post-transplantation. The University of Maryland reported its long-term experience in 41 flow cytometry cross-match-positive patients using PP/low-dose IVIG with OKT3 or antithymocyte globulin induction treatment. Patients had lower acute ABMR (12%) compared with the studies presented above, but patient survival and graft survival at 4 years were only 78% and 66% respectively [67]. See Box 68.2 for key points.

Box 68.2. Key points: desensitization protocols

- DSA removal through immunoadsorption or plasma exchange, and DSA inactivation using high-dose intravenous immunoglobulins are the backbone desensitization therapies with good short- to intermediate-term outcomes.
- The value of adding rituximab is still debated.
- New interventions aimed at the prevention of antibody-mediated allograft injury using complement blockade, or the inhibition of DSA synthesis using proteasome inhibitor-mediated plasma cell depletion look promising. Proteasome inhibition with bortizomib is emerging as a potential new strategy.

Safety of desensitization protocols

Specific side-effects of IVIG

There are many IVIG products with product-specific side-effects which depend on the individual preparations' osmolarity, pH, and sodium or sugar content. As shown by the Cedar-Sinai group, who reviewed the side-effects of IVIG in 279 desensitized patients [69], most adverse reactions to IVIG are mild and include headache, nausea, myalgia, back pain, and increased blood pressure, all of which typically respond to slowing the infusion rate or premedication with antihistamine drugs. Rare serious side-effects of IVIG were reported and included: antibody-mediated (Coombs-positive) hemolysis [70]; acute aseptic meningitis [71]; and acute renal failure (ARF). The predominant, known mechanism of ARF after IVIG infusion is the osmotic injury to proximal tubular epithelium associated with sucrose-containing formulations. Thrombotic events, such as acute myocardial infarction, deep venous thrombosis, and stroke, are related to high osmolarity and can be prevented by prophylactic anticoagulation. Very rare, serious anaphylactic reactions may occur in patients with IgA deficiency.

Adverse events related to plasmapheresis

The Johns Hopkins group evaluated the following PP-related adverse events in the largest cohort of live-donor transplant patients desensitized by PP/IVIG regimens (215 patients) [12]: minor reactions (10.9%); major events, including anaphylaxis with hypotension and airway edema (1.4%); and surgical site bleeding complications or bleeding after biopsies, some of which may have been associated because PP depletes coagulation factors.

Risk of infection and malignancy

Desensitized patients receive more immunosuppression that non-sensitized patients, and this confounds the direct association of any of the components of a desensitization protocol with infectious risk. Regardless, the overall impact of a desensitization approach is one of substantial immunosuppression, and this must be balanced against the risks of dialysis and failure to proceed with transplantation.

The development of progressive multifocal leukoencephalopathy (PML) is caused by the reactivation of latent JC polyomavirus. Safety alerts were issued by the FDA and WHO describing cases of PML in patients with systemic lupus erythematosus treated with

rituximab. No cases have been reported as attributed to rituximab in renal transplant patients [72].

Controlled clinical trials in rheumatoid arthritis and lymphoma treatment have demonstrated the safety of rituximab with no significant increase on infection rates [73,74]. Also, the prevalence on infection reported in three studies regarding desensitized patients was not higher than in average transplant patients [11,66,75]. Kamar et al. [76] report on a disturbing association between rituximab use and a significant risk of infection-related deaths post-transplant (9.1% in rituximab-treated group vs. 1.6% in the retrospective controls). However, the dose of rituximab given in this report was four times higher than used in desensitization protocols.

In summary, serious infectious complications can occur after desensitization protocols. Consideration should be given to viral polymerase chain reaction (PCR) monitoring, especially in those patients who receive agents that alter T-cell function in addition to rituximab [77]. As with other immunosuppressive agents, finding the most effective and safe dosing is mandatory.

Desensitization protocols for renal transplantation across ABO blood group antibody barrier

The use of ABO-blood-group-incompatible living donors in kidney transplantation is hardly a new phenomenon [78], having been pioneered by Guy Alexander and advanced subsequently in Japan, with the latter driven by the lack of a definition of brain death and the resulting ABO-compatible donor shortage. In general, the barrier presented by ABO-specific antibodies seems qualitatively less vigorous than that presented by HLA-specific alloantibody. Between 1989 and 2005, more than 850 ABO-incompatible kidney transplants from living donors were performed in Japan [79], giving excellent short and long-term results, with 1-year graft survival currently exceeding 95%.

The desensitization regimens in use differ little from those used for HLA incompatible transplants, and are based on antibody removal, using PP or IA [34], and prevention of antibody resynthesis, initially achieved by splenectomy and now replaced by the use of rituximab, together with conventional immunosuppression. Over the years, the immunosuppressive regimens have changed, imposing a limitation on the numbers of pretransplant PP sessions, replacing splenectomy by rituximab [80], and ceasing post-transplant PP, thus limiting the total amount of immunosuppression without any increase in rejection rates.

The rate of acute ABMR following ABO-incompatible transplantation varies from 15% to 33% [81,82], with a negative impact on graft survival. All protocols are based on pretransplant antibody removal through PP or, more recently, IA [34]. However, very high titers of isohemagglutinins may necessitate a great number of PP sessions, are associated with a high frequency of humoral rejections [83], and might represent a contraindication [84].

In a survey of North American centers, 80% used the combination of plasmapheresis and IVIG [85]. Two seminal observations have been drawn from these transplantations: (1) the pretransplant titer of isohemagglutinins, that is antidonor antibodies, does not need to be reduced to zero, demonstrating that successful transplantation can be performed despite existing low level of antidonor antibodies; moreover, the risk of rejection as well as graft survival are closely correlated with the pretransplant level of isoagglutinins [81,86], a finding also present in HLA incompatible transplants; and (2) long-term excellent function of the graft, without histological damage, is achieved despite persistence of antidonor antibodies, a phenomenon called accommodation [87], yet to be seen in HLA-incompatible transplantation.

Summary: outstanding issues in desensitization protocols

Numerous issues remain regarding the appropriate deployment of desensitization protocols. These have been summarized in the proceedings of a recent FDA-sponsored workshop on ABMR [88].

Who should benefit from desensitization protocols?

All published protocols have selected their patients on the basis of cellular assays, that is positive cross-match assays (either cytotoxic or by flow cytometry) for living donor transplantation, or high cytotoxic panel-reactive antibody for cadaveric donor transplantation. However, access to transplantation for patients on the deceased donor waiting list is now dependent in many countries, such as the USA or France, on CPRA, based on the definition of forbidden HLA antigens by Luminex assay [15,16]. Unfortunately, a growing number of patients are immunized solely by new highly sensitive techniques such as the Luminex assay, with little if any cytotoxic PRA. Those patients may have a high CPRA, barring them from transplantation, but cannot be enrolled in the canonical desensitization protocols based on cytotoxic tests. Thus, we need to reappraise inclusion criteria of desensitization protocols, also based on the current techniques of measure of sensitization and the sensitive techniques for the detection of HLA-specific antibodies.

Pretransplant immunologic risk assessment: how much is significant and what does this mean in term of unacceptable antigen?

There is no consensus on the definition of a forbidden antigen as defined by solid-phase antibody testing methods such as Luminex technology. As for clinical relevance, we have learned that the mere existence of a given HLA-specific antibody directed against the donor (donor-specific antibody or DSA) solely detected by Luminex Single Antigen is no longer a contraindication to transplantation, as excellent graft survival rates have been shown despite the existence of those antibodies [88–90]. Thus, a quantitative approach is mandated but, at the moment, each laboratory has defined its own threshold of mean fluorescence intensity (MFI) to define a forbidden antigen, which may vary from 500 to 3000. At our institution, we retrospectively studied 402 patients who underwent cadaveric transplantation after a negative T-cell cytotoxic cross-match [91]. In 83 of those patients, a DSA was detected using Luminex Single Antigen assay. Although the prevalence of acute humoral rejection rose significantly with increasing MFIs of DSAs, a threshold MFI value of 3000 was associated with increased graft loss. Our main challenge for the years to come is to precisely grade the immunologic risk of rejection and graft loss, allowing clinically relevant definitions of acceptable and forbidden antigens, leading to the precise estimation of the access to transplantation and, finally, to the best possible definition of the population of patients really needing desensitization protocols.

Need for active policy of management of the waiting list

Patients are shifted to desensitization protocols after wait times that are exceedingly long (5 to 10 years). From our standpoint this is an

unacceptable approach. We need to predict probability of transplantation for highly sensitized patients for much earlier identification of those who could benefit from desensitization protocols [16]. Simulation programs should allow us to check whether the national allocation system offers a realistic possibility of transplantation for these hypersensitized patients. We need to identify early—at the time of inscription on the waiting list—which patients have an insufficient pool of donors and will not benefit from the national prioritization programs, in order to allocate them to specific protocols of desensitization.

Integrating paired donation into desensitization protocols

Very broadly sensitized patients with high HLA reactivity who are both difficult to match and difficult to desensitize can be transplanted by combining kidney-paired donation (KPD) and desensitization, with the goal of finding a lower-immunologic-risk donor in the KPD pool, and thus increasing the practicality and success of desensitization. Decision about the best transplant option for a particular donor/ recipient phenotype can then be made rationally using KPD and desensitization as complementary modalities.

The challenge of long-term graft survival in desensitized patients

Preconditioning regimens currently in use for desensitization are administered with an immediate goal of preventing acute antibody-mediated injury. However, it is now clearly recognized that patients with preformed DSA are at risk not only for acute or accelerated ABMR but also for delayed graft function and impaired long-term graft survival event in the absence of clinical ABMR [91]. The studies have led to the discovery of the "underwater" part of the iceberg, representing progression of lesions leading to chronic humoral rejection and late graft loss [92–94]. The main question is, how can we prevent or stop this progression of antibody-mediated injury? Transplant recipients following desensitization protocols therefore require both pretransplant and post-transplant interventions that have separate but complementary aims.

CHAPTER 69

Clinical Allograft Rejection Syndromes in Kidney Transplantation

Brian J. Nankivell
Department of Renal Medicine, Westmead Hospital, Sydney, NSW, Australia

Introduction

Transplant injury from the immune response

Transplantation from a genetically non-identical donor initiates a recipient immune response directed toward donor antigens which is expressed as allograft rejection. Pre-existing immune memory represents residual heterologous immunity from cross-reactive past infections or previous immune stimuli, and correlates with rejection and graft loss [1]. Memory T cells can also become peripherally activated in tissues or in tertiary transplant lymphoid structures [2–4]. Rejection invokes the adaptive immune system of specific T lymphocytes, B cells, and plasma cells generating antibody, but also involves the innate system consisting of complement, NK cells, and macrophages. The alloimmune response is the cardinal threat to the transplanted kidney: uncontrolled rejection destroys the allograft [5].

The clinical syndrome of acute rejection has changed with the introduction of powerful calcineurin inhibitors (CNI) and better immunological matching. In the early azathioprine/corticosteroid era, acute rejection was common, approaching 70–80%, and presented with fever, graft tenderness, oliguria, and a rising serum creatinine. Rejection rates are now below 15% by 1 year, but those remaining episodes are clinically more severe. Disappointingly, as described in depth in Chapter 103, long-term attrition rates remain largely unaltered.

The impact of immune-mediated graft injury varies by the severity, timing, persistence, and histological type of rejection: which in turn determines the level of functional impairment and therapeutic response. Acute interstitial T-cell mediated rejection when treated promptly with pulse corticosteroids usually resolves without sequel. In contrast, vascular, steroid-resistant, or antibody-mediated acute rejection are more resistant to therapy, and—along with recurrent rejection, untreated subclinical rejection, chronic rejection, or late acute rejection from non-adherence—can irreversibly damage the transplant and require robust targeted therapy. Several divergent immune-mediated mechanisms and patterns of rejection can co-exist in a single episode, especially in progressive or late acute transplant dysfunction. Rejection-mediated injury stimulates a healing response within the kidney transplant, modified by immunosuppression [6–9].

Rejection can be described by timing into hyperacute (immediate–minutes), acute (early–days), late-acute or chronic (months to years post transplant); by transplant histopathology (interstitial/cellular, vascular and antibody/endothelial rejection); by histological severity (determined by the extent of inflammation and injury, scored and graded by the Banff schema [10]); by treatment response (steroid-resistant rejection or not); by level of renal dysfunction (acute versus subclinical rejection); and immunobiology (T-cell mediated and antibody of the adaptive immune system versus complement, macrophages, and innate mechanisms). Diagnosed by needle core biopsy, rejection is classified by pathophysiological subtype, which influences prognosis and dictates treatment options [11,12].

This chapter is organized into four clinical scenarios of transplant dysfunction, with their corresponding rejection patterns and non-immune differential diagnoses, occurring in the immediate, early, and late periods after transplantation. It focuses on practical management, with detail of immunological mechanisms, histopathological findings, treatments, and specific differential diagnoses found in Chapters 5–9, 67, and 81.

Primary non-function

Clinical scenario. The transplanted kidney initially fails to function after implantation.

Immediate graft function (IGF) ideally is the norm and occurs after vascular reperfusion, where the kidney transplant passes urine and functions with sequential reductions of serum creatinine. Primary non-function is characterized by post-operative oliguria that is unresponsive to fluid challenge or furosemide, and increasing serum creatinine levels. The most common cause is ischemia–reperfusion injury; however, ureteric obstruction, vascular impairment, and hyperacute rejection are important differential diagnoses.

Hyperacute rejection

Hyperacute rejection is mediated by preformed cytotoxic donor-specific antibodies (DSA), often directed against HLA class I antigens expressed on donor renal allograft endothelial cells

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

[13–15]. Most first transplant recipients do not have pre-existing antibodies to anti-HLA molecules, unless exposed to foreign human cells expressing HLA through pregnancy, blood transfusion, or previous transplantation—which are risk factors for sensitization. See Chapters 36 and 89 for detailed descriptions of HLA antibodies and their clinical detection, respectively.

Hyperacute rejection presents almost immediately after release of the vascular cross-clamps where the kidney becomes flaccid with variable surface mottling, instead of "pinking up" with normal reperfusion. Progressive microvascular DSA deposition is followed by rapid activation of classical complement cascade, innate immune, and coagulation pathways. Acute inflammatory leukocytes then adhere to endothelial cells of glomeruli ("glomerulitis") and peritubular capillaries (PTC). Once established, it is usually impossible to reverse. Endothelial necrosis, platelet, and fibrin deposition and local coagulation then progresses to patchy cortical necrosis and severe acute tubular necrosis [13]. The transplant remains anuric, progressively blackens with large-vessel thrombosis, associated with a consumptive thrombocytopenia and anemia. The operation usually ends with transplant nephrectomy.

Hyperacute rejection was initially described from kidneys transplanted against a positive direct complement-dependent lymphocytotoxicity (CDC) cross-match [16], which later became an absolute contraindication. More sensitive and specific cross-matching techniques (including antihuman globulin augmented CDC cross-match, flow cytometric or solid-phase serum screening; Chapter 89), which identify pretransplant DSA, has largely eliminated this problem [15]. Rarely, undetected non-HLA DSA (such as antiendothelial cell antibodies) can mediate early hyperacute rejection [17].

ABO incompatible kidney transplantation

Hyperacute rejection also occurs with ABO-incompatible transplantation. Anti-A and anti-B antibodies (isohemagglutinins) are isoantibodies directed against blood group antigens expressed on endothelial and red blood cells, and pose a barrier to transplantation. The lesson of ABO incompatibility, discovered a century ago with blood transfusion (massive hemolysis, acholuric jaundice, hemoglobinuria and renal failure), was again relearned in the 1950s with ABO-incompatible kidney transplantation, which rapidly failed with coagulative necrosis from hyperacute rejection. Transplants were then routinely assigned to ABO blood group compatible recipients.

However, increasingly, ABO-incompatible kidneys have been transplanted without hyperacute rejection using perioperative antibody removal in experimental protocols [18]. Pre- and postoperative plasma exchange or immunoadsorption columns (fixed A and/or B antigen remove plasma antibody) reduce antibody titers to low levels, which are combined with i.v. immunoglobulin immunomodulation, splenectomy or rituximab, and antiproliferative agents to prevent antibody rebound [19]. Circulating antibody titers recover after transplantation, adhere to the endothelium, and activate complement (with C4d positivity), but generally fail to cause capillaritis or overt injury, attributed to the phenomenon of "accommodation" of the microcirculation [20], probably mediated by up-regulation of protective endothelial genes. If it occurs, acute antibody-mediated rejection from isohemagglutinin also includes features of early segmental thrombosis of glomerular loops, mesangiolysis, and polymorphonuclear cell recruitment. Long-term results are similar to blood group matched recipients [21], and contrasted with anti-HLA antibody where accommodation is uncommon and poorer graft survival is associated with persistent antibody-mediated rejection. Additional detail on desensitization protocols can be found in Chapter 68.

Differential diagnosis of initial non-function

Ischemia reperfusion injury

Delayed graft function (DGF) is where the implanted kidney passes urine but fails to initially function due ischemia–reperfusion injury related to donor factors, procurement techniques, and prolonged ischemic times. It is defined for registry purposes by dialysis need within 7 days post-transplantation, but other functional definitions (slower fall in serum creatinine, e.g. by 10% daily over 3 days) also correlate with graft failure (HR = 1.47; 95% CI 1.06–2.03) [22]. The DGF incidence has increased from 14.7 to 21–23% over two decades [23], with kidneys from older deceased donors with vascular co-morbidity (expanded criteria donors, ECD), or following circulatory death (DCD or non-heart beating donors), being used because of organ shortages. These marginal kidneys yield inferior initial function rates, and patient and allograft survivals relative to standard criteria donors, but still improve overall recipient survival compared with remaining on dialysis [24]. DGF increases graft loss by 41% (RR 1.41; 95% CI 1.27–1.56) by systematic meta-analysis [25]. Other factors that increase DGF include donor age, organ size and quality (older donor, hypotension, diabetes, renal impairment, and hypertension), and transport or "shipping" issues prolonging ischemia times [26,27]. The turbulent peritransplant stressor impacting deceased donor organs can be mitigated by optimal ICU management, pulsatile ex vivo machine perfusion [28,29], rapid transfer, and prompt implantation [30]. Donor organ quality influences its response to stressors and ultimate longevity.

Metabolically active renal tubular epithelial cells are vulnerable to ischemia, which depletes oxygen, limits cellular metabolism, and Na/K ATPase exchanger function. Reperfusion injury with oxygenated blood generates reactive oxygen species including superoxide, nitric oxide, and peroxynitrates, leading to DNA breakdown, lipid peroxidation, apoptosis, and cellular necrosis. Vascular endothelial cell ischemic injury causes phospholipolysis, thrombin-mediated fibrin deposition, surface signal up-regulation of P-selectin receptors, β-integrins, and chemokines, and leukocyte adherence [23].

Donor brain death or perioperative ischemia–reperfusion injury also stimulates a cascade of chemokines, proinflammatory cytokines (IL-6, TNF-α, IFN-γ), and adhesion molecules (CD54 [ICAM-1], VCAM-1, CD18/11a [LFA-1]), which up-regulate MHC antigen expression within the kidney transplant. Injured tissues express innate danger receptors or Toll receptor system ligands (normal protecting against infectious pathogens) [31], which promote immune cell maturation, activation, and rejection [32]. This increased immunogenicity promotes greater cellular infiltration and rejection rates [32,33].

An on-table postperfusion or early postoperative biopsy of an oliguric kidney often confirms acute tubular necrosis and excludes unsuspected rejection (in rare cases, humoral rejection with DSA only displays acute tubular necrosis and C4d). Commonly, minor non-specific tubular changes from ischemia by light microscopy are contrasted to profound intracellular transcriptome abnormalities. DGF increases clinical rejection (pooled incidence 49% vs. 35%, RR 1.38; 95% CI 1.29–1.47), requiring careful monitoring and immunosuppression (CNI doses are sometimes reduced to promote graft function) [25]. Regular protocol biopsy surveillance of non-functioning kidneys (every 5 to 7 days) screen for undiagnosed

rejection during supportive dialysis (a period ranging from days to weeks), when interval serum creatinine monitoring is unreliable. Functional renal transplant recovery is heralded by an increasing urine output (1–1.5 L/day needed for dialysis suspension), falling predialysis serum creatinine that subsequently plateau, and then progressively decline off dialysis. Up to 3% of implanted kidneys never function [6].

Arterial or venous vascular compromise

Surgical vascular compromise (with patchy perfusion from a suboptimal arterial anastomosis or kinked renal vessels) or overt thrombosis (clinically apparent immediately or soon afterwards with complete anuria) are uncommon differential diagnosis, and are evaluated by urgent Doppler ultrasound. Clinical evaluation of fluid status, blood pressure, and cardiovascular output are also important. It is important to note that urine output is unreliable as a sign of vascular compromise in recipients with residual native kidney urine output, and in these cases a high index of suspicion prompting early urgent ultrasound or re-exploration is required to detect vascular compromise in a clinically meaningful time frame.

Transplant ureteric obstruction

Ureteric obstruction is diagnosed with transplant hydronephrosis by ultrasound imaging. Use of a ureteral stent reduces the potential for as an early complication.

Early graft dysfunction

Clinical scenario. Initial graft function is followed by dysfunction and a rising creatinine within the early transplant period.

Early transplant functional monitoring

Assessment of transplant function is the primary monitoring tool to screen for graft pathology. Routine serum creatinine monitoring begins immediately after transplantation (daily to screen for ischemic DGF and early rejection), reducing to monthly intervals by 1 year in stable patients [34]. The constant daily creatinine generation rate means that serum level is sensitive to relative changes in individual allograft function. Serum creatinine is cheap, convenient, and simple to measure, with a rapid laboratory turn-around time, excellent measurement precision (intralaboratory variation below 3%), and accuracy (about 10–20 μmol/L or 0.10–0.20 mg/dL). For detection of acute rejection, serum creatinine yields adequate sensitivity ("subclinical" rejection is missed), modest biological variation (intrapatient CV is 7%), but is relatively non-specific, because physiological factors such as dehydration and blood pressure also affect glomerular filtration rate (GFR).

Serum creatinine generally falls within the first 2 weeks post-transplant to a baseline level determined by early ischemic injury, donor quality and donor–recipient size mismatch, calcineurin inhibitor levels, and the recipient's muscle creatine generation. Early acute increases in creatinine (e.g. 25% above baseline), or even a failure to decrease, should initially prompt repeat testing with adequate hydration, and exclusion of reversible causes (by Doppler ultrasound for vascular supply and hydronephrosis). A diagnostic transplant biopsy may show rejection, acute tubular necrosis, or be near-normal (acute CNI nephrotoxicity is then inferred, especially if isometric tubular vacuolization and high blood CNI concentrations are present) (Table 69.1).

Table 69.1. Clinical investigation of transplant dysfunction

1. Clinical examination of blood pressure, hydration status, palpation of kidney transplant for tenderness, and auscultation for bruit
2. Check medications for compliance, nephrotoxins, and drugs that alter calcineurin inhibitor concentrations
3. Repeat serum creatinine with adequate hydration and elimination of any reversible factors
4. Check blood calcineurin inhibitor levels for toxicity (higher levels suggest nephrotoxicity versus low or variable levels indicate inadequate dosing or non-compliance with risk of rejection)
5. Renal transplant Doppler ultrasound to evaluate arterial blood flow and exclude ureteric obstruction; ^{99m}Tc mercaptoacetyl-triglycine (MAG3) scan when ultrasound is inconclusive
6. BK evaluation by blood nucleic acid testing, with quantification if positive
7. Urinalysis for proteinuria and hematuria (suggestive of glomerulonephritis or transplant glomerulopathy)
8. Transplant biopsy for specific diagnosis
9. Donor-specific antibodies (if antibody-mediated rejection suspected)

Early acute antibody-mediated rejection

Antibody-mediated rejection (AMR) is mediated by pathogenic antibodies directed against specific donor molecules. Although most DSA are HLA-specific, some are non-HLA directed, which encompasses antibody against ABO blood group antigens and other polymorphic antigens. Antibodies against the polymorphic MICA (MHC class I-related chain A expressed on endothelial cells) [35,36], the AT_1 receptor, or antiendothelial cell antibodies have been rarely implicated in hyperacute, acute, and chronic organ allograft rejection. IgG antibodies targeting the vascular AT_1 receptor have been reported to present with refractory vascular rejection (histologically as endarteritis and/or fibrinoid necrosis) and malignant hypertension, and to respond to adjunctive angiotensin receptor blocker (ARB) therapy (e.g. losartan) [37].

DSA produced by pre-existing plasma cells, or memory B cells converted to new plasma cells, mediates AMR. This anamnestic or "recall" antibody response from previous antigen exposure can rapidly generate high-titer complement-fixing HLA antibody [15], targeted to MHC antigens expressed on donor endothelium (Figure 69.1). Injured endothelial cells release von Willebrand factor and P-selectin (promoting platelet aggregation), inflammatory molecules (such as IL-1α, IL-8, and CCL-2), and chemoattractants (C3a and C5a), causing leukocyte adherence within glomeruli ("glomerulitis") [38] or dilated peritubular capillaries (colloquially called "PTCitis") [13]. Assembly of C5b-9 membrane attack complex leads to localized endothelial necrosis and apoptosis, detachment of cells from their basement membrane, and deposition of capillary fibrin microthrombi. Arterial wall necrosis with hemorrhage or local intravascular thrombosis with distal infarction occurs in severe cases [13].

Acute AMR presents early with inflammatory graft dysfunction (within days after transplantation, but delayed by antilymphocyte induction), acute oliguric graft failure, and sometimes with a low-grade fever and allograft tenderness. Doppler imaging demonstrates reduced diastolic blood flow, allograft swelling, and high resistive indices. Urgent histology shows inflammatory microvascular injury accompanied with polymorphonuclear or mononuclear cells adhering to endothelium of peritubular and glomerular capillaries [38], with C4d deposition and tubular injury [14].

The pathological triad for the diagnosis of acute AMR [9,13] with allograft dysfunction is:

1. Morphological evidence of acute tissue injury (glomerular or peritubular capillary leukocyte endothelialitis, arterial inflammation or acute tubular injury). Leukocyte margination of cortical

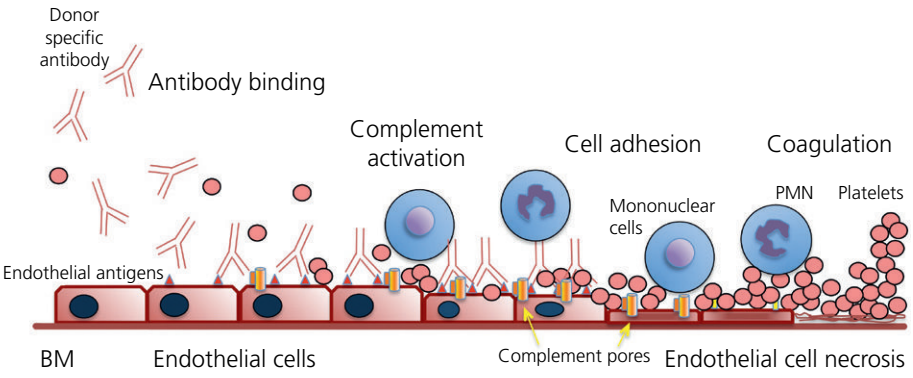

Figure 69.1. Pathophysiology of acute antibody-mediated rejection. Donor-specific antibody binds to antigen expressed on endothelial cells with complement activation, cell adhesion, and endothelial damage followed by platelets deposition and coagulation. BM, basement membrane; PMN, polymorphonuclear leukocyte.

peritubular and glomerular capillaries (outlined by PAS stain) is the most important diagnostic feature, allowing initiation of antirejection treatment with pulse steroids.

2 Immunopathological evidence of antibody activity (C4d staining, classically defined as "intense and diffuse and involving >50% of PTC" but lesser amounts >10% are clinically relevant) [39].

3 Circulating DSA directed towards Classes I and/or II HLA antigens or (rarely) other defined polymorphic specificities.

C4d, a diagnostic marker of classic complement activation, is frequently present in peritubular capillaries but variably insensitive [40], C4d can be occasionally absent in very early biopsies with humoral rejection manifest only by endothelialitis (later becoming clearly positive) [13]. C4d forms a stable and long-lasting covalent bond to endothelium, remaining positive for days to weeks after successful AHR treatment (residual empty dilated PTC may be seen). A new subcategory of "C4d deposition without morphological evidence of active rejection" has been added to the Banff system. Discrepancies in C4d sensitivity (ranging from 23 to 95%) against of a marker of acute AHR (such as DSA), reflect different techniques (less sensitive immunohistochemistry when using paraffin sections but allowing glomerular C4d detection and clear structural visualization versus more sensitive indirect immunofluorescence using impermanent frozen samples), antibody used (monoclonal or polyclonal antibodies), differing cut-off threshold levels (10% versus 50% of peritubular capillaries), and biopsy timing [41]. The focal C4d category (10–50% of PTC with strong linear staining) is associated with capillaritis, glomerulitis, and an intermediate prognosis is abnormal [39,42]. A positive C4d yields an excellent specificity (93–96%) for humoral rejection, especially if supported by DSA, endothelial inflammation, and appropriate clinical context (e.g. regraft, highly sensitized recipient, known pre-transplant DSA) [40,43–46].

Early diagnosis and active therapy are essential to salvage these kidneys. Treatments include pulse corticosteroids, removal of circulating antibody by plasmapheresis (which also removes clotting factors, therefore the first postbiopsy exchange is against fresh frozen plasma to avoid bleeding, and later albumin), low-dose intravenous immunoglobulin (e.g. 100 mg/kg postexchange to a cumulative total of 1–2 g/kg), and antiproliferative agents (i.e. mycophenolate) to suppress B- and T-cell expansion, and limit recovery of antibody synthesis. Monitoring is by renal function, serial DSA levels, and end-treatment repeat biopsy.

Supplementary therapies include rituximab, a chimeric monoclonal antibody against CD20-bearing B lymphocytes, which rapidly depletes B cells in a way that is sustained for up to 1 year (following a single 375 mg/m^2 i.v. dose). Rituximab operates by antibody-dependant cell-mediated cytotoxicity, complement-mediated cytotoxicity, and apoptosis of B cells (but not plasma cells). It is generally well tolerated with occasional acute infusion reactions, and marginal risk of bacterial infections and latent viral reactivation (hypogammaglobulinemia is mild) [47]. In a randomized study of pediatric acute rejection with B-cell infiltrates, rituximab improved graft function, subsequent protocol biopsy rejection scores, and abolished C4d reappearance, independent of unchanged DSA levels [48]. Its role as adjunctive therapy for acute AHR remains unclear because of confounding treatments in observational studies. Antilymphocyte antibody (with some anti-CD20 specificity) can also be used with co-existent T-cell rejection ("mixed" rejection) [11].

Other investigational agents include eculizumab (a humanized C5 cleavage inhibitor of terminal complement activation), which quickly prevents complement pore formation and shows promise in AMR [49,50]. Bortezomib (a proteasome inhibitor directed against plasma cells) targets the source of production and slowly reduces DSA levels (the IgG half life is 7 to 21 days, according to subclass). When given as three to five infusions of 1.3 mg/m^2 (one myeloma cycle dose) with plasmapheresis as rescue therapy, bortezomib has been associated with successfully reduced DSA and reversal of AMR. Side-effects include peripheral neuropathy (about 30%), myelosuppression, and herpes reactivation [50]. No randomized data regarding the use of bortezomib or eculizumab exist.

Previous HLA mismatched transplantation is a powerful sensitizer, commonly generating higher-titer class II HLA antibodies in patients listed for re-transplant [51]. One-third will have antibodies of sufficient titer to reduce transplant offers and increase dialysis waiting times [52]. Transplantation of highly presensitized candidates with DSA is frequently complicated by acute and/or chronic antibody-mediated rejection, with reduced graft function and survival. Many units avoid such donor–recipient pairs, and seek an alternative donor. However, transplantation with prior antibody removal and augmented immunosuppression can succeed, albeit at a cost of greater infection rates and potential later chronic antibody mediated rejection (CAMR) [53]. Living donor exchange programs circumvent the problem of living kidney donors excluded by recipient ABO incompatibility or donor-specific anti-HLA antibodies

[54]. Comprehensive approaches to the sensitized individual are presented in Chapter 68.

Early acute T-cell mediated rejection

Acute cellular rejection is mediated primarily by T lymphocytes invading the interstitial space and renal tubular epithelium; it is clinically signaled by increased serum creatinine levels and confirmed by biopsy [5]. Naïve recipient T cells, activated by direct presentation of donor antigen within lymphoid organs by dendritic cells, differentiate and clonally expand into T helper subsets and return as destructive effector lymphocytes [55]. Circulating lymphocytes tether to endothelium, transmigrate across peritubular capillaries [33], and accumulate in the interstitial compartment in acute cellular rejection, producing inflammatory cytokines and chemokines (such as TNF-α, TNF-β, CCL5/RANTES, CCL3/MIP-1α, and IFN-γ) and inducing IFN-γ genes within the graft (Figure 69.2) [56,57]. CD4 and CD8 T cells may be accompanied by B cells (detected by gene expression signatures and CD20 histochemistry) [58] or eosinophils; both B cells and eosinophils are associated with severe steroid-resistant cellular rejection. Activated macrophages secrete proinflammatory cytokines (such as IL-1, IL-12, and IL-18, TNF-α, and IFN-γ), and are associated with functional impairment and residual T-cell rejection [59].

The invading allospecific CD8 T lymphocytes enter renal tubules ("tubulitis") attracted by secreted chemokines (CCL2, CCL5, and CX3CL1) [60], mediating local tubular injury by direct contact (cell-mediated cytotoxicity), locally released cytokines, or indirect inflammatory cell activation. CD8 T cells release perforin (allowing entry of granzymes A and B through membranes pores), and interact with Fas death receptor by Fas ligand—inducing caspase-mediated apoptosis (Figure 69.2) [61]. Effector CD4 T cells can also mediate cytotoxicity to minor antigens, via TNF [62]. Injured tubular cells can transition into more primitive phenotype of mesenchymal myofibroblasts, or progress to epithelial cell necrosis with basement membrane rupture with urinary leakage, graft dysfunction, and tubular atrophy with severe injury [63].

Clinical immune risk factors for acute rejection include HLA mismatches, living unrelated donor status, pre-existing alloantibodies, particularly when donor specific, regraft, and donor ischemia (e.g. particularly when prolonged or associated with extended criteria donor status), which increases transplant immunogenicity via respondent expression of injury molecules and their recognition by the innate immune system [64]. Tacrolimus (vs. cyclosporine), mycophenolate (vs. azathioprine), and induction therapy have all reduced acute rejection rates in randomized controlled trials. One-year rejection rates have fallen to 10–15%, although remaining episodes are more severe and treatment-resistant than in prior eras. Better HLA-matching and DSA detection technologies (reducing rejection risk) and effective CMV prophylaxis and anti-infective treatments (allowing safe immunosuppressive dose escalations) have also helped. About 4% of kidneys are lost from early rejection [64].

The key diagnostic components of acute T-cell mediated rejection pathology are mononuclear leukocyte cell inflammation of the interstitial space and renal tubules, where their relative proportions and extent determine the grade of severity. The Banff acute T-cell-mediated rejection (TCMR) [9] grades are as follows (also see Chapter 81):

Borderline "suspicious" for rejection. Foci of tubulitis (t1, t2, or t3) are present with minor (i0, or i1 interstitial infiltration score as 10–25% cortex), or moderate interstitial infiltration (i2, i3) with mild (t1) tubulitis (without any intimal arteritis).

Grade IA rejection. Significant interstitial infiltration (>25% of parenchyma affected, i2 or i3 score) and moderate tubulitis (t2).

Grade IB rejection. Significant interstitial infiltration (>25% of parenchyma) and severe tubulitis (t3).

The rejection severity by the Banff schema critically hinges on the tubulitis score, which determines final rejection grade and

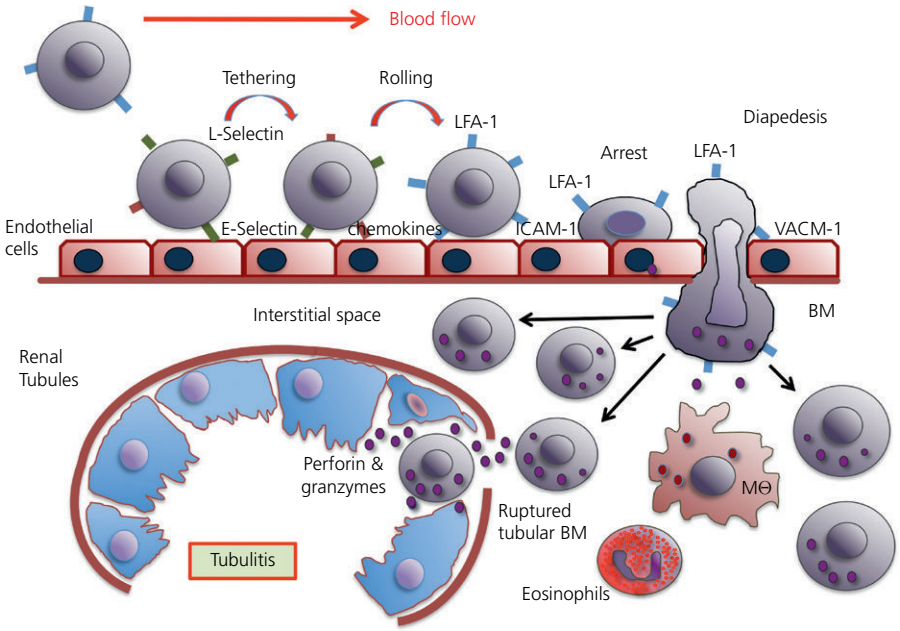

Figure 69.2. Mechanism of T-cell-mediated rejection with trafficking of cells into the kidney transplant. Following initial tethering, rolling, and arrest of effector lymphocytes binding selectins and integrins expressed on endothelial cells, lymphocytes and other immune cells enter the interstitial compartment and invade tubules, mediating local tissue destruction. BM, basement membrane; MO, macrophage.

defaults to the most severe lesion. Localized severe tubulitis can (inappropriately) advance grading if present in a single isolated tubule. Tubulitis can be difficult to appreciate within areas of inflammatory tubular destruction without PAS staining. The extent of interstitial inflammation (Banff i score) is clinically useful for diagnosis and predicts subsequent tubulointerstitial damage if persistent [65]. The older CCTT system used at least 5% cortex lymphocytic inflammation and two injury markers (edema, tubular degeneration/injury or reactive lymphoblasts), with tubulitis (minimum of three tubules affected within the maximal infiltrate) to define rejection. Any patient with an increasing creatinine and an interstitial lymphocytic inflammation exceeding 10% of the cortical area with tubulitis should be clinically treated as rejection until proven otherwise.

Biopsy confirms the diagnosis of rejection, but also categorizes its histological type and severity, which critically determines therapy. Initial treatment for simple cellular rejection is pulse corticosteroids (e.g. 500 mg i.v. methylprednisolone for 3 days) or short-term oral high-dose therapy (e.g. 100 mg daily then tapered), with the serum creatinine expected return to baseline. Successfully treated acute cellular rejection leaves neither histological consequences nor excess graft loss by registry studies. However, partial resolution of renal dysfunction may follow recurrent or serious episodes of acute rejection [64]. Severe, relapsing, multiple or steroid-resistant cellular rejection should be managed by re-biopsy with C4d staining, DSA testing, compliance checks, and strengthened baseline immunosuppression, with consideration for antithymocyte treatment.

Vascular rejection

Vascular rejection (termed "arteritis" or "endarteritis") is a severe, steroid-unresponsive type of rejection characterized by vascular mononuclear infiltration, ingress of intimal myofibroblasts secreting matrix proteins and collagens, and endothelial cell apoptosis. CD4 and CD8 T cells and macrophages invade the subendothelium and intima of small muscular arteries, helped by adhesion molecules (ICAM-1 or VCAM) expressed on activated endothelium, and chemokine (CCL4, CCL5, and CXCL8) gradients [66]. Anti-MHC antibody, T cell–mediated immunity to minor antigens, NK cells pathways and IFN-γ contribute to pathophysiology in experimental studies.

Vascular rejection was originally classified within the Banff T-cell mediated rejection umbrella, and rejection grades are as follows (also see Chapter 81):

Grade IIA rejection. Mild to moderate intimal arteritis (v1 arteritis score).

Grade IIB rejection. Severe intimal arteritis comprising (>25% of luminal area narrowed, v2).

Grade III rejection. Transmural arteritis and possible fibrinoid change and necrosis of medial smooth muscle cells with accompanying lymphocytic inflammation of the artery (v3).

Vascular rejection clinically presents with progressive graft dysfunction, which fails or partially responds to pulse corticosteroids, with a characteristic arteritis on biopsy. Vascular rejection causes irreversible tubular loss with chronic interstitial fibrosis, frequent incomplete functional recovery, and a greater risk of subsequent graft loss (HR 2.07; 95% CI 1.60–2.68) [64]. Occasionally presenting as isolated arteritis, vascular rejection is generally accompanied by interstitial cellular infiltration, and potent immunosuppression such as antithymocyte globulin with pulse corticosteroids is recommended. Arteritis is often mediated by humoral mechanisms, with poor allograft outcomes, associated with severe arteritis, high DSA levels and associated interstitial inflammation [67]. Robust treatment against pathogenic DSA including PE, IVIG and rituximab, are warrented.

Subclinical rejection

Subclinical cellular rejection

Subclinical rejection (SCR) occurs when acute T-cell mediated rejection (acute or borderline) is present on protocol biopsy-derived histology without concurrent functional deterioration [68]. Allografts with SCR develop more damage on subsequent histology with reduced graft survival, and some will progress to chronic rejection. A causal role for SCR contributing to tubulointerstitial damage is supported by co-localization with prior interstitial inflammation, temporal sequence of SCR before damage, SCR intensity correlating with severity of chronic damage ("dose–response"), biological plausibility, and confirmation in several transplant populations.

Treatment of SCR by pulse corticosteroids decreased acute rejection episodes, chronic 6-month tubulointerstitial scores, and serum creatinine at 2 years, in a randomized trial using cyclosporine-based immunosuppression (background prevalence 30%), with a trend to better survival [69]. Another trial (cyclosporine and some tacrolimus with 28% SCR prevalence) of SCR treatment showed better eGFR at 6 and 12 months [70], but no benefit occurred in a third trial using tacrolimus in low-immune-risk patients where SCR prevalence was only 4.7% [71].

Subclinical antibody-mediated rejection

Subclinical antibody-mediated rejection (SAMR) can be present in protocol biopsies showing a C4d-positive capillaritis associated with DSA. Peritubular leukocyte margination is a sensitive and useful marker of DSA, but is not specific being present in T-cell mediated rejection. Relatively common in "positive cross-match" or sensitized recipients, or following treatment of late antibody-associated rejection, early SAMR is also reported in 10% of standard-risk individuals [7,72,73]. Persistent sublethal microcirculation injury from circulating DSA can activate glomerular endothelial cells and widen the subendothelial space with glomerular basement membrane (GBM) reduplication, which evolves into chronic transplant glomerulopathy, or be associated with PTC basement membrane multilamination, tubulointerstitial damage, renal impairment, proteinuria, and reduced graft survival [72,74–77].

Diagnostic kidney transplant biopsy

Diagnostic needle core biopsy should be considered after exclusion of reversible causes of transplant dysfunction (Figure 69.3). Histology remains the key investigation for the detection of rejection, although transcriptome microarray data for disease categorization and prognostication may supplement histology in the future [58,78]. Most biopsies are indication-driven ("for cause"), but "protocol" biopsies can be undertaken at prespecified times in patients with stable function for surveillance of rejection in several high-risk clinical situations, including delayed graft function, high DSA risk, or ABO incompatibility, or for other situations requiring surveillance of subclinical rejection, particularly clinical trial participation [68].

Biopsies are performed under local anesthetic using an automated spring-loaded needle core deployment device. The risk of major complications (e.g. macroscopic hematuria with ureteric obstruction) is 1%, and graft loss is 0.03% [68]. Minor complications (resolving without intervention) include gross hematuria

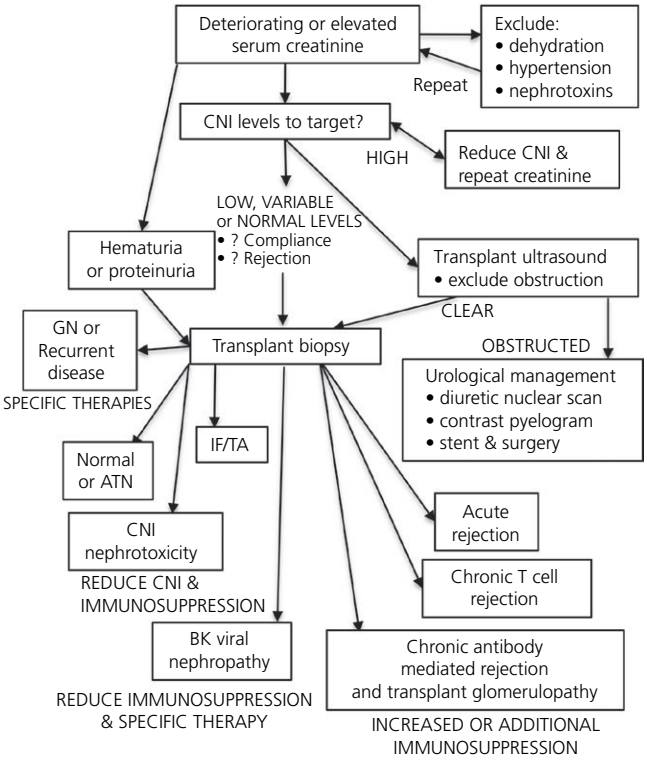

Figure 69.3. Diagnostic evaluation of transplant dysfunction. CNI, calcineurin inhibitor; IF/TA, interstitial fibrosis/tubular atrophy; GN, glomerulonephritis; ATN, acute tubular necrosis.

in 3.5%, perirenal hematomas 2.5%, asymptomatic arteriovenous fistulas 7.3%, and vasovagal reactions 0.5% [10]. Risks are greater with indication (compared with protocol) biopsy, extraperitoneal or transperitoneal adult kidneys in infants, or with larger needles (16 g or greater) [11]. Safety should be maximized by a skilled operator using ultrasound guidance [10]. Particular care is required in patients with uncontrolled hypertension, those on anticoagulation therapy, and those with platelet dysfunction caused by advanced uremia.

While pathology offers diagnostic confirmation of rejection (often clinically obvious), an important additional role is histological categorization and grading of severity, which determines second-line therapy use and graft outcome. Rejection can be patchy, so a minimum of two biopsy cores with two muscular arteries is needed. Assessment of peritubular and glomerular capillaries, small arteries, and C4d staining are important to exclude antibody or vascular rejection subtypes.

Differential diagnosis of early graft dysfunction

Ischemia reperfusion injury with delayed graft function

Ischemia–reperfusion injury can cause early graft dysfunction, with risk factors including donor (extended cold and warm ischemic times, brain death with inflammatory signaling) and recipient (reperfusion injury, cardiovascular compromise) factors. Acute tubular necrosis is confirmed and acute rejection excluded by diagnostic biopsy.

Acute allograft thrombosis

This early technical complication occurs from transplant renal artery injury (usually at the anastomosis), or renal vein obstruction from kinking or external compression, and contributes to 2–7% of early adult allograft losses, and 12–35% of losses in children and infants. It usually occurs within the first week, with a peak incidence at day 2 [79]. Contributing risk factors are the "Virchow's triad" of: (1) vessel wall factors (small, female, deceased donors, vessel wall atheroma, pediatric or diabetic recipient, multiple or reconstructed vessels, small accessory arteries, or vascular clamp or perfusion cannula injury); (2) transplant vascular blood flow (hypotension, cardiac failure, under-filling); and (3) blood coagulation disorders (pre-existing prothrombotic states, factor V Leiden mutation, lupus anticoagulant, antiphospholipid syndrome, high hematocrit). Clinical clues are abrupt catheter-proven *anuria* (when there is no native kidney function, most DGF kidneys are oliguric) and acute graft tenderness with a consumptive thrombocytopenia, confirmed by immediate Doppler ultrasound and/or urgent surgical or radiological intervention for thrombectomy or thrombolysis. Salvaged kidneys experience severe acute tubular necrosis from prolonged warm ischemic injury, poor residual graft function and develops tubular atrophy with interstitial fibrosis.

Ureteric obstruction

The transplant ultrasound typically shows hydronephrosis. However, partial obstruction such as that seen in cases on modest lymphocele-related compression can be less obvious.

Urinary leak

The transplant pelvicalyceal system or ureter can leak (1) externally (diagnosed by elevated creatinine surgical drain fluid concentrations compared with serum) or (2) internally with reabsorption across the peritoneal membrane (suspected by unexplained serum creatinine elevation despite normal graft histology), and diagnosed by nuclear renal transplant scan with delayed abdominal images.

Acute interstitial nephritis

Rarely, routine trimethoprim–sulfamethoxazole prophylaxis causes an acute interstitial nephritis, presenting with subacute graft dysfunction, eosinophilia, and eosinophilic tubulointerstitial nephritis on biopsy. It is easily treated by pulse steroids and co-trimoxazole cessation. Viral acute interstitial nephritis (e.g. from BK, CMV or adenovirus pyelonephritis) differs by graft pathology.

Early recurrent renal diseases

Early acute renal failure can rarely be due to recurrent hemolytic–uremic syndrome (HUS) or primary hyperoxaluria. Recurrent focal segmental glomerulosclerosis (FSGS) initially presents with isolated proteinuria, with progressive graft dysfunction developing much later (see below).

Hemolytic–uremic syndrome

Classical HUS comprises the diagnostic triad of microangiopathic hemolytic anemia, thrombocytopenia, and renal impairment, causing renal failure associated with diarrhea (usually enterotoxic *Escherichia coli* 0157:H7) generating Shiga toxin promoting endothelial injury. Atypical HUS from genetic dysregulation of the alternative complement pathway (occasionally from autoantibodies) causes complement over-activity and chronic renal failure. It is often undiagnosed pretransplant, but can present abruptly with post-transplant HUS and graft dysfunction, especially when combined CFH and CFI (versus lower risk MCP) mutations are present [80]. Treatment is plasma exchange against fresh frozen plasma, eculizumab (an anti-C5 inhibitor developed for paroxysmal

nocturnal hemoglobinuria but effective for both atypical and Shiga-toxin HUS), and CNI avoidance. Combined liver–kidney transplantation corrects the genetic complement pathway defect but with greater patient risks [80].

Primary hyperoxaluria

Primary hyperoxaluria (type 1 is most common) is an autosomal recessive defect of hepatic alanine-glyoxylate aminotransferase, causing systemic overproduction and urinary excretion of oxalate (its metabolic end-product), insoluble calcium oxalate renal accumulation, nephrolithiasis, and progressive renal failure (of "unknown cause"). It manifests as subacute transplant renal failure as circulating systemic oxalate deposit in renal tubules, seen as striking birefringent calcium oxalate crystals by polarized microscopy. Treatment involves hydration, and sodium citrate and/or phosphate administration, hemodiafiltration and pyridoxine in sensitive cases to minimize systemic oxalosis and limit further deposition, but often with disappointing results [81]. High-dose vitamin C causes secondary oxalosis in dialysis patients and should be avoided.

Recurrent focal segmental glomerulosclerosis

Focal segmental glomerulosclerosis is a podocyte (glomerular visceral epithelial cells) disease caused either by: (1) genetic mutations in critical podocyte proteins (such as podocin, identified by DNA analysis) presenting as familial or sporadic nephrotic syndrome; or (2) from a putative 30–50 kDa circulating protein(s) ("FSGS factor or "toxic permeability factors"), which injures the podocyte, increasing glomerular permeability. Idiopathic focal segmental glomerulosclerosis recurs in 20–50%, with half failing by 5 years [82]. Risk factors for recurrence include childhood onset (age <15 years), diffuse mesangial hypercellularity, or collapsing glomeruli, and rapid progression to dialysis in native kidney disease, or fulminant recurrence in previous allografts [83].

Recurrence is suspected by increasing weekly spot urine protein/creatinine ratios (residual native kidney proteinuria gradually abates after transplantation), and is diagnostically confirmed by podocyte foot process effacement on electron microscopy, which occurs well before segmental glomerulosclerosis appears on light microscopy.

A regimen of plasma exchange to remove circulating protein (initially three sessions/week reducing to monthly by 6 months), high-dose cyclosporine (initial 2-hour cyclosporine target 1200–1400 ng/mL, which stabilizes the podocyte actin cytoskeleton), corticosteroids (starting at 1 mg/kg/day and tapering to 10 mg/day), and ACE inhibitors (or ARB) as antiproteinuric agents, can achieve complete or partial remission in 80 to 90%, with occasional late relapses [84]. mTOR inhibitors (sirolimus and everolimus), which affect the podocyte and cause proteinuria, should be avoided.

De novo antiglomerular basement membrane disease in Alport's recipients

Rarely, patients with Alport's disease (from *COL4A5* gene mutations of GBM collagen in X-linked male form) develop anti-GBM antibody disease to the "novel" alpha5 chains (or to alpha3 in recessive disease) of the kidney transplant, appearing "foreign" to the recipient's immune system [85]. Presenting early (few weeks or months), with acute dysfunction, necrotizing and crescentic glomerulonephritis, and linear IgG immunofluorescence resembling Goodpastures's disease can be seen on biopsy. The treatment involves plasma exchange and cyclophosphamide.

Chronic slow graft deterioration

Clinical scenario. Gradual deterioration with slow but inexorably increasing serum creatinine over months to years.

Long-term transplant monitoring and progressive graft dysfunction

Interval serum creatinine is main monitoring tool of transplant health, as GFR correlates with tubulointerstitial injury [86]. Relative changes in serum creatinine level are meaningful, allowing for biological variation, and progressive transplant dysfunction can be the harbinger of graft failure.

Estimated GFR (eGFR) from predictive equations (e.g. "abbreviated" MDRD, Nankivell or CKD-EPI formulae) are more accurate than unmodified serum creatinine measurements; however, they perform indifferently against reference methods because of differences of muscle mass, creatinine generation, tubular creatinine secretion, and assay calibration factors [87,88]. Trimethoprim, routinely used with sulfamethoxazole for prophylaxis against urinary tract and pneumocystis infection, inhibits tubular creatinine secretion and results in a harmless elevation of serum creatinine. Serum cystatin reflects GFR independently of muscle mass, but is more expensive, requiring an optimized formula, and is not clearly superior to creatinine-based eGFR. Plasma clearance of ("cold") iohexol or isotopic-labeled Tc^{99m}DTPA, Cr^{51}EDTA or I^{125}iothalamate are accurate reference methods (replacing inulin clearance), but is used sparingly because of cost and patient inconvenience.

Serum creatinine appreciably rises only after substantial transplant damage has occurred because of its log-linear relationship with GFR, and hyperfiltration from residual nephrons, moderating the increase. The plot of transplant GFR against time is the combination of baseline level ("intercept" from donor quality and early events) and rate of loss ("slope" from continuing injury) (Figure 69.4). Declining reciprocal creatinine (30% reduction RR = 2.56) or increasing creatinine (OR = 2.2/1 mg/dL = 88.4 μmol/L) both

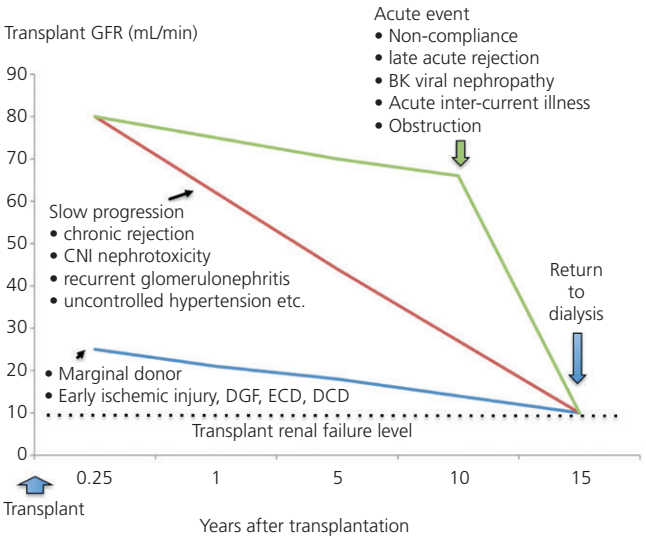

Figure 69.4. Transplant glomerular filtration rate and time to graft failure according to differing pathophysiological events. CNI, calcineurin inhibitor; GFR, glomerular filtration rate; DGF, delayed graft function; ECD, expanded criteria donor; DCD, donation after circulatory death.

correlate with time to graft failure [13]; however, they poorly predict late graft failure when prospectively tested [89,90]. Many individual GFR time curves are non-linear, with a breakpoint and abrupt decline when new pathologies develop (e.g. glomerulonephritis, acute rejection, or BK nephropathy). Alternatively, a transplant with early severe ischemic damage can remain functionally stable for years. Hence, while graft function statistically correlates with graft loss in cohorts, its individual predictive capacity is weak.

Urine testing and transplant imaging

Dipstick urinalysis can be used to screen for transplant glomerular diseases. Proteinuria quantified by spot urine protein/creatinine ratio or 24-hour urinary excretion can also be used. Proteinuria is a powerful independent risk factor for graft loss and patient survival, even at modest levels of 0.5 g/day [91]. Hematuria and proteinuria suggests recurrent or de novo glomerulonephritis.

Initial ultrasonography excludes ureteric obstruction or vascular arterial stenosis as causes of graft dysfunction. Acute and complete ureteric obstruction is rare, presenting with transplant dysfunction, oligoanuria, and hydronephrosis. The obstruction is confirmed and localized by antegrade or retrograde pyelography, decompressed by ureteric stenting, and definitively corrected surgically. Chronic or partial ureteric obstruction is a diagnostic challenge because mild transplant hydronephrosis is common. Diuretic isotopic renography using ^{99m}Tc mercaptoacetyl-triglycine (MAG3), secreted by tubules despite poor graft function, has excellent sensitivity and specificity [92]. Whether untreated chronic transplant vesicoureteric reflux produces irreversible parenchymal scarring is unproven [93–95].

The Doppler "resistive index" correlates with intrarenal compliance, interstitial fibrosis, and subsequent graft loss ($0.80\geq$ values ninefold risk), and recipient mortality (reflecting recipient's noncompliant systemic vasculature) [96,97]. Renal vascular resistance, magnetic resonance, or gadolinium-enhanced dynamic turbo-FLASH are relatively insensitive imaging methods, becoming abnormal only with significant parenchymal damage [98].

Diagnostic algorithm for a chronically failing graft

A gradually deteriorating or persistently elevated serum creatinine should be evaluated. Reversible causes such as dehydration (fluid state examination, diarrhea, diuretic use), acute calcineurin inhibitor nephrotoxicity (by drug levels), nephrotoxins (ACE inhibitors, and angiotensin receptor II blockers, NSAID, or COXII inhibitors) that reduce GFR, early recurrent glomerular disease (by urinalysis), and ureteric obstruction or vascular impairment (by imaging), should be excluded (Table 69.1).

Transplant biopsy should be obtained without undue delay after exclusion of reversible causes (Figure 69.3), as severely damaged grafts lose their diagnostic specificity and poorly respond to therapy. An adequate tissue sample can be processed for immunofluorescence (for glomerulonephritis), light and electron microscopy, and C4d staining. Careful histological and clinical evaluation should establish a cause(s) of transplant dysfunction. A collaborative diagnosis involving clinician (evaluating immune risk, antibody status, previous rejections, current treatment and compliance, donor quality, and renal function) and pathologist (see Chapter 81), optimally interprets findings. A specific etiologic diagnosis is required for rational treatment directed towards underlying pathophysiological cause(s) of transplant dysfunction (Tables 69.2 and 69.3) [86,99].

Chronic cellular interstitial rejection

Chronic active T-cell-mediated rejection involves persistent immune transplant injury from failure of maintenance immunosuppression to control residual alloimmune activity. Progressive renal functional decline is associated with interstitial T-lymphocyte infiltration, often accompanied by B cells and macrophages, and tubulitis. Occasionally, fibrointimal hyperplasia of small muscular arteries (from smooth muscle proliferation and hyperplasia forming a neointima with focal internal elastic lamina destruction) is seen, which can progresses to vascular occlusion [10].

Treatment options involve strengthened immunosuppression, such as conversion from cyclosporine to tacrolimus (initial target levels approaching 10 ng/mL) [100], azathioprine to mycophenolate mofetil [101], and addition or augmentation of corticosteroids. Compliance checks, review of appropriate target blood drug levels, and exclusion of interfering agents (e.g. St John's wort or phenytoin inducing metabolizing enzymes and reducing CNI levels) are recommended.

Chronic antibody-mediated rejection

Chronic antibody-mediated rejection (CAMR) occurs from unrecognized pre-existing low titer DSA (missed by transplant CDC cross-match) or de novo antibodies developing after transplantation [50,102]. Late anti-HLA antibodies correlate with chronic humoral rejection, transplant glomerulopathy, and allograft failure [45,102,103]. Late de novo DSA appearing years after transplantation correlates with early cellular or mixed rejection episodes (often with PTC margination) and HLA mismatch, non-adherence with medications, and indolently progressive transplant dysfunction [77].

CAMR clinically presents with progressive functional decline, hypertension, and worsening proteinuria. Chronic persistent DSA affects the transplant's microcirculation, especially glomerular and peritubular capillaries, producing characteristic activated phenotype with altered production of underlying basement membrane material. Glomerular endothelial cells become hypertrophied and activated by sublethal DSA interacting with capillary endothelium, widening the subendothelial space from fibrillary material, and/or GBM duplication. Peritubular capillary cells produce multilayering of basement membranes (variably defined threshold as five layers for diagnosis, but normal is actually only one layer) [9]. Glomerular capillaries become thickened and, along with mesangial cell interposition, create "double contours" recognized by methenamine silver staining, the hallmarks of transplant glomerulopathy. Differential diagnoses are thrombotic microangiopathy (excluded by blood film, haptoglobin, and lactate dehydrogenase levels) and hepatitis C mesangiocapillary glomerulonephritis (by serology, blood viral nucleic acid testing, and GBM deposits) [104]. Transplant glomerulopathy, the glomerular expression of CAMR, is reported in 5 to 15% of failing and failed grafts [6,45,50,105] and up to 20% of protocol biopsies, where many are subclinical [50,106].

The current diagnostic triad of CAMR includes: (1) circulating donor-specific antibody (often class II anti-HLA antibodies); (2) capillary C4d deposition, the "footprint" of classical complement activation by antibody in peritubular capillaries (but relatively insensitive and often negative); and (3) chronic transplant glomerulopathy, by light microscopy, in the context of organ dysfunction [9,13,45,73,107].

Electron microscopy demonstrating glomerular endothelial swelling, subendothelial widening and GBM duplication, and/or

multilamination of PTC basement membranes confirms the diagnosis. Peritubular leukocyte inflammation and glomerulitis support DSA-mediated microcirculation injury. Progressive fibrointimal arterial hyperplasia from CAMR is relatively rare. Commonly, CAMR is associated with progressive transplant dysfunction, persistent interstitial cellular rejection, and tubulointerstitial damage (interstitial fibrosis and tubular atrophy, IF/TA), indicative of an uncontrolled broad alloimmune response [77].

Evidence for treatment is limited to uncontrolled cohort studies, adapted from acute AMR, involving strengthened baseline immunosuppression, increased tacrolimus and mycophenolate dosages (suppressing B and T-cell expansion), and corticosteroids (re-added if steroid free), and ACEI or ARB to limit proteinuria [13,50]. Aggressive treatments such as plasmapheresis to remove circulating DSA with intravenous immunoglobulin, and rituximab produce variable results. The roles of bortezomib (a proteasome inhibitor of plasma cells) and eculizumab (an anti-C5 antibody inhibitor) in CAMR are unclear, needing further clinical evaluation [13,50].

Differential diagnosis of chronic graft deterioration

Interstitial fibrosis and tubular atrophy

The most common pathology of slowly progressive graft failure is chronic IF/TA, accompanied by vascular changes and glomerulosclerosis [12]. IF/TA occurs in 27–45% of late graft losses [6,7], and is present in most late indication- or protocol-driven biopsies [7,12,108–110]. Formally designated as sclerosing "chronic allograft nephropathy" (CAN) [111], it represents the final common pathway of nephron injury with its fibrotic healing response, rather than a specific diagnostic entity [112]. While multiple potential etiologies and pathogenic pathways can lead to IF/TA, the alloimmune response is the most common and important cause [12,65].

Early tubular damage begins with ischemia–reperfusion injury, and subsequent acute or subclinical rejection episodes superimposed upon pre-existing donor disease. IF/TA associated with inflammation portends a worse prognosis [65,108,113]. A nonspecific pattern in a late biopsy of unknown cause is classified as "IF/TA not otherwise specified" [112]. Later microvascular abnormalities and glomerulosclerosis in transplanted kidneys slowly develop over years from calcineurin inhibitor nephrotoxicity, hypertension, diabetes, and hyperlipidemia, possibly admixed with specific diagnostic entities, such as recurrent glomerulonephritis or late alloimmune injury [12].

One treatment strategy for the IF/TA-CAN pattern is CNI minimization (assuming causal CNI nephrotoxicity as the primary pathology). CNI sparing regimens supplemented by mycophenolate increase transplant GFR (by 4.4 mL/min; 95% CI 2.9–5.9) in a meta-analysis of randomized controlled trials, and tended to improve graft survival (OR = 0.72; 95% CI 0.52–1.01). Acute rejection episodes increased only in trials of mandated CNI elimination, but not with avoidance or dysfunction [114]. The large randomized CONVERT study of transplant dysfunction (CAN proven in 91.3%) switched patients from CNI to sirolimus ("substitution") but failed its primary eGFR difference endpoint versus continued CNI. Sirolimus substitution was futile with severe transplant dysfunction (eGFR <40 mL/min) or proteinuria above 0.5 g/day [110]. CNI elimination (with sirolimus substitution or initial avoidance) reduced vascular and tubulointerstitial damage in other controlled trials [109,115].

The clinical approach to a failing graft with IF/TA begins by considering potential immune and non-immune-mediated etiologies with corroboration of clinical, biological, and histological information [86]. IF/TA should be pathophysiologically classified as primarily attributable to (1) early non-immune causes such as donor disease or ischemia–reperfusion tubular damage; (2) immune injury, including acute, severe, persistent, or late rejection; and/or (3) other specific diagnostic entities, including recurrent disease, BK virus, hypertension, or CNI toxicity. Several causes of injury may coexist at one time, or be differentially expressed over the graft's lifetime (Table 69.2).

Table 69.2. Differential diagnosis of chronic renal allograft dysfunction

Structural/infective
Ureteric obstruction or lower urinary tract obstruction
Recurrent allograft pyelonephritis and/or vesicoureteric reflux
Polyoma (BK) virus nephropathy
Renal arterial stenosis
Alloimmune injury
Late acute rejection (iatrogenic or patient non-compliance)
Chronic T-cell-mediated rejection
Chronic antibody-mediated rejection
Mixed acute or chronic rejection
Other causes
Non-specific sclerosing tubulointerstitial damage (formally designated as chronic allograft nephropathy)
Chronic calcineurin inhibitor nephrotoxicity
Recurrent thrombotic microangiopathy
Acute interstitial nephritis
Recurrent or de novo glomerulonephritis
Recurrent diseases (e.g. diabetic nephropathy)
Poorly controlled hypertension and hypertensive nephrosclerosis
Metabolic disturbances (e.g. uncontrolled hypercalcemia or hyperglycemia)
Concomitant medications: nephrotoxins (e.g. NSAID or COX-II inhibitors, contrast), drugs affecting glomerular hemodynamics and GFR (e.g. ACE-I, ARB, calcium channel blockers) or affect metabolism of CNI (e.g. phenytoin, diltiazem, verapamil, azole antifungal agents such as ketoconazole, fluconazole, etc.)
Acute kidney injury associated with major medical illness

Pointers for treatment assignment include the recipient's prior rejection and non-compliance history, sensitization, HLA mismatch, and circulating DSA status, all of which help quantify immune risks when considering any CNI minimization. Recent graft pathology is important to exclude ongoing alloimmune activity (histological clues include fibrointimal hyperplasia of small arteries, interstitial lymphocytic infiltration, lymphocytes in peritubular capillaries, transplant glomerulopathy, or positive C4d staining). Subclinical interstitial rejection leads to progressive IF/TA assessed by sequential biopsy pairs [65] where immunosuppression could be strengthened.

BK virus nephropathy

BK virus is an endemic polyoma virus causing a mild primary infection in children with a seroprevalence rate of 60–80%. Residual virus can be reactivated by powerful immunosuppression, usually within the first year with asymptomatic viremia. Severe BK virus nephropathy can develop with tubulointerstitial nephritis, leading to progressive renal dysfunction and graft loss (incidence 5% where 46% fail) [116]. Transplant biopsy demonstrates diagnostic intranuclear inclusions with enlarged nuclear chromatin from replicating virus within renal tubular cells, confirmed by SV40T viral immunostaining. Allograft BK infection can be accompanied

by tubular cell degeneration, apoptosis and detachment (forming diagnostic urinary "decoy" cells), and mononuclear interstitial inflammation [117].

Current antiviral agents are ineffective against BK. Prevention is the best strategy by avoidance of excessive immunosuppression, coupled with regular viral surveillance (by blood nucleic acid or PCR testing). Early detection of viremia (with viral load quantification) before graft dysfunction, and cautious reduction of therapy (usually 50% CNI dose reduction and weakening or elimination of antimetabolite), typically reduces or eliminates circulating virus, preventing destructive parenchymal infection.

Established BK viral allograft nephropathy is serious threat and difficult to eradicate [116,117]. Ciprofloxacin (for 1 month), low-dose cidofovir (0.5 mg/kg i.v. every second week with saline hydration), elimination or substitution of mycophenolate with leflunomide (all weak antiviral agents) or azathioprine, conversion from tacrolimus to low-dose cyclosporine (target C2 500 ng/mL), or CNI dose reduction, or regular intravenous immunoglobulin therapy (a non-depleting immunomodulatory agent for BK infection coexisting with "rejection"), had limited benefit in small cohort studies [34,118].

Calcineurin inhibitor nephrotoxicity

The introduction to transplantation of cyclosporine and later tacrolimus substantially reduced early acute rejection episodes, producing excellent 1-year graft survival rates and underpinning modern immunosuppression. But CNIs are nephrotoxic and this represents the primary drawback to this class of drug [119]. Evidence that CNI nephrotoxicity contributes to late graft injury is inferred from: (1) unchanged long-term graft loss rates despite suppression of acute rejection; (2) characteristic toxicity lesions in longitudinal histopathology studies [120]; (3) clinical trials of CNI avoidance, early withdrawal (to prevent toxicity), and dose reduction or late withdrawal (for established CNI damage), demonstrating functional or structural improvement [109,115,121,122]; and (4) by classical CNI histopathology and renal failure occurring in native kidneys of non-renal solid organ transplant recipients or autoimmune disease patients treated with CNI [123].

Progressive arteriolar hyalinosis is the most reliable diagnostic marker of chronic CNI nephrotoxicity, associated with downstream glomerulosclerosis and a common secondary diagnosis in 30% of "troubled transplants" [7]. Arteriolar hyalinosis becomes increasingly prevalent from sustained chronic exposure and increasing transplant age, and so by one decade post-transplant it is present in the vast majority, but with variable severity (suggesting individual susceptibility) [12,120]. Arteriolar hyalinosis can also originate from the donor kidney [124] (older donor age, vascular disease, or smoker, where baseline implantation biopsy helps later histological interpretation), or from subsequent development of other conditions such as diabetes mellitus (as diabetic glomerulopathy with GBM thickening on biopsy and proteinuria), other than CNI nephrotoxicity.

Isolated CNI nephrotoxicity (either acute cyclosporine-mediated glomerular vasoconstriction or chronic changes without rejection), has a relatively good outcome if recognized early, and is easily treated with CNI-sparing regimens [7]. CNI withdrawal from failing transplants reverses the functional decline and improves eGFR in cohort and uncontrolled studies [115]. Randomized trials of CNI reduction or withdrawal improved renal function in 90% of patients with a small risk of rejection and graft loss [121]. Patients interconverted from cyclosporine to low-dose tacrolimus showed improved renal function, lipids, hypertension, and cardiovascular markers, but 5-year graft survival was unaltered [125].

Table 69.3. Management of chronic allograft injury

Prevention and screening
Minimize ischemia–reperfusion damage (shortest ischemic times, optimal procurement, preservation and transport measures)
Minimize donor–recipient histoincompatibility
Rapid histological diagnosis and effective treatment of acute rejection
Early optimal immunosuppression (including IL2R blocker or antithymocyte induction with medium to high immune risk recipients, as appropriate)
Control of early subclinical rejection by adequate immunosuppression (only available as protocol biopsy diagnosis)
Early prophylaxis for CMV with (val)ganciclovir or valaciclovir
Early BK screening (especially if using high-dose immunosuppression)
Regular monitoring of renal function by serum creatinine
Interval dipstick urinalysis and imaging (for ureteric obstruction)
Regular compliance review and (re-)education if required
Control of progression factors
Control hypertension (calcium channel blockers ideally but there are theoretical advantages for ACEI or ARB therapy), diuretics may be needed
Avoid added salt, stop smoking, control lipids, limit weight gain, lifestyle modifications (risk of metabolic syndrome)
Control diabetes and urinary tract infections if these occur
Consider minimization of long-term CNI by dose reduction in low to medium immune risk recipients, or, if chronic allograft injury or CNI nephrotoxicity develops, by elimination or substitution
Avoid under-immunosuppression (risks of subclinical rejection or acute late rejection)
Match immunosuppression with individual immunological risk of rejection (e.g. HLA-mismatch, previous rejection history, re-transplantation, and DSA)
Manage acute transient recipient events (such as acute tubular necrosis from sepsis) with restitution of appropriate immunosuppression after stability of acute insult

When deteriorating function from CNI nephrotoxicity occurs in low immune-risk patients (and subclinical rejection is excluded by biopsy), CNI withdrawal and maintenance with concentration-controlled mycophenolate mofetil and corticosteroids are recommended [126]. For CNI nephrotoxicity in recipients with higher immune-risk, retransplants or previous rejection(s), then CNI can be either minimized or substituted (with sirolimus or everolimus), and carefully monitored by serum creatinine (the rejection risk for withdrawal approximates 10%) [34]. mTOR inhibitors are weaker immunosuppressive agents and poorly tolerated at high doses, and side-effects of mouth ulcers, peripheral edema, proteinuria, anemia, or thrombocytopenia result in discontinuation in 30–45% of patients [127,128]. When active rejection and chronic CNI nephrotoxicity occur together, treatment is prioritized to controlling the alloimmune response, as the greater immediate threat to the transplanted kidney (Table 69.3).

Newer non-nephrotoxic immunosuppressive agents also offer some promise, although clinical data are incomplete. Belatacept (targeting the CD28-CD80/86 pathway and T-cell costimulation) and tofacitinib (a Janus kinase 1/3 inhibitor) when combined with mycophenolate have been shown to decrease graft failure (OR 0.61; 95% CI 0.39–0.96) in a meta-analysis of CNI-sparing trials [129]. Voclosporine (a cyclosporine analog that is immunologically non-inferior to tacrolimus) has claimed reduced toxicity to the kidney. The CD2-specific fusion protein alefacept (targeting LFA3-CD2 pathway and selectively eliminating memory T cells, and effective in psoriasis) and sotrastaurin (AEB071, a protein kinase C inhibitor reducing T-lymphocyte activation and cytokine release) are largely preclinical at present.

Late-occurring glomerular diseases

Recurrent or de novo glomerulonephritis fail up to 8.4% of grafts by 10 years [130–132]. Clinical clues are hematuria or proteinuria, and diagnosis is made by transplant pathology. Despite fewer early rejection losses with modern immunosuppression producing more "at risk" recipients, late graft failures from recurrent glomerulonephritis are not increasing [133]. Transplant immunosuppression usually controls most immune-mediated renal diseases, including ANCA vasculitis, lupus nephritis, membranous glomerulonephritis, and Goodpasture's disease. IgA nephropathy commonly recurs but generally with a relatively milder clinical impact [130]. The use of corticosteroids is associated with reduced recurrent IgA by registry analysis (subhazard ratio 0.50; 95% CI 0.30–0.84) [133]. Mycophenolate (showing benefit in native IgA disease) also is suggested to be of benefit in avoiding consequential recurrence.

Light chain deposition disease mostly recurs, and dense deposit disease recurs in 50–90% with graft failure (there are case reports of benefit with eculizumab). Fabry disease recurs late and requires specific agalsidase therapy. Transplant diabetic nephropathy also reappears late with proteinuria and graft dysfunction and typical pathology. Blood pressure control and renin angiotensin system blockade appear beneficial in cohort studies, and are suggested.

Transplant hypertension and dyslipidemia

Hypertension occurs in 70–90% of recipients, correlating with graft loss and death. The high prevalence is usually related to pretransplant hypertension and recipient vascular disease, glucocorticoid and cyclosporine therapy, transplant dysfunction, or rarely from transplant renal artery stenosis [134]. Calcium channel blockers (antagonizing cyclosporine-mediated vasoconstriction) are well tolerated and effective, reducing graft loss (RR 0.75; 95% CI 0.57–0.99) and improving GFR (by 4.5 mL/min compared with placebo/nil treatment) in meta-analysis [135]. While renin–angiotensin system blockade has theoretical benefits, reducing allograft fibrosis, proteinuria, and graft loss [136], there is no proven benefit for graft outcomes. ACE inhibitors reduce GFR (difference −8.1 mL/min), proteinuria (by 0.28 g/day), and hemoglobin (by 0.28 g/day), and worsens hyperkalemia [135]. Loop diuretics are useful for symptomatic edema or when hypertension originates from the failing transplant's inability to clear salt and water. A target blood pressure of 130/80 mmHg is suggested [34].

HMG CoA reductase inhibitors ("statins") are well tolerated, significantly reduce hyperlipidemia, and tend to reduce cardiovascular events by randomized controlled trial [137]. Recipient cardiovascular event rates approximate 3.5–5% per year, and so treatment of dyslipidemia, a healthy diet and lifestyle, and appropriate management of diabetes mellitus are all suggested [34].

Late ureteric stenosis with obstruction

See Section Urine testing and transplant imaging.

Late acute graft failure

Clinical scenario. Transplant recipient presents (sometimes after prolonged absence) with severe transplant renal failure and a markedly elevated serum creatinine, compared to their previous baseline.

Late acute rejection

Acute rejection arising beyond 3 months ("late") after transplantation, from non-compliance or iatrogenic under-immunosuppression, presents with subacute or acute renal dysfunction. It can develop in sensitized patients with increased immunoreactivity against their kidneys, but usually occurs from patient medication non-compliance (see below) or iatrogenic under-immunosuppression (e.g. reductions following cancer diagnosis or severe infection) [77]. Clinician-directed mycophenolate dose reductions for diarrhea have been associated with acute rejection [138].

Acute rejection occurring late is often severe, relatively steroid-resistant, difficult to reverse, and accompanied by widespread tubulointerstitial damage [46]. Complete or partial cessation of maintenance immunosuppression results in (uncontrolled) allograft rejection—involving the adaptive and innate immune systems, antibody production, and mixed infiltration T and B cells, eosinophils, plasma cells, and macrophages. Initiation of chronic transplant rejection can also occur with persistent cellular interstitial infiltration and/or de novo DSA production (often Class II antibodies) [77]. Diagnostic biopsy usually shows well-established acute rejection with extensive interstitial lymphocytic infiltration and edema, associated with chronic interstitial fibrosis, tubular destruction, and glomerulosclerosis. Antibody-mediated rejection (circulating DSA, endothelialitis, and C4d positive) and vascular rejection are common [6,7,77].

Initial treatment by pulse corticosteroids and subsequent strengthening of baseline immunosuppression has limited success, with ongoing functional decline frequently progressing to end-stage failure. Transplants are often irreversibly damaged by late rejection episodes, displaying severe IF/TA (grade 2 involving 25–50% or more cortex) and limited potential for functional recovery. An important therapeutic question, the use of potent second-line therapies, requires the clinician to consider each individual's risk–benefit ratio carefully. The decision to use antithymocyte globulin and/or plasma exchange with i.v. immunoglobulin or rituximab depends on: (1) the severity of irreversible underlying nephron loss (best assessed by IF/TA biopsy scores, duration and pattern of renal functional decline); (2) the expected treatment response (antibody, vascular, and mixed rejections are more treatment resistant); (3) the recipient's ability to safely withstand powerful immunosuppressive regimens (elderly, frail patients with co-morbidities, persistent chronic infections such as bronchiectasis are relative contraindications); and (4) the underlying circumstances (acute rejection from transient situational problems versus more chronic disease and un-modifiable medication issues).

Overall nephron loss is best judged by the extent of tubulointerstitial damage, which guides prognosis (glomerulosclerosis is variable and misleading, some glomeruli are atubular). Transplant pathology should be viewed (not evaluated by only reading the report) to assess potential reversibility of the immune infiltrate. Balancing the recipient's risk of immunosuppression (primarily death from uncontrolled bacterial sepsis, invasive fungal infections, late CMV or PTLD, etc.) versus salvage of a damaged kidney (with potential stabilization or improvement of renal function) requires good clinical judgment. The default option is conservative treatment of pulse steroids, increased baseline therapy, and/or IVIG, accepting likely treatment failure with eventual return to dialysis.

Medication non-adherence

Non-compliance occurs in 23–50% of recipients at some time [139], varying from intermittent omission of some tablets (simple mistake or deliberate, or related to alcohol or drug use, chaotic life style, dementia, or forgetfulness), surreptitious dose reductions

or avoidance of particular medications (because of side-effects or other concerns), or complete cessation of therapy and presentation with acute rejection [77,140]. A history of poor medication adherence increases the risk of acute rejection and graft loss by sevenfold, contributing up to 36% of losses in some studies [139]. Medication non-compliance differentially effect recipients of higher immune risk, such as those with prior rejection, HLA mismatch, known DSA or regraft, where the margin for error is much less.

Risk factors include previous poor compliance with dialysis, psychiatric illness or personality disorders, substance abuse, high-risk behaviors, poverty, or when socioeconomic support is suboptimal. Children transitioning to adult transplant programs or adolescents are also vulnerable, and so bridging programs can help. Non-compliance increases with longer transplant duration and human complacency [141].

Clinical clues include missed appointments, fluctuating or undetectable CNI blood levels, differences between medication prescribed and dispensed, or an unexpected acute rejection episode—despite apparently adequate therapy. Often difficult to establish in practice, skipped medications can be clouded by overt denial (to avoid the clinician's displeasure), suspected by a pharmacist's medication audit, or acknowledged by guarded admission (sometimes to a nurse). Ask indirect, non-threatening questions and carefully listen to the patient's response (the "art of medicine"). Understanding the personal reasons for a patient's non-adherence and their situational stressors helps the formulation of a holistic strategy to minimize relapse.

Immunosuppressive therapies display differing non-renal toxicity profiles, influencing their use or misuse. Cosmetic side-effects, such as hirsutism in young women from cyclosporine (tacrolimus can be substituted), a moon face and acne (topical treatments or doxycycline can be used) with corticosteroids can be disconcerting and provoke non-adherence. Steroid withdrawal or minimization can reduce diabetes, cataracts, osteoporosis, fractures, growth retardation in children, and dyslipidemia. The benefits of better hypertensive and cholesterol control and less diabetes are balanced against increased rejection rates (10–15% in trials versus continued steroids) and worse renal function [142, 143]. Tacrolimus causes more post-transplant diabetes mellitus, tremor, headache, neurological symptoms, and diarrhea, compared with cyclosporine, which also causes gingival hyperplasia and dyslipidemia. mTOR inhibitors (sirolimus or everolimus) commonly have dose-dependent side-effects such as edema and mouth ulcers.

Preventive strategies include individualized and repeated education by a specialized transplant pharmacist, minimization of medication side-effects, complexity, and costs, and regular clinical support addressing patient's concerns [34,144].

Differential diagnosis of late acute dysfunction

Acute kidney injury from associated intercurrent illness

Transplant acute kidney injury may be triggered by medical or surgical events, such as myocardial infarction, sepsis, late CMV, abdominal emergencies, etc. Specific treatment is directed to the underlying acute illness, with optimization of cardiovascular medications, transient reduction of immunosuppression for severe life-threatening infections (resuming doses after recovery), and supportive intravenous hydration where needed. Transplant dysfunction usually resolves with physical recovery; however, incomplete recovery can follow a severe acute illness (Table 69.3).

Late transplant ureteric stenosis

As discussed above, this can present in settings following recurrent rejections, leading to ischemic injury to the distal ureter. BK virus also is an underlying cause of late ureteral stricture.

Late de novo or late recurrent glomerulonephritis

As described in Section Late-occurring glomerular diseases.

Late graft thrombosis

This is exceedingly uncommon, and related to underlying hypercoagulable states or conditions of severe systemic hypoperfusion.

Management of the recipient with a failing graft

Chronic transplant failure is often insidious and sometimes unpredictable. Many kidneys function for years at moderate or severe chronic kidney disease levels, before reaching stage 5 (<15 mL/min/1.73 m^2) when dialysis (re)institution is commenced. Many recipients with a failing graft are older (15% of wait-listed patients are over 65 years) and medically complex with excess cardiovascular disease, diabetes, prior malignancy, or chronic pulmonary disease contributing to mortality [145,146]. Recipients with a poorly functioning transplant are uremic, anemic, malnourished, and medically compromised, with excess mortality rates (HR 13.6 for the first week after failing, but remaining abnormal to 10 years) [146]. Late opportunistic infections from immunosuppression are often present and include CMV, and bacterial or fungal diseases requiring specific antimicrobial therapies. Surgical or cardiovascular emergencies can cause acute kidney injury and precipitate graft failure, especially in those with pre-existing poor function.

Early management of chronic kidney failure complications should commence. Treatment of anemia by erythropoietin, hyperphosphatemia and hyperparathyroidism by phosphate binders and vitamin D analogues, hypoalbuminemia with adequate nutrition, and hypertension with appropriate antihypertensive regimens should be undertaken [147,148]. Advance planning of dialysis access, appropriate psychological support, and careful tapering of immunosuppression, using expert multidisciplinary care, can minimize transitional morbidity and mortality.

Summary

Dysfunction of the transplanted kidney has an extensive differential diagnosis, which is weighted toward technical and ischemic-related problems early, transitions shortly after transplantation to immune rejection, and is dominated late by recurrent disease and consequences of inadequate or overly aggressive immunosuppressive drug use. Experienced clinical assessments, prompt use of diagnostic maneuvers including biopsies, and collaborative relationships with transplant pathologists are required to mitigate the many potential causes of allograft failure. While acute rejection is a transplant-specific diagnosis, numerous other pathologies should be considered prior to augmented immunosuppressive therapy.

CHAPTER 70

Clinical Allograft Rejection Syndromes in Liver Transplantation

Matthew H. Levine[1] and Sandy Feng[2]

[1] Division of Transplant Surgery, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA
[2] Division of Transplant Surgery, University of California San Francisco, San Francisco, CA, USA

Introduction

Liver transplantation is recognized as the ideal standard of care to treat acute non-recoverable liver injury, chronic end-stage liver disease, certain metabolic diseases, and hepatocellular carcinoma in the cirrhotic patient. In the past four decades, this procedure has evolved from an experimental high-risk procedure to one performed world-wide with excellent outcomes, including 1- and 5-year patient survival exceeding 90% and 75%, respectively [1]. While the improvement in outcomes after renal transplantation have been attributed in large part to a significant decrease in early acute rejection rates, this has not been the case in liver transplantation, where acute rejection rates continue to exceed 30% in most reported series and compiled data sets [2–5]. The vast majority of these acute rejection episodes occur within the first 3 months after liver transplantation, but both acute and chronic rejection can occur later after transplantation [6]. Compared to other solid organs transplanted, the incidence of chronic rejection is lower, perhaps due to the regenerative nature of the liver itself, such that injury does not accumulate over time but is efficiently repaired with preservation of structure and function [7]. This ability to repair injury through regeneration likely explains the dissociation between acute rejection and inferior graft survival that is unique in solid organ transplantation [3,8–10]. An additional difference between rejection of the liver compared to other allografts is the apparent relative unimportance of HLA antibody-mediated processes [11,12]. Cross-matching is routinely performed for all solid organ transplants except for the liver [4,12]. Moreover, the vast majority of acute rejection episodes are successfully reversed without consideration or treatment of antibody-mediated processes. The relative resistance to antibody-mediated damage by the liver may be due to the liver's ability to adsorb antibody, an intrinsic property of the liver that may protect syngeneic organs such as the kidney which is vulnerable to antibody-mediated damage [4]. This convention has recently been challenged by data implicating antibody-mediated rejection in graft loss and chronic rejection of the liver [13–16].

This chapter will build on prior chapters that have delineated the molecular and cellular basis of organ rejection to outline the clinical presentation of liver allograft rejection according to time of presentation and type of rejection. It will also present standard approaches to diagnose rejection among the other causes of liver allograft dysfunction. Treatment strategies for liver rejection will be presented. Lastly, controversies, specialized cases, and future directions in the diagnosis and management of liver rejection will be outlined.

Cellular basis for rejection

The molecular and cellular basis as well as the histopathological aspects of rejection are discussed in detail in Chapters 5–7, and Chapters 81–87 refer to the histopathological aspects. As a summary, the most common type of liver rejection encountered is acute rejection, manifested histologically by lymphocytic infiltration of the portal tract structures (bile duct, portal vein, and hepatic artery), with or without involvement of the central veins [17–20]. The preponderance of the infiltrating lymphocytes is $CD4^+$ and $CD8^+$ T cells accompanied by macrophages, leading to the term acute cellular rejection (ACR). $CD4^+$ T cells are the dominant infiltrating cells, although greater numbers of activated $CD8^+$ T cells are seen in clinical rejection [2,21]. Eosinophils are often present in the infiltrate along with natural killer (NK) cells [17,18]. The severity of ACR—mild, moderate, and severe—is graded according to Banff criteria (Table 70.1) [17,18].

The antigenic target of ACR is likely mismatched donor cell surface-bound major histocompatibility (MHC) antigens, although the degree of human leukocyte antigen (HLA) mismatch is not predictive of risk of rejection in human liver transplantation, as it is in other organs [2,4,22,23]. Hepatocytes and biliary epithelial cells typically express only MHC class I at low levels. However, biliary epithelial cells can up-regulate MHC class I and class II antigen expression under the influence of an inflammatory state [4]. Liver sinusoidal endothelial cells (LSECs) are the major non-parenchymal cells of the liver. They express not only MHC class II but also costimulation molecules, such that they can present antigen to both $CD4^+$ and $CD8^+$ T cells in experimental systems [4,24–27]. However, the donor LSECs may actually function as a barrier to lymphocyte infiltration by effectively forming a continuous lining of the sinusoids. Moreover, experimental evidence supports a tolerogenic role for the interaction between donor LSECs and recipient T cells via cross-presentation of endogenous antigen on MHC Class I, resulting in clonal deletion and T-cell anergy. Thereby, LSEC may play a role in the relative tolerogenicity ascribed

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Table 70.1. Grading of acute liver allograft rejection

Global Assessment*	Criteria
Indeterminate	Portal inflammatory infiltrate that fails to meet the criteria for the diagnosis of acute rejection (see text)
Mild	Rejection infiltrate in a minority of the triads, that is generally mild, and confined within the portal spaces
Moderate	Rejection infiltrate, expanding most or all of the triads
Severe	As above for moderate, with spillover into periportal areas and moderate to severe perivenular inflammation that extends into the hepatic parenchyma and is associated with perivenular hepatocyte necrosis

Note: Global assessment of rejection grade mode on a review of the biopsy and after the diagnosis of rejection has been established.
* Verbal description of mild, moderate, or severe acute rejection could also be labeled as Grade I, II, and III, respectively.
Source: Banff Schema Group 1997 [17]. Reproduced with permission from John Wiley and Sons.

to liver transplantation [25,28]. Kupffer cells, another nonparenchymal cell resident within the liver, comprise a major percentage of total body macrophages. Kupffer cells can also present antigen to recipient T cells. T-cell apoptosis induced by Kupffer cells is associated with liver graft tolerance in experimental systems [29,30].

Antibody basis for rejection

The liver appears to be relatively resistant to hyperacute antibody-mediated rejection [31–34]. While hyperacute rejection of a liver allograft can occur in sensitized animal models, it is extremely rare in human liver transplantation. As a result, the vast majority of liver transplant programs do not perform pretransplant cross-matching and many do not even characterize recipient or donor HLA type [35,36]. In ABO-incompatible liver transplantation, preformed antibodies to donor blood group antigens can induce early and severe rejection with higher rates of biliary and vascular complications, particularly in adult recipients. This indicates that antibodies can be pathogenic for liver grafts [37–40]. The ABO incompatibility barrier may be crossed in the setting of low antibody titers (more common in infants) with enhanced anticellular and antihumoral therapies, such as exchange transfusion, plasmapheresis, antibody adsorption with affinity columns, intravenous immune globulin, splenectomy, and/or anti-CD20 antibody therapy [38,41–44].

The biological mechanisms conferring relative resistance of liver allografts to alloantibody-mediated damage are poorly defined. Proposed mechanisms include the regenerative capacity of the liver itself, the shielding of liver parenchyma by LSEC and other endothelial cells, the secretion of soluble MHC class I molecules which may complex with and clear antibody, and potential direct cellular effects of the liver on immune cells [45,46]. None of these hypotheses have a proven role in human transplantation but remain areas of current investigation. The effect that the liver can have on antibody pathogenesis is demonstrated by the fact that auxiliary liver transplantation can facilitate transplantation of a positive cross-match kidney from the same donor [47]. This protective effect is not universal, however, and antibody-mediated rejection (AMR) of either the liver or the kidney has occurred with high antibody titers [4,48–50].

In ABO-compatible liver transplantation, cases of acute AMR have recently been described and successfully treated with antihumoral agents and therapies [11,13,36,48,51,52]. There has been substantial debate over decades about the utility of antibody detection and testing of liver recipients and whether, in fact, AMR occurs with any frequency [51,53–58]. One study identified antibodies against liver sinusoidal epithelial cells as highly associated with late acute rejection in prospectively studied patients, proposing that such antibodies may alter TGF-β expression and allow increased T-cell responses in the liver [59]. This debate continues today, focusing on C4d staining in the transplanted liver and the association of C4d staining with inferior liver graft survival [14,15,54,60–67]. Moreover, additional data has linked the presence of donor-specific antibody with inferior survival of primary and secondary liver allografts [34,68–70].

There has been recent interest in the hypothesis that alloantibody contributes to the pathogenesis of chronic rejection of the liver. The rarity of chronic rejection substantially increases the difficulty of delineating relevant mechanisms along with their relative contributions [4]. A number of these studies have shown that C4d staining and emergence of donor-specific antibody is associated with subsequent chronic rejection. This is certainly intriguing as the process of chronic rejection is still not well understood at the cellular and molecular level [11,14,60,66,67,71]. Finally, donor-specific antibody also poses concern in the context of immunosuppression minimization or withdrawal [4,72,73]. The presence and/or emergence of donor-specific antibody as drug dosing is reduced may signal an antidonor response that could limit the success of such approaches. However, until there is a clear understanding as to the functional significance of alloantibody in liver transplantation, particularly in the context of an allograft that is functioning normally, these concerns remain theoretical.

Thus, in summary, the clinical significance of alloantibody and humoral rejection pathways in liver transplantation remains controversial. There is a growing sense that alloantibodies may play a role in at least some cases of rejection, both acute and chronic. However, more clinical and pathological investigation is needed to properly document their presence and assess their importance in liver transplant recipients with normal and abnormal allograft function.

Histopathology and molecular pathology in diagnosis of rejection

While the differential diagnosis of liver allograft dysfunction changes with timing after transplant, the identification of liver graft rejection is made by direct histopathologic analysis of liver tissue [17,19,74]. There are a variety of ways to obtain an allograft biopsy after liver transplant. The most straightforward is a percutaneous biopsy of the liver that is typically performed with ultrasound guidance. Complications include bleeding, bile leak, creation of an intrahepatic vascular fistula, and injury to adjacent structures [75–78]. Transjugular liver biopsy is an interventional radiology procedure that has been increasingly utilized in the past decade, particularly in the setting of coagulopathy or ascites. The major advantage of this approach is to limit bleeding to the intravascular space unless the liver capsule or major biliary structure is punctured. Disadvantages include lower tissue yields and substantial procedural cost associated with this approach [79]. Open liver biopsy by wedge or needle is always possible when the patient is being explored for other reasons or no other safe approach exists. Fine needle aspiration (FNA) biopsy compromises cellular architecture and is currently inappropriate to assess rejection [80]. However, FNA may

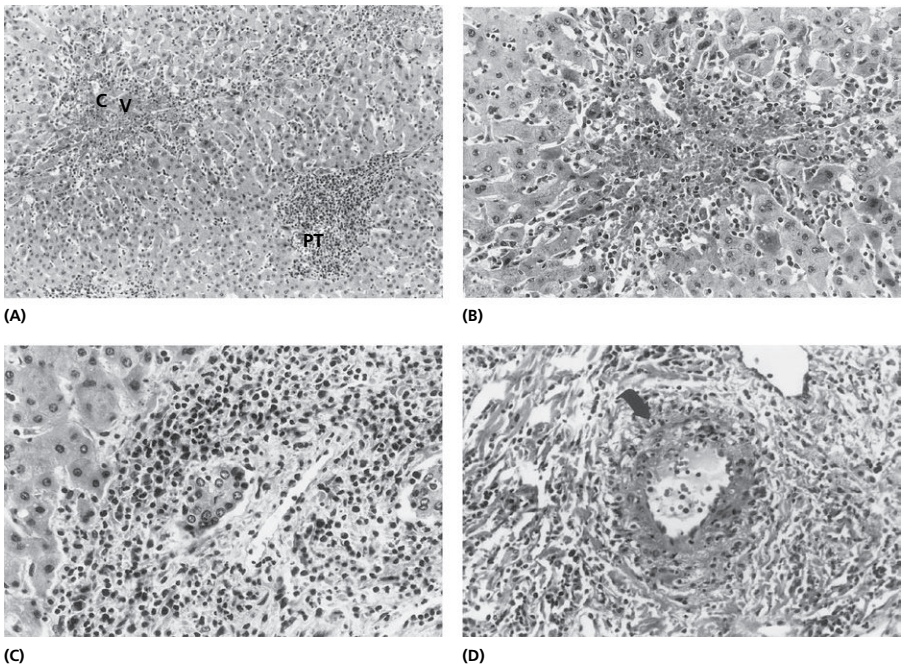

Figure 70.1. Low-power photomicrograph of a failed liver allograft with severe acute rejection. Note the prominent portal tract (PT) and central vein (CV) inflammation, associated with confluent perivenular necrosis, which is shown at a higher magnification in (B). These findings would elicit a diagnosis of severe acute rejection. (C) In the same liver allograft, the bile duct inflammation and damage was widespread and there was focal lumenal disruption, eliciting an RAI score of 3 for bile duct damage. Both the portal and venous endothelial inflammation was also scored as severe, or "3", resulting in a total RAI score of 9/9. (D) Sections from the hilum of this failed allograft also revealed clear-cut necrotizing arteritis (arrow), which is rarely detected with certainty in needle biopsies. Source: Banff Schema Group 1997 [17]. Reproduced with permission from John Wiley and Sons.

become a viable alternative if the diagnosis of acute rejection can be made with molecular rather than histological analysis [81]. Lastly, there have been attempts to diagnose rejection using bile cytology but this technique is unreliable [82,83].

The classification of histopathological findings associated with ACR of the liver were delineated by a Banff consensus conference in 1997 [17]. ACR is adjudicated on a scale of 0–3 (none, mild, moderate, severe) for three categories of inflammation: portal inflammation, bile duct inflammation and damage, and venous endothelial inflammation. The three scores are summed to yield a composite score from 0–9 that represents the rejection activity index (RAI). Mild acute rejection was diagnosed with RAI $\leq$4 and was not associated with firm treatment recommendations. Moderate or severe ACR with RAI $\geq$6 (Figure 70.1; also see Chapter 82 for extensive characterization of the cellular infiltrate) was generally associated with liver test abnormalities and treatment with additional immunosuppression is recommended (see Table 70.1 listing the grading of acute liver allograft rejection and Table 70.2 listing the rejection activity index, both from Banff 1997; also see Chapter 82 for additional characterization of the Banff grading system). The consensus conference acknowledged that early liver allograft injury from preservation and ischemia as well as effects of recurrent viral disease may complicate the diagnosis of rejection, particularly as multiple processes can be present concurrently.

Graft infection with hepatitis C virus (HCV) is universal in patients with viremia at the time of transplantation [84]. There is significant overlap in histological appearance between recurrent HCV and ACR and the differentiation of these phenotypes can be challenging. Both processes can also occur in the same recipient simultaneously. Treatment of these two conditions

Table 70.2. Rejection activity index

Category	Criteria	Score
Portal Inflammation	Mostly lymphocytic inflammation involving, but not noticeably expanding, a minority of the triads	1
	Expansion of most or all of the triads, by a mixed infiltrate containing lymphocytes with occasional blasts, neutrophils and eosinophils	2
	Marked expansion of most or all of the triads by a mixed infiltrate containing numerous blasts and eosinophils with inflammatory spillover into the periportal parenchyma	3
Bile Duct Inflammation Damage	A minority of the ducts are cuffed and infiltrated by inflammatory cells and show only mild reactive changes such as increased nuclear:cytoplasmic ratio of the epithelial cells	1
	Most or all of the ducts infiltrated by inflammatory cells. More than an occasional duct shows degenerative changes such as nuclear pleomorphism, disordered polarity and cytoplasmic vacuolization of the epithelium	2
	As above for 2, with most or all of the ducts showing degenerative changes or focal lumenal disruption	3
Venous Endothelial Inflammation	Subendothelial lymphocytic infiltration involving some, but not a majority of the portal and/or hepatic venules	1
	Subendothelial infiltration involving most or all of the portal and/or hepatic venules	2
	As above for 2, with moderate or severe perivenular inflammation that extends into the perivenular parenchyma and is associated with perivenular hepatocyte necrosis	3

requires differing approaches so this can be a crucial clinical distinction. Features favoring recurrent HCV infection include steatosis, lobular inflammation, spotty necrosis, and acidophil body formation [17,85,86].

An update to the Banff criteria was published in 2000 to account for the histopathology of chronic liver allograft rejection [18]. This classification emphasizes that the term "chronic rejection" is not meant to imply a late-developing process, as this injury pattern has been observed within months of transplantation and, on occasion, is associated with rapid progression to allograft failure. Chronic rejection is generally felt to result from unresolved acute rejection that leads to severe duct damage and, eventually, loss of bile ducts, hepatic arterial braches, and terminal hepatic venules. Chronic rejection is often associated with a diminution or resolution of the typical necroinflammatory portal infiltrates that are crucial for a diagnosis of acute rejection. The presence of active inflammation can denote reversibility with immunosuppression modulation, while structure loss in the absence of inflammation is a later phenotype that can denote irreversibility (Table 70.3 [84] ; also see Chapter 82) [18,87]. Finally, there has been a recent assessment, but no consensus, as to whether C4d staining and donor-specific antibody titers should be considered in the histopathologic analysis of acute and, in particular, chronic rejection [11,14,15,60,61,65,67,88].

Significant effort has focused on the non-invasive molecular diagnosis of liver rejection events using peripheral blood transcriptional biomarkers and serum microRNAs. The statistical validation of such approaches remains challenging but offers the potential to streamline the diagnosis of rejection. Moreover, validated biomarkers may facilitate ongoing monitoring for rejection and responses to antirejection treatment, which may allow for individualized tailoring of immunosuppression regimens including minimization and/or complete withdrawal [89–94].

Table 70.3. Features of early and late chronic liver allograft rejection (CR)

Structure	Early C.R	Late CR
Small bile ducts (<60 μm)	Degenerative changes involving a majority of ducts: eosinophilic transforma tion of the cytoplasm: increased N:C ratio; nuclear hyperchromasia; uneven nuclear spacing; ducts only partially lined by biliary epithelial cells Bile duct loss in <50% of portal tracts	Degenerative changes in remaining bile ducts Loss in ≥50% of portal tracts
Terminal hepatic venules and zone 3 hepatocytes	Intimal/lumenal inflammation Lytic zone 3 necrosis and inflammation Mild perivenular fibrosis	Focal obliteration Variable inflammation Severe (bridging) fibrosis
Portal tract hepatic arterioles Other	Occasional loss involving <25% of portal tracts So-called "transition" hepatitis with spotty necrosis of hepatocytes	Loss involving >25% of portal tracts Sinusoidal foam cell accumulation; marked cholestasis
Large perihilar hepatic arteiy branches Large perihilar bile ducts	Intimal inflammation, focal foam cell deposition without lumenal compromise Inflammation damage and focal foam cell deposition	Lumenal narrowing by subintimal foam cells Fibrointimal proliferation Mural fibrosis

Clinical presentation of liver rejection

We will separate our discussion regarding the clinical presentation of acute rejection into early and late using 6 months after transplant as the separation threshold. Suspicion of rejection is most commonly raised by elevations in aminotransferases, alkaline phosphatase, and/or bilirubin. No single pattern of abnormalities has proven to be diagnostic [95,96]. Histological severity of rejection has been correlated with higher serum levels of total and direct bilirubin and aminotransferases but not alkaline phosphatase or γ-glutamyl transferase at the onset of rejection [6]. Clinical signs, including fever, malaise, abdominal pain, and hepatomegaly, can also be observed, although these are less common and not individually diagnostic [6].

Early acute rejection

Differential diagnosis

Early acute rejection has been variably classified but we will define it as occurring within 6 months of liver transplantation [97]. The most recent published incidence of early acute rejection is approximately 25% and is equivalent for deceased-donor and living-donor liver transplants (Figure 70.2) [5]. When allograft dysfunction is identified by abnormal liver tests, a substantial differential diagnosis often exists. Figure 70.3 presents a schematic flowchart to guide diagnostic choices based on presentation and time from transplant. In the initial period after transplantation, it is incumbent to assess for vascular and biliary complications. Early after transplantation, hepatic artery thrombosis (HAT) can be associated with significant elevations of aminotransferases, severe allograft dysfunction approaching acute hepatic failure, biliary necrosis, and/or hepatic abscess formation, as collateral circulation has not yet developed. As such, retransplantation may be necessary. Current allocation policies specify criteria for listing status elevation or Model for End-stage Liver Disease (MELD) exception point allocation if HAT is diagnosed within 2 weeks of transplantation. Exception scores can be requested if a diagnosis is made outside of this time period and clinical circumstances merit. Less common vascular complications, such as portal vein thrombosis or hepatic vein obstruction, are also in the differential and each of these conditions can be

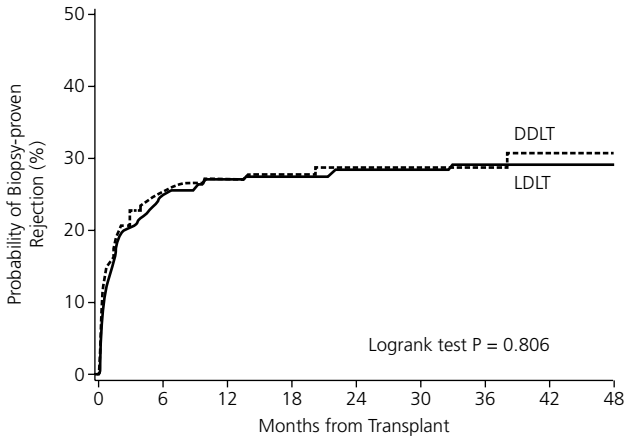

Figure 70.2. Incidence of early acute rejection. DDLT, deceased donor liver transplantation; LDLT, living donor liver transplantation. Source: Shaked et al. 2009 [5]. Reproduced with permission from John Wiley and Sons.

suggested by duplex ultrasonography with definitive diagnosis by angiography.

The next major branch point in the differential is whether the liver test abnormalities may be secondary to a biliary complication. The relative likelihood of this will determine whether biliary interrogation or allograft biopsy is the next planned intervention. If ultrasound examination shows dilatation of the biliary tree, which is uncommon in the early post-transplant period, then biliary imaging should come next in the form of endoscopic retrograde cholangiopancreatography for duct-to-duct reconstruction and percutaneous transhepatic cholangiography (PTC) for Roux-en-Y reconstructions. These invasive approaches also offer the possibility of therapeutic intervention. Alternatively, magnetic resonance cholangiopancreatography (MRCP) or computed tomography cholangiography are non-invasive diagnostic approaches that depend upon bile excretion for image generation. Cholangitis or biloma may also accompany biliary leak and/or stricture and necessitate specific treatment. The timing and nature of intervention—surgical or interventional—with a fresh biliary anastomosis may vary based on individual discretion.

If the suspicion of biliary complications is low or if the biliary imaging does not identify a complication, the next step in the diagnostic algorithm is allograft biopsy. Active cholangitis is a relative contraindication to liver biopsy so identifying biliary complications prior to liver biopsy is preferred. The tissue may evidence acute rejection, preservation injury, recurrence of primary disease, or infection (viral hepatitis or cytomegalovirus [CMV]), and/or chronic rejection. Histological assessment can also suggest the presence of a vascular or biliary complication. It is also possible that two processes are occurring simultaneously, such as recurrent hepatitis C with acute rejection. Follow-up biopsy can be done if the initial biopsy was non-diagnostic or to assess efficacy of administered therapy. Adjuncts to diagnosis of early allograft dysfunction include obtaining hepatitis C RNA viral load in patients with known hepatitis C, CMV DNA titers, blood cultures, and cross-sectional imaging if there is evidence of infection or fever. Additional discussion of the differential diagnosis and recurrent disease is found in Chapter 78.

Immunosuppression regimens and rejection

Multiple studies have determined rates of ACR and steroid-resistant rejection associated with different immunosuppression regimens. According to a compendium of 16 randomized trials comparing cyclosporine-based to tacrolimus-based immunosuppression

regimens, the latter exhibited 20% lower risk of ACR and 50% lower risk of steroid-resistant rejection in the first post-transplant year [98,99]. Both mycophenolate mofetil and tacrolimus originally gained traction as rescue agents for the treatment of refractory rejection [100–102]. Mycophenolate mofetil has been shown to be more potent than azathioprine, particularly in combination with cyclosporine [103,104]. With the currently available armamentarium of medications, double or triple regimens comprised of corticosteroids and tacrolimus, with or without mycophenolate derivatives, are standard and associated with comparable rates of early ACR [105,106]. Induction immunosuppression with either an IL-2 receptor antibody or rabbit antithymocyte globulin is administered most frequently to facilitate complete corticosteroid avoidance or corticosteroid and/or tacrolimus minimization. This tradeoff approach has been associated with either similar or lower rates of early ACR, compared to standard, non-induction regimens [107–109]. The use of m-TOR inhibitors in maintenance immunosuppression regimens has evolved in response to the toxicity profile of calcineurin inhibitors (CNI), including renal dysfunction and increased malignancy risk. Conversion of transplant recipients with deteriorating renal function from a CNI-based regimen to an m-TOR-based regimen may stabilize or even improve renal function [110,111]. There is also interest in administering m-TOR inhibitors to recipients with a history of hepatocellular carcinoma or with hepatitis C infection secondary to the antiproliferative effects of m-TOR inhibitors that may deter recurrent malignancy or allograft fibrosis [112]. In the United States, sirolimus and everolimus are two m-TOR inhibitors approved for prophylaxis against kidney allograft rejection. While everolimus is now approved for liver transplantation, it should be noted that sirolimus carries a black box warning pertaining to increased risk of hepatic artery thrombosis [113].

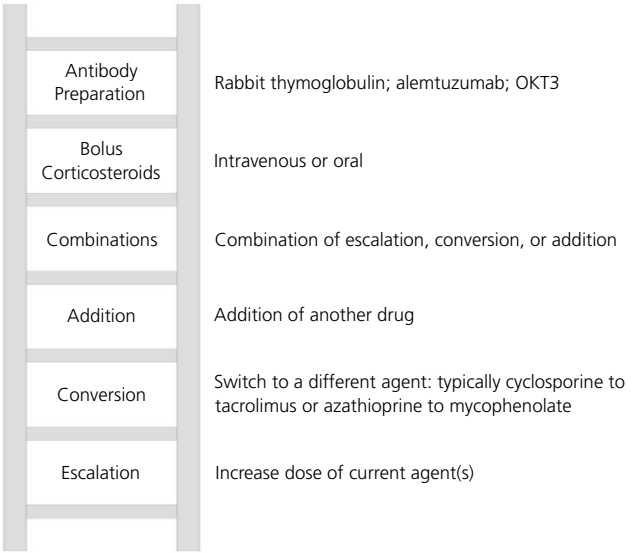

Figure 70.4. Treatment ladder for acute rejection after liver transplantation.

Treatment of early acute rejection

Once the diagnosis of ACR is made, the treatment decision must be made within the context of multiple factors. First, the clinical and histological severity of acute rejection should be considered. Second, background liver disease is important. Autoimmune etiologies of liver disease, including autoimmune hepatitis, primary biliary cirrhosis, and primary sclerosing cholangitis, are associated with increased rejection risk and may motivate more potent treatment. In contrast, hepatitis C may motivate less potent treatment as over-immunosuppression can exacerbate recurrent disease. Other clinical morbidities and/or laboratory abnormalities can affect the choice of treatment, including renal dysfunction, proteinuria, diabetes, hypertension, hyperlipidemia, and cytopenias. Third, the intensity of immunosuppression at the time of the acute rejection episode merits consideration. Because episodes of acute rejection, particularly for recipients without hepatitis C, do not exert a negative impact on long-term outcomes, selection of a treatment strategy that is adequate but not excessive is highly desirable. However, incomplete resolution of acute rejection can predispose to chronic rejection, which is more difficult to reverse and can threaten graft survival. A balanced and judicious approach to the treatment of acute rejection can be associated with a more gradual normalization of laboratory abnormalities, requiring close monitoring and frequent assessment until complete resolution is achieved. For more general discussions of rescue immunosuppression, see Chapter 67.

The treatment options for acute rejection can be considered as a ladder with a stepwise increase from less to more aggressive options (Figure 70.4). The lowest rung is intensification of baseline immunosuppression, defined as an increase in the dose of one or more pre-existing drugs. The second rung is conversion, defined as a switch from a less potent to more potent drug, typically in the same class. This includes conversion from cyclosporine to tacrolimus, or from azathioprine to mycophenolate or to an mTOR inhibitor [98,101,102]. The third rung in the treatment of acute rejection is addition, defined as adding a new drug to the existing regimen and thereby going from a one or two-drug regimen to a two or three-drug regimen, respectively. These approaches are typically exercised in the setting of mild histological severity and modest elevations in liver tests. Historically, the fourth step, corticosteroids, was the starting point for the treatment of ACR. Dosing often begins with two or three doses of bolus intravenous corticosteroids and is typically followed by a tapering course of oral corticosteroids. Alternatively, solely the oral "recycle" of corticosteroids can be administered. Corticosteroids have been associated with increasing the aggressiveness of recurrent hepatitis C, so the risk/benefit ratio must be considered carefully in this patient population.

Rejection that fails to respond to corticosteroids is termed steroid-resistant rejection. T-cell-directed antibody therapies, such as monoclonal anti-IL-2 receptor antibodies (basiliximab), monoclonal anti-CD52 antibody (alemtuzumab), and polyclonal rabbit antithymocyte globulin (rATG), have all been used, although rATG is the most common choice [114–119]. Overall, 60–75% of steroid-refractory rejection is successfully reversed, with episodes that occur earlier after transplantation more amenable to treatment than those that occur later after transplantation.

The strategies delineated above are standard approaches to treat ACR. If humoral rejection is diagnosed, then different therapies targeting antibody presence and production should be considered. AMR-directed therapies include plasmapheresis and IVIG in tandem, as well as monoclonal anti-CD20 antibody (rituximab), which target predominantly B cells. Because this drug does not appreciably affect the repository of B-cell memory (plasma cells), agents directed at plasma cells are being actively evaluated in

kidney transplant recipients but have not been tested in liver transplantation.

Mitigating factors to consider in selecting treatment for early acute rejection

A primary considerations when determining the treatment strategy for early ACR after liver transplantation is the recipient's hepatitis C status. The aggressiveness and tempo of recurrent hepatitis C infection is determined by multiple donor, recipient, and viral factors [120–122]. The immune status of the recipient is believed to play a role in disease control. As such, treatment of ACR with pulse corticosteroids and, in particular, antibody preparations, has been associated with more rapid and severe recurrent disease [107,123–125]. It is also important to consider the histological ambiguity between ACR and recurrent hepatitis C, leading to the possibility of a mistaken diagnosis [86,126,127]. The presence of hepatitis C virus has therefore encouraged a balanced approach to treatment of ACR, motivating the selection of as low a rung on the treatment ladder as effective. Repeat biopsy to monitor the evolution of the rejection episode, the response to treatment, and the degree of virus-induced damage is encouraged [86,127–129]. The dilemma posed by the possibility of ACR within the hepatitis C context has intensified efforts to deliver and maintain adequate immunosuppression early after transplant to minimize the risk of ACR.

An additional, major consideration in the choice of antirejection treatment is renal dysfunction. The implementation of MELD allocation has increased the prevalence and severity of renal dysfunction, particularly early after transplantation, which often limits dosing of CNIs. Recipients with renal dysfunction are typically maintained on both corticosteroids and mycophenolate in addition to a CNI to complete the immunosuppression regimen. Therefore, if early ACR does occur, then the threshold to use bolus corticosteroids is lowered, even for hepatitis C recipients as the alternatives (intensification, conversion, and/or addition) are either impossible or unlikely to be sufficient to control ACR.

Another factor in the choice of antirejection treatment is bone marrow suppression in the early post-transplant timeframe. Relative neutropenia and thrombocytopenia are common. Contributing factors include residual hypersplenism and drug effect related to anti-CMV (valgancyclovir) and/or immunosuppression medications (mycophenolate mofetil, m-TOR inhibitors, or azathioprine). Reduction of immunosuppression dosing as a result of cytopenias may increase vulnerability to ACR. Currently, there is no readily available therapy for thrombocytopenia but filgrastim can be administered to treat leucopenia/neutropenia. Similar to renal dysfunction, cytopenias reduce antirejection treatment options, increasing the likelihood that bolus corticosteroids will be administered [130,131].

Special cases of early acute rejection

ABO-incompatible (ABOi) transplantation has historically been associated with poorer outcomes and higher rejection rates than ABO-identical or compatible liver transplantation for adults [42,44]. The hallmark histological feature of ABOi graft rejection is intragraft disseminated intravascular coagulation, leading to thrombosis and necrosis [41,132]. This pattern can appear histologically similar to humoral rejection in renal transplantation. This is despite the fact that, rather than anti-HLA antibody, the pathology is driven by anti-blood group antibodies. Much of the investigation into and practice of ABOi liver transplantation comes from living donor liver transplantation in Japan, a country where deceased-donor liver transplantation is rare. Adjunctive therapies that have been typically used in various combinations to mitigate antibody-mediated rejection of ABOi livers include plasmapheresis/exchange transfusion, intravenous immunoglobulin, anti-CD20 monoclonal antibody, splenectomy, and infusion of various agents into the portal vein and/or hepatic artery such as high-dose corticosteroids, prostaglandin E1 (vasodilator), and gabexate mesilate (a protease inhibitor to prevent platelet aggregation) [37–40]. In addition to these therapies unique to ABOi transplantation, standard immunosuppression is augmented such that four-drug maintenance regimens are often employed.

The risk of ACR after liver re-transplantation has not been well documented relative to the risk after initial liver transplant [133,134]. It is described that the risk of rejection is higher after renal re-transplantation [135–137]. One single-center series of 32 liver re-transplant patients described no ACR, although the overall 1-year survival in this group was low [138]. Models aiming to predict survival after liver re-transplantation did not include rejection during the initial transplant course as a prognostic factor for re-transplant graft outcome [134,139,140]. Overall, it there is not sufficient data to determine if rejection rates differ after primary versus non-primary liver transplantation.

Outcomes after early acute rejection

Unlike other transplanted organs, early ACR rejection in liver transplantation is not believed to exert an impact on long-term graft and patient survival [8]. In fact, univariate analysis has shown that early ACR rejection is associated with significantly lower post-transplant mortality [6]. The association was attributed to the better overall health status of recipients with rejection compared to those without rejection. Notably, this study was performed more than one decade ago and has not been replicated in the era of MELD allocation. However, reduction in early ACR rates has not translated into improved long-term outcomes, lending further credence to the concept that early ACR is less important to long-term outcomes compared to other factors such as hepatitis C status [141].

Late acute rejection

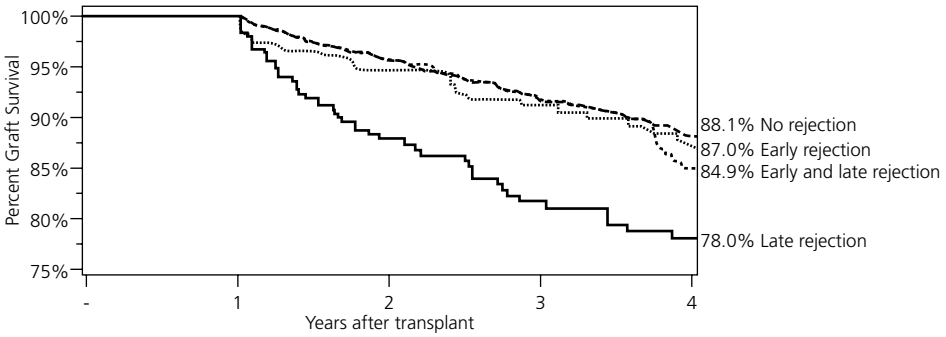
Definition

Late acute rejection (LAR) has been variably defined as acute rejection occurring more than 1, 3, 6, or 12 months after transplantation, with 6 months as the most common threshold. Reported frequency of LAR have varied widely from 7% to 23% depending on the timeframe considered, the diagnostic rigor (biopsy proven or not), and the follow-up duration [142–145]. Although broad assessments using national registry data have been reported [104], the literature on LAR is dominated by single-center studies that have tried to elucidate predisposing and/or precipitating factors, clinical and histological severity, therapeutic approaches and responses, and patient and graft outcomes [142–144].

Risk factors for late acute rejection

Predisposing recipient characteristics for LAR include demographics and etiology of liver disease. Younger age at transplant has emerged as a consistent association [97,142,144,145]. Autoimmune etiologies of liver disease such as autoimmune hepatitis, primary biliary cirrhosis, or primary sclerosing cholangitis are strong risk factors [97,143]. Interestingly and notably, the occurrence of early ACR has not exhibited a strong correlation.

As for immunosuppression practices, the occurrence of LAR clearly signifies insufficient immunosuppression for that patient at



Early rejection (0-6 mos)	451	451	426	248	246
Late rejection (6-12 mos)	255	255	217	143	107
Early and late AR	261	261	243	165	121
No rejection (0-12 mos)	3742	3742	3614	2613	1893

Figure 70.5. Detrimental impact of late acute rejection. Source: Wiesner et al. 2006 [145]. Reproduced with permission from John Wiley and Sons.

that time. Within the literature, there is strong speculation linking non-compliance with LAR [146,147]. Available data is, however, conflicting as to whether a specific agent or the overall intensity of maintenance immunosuppression poses increased risk for LAR. Some studies show that patients who suffer LAR, compared to those who do not, are more frequently maintained on triple therapy and have comparable trough levels of CNIs [97,142]. In contrast, other studies show that patients who suffer LAR, compared to those who do not, are more likely to be on cyclosporine as opposed to tacrolimus maintenance immunosuppression [142] or more likely to have undergone immunosuppression reduction (such as corticosteroid discontinuation or more substantial reduction secondary to post-transplant lymphoproliferative disorder) [97,144]. Finally, registry analyses of patient cohorts separated according to liver disease etiology have assessed the risk of LAR according to immunosuppression regimens at discharge from the transplant hospitalization. Patients discharged on two and three-drug maintenance regimens of corticosteroid and tacrolimus, with or without mycophenolate, were compared. For each diagnostic group—hepatitis C, hepatitis B, and non-viral disease—those discharged on the three-drug regimen compared to the two-drug regimen enjoyed greater freedom from LAR in multivariable analyses [145].

Diagnosis, severity, and treatment of late acute rejection

Since LAR typically occurs when follow-up transplant recipients are no longer followed at a high frequency or intensity, diagnosis may be delayed. When liver tests are elevated more than 6 months after transplantation, particularly if immunosuppression dosing has been recently reduced or there is evidence of insufficient immunosuppression exposure, liver biopsy is often performed as the first diagnostic test (Figure 70.3). Histologic severity of LAR episodes vary, with preponderance of mild ACR (79%) reported in one study [144] and moderate to severe ACR (51%) in another [143]. The treatment of LAR theoretically parallels that of early ACR with a hierarchy of options. However, lower-tier therapy such as dose escalation and conversion is infrequently administered. The more aggressive approach reflects concern that the diagnosis may have been delayed and that LAR is generally more refractory to treatment. The vast majority of patients are therefore treated with intravenous and/or oral corticosteroids [142–144]. Use of antibody preparations is not infrequent in the setting of severe and/or corticosteroid-resistant LAR.

Outcome of late acute rejection

In contrast to early ACR, it is widely believed that LAR compromises graft and patient survival. One primary mechanism is by predisposing to chronic rejection (ductopenic or vascular) which can necessitate re-transplantation and/or lead to patient death. The reported frequency of chronic rejection after LAR varies between 4.1 and 16.3% [97,143,144], although no chronic rejection was observed in patients with LAR after living donor liver transplantation [142]. Registry analyses have examined 4-year graft survival among patients alive 1 year after transplantation [145]. Defining ACR as early if it occurs within 6 months of transplant and as late if it occurs between 6 and 12 months of transplant, all patients were classified as having early ACR, LAR, neither, or both (Figure 70.5). Cox regression analyses showed that the hazard ratio for late graft loss, relative to patients with neither early ACR nor LAR, was 0.99 (95% confidence interval 0.75–1.31), 1.50 (95% CI 1.09–2.07) for patients with early ACR and LAR, and 1.99 (95% CI 1.50–2.66) for patients with LAR alone. While patients with no rejection or early ACR alone enjoyed comparable 4-year survival of 88.1% and 87.0%, respectively, those with both early ACR and LAR and those with LAR alone had 4-year survival of 84.9% and 78.0%, respectively.

Chronic rejection

Background of chronic rejection

It is well recognized that, among the solid organs that are transplanted, the liver is the most resistant to chronic rejection. Historically, in the cyclosporine era of the 1980s, the prevalence of chronic rejection was as high as 20–40% [7,148–152]. Since the 1990s, and coincident with the introduction of tacrolimus, chronic rejection occurs much less frequently with an estimated prevalence of 2–5% [87,150,152–155]. The natural history has also changed over time. Classically, chronic rejection of liver allografts occurred within the first post-transplant year and progressed rapidly, within 3 to 6 months, to graft loss. Currently, in the modern era of immunosuppression, chronic rejection occurs later after transplantation and

can run a more indolent course [61,156]. Moreover, unlike chronic rejection after kidney, heart, and lung transplantation that gradually and inexorably leads to graft loss, chronic rejection after liver transplantation can be reversible with intensification of immunosuppression, if diagnosed early in the process [18,61,154,157–160]. Nevertheless, chronic rejection remains an important cause of late graft dysfunction, which can lead to both significant mortality and morbidity for liver transplant recipients.

Risk factors for chronic rejection

The most potent risk factor for chronic rejection universally cited is the number and severity of ACR episodes [6,9,87,97,148–150,152,153,161]. Chronic rejection frequently evolves out of an episode of ACR that is resistant to corticosteroid treatment and does not fully respond to treatment [18,61,148,150,152]. A second strong association is cyclosporine-based, compared to tacrolimus-based immunosuppression regimens [87,150,152,153,162]. Three lines of direct and indirect evidence substantiate this association. Tacrolimus is superior to cyclosporine for the prevention of ACR [98,162]. Conversion to tacrolimus is an efficacious treatment of chronic rejection for patients on cyclosporine [157,163]. In addition, the University of Pittsburgh group reported that tacrolimus offered "virtual freedom from chronic rejection after primary liver transplantation" for both adult and pediatric liver transplant recipients [153,164]. Another factor associated with increased risk of chronic rejection is autoimmune disease (autoimmune hepatitis, primary biliary cirrhosis, and primary sclerosing cholangitis), leading to liver transplantation [87,150,152,153,165]. Finally, reduction of immunosuppression, whether secondary to a routine management decision, to the development of a contraindication to immunosuppression, or to non-compliance, has also been associated with subsequent development of chronic rejection [150,152,153,166].

More recently, a potential association between chronic rejection and treatment of recurrent hepatitis C with interferon and ribavirin has been raised and debated. It is well known that interferon administration to renal transplant recipients can precipitate acute and chronic rejection of the renal allograft [167,168]. However, the association with liver allograft rejection, both acute and chronic, has been more controversial [169]. Multiple factors may contribute to blurring the relationship, including the different rates of ACR as a function of time after transplantation, the highly variable timing of initiating interferon therapy with the concomitant variability in immunosuppression intensity, and the inherently abnormal liver test profiles that likely reduced biopsy frequency. Moreover, there are multiple formulations, including pegylated versions which, in both theory and practice, can pose differential risks. Finally, the adjunctive use of ribavirin, an immunomodulatory agent, introduces yet another factor that might modify the association of treatment with rejection.

In spite of these caveats, several detailed single-center analyses have provided data that correlate interferon-based treatment with chronic rejection [170–173]. The reported rates of 8.7–17% are distinctly high, considering the fact that many patients initiated treatment years after transplantation. Chronic rejection typically developed soon after treatment initiation, within a few weeks to months, further lending credence to the association. And intriguingly, viral clearance has been suggested as a risk factor for the development of chronic rejection [170–172]. It has been postulated that successful treatment, by definition, signifies an efficacious antiviral response, which may have been mediated through enhancement of immunologic mechanisms that led to viral clearance.

Diagnosis and treatment of chronic rejection

Chronic rejection has been a difficult diagnosis to make, particularly early in its course when it is amenable to treatment [18,96,149,152,154,158]. As a result, clinicians have been warned to raise their index of suspicion such that any episode of ACR with an unfavorable profile (e.g. histological grading of severe or resistance to corticosteroids) merits consideration of impending or evolving chronic rejection. The classic diagnostic criteria of bile duct loss from 50% or more of the portal tracts or obliterative foam cell arteriopathy are late and potentially terminal manifestations, signaling the need for re-transplantation [18,61,149,152,154,158–160,174]. Moreover, these features are notoriously difficult to identify in the limited sample provided by a needle biopsy [18,62,154,160]. Bile duct loss cannot be accurately quantified unless the biopsy contains a sufficient number of portal tracts. Foam cell arteriopathy occurs predominantly in larger arteries than those typically sampled.

Nevertheless, there have been concerted efforts to delineate early histological features of chronic rejection [18,61,87,154,157,158,161,175]. Early biliary changes are dominated by degeneration with dysplasia or atrophy and with the variable presence of inflammation, rather than bile duct loss. These changes are thought to reflect direct immunologic attack on the biliary epithelium in combination with indirect ischemia induced by loss of small arterial branches. Additional arterial findings indicative of early chronic rejection include inflammatory lesions with the presence of lymphocytes and lipid-laden macrophages. Characteristics of early chronic rejection can also be found in the centrilobular regions with central perivenulitis along with ballooning and dropout of centrilobular hepatocytes, leading to mild perivenular fibrosis. As chronic rejection progresses, inflammation generally diminishes with bile duct disappearance, arterial obliteration, and severe fibrosis and cholestasis.

More recently, humoral mechanisms have been invoked as a potential association with the development of chronic rejection [14,15,58]. While the two hallmarks of antibody-mediated responses—donor specific antibodies [14,58] and C4d staining [14,15]—may be increased in the chronic rejection setting, the biological significance of these associations are insufficiently clear. There is, as yet, no prospectively collected cross-sectional or longitudinal data on large recipient populations to determine the prevalence of these two findings in normal allografts or in allografts involved in other processes, including acute rejection and recurrent disease.

Treatment of chronic rejection focuses on augmenting immunosuppression. One of the primary considerations is whether an acute inflammatory component is present that merits administration of bolus corticosteroids or antibody preparations—treatment options typically exercised for acute rejection. As discussed above, inflammatory changes are typically present early and wane as chronic rejection evolves. Beyond this important decision, treatment options are largely determined by the immunosuppression regimen in place when chronic rejection develops. For patients on cyclosporine, conversion to tacrolimus can be strongly recommended based on available data [157]. Mycophenolate has also been reported as a potential rescue agent either as an additional agent or as a more potent alternative to azathioprine [101,176–178]. More recently, sirolimus has also been cited as efficacious for the

treatment of chronic rejection, perhaps due to antifibrotic properties [113].

Outcome of chronic rejection

The outcome of chronic rejection substantially depends upon timely diagnosis and treatment at an early, reversible stage. Favorable clinical factors include lower aspartate transaminase and lower serum bilirubin [153,154,157]. Favorable histological factors include decreased bile duct and arterial loss, fewer foam cell clusters, and less severe perivenular fibrosis [153,154,157,158]. Overall, between 20 and 70% of chronic rejection spontaneously resolve or respond to treatment with long-term maintenance of allograft function [87,113,152,153,157,158,177]. Failure to reverse chronic rejection typically leads to graft failure, necessitating re-transplantation or death from sepsis or allograft dysfunction.

Summary

The manifestations of liver allograft rejection differ from those of alloimmunity directed toward other organs in their relative benign consequences and limited involvement of alloantibody-dependent mechanisms. However, this generally favorable profile is dependent on prompt and accurate diagnosis, and appropriate treatment. The prevalence of viral hepatitis confounds the diagnosis of rejection, and impacts treatment decisions to avoid over immunosuppression. The evolution of proper treatment algorithms is a clear factor in the generally excellent outcomes achieved in modern liver transplantation.

Introduction

In an early report after performing his second heart transplant, Dr. Christiaan Barnard described the manifestation of allograft rejection as a compilation of clinical findings:

> The immunologic attack of the recipient on the transplanted organ may be detected by (1) systemic changes such as fever, tachycardia and anorexia, among others; (2) local changes that result in enlargement of the transplanted organ; (3) clinical and laboratory evidence of deterioration in function of the transplanted organ; (4) evidence of parenchymal destruction; and (5) immunologic changes indicating response to allogeneic tissue [1].

It is essential to recognize that since the advent of clinical cardiac transplantation, the diagnosis of allograft rejection has not been made with a single lab test or clinical finding, but by analyzing a constellation of clinical symptoms, physical examination findings, electrocardiographic measurements, and laboratory data measuring immunologic activity and muscle injury [1–4]. As immunosuppressive agents have evolved, so have the clinical manifestations of cardiac allograft rejection. It is now recognized that there is heterogeneity in the clinical and histopathologic manifestations of the alloresponse: acute or insidious and chronic; cellular or antibody mediated or mixed variety; symptomatic or clinically quiescent.

Many of the newer immunosuppressive therapies target cellular rejection; as such, we now see less of this type of rejection in isolation. Instead, cellular rejection is most commonly observed in combination with the more prevalent form of rejection—antibody-mediated rejection (AMR). Because allograft rejection is still a significant concern, application of a multimodality surveillance regimen, including immunologic monitoring, clinical allograft performance evaluation, and direct histology of the cardiac allograft, continues to be an important part of contemporary practice.

In this chapter we review ways to diagnose cellular- and antibody-mediated rejection, new therapies to prevent rejection in high-risk individuals, and we briefly discuss the treatment of different types of rejection.

Cellular rejection

Acute cellular rejection (ACR) is a recipient T-cell-mediated attack of the donor allograft tissue which is most prevalent early after transplantation (see Chapter 5). The histopathology of cellular rejection (see Chapter 83) is notable for lymphocytic infiltrates, which in mild cases of rejection are localized to the perivenular regions. In more severe cases of cellular rejection, the infiltration of lymphocytes is more pronounced and progresses into the cardiac interstitium. Furthermore, other inflammatory cells, including neutrophils and eosinophils, are observed in addition to evidence of myocyte injury, intramyocardial hemorrhage, and/or vasculitis.

Myocyte injury is associated with the highest grades of rejection, manifesting as sarcoplasmic scalloping, hypereosinophilia, and nuclear pyknosis on endomyocardial biopsy samples.

In 1990, the International Society for Heart and Lung Transplantation (ISHLT) formulated criteria to standardize the pathologic grading and diagnosis of cellular rejection (Table 71.1) [5]. The initial system consisted of seven categories; however, it was criticized for having high rates of interobserver variability [6]. Furthermore, the clinical relevance of several of the subcategories was questioned. The diagnosis of focal, moderate rejection (grade 2) was frequently applied to Quilty lesions, which have never been found to have any clinical relevance [7]. Mild, diffuse rejection (grade 1B) was a rare diagnosis and difficult to distinguish from moderate, diffuse rejection (grade 3B). The pathologic criteria were eventually revised in 2004, when the grades 1A, 1B, and 2 were consolidated into the revised grade 1R; grade 3A became the revised 2R and the severe rejections grades of 3B and 4 were combined into the revised grade 3R (Figures 71.1 and 71.2A,B) [8].

Risk factors

An analysis of the Cardiac Transplant Research Database (CTRD) showed that the hazard ratio for ACR peaked at 1 month after transplantation, decreased until 1 year, and leveled thereafter [9]. Risk factors for rejection include female recipient, younger age, black race, cytomegalovirus infection, female donor, mechanical circulatory support, and greater donor–recipient human leukocyte antigen (HLA) mismatch [9–11].

Similar to kidney transplantation, HLA compatibility between the donor and the recipient may affect rejection rates and subsequent allograft survival after heart transplantation; however, the data are controversial. While smaller studies failed to show a

Table 71.1. Histopathologic criteria for the diagnosis of cellular rejection

ISHLT working formulation 1990	Pathology findings	ISHLT working formulation 2004	Pathology findings
Grade 0	No evidence of cellular rejection	Grade 0R	No evidence of cellular rejection
Grade 1A (focal, mild acute rejection)	Focal infiltrate of inflammatory cells *without* necrosis	Grade 1R (mild, low-grade, acute cellular rejection)	Interstitial and/or perivascular infiltrate of mononuclear cells with up to 1 focus of myocyte damage, otherwise normal myocyte architecture
Grade 1B (diffuse, mild acute rejection)	Diffuse, but sparse, infiltrate of inflammatory cells *without* necrosis		
Grade 2 (focal, moderate acute rejection)	One focus of aggressive infiltration, typically with local myocyte damage		
Grade 3A (multifocal moderate rejection)	Multiple foci of aggressive infiltration, typically with local myocyte damage	Grade 2R (moderate, intermediate-grade, acute cellular rejection)	Two or more foci of infiltrate with associated myocyte damage, with normal myocardium in between
Grade 3B (diffuse, borderline severe acute rejection)	Diffuse infiltration of inflammatory cells with evidence of myocyte damage	Grade 3R (severe, high-grade, acute cellular rejection)	Diffuse infiltrate with multifocal myocyte damage; may be accompanied by edema, hemorrhage and/or vasculitis
Grade 4 (severe acute rejection)	Diffuse infiltration of inflammatory cells, with polymorphous collection of infiltrates, myocyte damage and edema, hemorrhage and/or vasculitis		

ISHLT, International Society for Heart and Lung Transplantation.

protective effect of HLA matching of the donor and recipient, Opelz and Wujcik reported a study of over 8000 patients included in the Collaborative Transplant Study which showed improved allograft survival in patients who had two or fewer mismatches at the HLA-A, B, or DR loci [12–14]. The survival benefit in this study was primarily in the first 3 to 6 months after transplantation, suggesting a protective effect of HLA matching on the incidence of acute allograft rejection [12]. An analysis by the CTRD of nearly 1200 patients showed that individuals with two or fewer HLA mismatches had no rejection-related death or re-transplantation in the first year after transplantation [10]. The incidence of allograft rejection episodes (grade 2 or higher) in the first month after transplantation was especially increased (65% vs. 40%) in those patients who had two recipient donor mismatches at the MHC-II DR loci [15]. The incidence of rejection associated with HLA-DR mismatch is independent of induction therapy with OKT3 or IL-2 inhibitors; however, it may be reduced with utilization of antithymocyte globulin for induction, and tacrolimus instead of cyclosporine for maintenance immunosuppression [16–18]. Despite these findings, implementing HLA matching for heart allocation protocols has many practical limitations. Considering the time sensitivity of the operation, scarcity of organ donors, and critical nature and instability of the recipient, HLA matching algorithms are not currently used to determine organ allocation.

Cytomegalovirus (CMV) infection after heart transplantation increases the risk of both acute and chronic allograft rejection. Active CMV infection has a proinflammatory and immune-activating effect. Prophylaxis for CMV infection in selected patients has been shown to reduce episodes of acute and chronic rejection [19]. Typically, during an active CMV infection, immunosuppression is reduced to facilitate viral control, often leading to a heightened risk of cellular rejection in the post-CMV recovery phase.

There may be race-specific responses to immunosuppression as black heart transplant recipients have consistently been shown to have poorer survival than Caucasians due to increased rates of allograft failure and graft rejection [20]. However, further study is required to understand the demographic or biological mechanisms to account for the discrepancy. This risk may be mitigated by the use of more targeted immunosuppression in black cardiac transplant recipients [21].

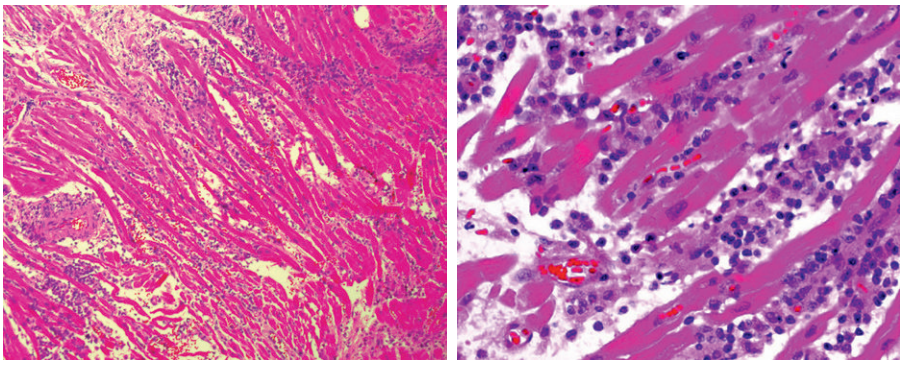
Recipients of female gender have also been shown to be at higher risk for allograft rejection. While previous pregnancy is an accepted risk factor for sensitization and increased risk of rejection, other gender-specific mechanisms may play a role in allograft rejection. Researchers have shown that gender matching may protect against rejection episodes independent of weight matching of the recipient and donor [22].

Diagnosis

Spectrum of symptoms

The signs and symptoms of cardiac allograft rejection are nonspecific. Therefore, the diagnosis of rejection is commonly made by the histologic assessment of protocol-driven, surveillance endomyocardial biopsies. Most episodes of acute rejection occur within the first 3 to 6 months after transplantation and most of those episodes are mild and usually asymptomatic.

Patients with severe rejection may present with signs and symptoms of heart failure, including decreased exercise tolerance, shortness of breath, fluid retention, orthopnea, paroxysmal nocturnal



(A) (B)

Figure 71.2. (A) Low magnification and (B) high magnification hematoxylin and eosin stain showing a grade 3R (previously grade 3B) rejection with diffuse infiltrates, myocyte necrosis, and disruption of cellular architecture. (Images provided by Dr. Margaret M. Grimes, Richmond, VA.)

dyspnea, and fatigue. Clinicians should always be wary of gastrointestinal complaints, including right upper quadrant tenderness, nausea, and vomiting, which may be related to right ventricular dysfunction and elevated central venous pressures. Any of the above findings, especially early after transplantation or in the setting of medication non-compliance, should be presumptively treated with intravenous steroids and worked up with an endomyocardial biopsy.

Since the transvenous bioptome was first devised in Japan and modified by Caves and colleagues at Stanford University, endomyocardial biopsy has been the gold standard for surveillance of the host's immune response toward the graft [23,24]. The contribution of surveillance endomyocardial biopsies to the overall success of heart transplantation, especially in the precalcineurin inhibitor era, cannot be overstated. However, despite the low risk of complications, the use of frequent endomyocardial biopsies has been criticized for high cost, patient discomfort, and questionable clinical utility in the modern immunosuppressive era. The incidence of biopsy-proven rejection during surveillance in clinically asymptomatic patients in the first year after transplantation was less than 2% with contemporary immunosuppression. Furthermore, the clinical significance of low and moderate grades of rejection discovered on surveillance biopsies is uncertain because nearly 85% of patients diagnosed with moderate, cellular rejection have spontaneous resolution of the histopathologic findings without any medical intervention [25]. Other issues include the fact that the distribution of inflammatory cells in the myocardium can be heterogeneous, which can lead to false-negative biopsies [26], and that—even when adequate samples are obtained—there can be high interobserver variability in the interpretation of moderate grade rejection [7].

In spite of these limitations, endomyocardial biopsy continues to be the primary tool for allograft rejection surveillance due to the lack of specificity and sensitivity in the available alternatives. However, these concerns and considerations have prompted further investigation into non-invasive and laboratory-based surveillance techniques, as described next.

Electrocardiography

While surveillance ECGs help identify conduction and rhythm disturbances associated with severe acute cardiac rejection, the findings are typically non-specific. Furthermore, the sensitivity of this method for early or moderate rejection, especially with contemporary immunosuppression, is poor [27,28]. During an episode of acute rejection, myocardial edema caused by inflammation and cellular infiltration may alter conduction properties of the myocardium. Rightward deviation of the QRS axis and decreased ECG voltage are classically described features of acute rejection [1–4].

Echocardiography

Two-dimensional and Doppler echocardiography of the allograft can identify changes in myocardial structure and function associated with acute rejection.

It is imperative to understand the normal echocardiographic findings after heart transplantation in order to appreciate changes associated with rejection. In comparison to age-matched normal controls, transplanted hearts have several distinguishing features. The ventricular mass is increased and the myocardial walls are at peak thickness immediately after surgery, and then gradually decrease over time. While the left ventricular cavity size and systolic function are usually normal early after transplant, the right ventricular cavity dimension can be dilated and the systolic function reduced. The reason for early right ventricular dysfunction is not clear but may relate to the fact that the right ventricle is more sensitive to ischemic injury, brain-death-mediated catecholamine injury, and the increased pulmonary resistance seen in some recipients. Usually, early right heart dysfunction is transient and improves over the first few weeks to months after transplantation.

If a bi-atrial anastomosis is performed, the atria will appear elongated and hourglass-shaped and an echodense cuff will identify the suture line. The intraventricular septum will have a paradoxical motion due to anterior swinging motion of the allograft which, unlike the native heart, is not adherent to the posterior thoracic wall [29–32].

Color flow interrogation of the tricuspid valve will frequently reveal significant tricuspid regurgitation immediately after transplantation [33]. As the allograft's right ventricular function improves and the recipient's pulmonary vascular resistance decreases, the severity of the regurgitation diminishes. Persistent tricuspid regurgitation resulting from continued pulmonary hypertension, endomyocardial biopsy-induced chordal injury, post-surgical annular remodeling, or right ventricular dysfunction is associated with a less favorable outcome [34].

Two-dimensional echocardiography can detect changes in cardiac structure and function; however, these parameters lack sensitivity (<50%) for the reliable early detection of rejection, making

it untrustworthy as routine screening tools [35]. Rejection causes an acute increase in ventricular mass and myocardial wall thickness [4,36]. Decreased left ventricular systolic function is usually apparent only in severe rejection. Right ventricular dysfunction may, however, be more pronounced even during mild episodes of rejection and a pericardial effusion often develops with inflammation [31,37,38].

During an episode of rejection, diastolic dysfunction precedes systolic dysfunction. Echocardiographic indices of diastolic filling properties may detect early acute rejection. Doppler measurements of blood flow properties reveal a profile similar to patients with a restrictive cardiomyopathy. Acute rejection has been associated with shortening isovolumetric relaxation time (IVRT), decreasing pressure half time (PHT) of the early mitral inflow velocity (Em), increasing ratio of early to late mitral inflow velocities, and sustained flow reversal of the atrial component of pulmonary venous flow [37–42]. However, these variables have limited reliability because they are influenced by loading conditions [42]. Tissue Doppler imaging is less influenced by hemodynamic factors, and measures decreased diastolic and systolic velocities of the mitral annulus and posterior left ventricular wall during acute rejection [43]. However, the specificity of theses indices is also limited because the diastolic properties of the allograft are modulated by other factors including immunosuppression-related hypertension, left ventricular hypertrophy, and fibrosis from previous rejection episodes. Accordingly, variable diagnostic accuracies have been reported and studies evaluating the role for screening serial echocardiographic evaluations have been inconclusive [40,44–48].

Magnetic resonance imaging

Cardiac magnetic resonance imaging (CMR) is emerging as a powerful diagnostic tool for cardiac disease. CMR has superior image quality and spatial resolution and has become the reference standard for evaluating ventricular mass and systolic function [49]. CMR is an emerging tool in patients with coronary disease for the assessment of regional wall motion, myocardial viability, and ischemia [50–52].

The utility of CMR in patients with heart transplantation, however, is yet to be defined. Cardiac magnetic resonance imaging, compared to echocardiography, has greater reproducibility for the measurement of allograft myocardial mass, systolic ejection fraction, and ventricular volumes [53]. However, changes in these parameters usually identify only late, severe rejection [54]. During acute allograft rejection, the increased water content of the myocardium and inflammation can also prolong the T2 relaxation time (measured by spin-echo techniques). Early animal studies showed that T2 relaxation times are prolonged and wall thickness is increased in dogs with severe rejection who are not receiving immunosuppression [55]. However, in humans treated with modern immunosuppressive therapies, studies with this technique have shown conflicting results precluding clinical application [56–59].

Magnetic resonance imaging techniques that detect the accumulation of the tagged immune cells within cardiac allograft are an area of active investigation [60,61].

Biomarkers

Elevation of markers of myocyte injury, including creatine kinase MB isoforms and troponin, have been observed to be increased in severe forms of allograft rejection [62]. Levels are seen to be increased uniformly in all patients early after transplant, presumably related to preoperative ischemic time [63,64]. Patients who continue to have elevated or detectable troponin concentrations—likely indicating microvascular disease and myocyte necrosis—are more likely to develop early angiographic coronary graft vasculopathy or allograft failure [63].

In general, markers of myocyte necrosis are detectable only in more severe cases of allograft rejection and are too insensitive for routine surveillance [65,66]. Contemporary ultrasensitive troponin assays may have clinical utility, but have yet to be comprehensively studied.

B-type natriuretic peptide (BNP) is an amino acid polypeptide secreted by myocytes in the heart in response to cardiomyocyte stretch. BNP and amino-terminal-BNP (NT-BNP) have been identified as useful markers for the diagnosis and prognostication of patients with heart failure. BNP concentrations have been observed to be elevated early after heart transplantation and seem to plateau by 4 to 6 months after surgery [67,68].

Elevated BNP concentrations correlate with echocardiographic findings of acute rejection, including increased wall thickness, ventricular mass, right ventricular dilation, and right ventricular dysfunction [69]. In patients with apparently normal ventricular systolic function, BNP concentrations correlate with hemodynamic derangements including elevated filling pressures, decreased cardiac output, and restrictive filling pattern [69,70]. However, BNP concentrations can be increased independent of echocardiographic hemodynamic measurements, suggesting alternative, stretch-independent pathways of peptide secretion [71]. In fact, BNP secretion in heart transplant patients is independent of other stretch-sensitive markers, including atrial natriuretic factor [72].

In an investigation of peripheral gene expression in clinically stable heart transplantation recipients with normal filling pressures and cardiac function, genes up-regulating immune activity, and specifically those related to the HLA system, mast cells, heat shock protein, and B-cell lineage, were correlated with BNP concentrations [73]. Cytokine-mediated BNP secretion may occur through a common p38 signaling pathway that links inflammation to cardiac peptide secretion [74]. Together, these data suggest that in addition to hemodynamic derangement associated with myocardial rejection, the inflammatory process modulates and up-regulates BNP secretion.

Elevated BNP levels portend a poor prognosis in allograft dysfunction in the first year and beyond after heart transplantation [75,76]. While increased BNP concentrations in heart transplant patients have been correlated with episodes of acute allograft rejection, the discriminatory power is poor (c-statistic: 0.71–0.76), much less than for diagnosing acute heart failure in a patient presenting with acute dyspnea [77,78]. Therefore, BNP has not replaced endomyocardial biopsy as a surveillance tool.

Invasive hemodynamics

Early after transplantation, patients often have a restrictive filling pattern with elevated filling pressure observed during invasive hemodynamic measurement. A non-compliant right ventricle may cause a Kussmaul's sign (increase in right atrial pressure during inspiration) and the right atrial pressure may often be elevated with prominent "a" and "v" deflections and a rapid "y" descent. These early hemodynamic abnormalities may be attributed to postoperative myocardial stunning, rejection, pre-existing recipient pulmonary hypertension, donor catecholamine surge, and/or intraoperative volume expansion [79–82]. Although intracardiac pressures usually approach the normal range within a few months of surgery, they

may not completely correct even in the absence of biopsy evidence of rejection or fibrosis [81]. The restrictive filling pattern typically disappears months after transplantation, but can be unmasked with volume loading [82].

During episodes of acute rejection, the thin-walled right ventricle, having less functional reserve, is more vulnerable to injury and becomes edematous and non-distensible. Findings consistent with restrictive filling may become apparent in hemodynamic tracings. Invasive hemodynamics often reveal elevations in filling pressures. The cardiac output is decreased in severe episodes of rejection. Improvement in filling pressures may accompany treatment of rejection and resolution of acute inflammation; however, hemodynamic abnormalities may persist, possibly related to irreversible myocardial injury and fibrosis [83,84].

Gene expression profiling

Gene expression profiling refers to the comparison of mRNA production from many genes to identify gene activation patterns associated with a disease process or a clinical event. Acute rejection-related up-regulation of gene expression in various signaling pathways has been observed in studies of allograft tissue and peripheral blood [85–89]. Through a gene-discovery process with microarray analysis, a clinically applicable scoring system and commercial test has been devised to predict cellular rejection in cardiac allografts. A set of 11 genes measuring macrophage activation, steroid responsiveness, platelet production, hematopoiesis, T-cell activation, and cell morphology were identified and a scoring system for gene expression was validated for predicting allograft rejection [90].

A non-invasive surveillance strategy for allograft rejection comparing gene expression profiling to endomyocardial biopsy was evaluated in the Invasive Monitoring Attenuation through Gene Expression trial (IMAGE) [91]. The IMAGE trial evaluated low-risk heart transplant patients who were predominantly greater than 1 year after orthotopic heart transplantation and without any history of rejection, vasculopathy, or allograft dysfunction. In the selected population, the two groups had similar event rates (14.5% vs. 15.3%) of the composite primary endpoint: greater than 25% decrease in left ventricular ejection fraction, any rejection with hemodynamic compromise, or all-cause mortality.

This was the first trial to compare an alternative surveillance mechanism to the long-accepted standard of endomyocardial biopsy; however, further study is necessary to implement this testing in higher-risk patients closer to the time of heart transplantation. The score is valid for surveillance of stable patients well after heart transplantation and should not be performed in close proximity to a blood transfusion or treated rejection. It is also invalid for patients receiving more than 20 mg of corticosteroids daily due to the steroid-responsive nature of the test. Further comparisons of gene expression profiling to serial biopsy could establish this surveillance modality as being advantageous to the patient (less invasive) and the hospital (less cost).

Antibody-mediated rejection

The concept and existence of non-cellular, antibody-driven cardiac allograft rejection has been proposed and debated for many years. In1983, Hess and Mohanakumar made the observation that antibodies directed toward B cells may play a role in acceleration of the atherosclerosis in the transplanted heart [92]. Herskowitz et al. went on to observe that there was a type of rejection associated with arteriolar vasculitis found on endomyocardial biopsy in patients with allograft failure [93]. Later, Hammond et al. described a pattern of rejection consisting of immunopathologic findings of immunoglobulin deposition and complement fixation on immunofluorescence, along with histopathologic findings of endothelial swelling and interstitial edema on routine light microscopy [94]. The pathologic findings of "humoral" rejection were associated with decreased survival compared to those with cellular rejection. These and other early works set the stage for years of debate, eventually leading to the growing acceptance of antibody-mediated rejection (AMR) as a clinically significant entity.

During AMR, antibodies specific for the donor allograft cause acute rejection by binding to the allograft and amplifying the immune response (see Chapter 6). In severe cases, this leads to acute allograft dysfunction and increased risk of coronary artery graft vasculopathy.

Due to the absence of practice guidelines for surveillance and diagnosis, AMR has been a diagnostic and therapeutic challenge after cardiac transplantation. The epidemiologic characteristics of AMR, including disease incidence, prevalence, and rate of progression, are unclear due to wide variation in surveillance patterns, histopathologic diagnostic criteria, and technical aspects of histopathologic and immunopathologic preparation of biopsy samples. The reported incidence of "non-cellular" rejection or AMR has been variable depending on clinical and histopathologic criteria employed; however, the estimated incidence varies from 8% to 20% with a higher prevalence in the first 6 months after heart transplantation [95,96]. Unlike the decrease observed in the incidence of cellular rejection, the incidence and morbidity associated with AMR has remained unchanged [97].

Patients with presensitizing events are at risk for AMR. For example, the incidence of AMR is higher in female patients, recipients with positive cross-matches, and/or elevated panel-reactive antibodies [95,96]. Other risk factors for AMR include blood product transfusions, mechanical circulatory support devices, pregnancy, and infection.

Diagnosis

The clinical and diagnostic criteria for cardiac allograft AMR are evolving. The inclusion criteria for early reports were variable. Most studies required that patients have evidence of antibody-mediated injury on endomyocardial biopsy, clinical diagnosis of allograft dysfunction, and/or serological evidence of circulating autoantibodies. Similar to cellular rejection, the current guidelines proposed by the ISHLT have made AMR a purely pathologic diagnosis, allowing for the diagnosis of clinically quiescent humoral rejection (Table 71.2).

Clinical findings

The diagnosis of AMR has traditionally been considered after the development of hemodynamic derangements or unexplained allograft dysfunction. Early clinical signs and symptoms of AMR can be subtle, non-specific, and easily overlooked. Patients may present with fatigue, weakness, or nausea and vomiting. They may have right upper quadrant pain from liver capsule tenderness due to hepatic congestion. However, with better histopathologic markers, appreciation for early or asymptomatic antibody-mediated rejection has been growing. While the clinical relevance of this entity is yet to be established, there are growing data suggesting that the detection of early presymptomatic AMR on surveillance endomyocardial biopsy identifies patients at higher risk for development of

Table 71.2. Histopathologic criteria for the diagnosis of antibody-mediated rejection

ISHLT working formulation 2004	Pathology findings	Proposed criteria 2011	Pathology findings
Grade AMR 0	No evidence of antibody-mediated rejection	Grade pAMR 0	No evidence of antibody-mediated rejection
Grade AMR 1	Histologic criteria: evidence of endothelial swelling and intravascular macrophage accumulation; severe cases will have neutrophil invasion and interstitial hemorrhage Immunopathologic criteria: immunoglobulin and complement staining of the capillaries (IF) *OR* positive CD68 staining for macrophages + complement deposition the capillaries (IC), or fibrin staining in the vessels	Grade pAMR 1 (I+): histopathologic AMR alone	Only histologic criteria for AMR are present Although not specifically defined, may include: endothelial edema, intravascular macrophage accumulation, interstitial edema, hemorrhage, intravascular thrombi and myocyte necrosis
		Grade pAMR 1 (I+): immunopathologic AMR alone	Only immunopathologic criteria for AMR are present Yet to be defined, but may include IC and IF stains for immunoglobulins, complement and macrophages
		Grade pAMR 2 pathologic AMR	Both histologic and immunopathologic criteria are met
		Grade pAMR 3 severe AMR	Histopathologic findings of marked edema, interstitial hemorrhage, capillary fragmentation, mixed inflammatory infiltrates, endothelial cell pyknosis, or karyorrhexis

ISHLT, International Society for Heart and Lung Transplantation; AMR, antibody-mediated rejection; pAMR, pathological antibody-mediated rejection.

Figure 71.3. (A) Hematoxylin and eosin stain showing histologic evidence of AMR: endothelial edema and inflammation including neutrophils. (B) Immunoperoxidase staining in AMR that is positive for CD68, identifying the intravascular cells to be macrophages. (C) Immunofluorescence positivity for C4d in AMR, indicating complement deposition on the capillary walls. (Images provided by Dr. Margaret M. Grimes, Richmond, VA.)

cardiac allograft vasculopathy (CAV) and allograft-related mortality [98,99].

Circulating HLA and non-HLA antibodies

The development of circulating donor-specific alloantibodies (see Chapter 36) in the recipient blood is supportive, but not required, for the diagnosis of AMR. However, the presence of antidonor HLA antibodies after heart transplantation has been associated with risk of AMR and the development of allograft vasculopathy [100–102].

The widespread application of solid-phase assays has allowed for reliable identification and quantification of circulating donor-specific HLA antibodies. But the quantification techniques are not standardized and their clinical application has yet to be validated. Cell-based assays are used in a complementary manner to confirm whether detected antibodies are donor-antigen reactive and thus clinically relevant.

Antibodies can also develop against non-HLA antigens and pose a diagnostic challenge, possibly accounting for cases of unexplained allograft dysfunction. There are published reports of antibodies toward major histocompatibility class I-related chain A (MICA), antiphospholipid antibodies, endothelial cells, vimentin, nuclear antibodies, and myosin heavy and light chains [102–106]. Routine testing for non-HLA antibodies is not recommended at this time and may be reserved for scenarios of unexplained allograft dysfunction.

Endomyocardial biopsy

Early AMR is associated with capillary injury, endothelial swelling with nuclear enlargement, and accumulation of macrophages within the vasculature (see Chapter 83). The finding of vascular adherence of macrophages or endothelial edema (Figure 71.3A,B) has unacceptably low sensitivities to be meaningful as a screening test alone [107]. Findings of intravascular thrombi, fibrin deposition, myocyte necrosis, interstitial hemorrhage, and degeneration of endothelial cells, however, are typically seen only in the most severe form of AMR. Additional immunopathologic assessment is routine at the time of tissue evaluation for AMR. The most widely accepted standard for immunophenotypic evidence includes staining for complement split product (C3d, C4d) in myocardial capillaries, while some centers also stain for macrophages (CD68) and immunoglobulin (Figure 71.3C).

Despite years of debate, the ISHLT only in 2005 recognized AMR as a specific histologic entity [8]. In 2011, the ISHLT modified the pathologic diagnostic criteria and proposed a preliminary grading scale for AMR. The working group excluded requirements for allograft dysfunction or the presence of circulating donor-specific antibodies for the diagnosis of AMR, making it strictly a pathologic diagnosis [108]. The preliminary categories proposed have yet to be validated for clinical use, but are composed of a 0 to 3 grading scale. A grade 0 represents a biopsy sample without any histologic or immunopathologic features of antibody-mediated rejection. Grade 1 is given to biopsy samples with features of either

histopathologic or immunopathologic features of AMR. Grade 2 has features of both histologic and immunopathologic AMR, and grade 3 is the most severe pathologic grade, which would include findings of interstitial hemorrhage, inflammatory infiltrates, endothelial cell thickness, and marked edema.

The frequency, timing, and utility of biopsy-guided surveillance in asymptomatic patients are not yet defined. Early immunopathologic staining for complement and immunoglobulin can yield false-positive results in patients treated with immunoglobulin-meditated induction therapies, and thus should be interpreted with caution.

Treatment strategies (see Chapter 67)

Clinically "quiescent" ACR

Patients with asymptomatic grade 1R cellular rejection on routine surveillance biopsy are treated with observation and without intensification of immune modulating therapies. Grade 1R rejection typically resolves spontaneously without progression or impact on allograft survival. Winters et al. observed that 85% of focal mild rejection resolved without any intervention, while Loveras et al. showed that intervention with prednisone in mild or moderate rejection offered no clinical benefit [25,109]. However, if any foci of myocyte damage/necrosis are present (previously grade 2), patients may be at higher risk of progressing to clinically significant rejection and warrant heightened surveillance [110].

If the endomyocardial biopsy reveals multiple foci of infiltrating inflammatory cells along with evidence of myocyte damage (grade 2R), patients are treated with brief pulse dosage of either oral or intravenous steroids and possibly intensification of maintenance immunosuppression. Doses of prednisone vary from center to center but typically range between 3 and 5 mg/kg total dose over several days with return to the patient's baseline prednisone dose afterwards. In a retrospective review of 100 patients with moderate-grade rejection, Park et al. reported a 75% response rate with histologic improvement in rejection after a 3-day pulse dose of 100 mg of prednisone [111]. Treatment is followed by repeat endomyocardial biopsy in 1 to 2 weeks. If the rejection has not resolved, treatment with pulse dose intravenous methylprednisolone is recommended.

ACR with hemodynamic compromise

Patients who present with pathological or clinical evidence of rejection accompanied by decrease in myocardial function should be managed with the highest urgency because the mortality associated with this condition can approach 40% at 3 months. Those with primarily cellular rejection, however, have a better prognosis with a 2-year survival near 84% [112]. Early hemodynamic support with intravenous inotropes, chronotropic agents, intra-aortic balloon pump support, or ventricular assist device should be instituted as warranted. In addition to immediate administration of intravenous steroids, it is appropriate to treat the patient with lymphocyte-depleting antibodies. Utilization of the murine monoclonal antibody, OKT3, has largely been replaced by the better-tolerated antithymocyte globulin (ATG). OKT3, which binds to the CD3 antigen on the T-cell surface, is associated with a high frequency of serum sickness and sensitization which precludes repeat dosing of therapy. Antithymocyte globulin is a polyclonal preparation directed at various antigens on the T-cell surface. Although better tolerated than OKT3, ATG is also associated with allergic immune-mediated reactions during drug infusion. Patients are treated with steroids, antihistamines, and antipyretic agents prior to infusion. CD3 cell count monitoring can be used to guide ATG dosing with a target of achieving an absolute CD3 count of less than 25 cells/μL [113]. During therapy the patient should receive antifungal, antibiotic, and antiviral prophylaxis, along with close hemodynamic surveillance. Repeat endomyocardial biopsies should be obtained in subsequent weeks to ensure resolution of rejection. Recurrent or persistent episodes can be treated with repeat intravenous steroid doses and courses of antilymphocyte antibodies, albeit the clinician must be wary of the increased risk of malignancies associated with lymphocyte-depleting therapies.

AMR with hemodynamic compromise or mixed rejection (ACR plus AMR)

Patients presenting with clinical evidence of AMR in the presence of cellular rejection or along with allograft dysfunction should have treatment directed at eliminating or inhibiting circulating antibodies and suppressing further antibody production. Initial treatment with intravenous steroids may have some beneficial effect through multiple mechanisms. Plasmapheresis or plasma exchanges are rapid ways to remove alloantibodies from circulation. There are various frequencies and treatment protocols; however, close surveillance for antibody levels and re-formation and concomitant intensification of immune-modulating therapies need to be instituted because rebound antibody production is common.

Intravenous immunoglobulin (IVIG) or cytomegalovirus hyperimmunoglobulin are often used together with plasmapheresis to treat AMR. Intravenous immunoglobulin has multiple anti-inflammatory and immune-modulating effects and may be beneficial in the setting of antibody-mediated rejection. Antibody preparations are predominantly IgG from pooled collections of plasma. Intravenous immunoglobulin is thought to work by removing potential circulating alloantibodies from circulation and down-regulating the effects of inflammatory cytokines; it has been used widely to treat antibody-mediated rejection due to its low side-effect profile. However, its efficacy has never been systematically proven in the setting of acute cardiac allograft AMR.

In addition to depleting antibodies, intensification of T-lymphocyte-directed inhibition with increased maintenance immune medications or ATG is often used.

Therapies directed at depleting B-cell lymphocytes or inhibiting plasma cells may be considered for patients unresponsive to standard interventions. Rituximab is a monoclonal antibody against CD20, a protein localized to the surface of B-cell lymphocytes. Rituximab has been used to decrease panel-reactive antibodies in sensitized patients prior to solid organ transplantation, and there is growing literature on its use for treating antibody-mediated rejection in cardiac allografts [114–116]. The marginal benefit of rituximab is unclear from these published reports because it has been used with multiple background therapies. Randomized data for the drug are lacking and enthusiasm is somewhat muted as the medication's efficacy is limited to depleting memory B-cells, with no effect on plasma cells.

There is growing enthusiasm for bortezomib, a proteasome inhibitor that binds the catalytic site of the 26S proteasome, which regulates protein expression and may prevent degradation of proapoptotic factors, permitting activation of programmed cell death in plasma cells. The medication has been effective for treating plasma cell disorders including AL type amyloidosis and multiple myeloma, and there is growing experience in solid organ transplantation for vascular rejection and desensitization [117–119]. Common

side-effects with bortezomib include thrombocytopenia, GI complaints, and paraesthesias.

Evolving therapies for AMR include complement inhibition with drugs such as eculizumab and novel B-cell suppressing agents including belimumab and epratuzumab.

Clinically "quiescent" AMR

There is a growing acceptance that clinically quiescent or subclinical AMR is a clinically relevant entity. Kfoury et al. studied nearly 900 patients and found that individuals with asymptomatic AMR, with or without evidence of concomitant cellular rejection, were at markedly higher risk for cardiovascular mortality [98]. Wu et al. showed that patients with clinically quiescent AMR were at increased risk of developing CAV [99]. While the histopathologic and immunopathologic findings of AMR on biopsy in asymptomatic patients identify those at higher risk, there are currently no data that support any alternative to continued medical therapy and surveillance.

Recurrent or recalcitrant rejection (AMR or ACR)

Recurrent rejection (repeat episodes despite augmentation of immunosuppression) or recalcitrant rejection (persistent pathologic finding of rejection without intervening rejection-free biopsy) are rare but challenging scenarios. Total lymphoid irradiation (TLI) has been available for several decades as a potential treatment for refractory rejection and is effective in treating persistent cellular rejection after cardiac transplantation [120,121]. Total lymphoid irradiation involves exposing all lymph nodes, the thymus, and spleen to high doses of radiation with the intention of altering T-lymphocyte-mediated immune actions. Enthusiasm for TLI has been tempered due to late recurrent episodes of rejection and increased risk of myelodysplasia and leukemia [122].

Photopheresis is an immunomodulating therapy in which leukocytes are treated with a photoactivatable drug and subsequent ultraviolet light exposure resulting in preferential damage to rapidly proliferating T-cell lymphocytes. Photopheresis has been effectively used to treat the patient with recurrent refractory cellular allograft rejection, and side-effects seem to be minimal [123–125].

There may be a role for splenectomy as rescue therapy for recurrent AMR because most plasma cells reside in the spleen before migrating to the bone marrow. Splenectomy has been performed in ABO-incompatible organ transplantation and the treatment of severe acute AMR after kidney transplantation [126].

Mimickers of allograft rejection

Clinicians must be cognizant of pathologic processes that may be misdiagnosed as allograft rejection, particularly because intensification of immunosuppression may worsen many of these conditions. Myocarditis from enterovirus infections may result in allograft dysfunction. Cytomegalovirus myocarditis has been observed after heart transplantation and can be distinguished from rejection on microscopy by identifying nuclear inclusions composed of large basophilic nuclei surrounded by a pale artifactual halo [127,128]. The frequency of this diagnosis has decreased with introduction and implementation of prophylactic antiviral therapies in high-risk populations. Reactivation or transmission of *Toxoplasma gondii* can lead to fulminate, disseminated disease or only involve one or two organ systems [129]. When the parasite causes myocarditis after heart transplantation, endomyocardial biopsy typically reveals non-specific inflammatory infiltrates with or without intramyocytic toxoplasmic cysts. Immunohistochemical staining and electron microscopy identifying intracystic oval-shaped organisms with double-layered pellicle and an anterior-placed conoid can confirm the diagnosis [130]. Post-transplant lymphoproliferative disorder (PTLD) involving the heart is characterized by infiltration of atypical lymphocytes. Identification of the Epstein–Barr virus with in situ hybridization can help with the diagnosis [131].

Conclusions

Advances in immunosuppression have decreased the incidence of traditional cellular rejection and focused attention the emerging importance of AMR. Despite improvements in non-invasive gene and biomarker-based surveillance strategies, the new epidemiology of AMR is not adequately addressed in the diagnostic realm. Collective pathologic consensus is now emerging to classify and standardize the recognition of clinical AMR, and its prognostic attributes in the short and long term are only now emerging. The challenge of therapy targeted to antibody suppression and elimination continues to vex investigators and clinicians alike, but targeted strategies using novel molecules and pathways are now emerging [132].

CHAPTER 72

Clinical Allograft Rejection Syndromes in Lung Transplantation

David C. Neujahr
Andrew McKelvey Adult Lung Transplant Program, Emory University Transplant Center, Atlanta, GA, USA

Introduction

Similar to other solid organ transplants, lung transplant recipients face the hurdle of repetitive immunologic attack upon the allograft. Roughly 30 years of clinical experience with lung transplantation has led to an appreciation of the various types of rejection. It is widely known that lung allografts are more susceptible to immunologic injury relative to other transplant types. There are several reasons that potentially underlie the high risk of rejection syndromes in lung transplantation. First, the lungs directly interface with the environment. As a result, lungs are vulnerable to pathogens that are acquired via the respiratory tract, including viral, fungal, and bacterial species. Further, as a respiratory organ, the lung is susceptible to triggers such as air pollution, which may provide danger signals to the immune system. Second, lungs develop during embryology as an embryonic foregut derivative. The airway maintains continuity through the digestive tract in postnatal life, and as a result humans remain susceptible to injury from aspiration of oral or gastric contents. Such aspiration also may trigger activation of the immune system. Third, lungs are relatively vulnerable to early ischemia reperfusion injury, which leads to recruitment of inflammatory mediators and cells into the lung early after transplantation. Finally, the surgical anastomosis in the bronchi causes a mechanical disruption in the mucociliary elevator that impairs the ability of the lungs to clear pathologic substances. This chapter will review the clinical aspects of the distinct types of rejection faced in lung transplantation and the immunopathologic mechanisms underlying them. Two distinct types of rejection, acute and chronic, will be separately explored, but it is important to note that these processes are mechanistically related. Throughout this chapter, risk factors associated with both acute and chronic rejection will be noted. Finally, treatment strategies for the different types of rejection will be addressed.

Acute allograft rejection

Diagnosis of acute rejection

The histopathology of acute and chronic allograft rejection is described extensively in Chapter 84. The key aspects of the pathologic scoring of acute cellular rejection (ACR) are that lung biopsy pieces can be scored for both a perivascular component (A-grade) and a bronchiolar component (B-grade) as defined by the Lung Rejection Study Group (LRSG). The major unresolved issues with respect to lung transplantation pertain to how to apply clinically this widely utilized histopathologic scoring system. Specific issues include the understanding of what constitutes an appropriate schedule for performing lung biopsies and how to treat patients in the event that rejection is detected.

The use of flexible fiberoptic bronchoscopy has allowed for the ability to periodically obtain small pieces of alveolated lung tissue for histologic assessment. Forceps biopsy of a single lobe or multiple lobes can be obtained with a relatively low risk of complications. Reported adverse effects from transbronchial lung biopsy include pneumonia (8%), pneumothorax (<3%), mild reversible hypoxemia (10%), and clinically significant bleeding defined as more than 100 mL (10%) [1–4]. There are no deaths specifically reported with the use of bronchoscopy in lung transplantation, but there is a very low overall risk of mortality (<0.02%) in the general pulmonary population [5]. Lung transplant centers employ one of two strategies to detect rejection: either protocol-determined periodic lung biopsies (termed surveillance biopsies) or biopsies in the setting of clinical deterioration (termed for-cause biopsies). The potential advantage of a surveillance biopsy approach is that subclinical ACR can be detected early. The unproven assumption with this approach is that it leads to improved outcomes in the long term, such as improved survival and maintenance of lung function. The theoretical advantage of a for-cause approach is that patients would only be subjected to an invasive procedure when the pretest probability of a positive finding (ACR and/or infection) is high. This would limit costs to the patient and system as well as decrease the potential for adverse outcomes. Of note, a recent analysis of 224 bronchoscopy procedures done as surveillance showed that the rate of A2 or higher rejection was 18.7% and that the results of such procedures altered clinical management 32% of the time [1]. These findings suggest that the pretransplant probability for rejection is relatively high even in otherwise stable patients. Yet in spite of this relatively high pretest probability for rejection and infection, small pilot studies have suggested that patients being managed using a for-cause approach have equivalent medium-term outcomes compared to subjects in whom lung biopsy is performed at regular intervals. Hence, at the present time, the question of whether surveillance or a for-cause approach to detection of ACR results in improved patient outcomes remains unsettled.

For-cause lung biopsy of the transplant patient should be considered in cases of clinical decline. These may include declining

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

spirometric values (discussed later), breathlessness, radiographic infiltrates such as ground glass opacities and pleural effusions, and systemic manifestations of an inflammatory process such as fever. In virtually all cases where for-cause bronchoscopy with lung biopsy is performed the differential diagnosis will include both ACR and lung infection.

The technique for performing transbronchial lung biopsies as surveillance or for-cause involves obtaining multiple pieces of alveolated lung tissue. This requires use of forceps placed via the bronchoscope and generally guided by uniplanar real-time fluoroscopy. While ACR could be involving any region of the lung, many clinicians feel the dependent portions of the lung have a higher incidence of ACR [6], and hence some biopsy pieces should be taken from one of the lower lobes. The total number of biopsy pieces to be taken is also uncertain. The LRSG recommends obtaining at least five pieces of alveolated lung tissue containing at least 100 alveolar air sacs, and processing this tissue immediately in formalin to preserve the alveolar architecture. In contrast, Snell and colleagues extrapolating from older literature recommend ten biopsies as a reasonable target [7,8]. An early study of lung transplant recipients reported that a mean of 17 biopsies were needed for a sensitivity of 94% and a specificity of 90% for the detection of ACR [7], a level of sampling which is not generally undertaken. An important aspect to considering transbronchial biopsy as the gold standard for rejection is understanding the consistency of interpretation between pathologists. The largest study to date aimed at assessing consistency of evaluation across different institutions showed that the kappa statistic for A grade rejection was modest at best (kappa = 0.426; a kappa of 0 indicates chance agreement and a kappa of 1 indicates perfect agreement) [9]. Further, this level of agreement exists only for biopsy samples felt to have adequate tissue for interpretation. Other smaller studies have mirrored the modest degree of interobserver agreement [10–12]. Hence, it is important to understand that when the pretest probability for ACR is high, lung biopsies that are reported as negative for ACR do not completely rule out ACR being present, particularly when the quality of the sample is poor.

Diagnosis of antibody-mediated rejection

The diagnosis of humoral rejection in lung transplantation is considerably less well defined and more controversial than that of other transplanted organs such as heart and kidney. Consensus exists within the transplant community that antibody-mediated rejection in solid organ allografts generally manifests as capillary endothelial cell injury. Hence much work has been devoted to understanding how endothelial antigens promote antibody binding, complement activation, and subsequent tissue injury [13,14]. Within the lung transplant community there is a growing consensus that the humoral component of the immune system does contribute to progressive loss of lung function over time. The primary controversy currently revolves around the concept of how to reliably detect antibody-mediated rejection within sampled lung biopsy histology specimens and whether an antibody-mediated acute rejection process exists as a separate entity distinct from ACR. The evidence that antibody responses are important for graft function is largely circumstantial, but convincing in aggregate. First, it has been shown in rare cases that hyperacute rejection characterized clinically by respiratory failure and pulmonary edema can be attributable in some cases to the presence of pre-existing antidonor antibodies [15–18] which were present but not detected prior to transplant. Second, antibody-mediated rejection is well described in both heart and lung transplant, as reviewed elsewhere in this textbook. Antibody-mediated rejection is known to contribute to loss of graft function for both heart and kidney allografts, so it is plausible that similar processes would exist in lung transplantation. Third, several studies have linked pretransplant panel reactive anti-HLA antibodies (PRA) to subsequent outcomes following lung transplantation. For example, in one large retrospective study of 656 subjects, patients who had a pretransplant PRA of >25% had a median post transplant survival of 1.5 years compared with 5.2 years in patients with lower or negative PRAs [19]. Similar findings were reached utilizing the UNOS registry of lung transplantation in which over 10 000 lung transplant cases were analyzed. In this analysis, high level PRAs conferred a 30-day mortality hazard ratio of 2.6 [20]. Fourth, the development of PRAs after transplant has been linked to ACR, lymphocytic bronchiolitis, and bronchiolitis obliterans syndrome (BOS) in numerous studies. Finally, the development of de novo donor-specific anti-HLA antibodies (DSA) has been strongly linked to the subsequent development of BOS [21]. Patients who were successfully treated with a protocol to decrease DSA had improved survival compared with patients in whom this treatment was unsuccessful.

Given the strong association between anti-HLA antibodies and various outcomes in lung transplantation, considerable interest has developed in trying to detect direct antibody injury in lung biopsy specimens and to develop a pathologic grading system for antibody-mediated rejection (AMR). At the present time the LRSG does not recognize a pathognomonic pattern of AMR, but there have been proposals to do so. The major pathologic hurdle to diagnosis of AMR in lung transplantation is that C4d deposition, which characterizes AMR in renal and cardiac transplant AMR lacks specificity in lung tissue. Early descriptions of AMR in lung transplantation relied on the use of immunofluorescence (IF) of frozen lung tissue. In these small studies utilizing relatively large biopsy samples, patients who had acute cellular rejection uniformly also demonstrated septal capillary C4d deposition [22]. These findings have been difficult to validate by other groups. For example, a relatively large study of 68 lung transplant patients, which utilized immunohistochemistry (IH) of previously paraffin embedded lung transplant biopsies, demonstrated that AMR with isolated C4d deposition in the capillaries and with relative sparing of venous or arterial endothelium was quite rare and did not correlate with acute cellular rejection. Further, similar lung samples from non-transplant subjects showed a comparable degree of diffuse C4d deposition, indicating that this phenomenon is not specific for an antibody-mediated rejection process [23].

Despite the lack of clear diagnostic criteria for AMR in lung transplantation, several case reports have highlighted the features of what the syndrome might look like clinically. Girnita published a case report on two patients who developed donor-specific anti-HLA antibodies and, on transbronchial lung biopsy, showed subendothelial capillary C4d deposition [24]. Both of these patients demonstrated worsening graft survival, which was refractory to augmented immunosuppression and eventually experienced total allograft loss. A similar case reported by Morrell described early graft worsening in a patient who developed donor-specific antibodies. Lung pathology showed C4d endothelial deposition, and the patient responded clinically to therapies implicated in antibody removal: IVIG, plasmapheresis, and anti-CD20 monoclonal antibody therapy [25]. Finally, Astor reported on a pediatric lung recipient whose lung biopsy showed C4d deposition associated with significant B cells populating the graft and the development of

antidonor HLA antibodies in the circulation. This patient also responded to antibody-lowering therapy [26]. Collectively, what these cases demonstrate is that while detection of AMR by histology may be difficult, AMR should be considered in the context of donor-specific anti-HLA antibodies, clinical worsening, a lack of responsiveness to traditional therapy for rejection, and a lung biopsy that does not show features of typical ACR.

Risk factors for acute rejection

An extensive literature links many patient factors to a risk of developing ACR. In broad terms these risk factors include immunosuppression, genetic variability, antigenic disparity between donor and recipient, and post transplant clinical factors. With respect to immune suppression, the vast majority of lung transplant recipients are treated with maintenance immunosuppression including a calcineurin inhibitor. Two studies have demonstrated superiority of tacrolimus (TAC) over cyclosporine (CSA) with respect to ACR risk, although this effect is modest—a 7–22% reduction in ACR incidence in the first year post transplant [27,28]. A significant ongoing question in lung transplantation centers is what constitutes the optimal lymphocyte depletion therapy at the time of transplant. Various types of induction agents are used across transplant centers, including polyclonal antithymocyte globulin, selective anti-IL2 receptor monoclonal antibodies such as basiliximab and daclizumab, and the potent panlymphocyte depleting agent alemtuzumab. Some centers do not employ any induction therapy. With respect to risk of ACR, several studies support the concept that induction is associated with a decreased incidence of ACR [29–32], and the ISHLT registry data show that patients who received induction therapy with anti-IL2 receptor agents had a modest decreased rate of ACR compared with no induction [33]. Similar to other solid organ transplants, a significant degree of HLA antigenic disparity between donor and recipient exists in the vast majority of cases. The degree of HLA mismatch of HLA A, B, and DR alleles has been linked to the incidence of ACR [34–36]. Several genetic polymorphisms with high frequency within the general population have been linked to ACR incidence. Genetic polymorphisms involving the toll-like receptor 4 protein, the CD14 lipopolysaccharide receptor, the CCL4L chemokine, and the cytokine IL-10 have been linked to alterations in ACR risk [37–40]. Finally, there is now evidence that gastroesophageal reflux disease (GERD), a risk factor for chronic rejection, may also increase the incidence of ACR [41].

Treatment of acute rejection

The vast majority of patients with ACR can be successfully managed by augmenting immune suppression. Nearly every center will elect to treat A2 and higher grade ACR episodes, with the main point of controversy being how to manage A1 rejection. Given the association of even minimal rejection and chronic lung failure (discussed later), some programs have taken an aggressive stance to minimal rejection. First-line therapy consists of intravenous methylprednisolone dosed at 10–15 mg/kg per day for 3 days. While this regimen is used across multiple centers worldwide, there exist no data to prove that this is the optimal dosing strategy. One prospective study has shown that time after transplant negatively correlates with steroid responsiveness: 85% of patients within the first year of transplantation demonstrated a significant response to high-dose corticosteroids, while only 55% responded to steroids for the treatment of ACR in patients more than 2 years out from their transplants [42]. The major adverse effects of such pulse corticosteroids are transient hyperglycemia, which may require insulin therapy, as well as a temporary increase in latent CMV reactivation. Most programs will institute temporary CMV prophylaxis for serologically at-risk patients in the weeks following such steroid pulses.

Persistent ACR, defined as any grade of rejection after conventional high-dose corticosteroids, can be managed with a variety of treatment modalities, including a second round of high-dose corticosteroids. Other therapies that have shown promise include the use of polyclonal antithymocyte globulins (ATG), monoclonal antibody to CD3 (OKT3), as well as the humanized monoclonal antibody to CD52 (alemtuzumab). All of the reports on rescue agents for refractory ACR are limited to small groups of patients, and as a result there remains no standard second-line agent for ACR beyond steroids. In addition to targeted antilymphocyte therapy, some clinicians recommend changing the baseline immune suppression in cases of refractory ACR: for example, exchanging CSA to tacrolimus or exchanging azathioprine to mycophenolate [43,44]. For very severe cases of refractory rejection, additional adjunctive rescue methods have been described including the use of total lymphoid irradiation and extracorporeal photopheresis [45,46].

Chronic allograft rejection

The majority of patients who undergo lung transplantation enjoy a significant increase in their quality of life. This is related to a decrease in the degree of breathlessness experienced as well as liberation from the need for chronic exogenous oxygen therapy. Spirometric testing of lung transplant recipients is the main monitoring tool used to measure lung function over time, with two specific measures, the forced expiratory volume in 1 second (FEV_1) and the forced vital capacity (FVC) being the most widely utilized. A third spirometric measure, the forced expiratory flow between 25% and 75% FVC ($FEV_{25–75}$) is a third value sometimes utilized. The majority of lung transplant patients achieve peak lung function between 6 and 12 months following transplantation. Chronic rejection occurs when lung function begins to decline after such a peak has been attained. The classic histopathologic finding in chronic rejection is luminal obliteration of the terminal (non-cartilaginous) airway. This is termed bronchiolitis obliterans (BO). Importantly, the pathology of BO is distinct from the pathology of A or B grade ACR. BO lesions are discreet anatomically, involving the terminal airway, without involvement of larger cartilaginous airways, the alveolar airspace or the pulmonary interstitium. Further, while ACR is characterized by an influx of perivascular or peribronchiolar lymphocytes, BO is characterized by a relative paucity of lymphocytes. The obstructing lesions of BO may be concentric, or eccentric. Additionally, foamy macrophages are sometimes associated with BO lesions. Because of the extensive fibrotic nature of the BO lesions, much work has focused on determining the origin of these fibroblasts, which are sometimes referred to as myofibroblasts due to their elongated structure and significant actin content. Theoretically, the myofibroblasts could arise from several sources. First, they may derive from donor resident fibroblasts present from the time of transplant. Second, they could be recipient-type cells derived from a circulating bone marrow-derived precursor termed the fibrocyte. Third, because they are present at areas where airway injury may have previously occurred, they may derive from previous bronchiolar epithelial cells in a process termed epithelial–mesenchymal transformation. None of these possibilities is mutually exclusive and there is circumstantial evidence that all the processes may be involved.

BO lesions are sometimes seen on transbronchial lung biopsy specimens, and have therefore been assigned a grading schema by the LRSG. However, it is important to note that the pathologic lesions of BO can be quite patchy. As a result, transbronchial lung biopsy has a relatively poor negative predictive value for the diagnosis of BO. This limitation has necessitated the development of a surrogate clinical designation for the diagnosis of chronic rejection termed bronchiolitis obliterans syndrome (BOS). The classification system for BOS as determined by the ISHLT has undergone two iterations to date, most recently in 2003 [47].

As shown in Table 72.1, BOS is defined as being present when the post-transplant FEV_1 drops below 80% of the best post-transplant value. Because early BO causes partial luminal obstruction, the loss in FEV_1 is generally out of proportion to the *FVC*, which is a much more resistant to changes in airflow resistance. Hence, one clue that BOS is developing will be a gradual loss in 1-second airflow by spirometry, which is manifest as an inward bowing of the expiratory limb of the flow volume loop, as shown in Figure 72.1. Many processes distinct from fibroblastic obliteration of the terminal airway can result in a decreased FEV_1. Therefore, in order to make the diagnosis of BOS, other etiologies must be ruled out. Common causes of airflow loss include entities such as ACR as well as infectious etiologies. Thus a standard approach to a patient experiencing a loss of airflow is to perform radiologic studies as well as bronchoscopy. The later affords the opportunity to assess for both an infectious etiology as well as rejection. It essential to remember that many other etiologies can result in a loss of airflow and should be considered prior to labeling a patient as having BOS. Airway stenotic lesions, typically at the bronchial anastomotic site, can result in a loss in FEV_1. Lung transplant recipients are at risk of developing focal narrowing at the sites of the bronchial anastomoses, as the bronchial arteries feeding these areas are not re-anastomosed during transplantation. Such anastomotic strictures can be appreciated on CT imaging as well as bronchoscopy (Figure 72.2). Body habitus can contribute to a patient's spirometry. Significant obesity will often result in decreased FEV_1. One clue that worsening obesity is the cause of declining spirometry is that both the *FVC* and FEV_1 will be reduced to a similar degree, but the $FEF_{25–75}$ is unchanged. Of all the spirometric values used to monitor lung transplant patients, the $FEF_{25–75}$ is the most

Table 72.1. Staging criteria for bronchiolitis obliterans syndrome

Stage	Criteria
BOS 0	$FEV_1 > 90\%$ of baseline and $FEF_{25–75} > 75\%$ baseline
BOS 0p	FEV_1 81–90% baseline and/or $FEF_{25–75} < 75\%$ baseline
BOS 1	FEV_1 66–80% baseline
BOS 2	FEV_1 51–65% baseline
BOS 3	$FEV_1 < 50\%$ baseline

BOS, bronchiolitis obliterans syndrome; FEV_1, forced expiratory volume in 1 second; $FEF_{25–75}$, forced expiratory flow between 25% and 75% *FVC*.

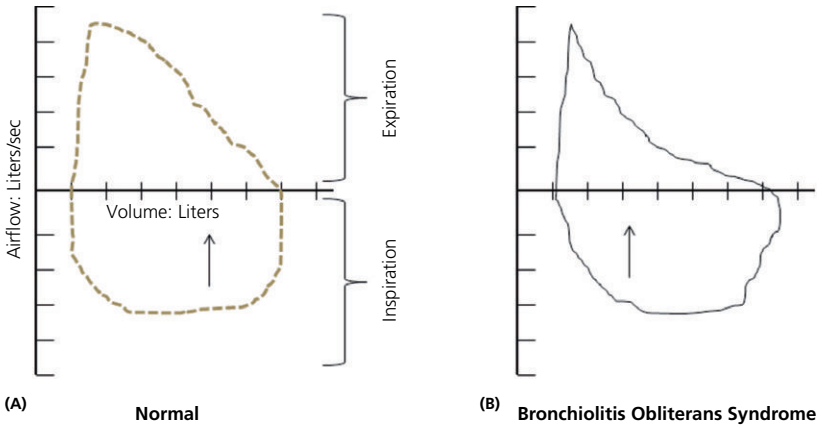

Figure 72.1. Spirometry trends after transplant. The flow/volume loops compare lung volumes (x axis) as a function of airflow (y axis). The tracing above the x axis depicts expiration while the tracing below depicts inspiration. In the normal patient (A), the FEV_1 (arrow) occurs at a relatively high lung volume. In the setting of small airway obliteration, as seen in bronchiolitis obliterans syndrome (B), there is an abrupt loss of airflow as a function of lung volume such that the FEV_1 (arrow) occurs at a smaller volume. With progressive loss of airflow, the expiratory limb converts from a convex to a concave configuration.

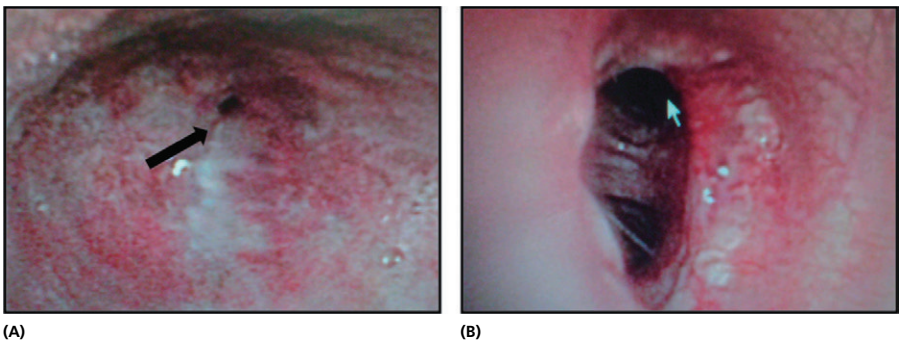

Figure 72.2. Focal airway narrowing. A lung transplant recipient presented with an abrupt loss in FEV_1. Bronchoscopy revealed pinpoint narrowing of the right mainstem bronchial anastomosis, shown by the arrow in (A). After bronchoscopic balloon dilatation, the airway was widely patent (B) and the FEV_1 returned to baseline.

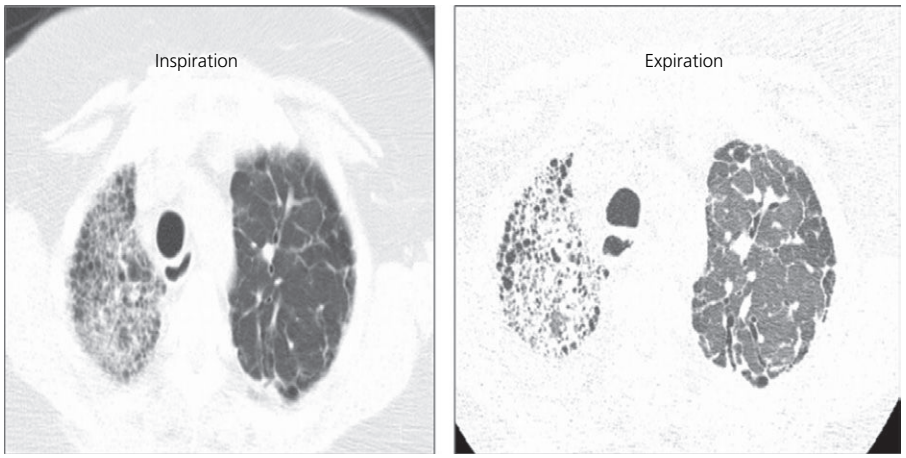

Figure 72.3. Radiographic appearance of bronchiolitis obliterans. A patient with a demonstrated loss in FEV_1 7 years after left single lung transplantation; (A) shows the inspiratory view with a limited degree of mosaic attenuation within the left lung; (B) shows the same region during exhalation with a significant variability in attenuation of the secondary pulmonary lobules consistent with areas of air trapping.

sensitive to small changes in airflow resistance. As noted in Table 72.1, an additional classification termed BOS0p (for potential BOS) exists. The criterion for BOS0p, which was added to the 2002 classification, is a 10% decline in the FEV_1 or a 25% decline in the $FEF_{25–75}$. The rationale for including BOS0p in the classification scheme was to alert clinicians when a particular patient's lung function was declining. A retrospective assessment of the two variables comprising BOS0p, FEV_1 and $FEF_{25–75}$, showed that only the drop in FEV_1 had a suitable prognostic value in determining BOS for recipients of bilateral lung transplants [48]. Similar conclusions were reached in a retrospective study of single lung transplant recipients, with the combined use of FEV_1 and $FEF_{25–75}$ showing a slightly higher prognostic value over the FEV_1 alone [49]. Given the fact that the majority of lung transplant patients do ultimately meet the criteria for BOS, and that treatment options for BOS remain limited, the clinical utility of BOS0p remains unclear aside from serving as an endpoint for investigational studies.

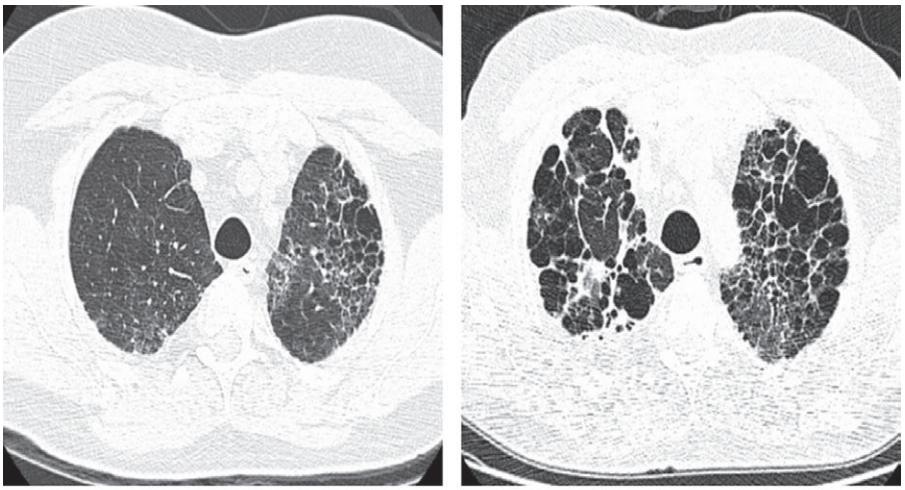
Clinical presentation of bronchiolitis obliterans syndrome

Every lung transplant recipient is at risk for the development of BOS. The most recent iteration of the ISHLT registry, which tracks the largest cohort of lung transplant patients worldwide, indicates that the rate of freedom from BOS is 90% at 1 year, 51% at 5 years, and 25% at 10 years post transplant [33] . Collectively, these data indicate a very high overall incidence of BOS, which tends to occur several years after transplantation. The symptoms of BOS can be quite variable. Most patients may begin with an asymptomatic presentation only detected by changes in spirometry, while some patients do present as acute dyspnea similar to a typical respiratory infection. Some investigators have classified patients according to the tempo of their BOS. In a study of 204 lung transplant patients, patients described as having an acute drop in the FEV_1 were compared to patients with a more linear, chronic drop in the FEV_1. The acute-drop patients experienced a median survival of 29 months compared with 58 months in the chronic group [50]. The most extensive study to date modeling the tempo of BOS over time showed that in most cases when BOS occurs, the drop in FEV_1 is most abrupt within the first 6 months of onset. After the abrupt loss of FEV_1, the rate of further decline in the next 18 months was much lower [51]. This non-linear relationship between FEV_1 loss and time is important to consider when assessing any treatment effects for BOS. Not surprisingly, patients who had a more precipitous decline into meeting the clinical criteria for BOS also demonstrated steeper further declines in FEV_1 and lower FEV_1 at 2 years post onset [51].

The radiologic studies in patients with BOS are generally subtle. Plain chest radiographs typically demonstrate normal to hyperinflated lungs without evidence of airspace opacity. High-resolution CT studies can provide additional details. For example, comparison of inspiratory to expiratory imaging on CT may reveal air trapping in the form of mosaic attenuation between adjacent secondary pulmonary lobules (Figure 72.3). Further, since OB involves the terminal bronchioles, patients with BOS may demonstrate tree-in-bud opacities in the periphery of the lung. It is important to note that many infectious processes that cause bronchiectasis can also result in tree-in-bud opacities.

Other clinical manifestations of chronic allograft injury

While the classic pattern of chronic rejection involves fibromyxoid luminal obliteration of the terminal airway resulting in airflow obstruction, other forms of chronic lung dysfunction have been described. These include entities termed restrictive allograft syndrome (RAS), neutrophilic reversible allograft dysfunction (NRAD), and follicular bronchiolitis. RAS is characterized by a decline in both the FEV_1 (>20%) and the total lung capacity (TLC, >10%). Some patients with RAS demonstrate upper lobe fibrosis, including radiographic honeycombing and pleural thickening (Figure 72.4), although these findings are not seen in all patients with RAS. NRAD refers to a phenotype characterized by: (1) FEV_1 loss, (2) bronchoalveolar lavage (BAL) neutrophilia, and (3) improvement in FEV_1 after the initiation of azithromycin (AZM) [52]. Follicular bronchiolitis is a rare small airway disease seen in non-transplant patients. It is characterized by lymphoid hyperplasia of surrounding the airway, and clinically characterized by progression to bronchiectasis. Two publications have reported the finding of follicular bronchiolitis in lung transplant patients, with the major findings including a strong association with prior



(A) 2 years post transplant (B) 5 years post transplant

Figure 72.4. Radiographic appearance of restrictive allograft syndrome (RAS). The patient developed progressive loss of lung volume with a 10% decrease in the total lung capacity (TLC) at 2 years post transplant and a 40% decrease in the TLC by 5 years post transplant. The decline in TLC was associated with development of apical honeycomb changes, which progressed over time.

Aspergillus infection, airway neutrophilia, and improvement following treatment with AZM [53,54]. Collectively, chronic lung dysfunction encompassing one of these patterns including OB has been termed chronic lung allograft dysfunction (CLAD) by some authors. When distinct types of CLAD have been compared, several studies suggest that CLAD with a BOS phenotype is associated with an improved survival compared with CLAD with a RAS phenotype.

Risk factors for bronchiolitis obliterans syndrome

The pathophysiology of BOS is thought to be multifactorial. Many risk factors have been linked to the subsequent development of BOS and mechanistic studies on these risk factors have moved the field of lung transplantation closer to a more complete understanding of how these factors are related. ACR is considered a strong risk factor for the development of BOS, as indicated by multiple studies [55–59]. These studies demonstrate that even minimal grade rejection is associated with some future risk of BOS. Further work has focused extensively on the relationship between lymphocytic bronchiolitis (LB), the B score of ACR grading scheme. The rationale for these investigations is that LB lesions and OB lesions occupy the same anatomic location, even if they are distinct histologically. This rationale is buttressed by animal tracheal transplant models showing a close temporal relationship between lymphocytic airway involvement and subsequent airway obliteration [60]. Several small studies in the early days of lung transplantation observed a similar close association between LB and subsequent OB [61–63]. More recently, Glanville examined the relationship between LB and BOS in an extensive longitudinal study of 341 lung transplant recipients [64]. These investigators demonstrated, in a multivariable model, the highest B-grade rejection score was associated with subsequent BOS and death. A-grade (vascular) rejection did correlate with subsequent risk of BOS in the univariable model, but fell out as a risk factor in the multivariable model [64].

Not every patient who experiences ACR goes on to develop BOS and some patients with BOS have no antecedent episode of ACR. Hence, either the diagnosis of ACR is imprecise, as noted earlier, or other factors may participate in increasing BOS risk. These factors, which are considered "non-alloimmue," include ischemia–reperfusion injury (also termed primary graft dysfunction [PGD]), gastroesophageal reflux disease (GERD), and respiratory infections. These three major factors are discussed below.

Table 72.2. Consensus grading scheme for primary graft dysfunction (PGD)

Grade	PaO_2/FiO_2	Radiographic infiltrates consistent with pulmonary edema
0	>300	Absent
1	>300	Present
2	200–300	Present
3	<200	Present

In addition to the grade of 0–3, PGD is subject to grading at several time intervals post transplant. Lung transplant patients have a PGD score determined at 0–6 hours, 24 hours, 48 hours, and 72 hours post transplantation.

Primary graft dysfunction

Injury to the transplanted allograft begins prior to implantation. Brain death itself results in activation of the neuroimmunologic axis, potentially resulting in subclinical epithelial and endothelial injury to an otherwise normal lung. Additionally, lung donors are at risk of aspiration and trauma from mechanical ventilation. Procurement followed by the transplant procedure results in a period of cold and warm ischemia. As a result, many normal-appearing transplanted lungs demonstrate significant non-cardiogenic pulmonary edema in the first days following lung transplant. Consensus guidelines have been developed to grade PGD [65]. As shown in Table 72.2, there are four potential grades of PGD derived at four time points (0–6, 24, 48 and 72 hours). Cardiogenic edema needs to be excluded for a patient to meet the criteria of having PGD.

This grading system has allowed investigators to assess the contribution of PGD to risk of BOS in several studies. A large single-center retrospective study of 337 lung transplant patients concluded that the severity of PGD was associated with a significant increased risk of subsequent development of BOS, both at early and later time

points [66,67]. A large international registry study demonstrated that survivors of severe PGD experienced increased mortality even when censored for those patients who lived at least a year, although there was only a trend toward increased BOS in the PGD group. While it is largely unclear how PGD predisposes to BOS given that these two events occur at distinctly different time points post transplantation, a recent finding by Bharat shows that patients who previously experienced PGD are at a significant risk for the development of antidonor HLA antibodies directed against MHC class II epitopes. Hence, it is possible that the pulmonary epithelial injury response during PGD contributes to increasing the antigenicity of the lung. Additionally, it is possible that PGD results in revealing previously cryptic self-antigens to the immune system. One such example of a cryptic antigen is type V collagen (Col V). Col V is a relatively rare constituent of collagen, which is usually intercalated within mature collagen bundles and therefore not accessible to T-cell surveillance. Rodent transplantation even in the absence of antigenic mismatch is associated with release of Col V into the airway, and leads to accumulation of T cells within the graft specific to Col V [68]. Some human subjects with idiopathic pulmonary fibrosis prior to transplant demonstrated a high frequency of T cells reactive to Col V in a single-center study. Severe PGD was significantly more common (55% vs. 22%) in patients with pre-existing Col V reactivity [69]. Hence, one potential mechanism linking PGD to subsequent development of BOS is that the early lung injury leads to exposure of previously cryptic autoantigens, which drives subsequent immune reactivity to the lung even after the allograft has recovered from the PGD.

Gastroesophogeal reflux disease

Many factors put lung transplant recipients at risk for GERD and subsequent aspiration. The surgery and postoperative course appear to impair normal swallowing. A study by Atkins et al. found laryngeal penetration or aspiration of thin liquids on swallowing evaluation in a third of patients [70]. Many of these patients had clinically silent aspiration. Patients have a high rate of gastroparesis. Factors that may impair GI motility and predispose to retrograde gastric reflux include vagal nerve injury during surgery and the use of calcineurin inhibitors, which may delay gastric emptying [71,72]. Decreased mucociliary clearance related to a blunted cough reflex and scar tissue formation at the anastomotic site also contribute to a heightened risk of exposure of the pulmonary epithelium to gastric contents. GERD is estimated to be present in at least 50% of patients [73]. Additionally, constituents of gastric fluid, such as pepsin and bile salts, are often found in bronchoalveolar lavage fluid of transplant patients [74,75]. Patients with GERD experience a higher incidence of ACR [41]. Because of these associations, some groups have begun routinely performing surgical gastrofundoplication on lung transplant recipients in the early postoperative period. While these studies are uncontrolled, they are associated with improved outcomes compared to historical experience. Interestingly, in the aftermath of surgical correction, a significant decrease in the number of activated CD8 T cells was observed in a small cohort of lung transplant patients [76]. Hence, GERD with aspiration of gastric contents into the lung may induce an injury response leading to increased immunity against the allograft. A study of both pre- and postlung transplant survival found that patients with GERD had increased T-cell reactivity to Col V; post transplantation, patients with GERD and Col V T cells developed BOS at an increased rate [77]. These findings thus may potentially link aspiration events to the development of autoimmunity.

Infection

Lung transplant patients are at high risk of developing a multitude of respiratory infections given that they are highly immunosuppressed and the lung is susceptible to environmental exposure. General discussions of the infectious risks of transplantation are covered in depth in Chapters 92–94. A diverse range of microbial pathogens has been linked to subsequent BOS development, including bacterial infections with pseudomonas [78], atypical bacterial infection with *Chlamydia* [79], fungal infection [80,81], community-acquired respiratory viruses (CARV) [82,83], activation of chronic CMV infection [84,85], and human herpes virus 6 [86]. A significant body of work has assessed the clinical sequela of CARV. CARV typically studied include influenza, parainfluenza, respiratory syncytial virus, metapneumovirus, adenovirus, and rhinovirus. Nearly all of the studies to date reporting on the association between CARV and outcome have been single-center retrospective reports. From these studies, CARVs appear to be strongly associated with respiratory symptoms such as cough and dyspnea. On the other hand, these single-center studies reach divergent conclusions regarding the association between CARV and ACR or BOS. One large, prospective, single-center study, utilizing very sensitive molecular tools for respiratory virus, showed a strong association between CARV infection and A2 rejection, while at least three others have not. Regarding the risk of BOS, most of the studies to date reporting BOS incidence contain a very small number of total cases, although a risk of BOS was found in three of the four studies. A meta-analysis of the literature to date on CARV and lung transplantation found that the variability between studies was so great that BOS risk related to virus could not be calculated with any appropriate statistical analysis. Collectively, these studies indicate that CARV infection is potentially harmful, but more controlled studies are required to fully quantify the risk. An important point to consider with respect to viral infection is that few agents exist with which to treat the majority of these infections. Influenza virus can be managed with agents such as oseltamivir, which decrease the length of viral shedding, and respiratory syncytial virus can be treated with ribavirin (inhaled or oral), but in general management of viral illnesses generally involves reduction of baseline immune suppression and supportive care. With respect to the 2009 pandemic of novel H1N1 influenza, the experience from Australia suggests that this outbreak was associated with an overall increase in BOS in influenza survivors [87].

In addition to CARVs, which are ultimately cleared by the infected individual, another potential threat to lung transplant recipients are the intrinsic viruses that set up latency in the host. The most extensively studied latent virus is cytomegalovirus (CMV), a member of the beta herpes family of viruses. Roughly 80% of the general population is serologically positive for CMV and hence at risk for reactivation and viral replication in the setting of immunosuppression. Of all the latent viruses, CMV appears to have the highest predilection for replication within the lung. In the early decades of lung transplantation, CMV was noted to confer a significant risk for BOS. This notion was based in part on international registry data showing that patients who were CMV naïve but received a lung transplant from a CMV positive donor—termed a CMV mismatch—were at increased risk for developing BOS compared to patients who had pre-existing immunity to CMV prior to transplant. CMV infection in the lung can result in CMV pneumonitis, resulting in recruitment into the lung of inflammatory cells as well as increasing the immunogenicity of the respiratory epithelium. Hence the mechanism by which

CMV infection leads to BOS would be related to chronic injury to the respiratory tract. One mechanistic study in human lung transplant recipients showed that CMV pneumonia was associated with elevated BAL levels of CCL2 and MCP-1, two chemokines with known association to risk of BOS [88].

In the last decade, improved therapies for CMV have become standardized. The most utilized is oral valganciclovir, which strongly inhibits viral replication. The use of valganciclovir for all patients at risk of CMV for some period of time, generally 3–12 months, after transplantation has resulted in a significant reduction in the risk of BOS attributable to CMV infection. This is best appreciated in the recent ISHLT registry, which compares mortality after transplantation among different combinations of CMV status between donor and recipient. In the new era of CMV prophylaxis, there is no longer a statistically different survival between CMV mismatched patients (D+/R−) and patients who are not CMV mismatched. This does not mean that in certain individuals, CMV replication is benign and there are compelling recent data that CMV pneumonia is indeed linked to a risk of subsequent BOS. Snyder demonstrated, in a large retrospective cohort of 231 lung transplant patients, that CMV pneumonia was associated with a twofold increased risk of subsequent BOS development [89]. Similarly, Paraskeva, utilizing a very sensitive PCR assay, showed in a study of 192 patients that CMV replication detected in BAL fluid was also associated with a twofold risk of BOS development [90]. Given these findings, significant effort has been devoted to defining the optimum prevention strategy for CMV disease in lung transplant recipients. A randomized placebo-controlled study from 11 US centers compared 3 months of oral valganciclovir prophylaxis to 12 months of prophylaxis. The key finding from this study was that patients receiving longer-term prophylaxis had a significantly decreased rate of CMV disease at 13 months (4% vs. 32%) [91]. It remains unclear whether longer-term prophylaxis post transplant will translate into a lower risk of BOS, though the long-term results of prospective trials will ultimately answer this question.

Treatment strategies in chronic rejection

Given that BOS remains highly prevalent following lung transplantation and contributes significantly to the mortality experienced in lung transplant recipients, it is fair to say that treatment methods for chronic rejection remain disappointing. In view of the significant association between ACR and subsequent BOS, many reports have cited some improvement in BOS outcomes through manipulation of standard immune suppression regimens, such as conversion from azathioprine to mycophenolate, from cyclosporine to tacrolimus [92–96], or through the use of cytolytic therapy [97–99]. None of these reports have convincingly shown a major improvement in lung function once BOS is established, but rather suggest that in some patients stabilization of lung function may be achieved. Because of the uncontrolled and retrospective nature of these studies it is unclear if their findings simply reflect the natural history of BOS.

The histology of BO in lung transplant is similar to a rare pulmonary disease termed diffuse panbronchiolitis (DPB). DPB can ultimately lead to end-stage lung disease. Further, one of the most effective class of agents used to treat DPB is the macrolide antibiotics [100]. Subsequent studies in patients with cystic fibrosis confirmed a clinical benefit from the use of the macrolide azithromycin (AZM) [101]. These findings formed the rationale for early pilot studies examining the potential of AZM to stabilize lung function in transplant patients with BOS. The first case report showed a trend toward stabilization of FEV_1 in five of six patients with established BOS [102]. A subsequent larger single-center study of 81 patients with BOS showed that treatment with AZM improved FEV_1 by 10% in 24 of the patients [103]. Responders were noted to have a higher pretreatment level of BAL neutrophilia than nonresponders. Some have suggested that response to AZM in the setting of BAL neutrophilia defines a subclass of CLAD distinct from BOS, termed NRAD as described earlier. The potential benefit of AZM has been assessed with one randomized, prospective trial with 40 patients in the AZM group and 43 patients in the placebo group. Treatment with AZM beginning at the time of transplantation was associated with a threefold decrease in BOS prevalence at 2 years post transplant, but survival was equivalent between the groups [104]. Given that AZM is generally well tolerated by patients, the use of AZM in patients with developing airflow obstruction following transplantation appears to be a reasonable approach as there are no other proven effective therapies for BOS treatments.

Multiple additional therapies for BOS have been proposed, which may have some therapeutic efficacy but yet do not have the weight of strong experimental evidence at this time. These include the use of antibody-lowering therapy for DSA, aerosolized CSA, photopheresis, and infusion of donor hematopoietic cells. As noted previously, a single-center study found that patients who developed de novo DSA, and had successful depletion of this DSA with a combination of rituximab and IVIG, had lower rates of BOS then patients in whom this therapy failed to lower the DSA [21]. Hence, it is tempting to speculate that antibody-lowering therapy in patients with DSA might reduce the risk of BOS. Inhaled CSA has been proposed as a potential therapy to decrease allospecific responses in the airway. A single-center prospective study of inhaled CSA, where a reduction in ACR was the primary endpoint, failed to show a treatment effect for ACR. Interestingly, retrospective analysis of that study showed that patients who received inhaled CSA had improved survival and decreased BOS [105]. Hence, results from future studies on inhaled CSA are anticipated. Extracorporeal photopheresis (ECP) involves treatment of patients with a photosensitizing agent followed by perfusion of the patient's blood over a pheresis circuit where leukocytes are subjected to UV light. ECP has shown promise in the treatment of allogeneic bone marrow transplant associated OB. In lung transplantation, one study has shown that ECP is associated with a stabilization of lung function in patients with BOS, although there was no control nontreatment group in this study [106]. Mixed hematopoietic chimerism may be one strategy to induce donor-specific tolerance in lung transplant recipients. One clinical study to date has explored this: 26 patients who received lung transplants and infusion with donor bone marrow were compared to 13 patients who received only a lung transplant. Five per cent of the donor marrow infused patients developed OB compared with 33% in the control group [107]. Importantly, the degree of donor chimerism waned to the threshold of detection by 1 year post transplant, so it is uncertain if true stable chimerism was achieved. These results will need to be validated by future studies before infusion of donor bone marrow becomes an established tool to prevent BOS.

Summary

Rejection, both acute and chronic, is common in lung transplant recipients, and proper management requires proactive surveillance, including protocol biopsies or biopsies triggered by a high index of suspicion. Close collaboration with a trained histopathologist is

required to differentiate alloimmune causes of graft inflammation from other maladies in the differential diagnosis. Prompt treatment and aggressive follow-up are similarly required.

CHAPTER 73

Clinical Allograft Rejection Syndromes in Pancreas and Islet Transplantation

Parsia A. Vagefi[1] and Peter G. Stock[2]

[1] Division of Transplant Surgery, Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA
[2] Division of Transplant Surgery, University of California San Francisco, San Francisco, CA, USA

Immunogenicity of the pancreas allograft—a historical perspective

Modern-day transplantation of the pancreas began on December 17, 1966 at the University of Minnesota when Drs. William Kelly and Richard Lillehei transplanted a simultaneous duct ligated segmental pancreas allograft with a kidney allograft into a 28-year-old woman [1]. Over the last four decades, transplantation of the pancreas has evolved to serve as an effective treatment option for patients with diabetes mellitus with or without end-stage kidney disease. As of December 2010, more than 35 000 pancreas transplantations had been reported to the International Pancreas Transplant Registry, with the largest proportion (24 000) occurring within the United States [2]. Of the pancreas transplants performed, 75% were with a simultaneous kidney transplant (SPK), 18% were pancreas transplants performed following a previous kidney transplant (PAK), and 7% represented isolated pancreas transplants alone (PTA) (Figure 73.1).

The refinements in operative technique, patient care management, and an expanding arsenal of immunosuppressive medications have allowed for the progressive improvement in both patient and graft survival. The rate of early loss of a pancreas graft due to surgical technique has decreased to 8%. However, the most significant advances contributing to improved results have been the ability to protect against both alloimmune and autoimmune destruction. The rate of immunological graft loss at 1 year is 1.8% for SPK recipients, 3.7% for PAK, and 6.0% in PTA recipients. These results reflect dramatic improvements in the ability to control the immune response against the highly immunogenic pancreas transplant [2,3]. The overall effects of the effort in optimizing pancreas transplantation have resulted in patient survival rates of 95% at 1 year post-transplantation, and 83% at 5 years post-transplantation. The best graft survival has been found in SPK recipients, with 86% pancreas and 93% kidney graft function at 1 year. PAK graft function reached 80%, and PTA pancreas graft function reached 78%, at 1 year post-transplantation. Long-term outcomes for pancreas transplantation are covered in more depth in Chapter 107.

The vast majority of pancreas transplant programs use induction with a T-cell depletion agent (alemtuzumab or thymoglobulin) for all recipients regardless of the degree of sensitization (Figure 73.2). This reflects the early experience with extremely high rejection rates following pancreas transplantation. Concomitant with induction via T-cell depletion is the administration of steroids, mycophenolate mofetil (MMF), and tacrolimus for maintenance therapy (Figure 73.3). Many centers are now maintaining unsensitized recipients of SPK on tacrolimus and MMF dual therapy and rapidly tapering steroids during the first week following transplantation. For the recipients at higher immunologic risk, including sensitized SPK, PAK, or PTA, maintenance therapy often consists of triple therapy including steroids. In patients who have had early problems with rejection, or recipients at an extremely high risk for rejection, limited duration quadruple therapy with the inclusion of sirolimus has been used.

Clinical presentation: pancreas graft dysfunction

The clinical presentation of pancreas graft dysfunction is often asymptomatic, discovered by incidental elevations in serum amylase and lipase levels and/or the presence of hyperglycemia. Although broad consideration for the potential etiologies for graft dysfunction should be entertained (Table 73.1), the clinical assessment should be standard for all recipients of pancreas allografts and should include an ultrasound with Doppler of the pancreas graft, or magnetic resonance imaging or computed tomography, depending on the expertise available at the center, and the degree of suspicion for technical complications. A complete laboratory panel including amylase and lipase also should be performed. In SPK recipients, a kidney ultrasound should also be obtained. Attention to the serum levels of amylase, lipase, HbA1c, C-peptide, creatinine (in the setting of SPK transplantation), and immunosuppression drug levels is warranted. A thorough physical exam should be performed, and blood cultures and CMV levels obtained if a high degree of suspicion for an infectious etiology exists. It should be recognized that clinical signs could be muted substantially in a heavily immunosuppressed patient. Thus, positive physical findings could be useful, but negative physical findings are less informative. For the patient presenting with severe hyperglycemia, hydration with concomitant insulin therapy is warranted.

Elevations in serum amylase and/or lipase following pancreas transplantation can be attributed to various non-specific or specific inflammatory reactions, as well as a host of infectious states, anastomotic leak, or drug-induced toxicity. During periods of pancreas rejection, mean serum amylase and lipase values have been demonstrated to be increased by 3.6 and 8.3-fold, respectively, and

correlate with biopsy-proven rejection in 80% of cases [4]. Other laboratory findings that should increase suspicion for graft dysfunction include a trend in increasing levels of HbA1c. The kidney allograft in SPK recipients may serve as a surrogate marker of pancreas rejection, particularly when an elevation in serum creatinine levels occurs concomitant with elevations in serum markers of pancreatic acinar cell injury. This form of synchronous rejection has been noted to occur in up to 73% of dual organ transplant recipients. Isolated pancreas or kidney allograft rejection has been noted to occur in 3% and 23%, respectively, of rejection episodes in SPK recipients [5].

Ultrasound assessment of the transplanted pancreas allows for the assessment of the pancreatic parenchyma, the detection of peripancreatic fluid collections, the presence or absence of venous or arterial blood flow, and allows for image-guided percutaneous needle biopsies to be performed [6] (Figure 73.4A). Although ultrasound assessment of the pancreas allograft vasculature avoids the need for intravenous contrast administration associated with computed tomography (Figure 73.4B) and magnetic resonance imaging, limitations associated with this imaging modality include operator variability, as well as difficulty with assessment of the pancreatic allograft given its intraperitoneal location with overlying bowel gas capable of obscuring adequate visualization.

Perhaps, the greatest application of ultrasonography for pancreas transplant recipients is the ability to facilitate percutaneous needle biopsy [7]. Given the lack of specificity of serum biochemical markers in allowing for the diagnosis of pancreas allograft dysfunction, allograft biopsy has emerged as an essential adjunct for the management of the pancreas transplant recipient. Pancreatic allograft biopsy is performed by insertion of an 18 or 20-gauge core biopsy needle through the peritoneum and directly into the pancreas body or tail under sonographic guidance. Doppler imaging is used to reveal pertinent vascular structures. Following tissue sampling, a sonogram is obtained immediately following biopsy to assess for any immediate biopsy-related complications. Pancreatic allograft biopsy has a high success rate, with up to 88% of tissue samples being adequate for histological evaluation. There is a low complication rate (2.8%) that includes bleeding following biopsy, biochemical evidence of postbiopsy pancreatitis, and the inadvertent biopsy of adjacent structures [8,9]. Poor visualization of the pancreas allograft secondary to adjacent bowel, patient body habitus, or a small allograft can result in increased risk of technical failure with ultrasound-guided biopsy. If an adequate window cannot be obtained secondary to overlying bowel gas, the ultrasound can be repeated after short intervals until an adequate biopsy window becomes available. Alternatively, CT-guided biopsy remains an option. As a last resort, operative pancreas allograft biopsy can be performed either through an open or laparoscopic approach [10].

A special note should be made of the differences in surveillance and diagnosis of rejection in bladder-drained versus enteric-drained pancreas allografts. Although currently the majority of grafts are drained via the enteric system (80%), the 20% drained via the bladder allow for the assessment of allograft function by evaluation of urinary amylase levels. Indeed, it has been suggested by some that stable urinary amylase levels reliably rule out rejection; this point is controversial, however. Although a decrease in urinary amylase can serve as a marker for acute rejection, this is a nonspecific finding and should be supplemented by pancreas allograft biopsy. As opposed to ultrasound-guided percutaneous biopsy of the pancreas allograft, bladder drained allografts are amenable to cystoscopic transduodenal biopsy [11].

Table 73.1. Pathological changes "other" than rejection in pancreas needle biopsies

Diagnosis	Main histological findings	Clinical presentation
Post-transplant ischemic pancreatitis	Inflammation: neutrophils, foamy macrophages Location: septal if mild or diffuse if severe Other features: fat necrosis, edema and interstitial hemorrhage Patchy coagulation necrosis of clusters of acinar cells may be present No fibrosis, the septa may be expanded due to edema/fat necrosis	Increase in amylase and lipase in serum Decrease in urinary amylase* Hyperglycemia if there is extensive necrosis
Peripancreatitis/ peripancreatic fluid collection	Inflammation: mixed (lymphocytes, plasma cells, eosinophils, neutrophils) Location: septa and periphery of lobules Other features: dissecting bundles of active fibroblastic proliferation with obliteration of septal structures, relative preservation of the center of lobules ("cirrhotic appearance")	Local or systemic infectious symptoms, abdominal pain, peritonitis Peripancreatic fluid accumulation Increase in amylase and lipase in serum
Cytomegalovirus pancreatitis	Inflammation: mostly mononuclear Location: septal and acinar, patchy Other features: cytomegalovirus cytopathic changes in acinar, endothelial or stromal cells	Increase in serum amylase and lipase Decrease in urinary amylase* Systemic symptoms if generalized disease Other: duodenal cuff perforation
Post-transplant lymphoproliferative disorder	Inflammation: ranging from polymorphic with lymphoblasts, plasma cells, eosinophils in low-grade disease, to monomorphic, predominantly lymphoid in high-grade disease (lymphoma) Other features: lymphoid proliferation is nodular, expansive Necrosis may be present	Asymptomatic, or increase in serum amylase and lipase Lymphadenopathy Tumor mass May coexist with acute rejection
Bacterial or fungal infection	Inflammation: variable; acute, chronic, purulent, necrotizing (abscess), granulomatous Location: random Other features: same as bacterial and fungal infections in other organs	Systemic and/or localized infectious symptoms Peritonitis, duodenal cuff perforation Increase in serum amylase and lipase
Recurrent autoimmune disease/ diabetes mellitus	Inflammation: islet-centered lymphocytic inflammation (isletitis) No inflammation in late stages after disappearance of beta cells Other features: immunohistochemical stains for insulin and glucagon demonstrate absence of insulin producing beta cells in some or all islets depending if early or late disease	Acute or chronic deterioration in glucose metabolism with increasing need for insulin Although not pathognomonic, islet cell autoantibodies typically present (i.e. GAD 65, IA-2, etc.)
Acute calcineurin inhibitor toxicity	Absence of inflammation Variable degrees of islet cell injury (cytoplasmic swelling, vacuolization, islet cell drop-out formation of empty spaces (lacunae), apoptotic fragments) Immunoperoxidase stains: markedly diminished staining for insulin in comparison to controls and to glucagon stain Electron microscopy: loss of insulin dense core granules with preservation of glucagon dense core granules	Acute hyperglycemia High levels of cyclosporine or tacrolimus with return to normoglycemia with adjustment of drug dose or discontinuation

Acute pancreas rejection

Acute pancreas rejection can be seen in up to 35% of pancreas transplant recipients [12,13]. The histopathological diagnosis of pancreas allograft rejection is detailed in Chapter 85. Although several features of the clinical presentation of rejection are unique to the pancreas, the pathophysiology is similar to that seen in other transplanted organs, and treatment approaches are similar to that of the rejecting kidney, with the potential caveat that treatment escalation tends to proceed at a faster pace in pancreas transplant rejection. General comments about rescue therapy for allograft rejection can be found in Chapter 67. At 1 year post-transplant, SPK recipients demonstrate lower rates of acute rejection (25%), when compared to PAK recipients (36%), and PTA recipients (40%) (Figure 73.5). Although analysis of these rejection episodes has demonstrated that the majority occur within the first 6 months post-transplant, the late (>6 months) rejection episodes occurred primarily in PAK and PTA populations. Indeed, it is the PAK and PTA groups that demonstrate the highest rate of graft failure

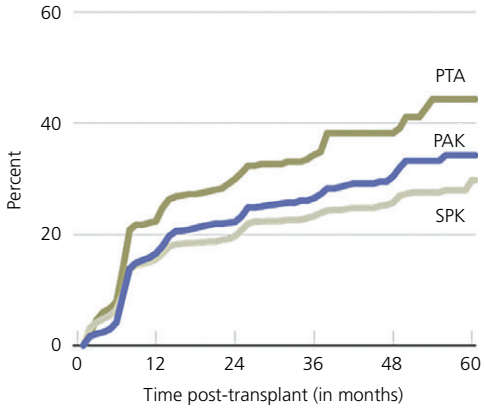

Figure 73.5. Incidence of first acute rejection among adult patients receiving a pancreas transplant in 2005–2009. From: Organ Procurement and Transplantation Network (OPTN) and Scientific Registry of Transplant Recipients (SRTR). OPTN/SRTR 2010 Annual Data Report. Rockville, MD: Department of Health and Human Services, Health Resources and Services Administration, Healthcare Systems Bureau, Division of Transplantation, 2011.

associated with acute rejection (1.8% and 2.9%, respectively) when compared to SPK recipients (0.3%). The need for appropriate and timely institution of antirejection therapy for pancreas transplant recipients is highlighted by the significantly increased risk of chronic rejection in those who have had multiple acute rejection episodes. Thus, with the associated increased rates of acute rejection seen in PTA and PAK recipients, there has been a demonstrated higher risk for chronic rejection in these recipients when compared to SPK recipients. The latter may be attributed to the absence of a surrogate marker for rejection in PTA and PAK recipients, as compared to the kidney allograft in SPK recipients, which may allow for a more expeditious appreciation of acute rejection and thus prevent delays in diagnosis or treatment of acute rejection. The cumulative effect of acute rejection episodes on the development of chronic rejection has been demonstrated. Despite improvements in immunosuppression protocols allowing for a reduction of rejection rates in recipients of solitary pancreas transplants [14], this population of patients is thought to benefit from prospective monitoring with protocol biopsies to allow for the earlier detection of allograft rejection, with the hopes of improving long-term graft and patient survival [15]. Although the timing of protocol biopsies varies with institutional protocols and expertise, biopsies at 3, 6, and 12 months should be considered.

Cellular-mediated rejection

Acute cellular-mediated rejection in a pancreas allograft, which has been well defined in 2008 by a consensus panel, is graded as mild (grade I), moderate (grade II), or severe (grade III) based upon histological assessment [16]. Prior to obtaining histological results, initial therapy should be directed at maximizing drug levels of calcineurin inhibitors and MMF, so as to not delay institution of therapy. Confirmation of the presence of acute cellular rejection should be treated by an additional round of T-cell depletion therapy for grade II and III rejection, whereas grade I rejection can be initially managed by pulse steroids. Failure of response in the latter scenario should prompt use of T-cell depletion for management of grade I rejection. Hyperglycemia associated with the rejection episode, or iatrogenic from high-dose steroid administration, should be managed with institution of insulin therapy with associated diet modification. Achievement of normoglycemia, normalization of amylase/lipase serum levels, as well as resolution of additional associated symptoms of rejection (graft pain, swelling, fever), should serve as indication of effective therapeutic intervention. Response to therapy for patients with grade I acute cellular rejection is nearly 90%, dropping to 71–85% for grade II rejection, and less than 50% for patients presenting with grade III rejection. Failure of symptomatic resolution, or concern for partial response, should prompt: (1) consideration for antibody-mediated rejection (see below), (2) further escalation of immunosuppression, and/or (3) an additional pancreas graft biopsy.

Antibody-mediated rejection

The effects of antibody-mediated rejection have gained wider appreciation with an improved understanding in not only pancreas transplantation, but other solid organ transplants as well. The Banff Grading Schema for pancreas rejection was updated in 2011 in order to address antibody-mediated rejection [17] (see Chapter 85). Routine pretransplant cross-matching and ABO matching has essentially eliminated antibody-mediated hyperacute and delayed hyperacute rejection. Of greater concern is acute antibody-mediated rejection, which typically manifests within the first few weeks following transplantation [18]. The presence of (1) allograft dysfunction, (2) donor-specific antibodies in the recipient's serum, and (3) capillary C4d deposition (consistent with complement deposition) allows for the diagnosis of acute antibody-mediated rejection to be established. Consensus on the significance of either isolated donor-specific antibodies or isolated C4d deposition, without the presence of the other or graft dysfunction, has yet to be determined. Currently, treatment should be reserved for those patients who present with at least two of the three above-mentioned criteria.

Once the diagnosis has been established, therapy aimed at attenuation of the antibody- mediated graft injury should be instituted. Current therapy often consists of various combinations of enhanced T-cell depletion with thymoglobulin, in conjunction with antibody-mediated therapy with plasmapheresis, IVIG, and rituximab administration. Utilization of additional antibody-mediated therapy (bortezomib, eculizumab, belatacept) have yet to gain wider acceptance [19]. Following graft rescue from acute antibody-mediated rejection, serial monitoring for the recurrence of donor-specific antibodies should be considered at 6-month or yearly intervals, with additional consideration for allograft biopsy for assessment of C4d deposition.

Chronic pancreas rejection

Cellular-mediated rejection

Pancreas graft survival following transplantation has gradually improved due to both advances in surgical techniques to limit graft loss from technical complications, and refinement in immunosuppressive protocols to prevent and manage episodes of acute rejection. With this success there has been a growing population of patients with long-term pancreas graft survival, and a subsequent increased appreciation of chronic allograft rejection as a source of pancreas graft loss [12]. The clinical presentation of chronic rejection is often manifested by the gradual loss of glycemic control during a late time course following transplant. In contrast to acute pancreas rejection, elevation of serum amylase/lipase is less prevalent [13]. A decline in C-peptide levels and elevation in HbA1c levels will further delineate the chronicity of graft loss. Pancreas

allograft biopsy will demonstrate graft sclerosis and loss of functional parenchyma in chronic rejection. The return of a hyperglycemic state late after transplant, in the absence of graft fibrosis on biopsy, but with evidence of insulitis and beta cell loss, should raise concerns for recurrent autoimmune disease as the source of allograft loss. There are single-center reports of temporary salvage of the pancreas allografts affected by recurrent autoimmune disease through enhanced immunosuppression [20]; however, there remains to be identified any therapeutic intervention capable of reversing chronic rejection. The latter further emphasizes the need for aggressive management of acute rejection, as the number and severity of acute rejection episodes are associated with the increased risk of chronic rejection and graft loss [13].

Antibody-mediated rejection

Chronic rejection of a pancreas allograft through antibody-mediated mechanisms is determined by graft biopsies demonstrating chronic graft sclerosis, concomitant with C4d-positive staining in parenchymal capillaries and the presence of donor-specific antibodies [17]. The clinical presentation is similar to that of chronic rejection mediated through cellular mechanisms, with the patient's gradual return to a hyperglycemic state. Unfortunately, like cellular-mediated chronic rejection, there currently are no therapies available and current efforts should be directed at aggressive detection and management of acute rejection episodes.

Immunogenicity of the islet allograft—a historical perspective

The origin of islet replacement in diabetic patients began in the late 19th century, with the reports of the transplantation of sheep pancreatic extracts without clinical success [21]. Although the clinical development of modern-day islet transplantation began in close parallel with pancreas transplantation, its establishment into the clinical armamentarium has been slow and limited in application. The demonstration, in 1972 by Ballinger et al., of the reversal of streptozocin-induced diabetes in rats by the transplantation of islet isografts helped establish the foundation on which current islet replacement is based [22]. Translation to a clinical reality ensued, with demonstration at the University of Minnesota of autologous islet transplantation success in patients undergoing near-total pancreatectomies [23,24]. Subsequent success across allogeneic barriers was demonstrated [25], with the largest advancement being improved success through utilization of a steroid-free immunosuppressive protocol, termed the Edmonton Protocol. However, insulin independence relied on the use of multiple pancreas donors for success [26]. Unfortunately, long-term follow-up of these islet transplant recipients who were initially rendered insulin-independent found that over 80% had returned to insulin dependence within 2 years. Furthermore, many of these recipients became sensitized, likely as the result of the use of multiple donors compounded by allograft rejection. Further understanding of appropriate donor selection, and advancements in islet isolation, have allowed for success rates utilizing single pancreatic donors for the achievement of insulin independence. In addition, calcineurin inhibitor/steroid-sparing immunosuppressive regimens that rely on costimulation blockade (belatacept or efalizumab) have demonstrated long-term islet allograft survival without the associated renal and beta cell toxicity associated with calcineurin-inhibitors [27]. The latter protocols have consisted of T-cell depletion at the time of islet transplant, and subsequent maintenance immunosuppression with MMF or sirolimus, as well as a costimulatory blocking antibody. A more comprehensive discussion of islet transplantation can be found in Chapter 61.

Islet allograft dysfunction—rejection versus islet "burn-out"

Although the clinical success of islet transplantation can be assessed by the reversal of the diabetic state, histological assessment of the islet graft following portal vein injection has remained elusive. Although percutaneous liver-needle biopsy is feasible following islet transplantation, it has been demonstrated to have limited practical application, with islet identification in only 31% of biopsy samples [28]. Non-invasive imaging of islet grafts following transplantation, with correlation of islet function or rejection, has yet to be formally established [29]. The inability to ascertain a histological assessment of islet engraftment has thus led to measures of islet transplant success based on degree of insulin requirement post-transplant, as well as serum C-peptide, HbA1c, and glucose levels.

The inability to accurately image islets infused into the portal system has made it difficult to resolve the question of whether islet dysfunction is related to rejection versus non-immune mediated islet loss (i.e. "burn-out"). It has been speculated that the islet loss may be related to the inability of islets to replace beta cells in the absence of a precursor population, or stem cell. However, recent success with long-term islet allografts following induction with lymphocyte depletion has suggested that the early graft dysfunction noted in the Edmonton trial may have been related to inadequate immunosuppression, rather than early islet burn-out. Indeed, single-center results with utilization of more rigorous immunosuppression protocols have demonstrated insulin independence for a mean of >3 years in up to 66% of islet recipients [30]. Most current clinical islet trials are using induction with lymphocyte depletion and more aggressive maintenance regimens, reflecting the concern with controlling the immune response following beta cell replacement in the type I diabetic recipient. This is analogous to the evolution of more aggressive immunosuppression regimens following solid organ pancreas transplantation, and may be related to the necessity to control both the alloimmune and autoimmune response. Long-term insulin independence rates following islet transplantation with lymphocyte depletion are approaching that achieved following PTA.

Islet rejection

Although a large body of literature on rodent and large animal models of islet transplantation and rejection exist, there remains limited information of the histological assessment of acute or chronic islet allograft rejection in humans. Based on studies of rodent islet transplant, it appears that islet rejection is driven principally by the indirect pathway of antigen presentation (see Chapter 5 for complete discussion of indirect pathway recognition). Although there is an obvious lack of data concerning the path of rejection in human islet transplantation, the potency of the alloimmune response can be implied based upon the problematic sensitization seen in clinical trials of islet transplants [31].

The diagnosis of clinical islet rejection, whether acute or chronic, is solely based upon the return to a hyperglycemic state, with the rate of return post-transplant determining the identification of an acute or chronic process. Intensification of immunosuppression is warranted, with consideration of therapy directed at antibody-mediated rejection should donor-specific antibody be detected in the postoperative period [32].

Summary

Whole-organ pancreas transplantation has emerged as a safe and durable treatment for the diabetic patient. Continued aggressive surveillance and treatment of acute rejection episodes, especially in pancreas-alone transplant recipients who remain at higher risk for acute rejection, is currently the only effective strategy to address late allograft loss from chronic rejection. Although islet transplantation remains experimental and hindered by the inability for postoperative histological assessment of the cellular grafts, there continues to be progress in long-term success rates utilizing single-donor pancreata for islet isolation concomitant with aggressive immunosuppression protocols. Further refinements in islet isolation, investigations into various islet sources (stem cell-derived beta cells), as well as novel safe and effective immunosuppressive agents, will increase the option for beta cell replacement in the type I diabetic recipient.

Introduction

Rejection is one of the foremost complications of intestinal transplantation; it is second only to sepsis (which frequently follows treatment of rejection) as the leading cause of mortality, graft loss, and morbidity [1–5]. Severe, unrelenting acute rejection can progress to the most feared form—known as the exfoliative form—in which large segments of the intestinal mucosa slough off as a result of a massive epithelial damage [6,7]. Predictably, such forms of severe rejection have been associated with the worst outcomes for patients.

The intestinal graft is at particular risk for the development of rejection for multiple reasons, including the diversity of tissues and cell types within the intestinal wall, the large amount of immune-competent hematopoietic and lymphoid cellular mass in the mesentery and intestinal submucosa, and the presence of bacteria within the lumen of the intestine, which can trigger immunological responses [8,9]. Additionally, as the rejection process ensues, the loss of integrity of the epithelial intestinal mucosa allows for translocation of the intraluminal bacteria and subsequent development of sepsis. The latter is at times the only heralding sign of an acute rejection episode [10]. Rejection also impairs the absorption of immunosuppressive medications, thus thwarting attempts to bring it under control.

Development of acute rejection in the intestinal graft can occur at any time after transplant and usually presents as either cellular rejection or humoral rejection. Chronic rejection can develop as an unexpected long-term complication or, more commonly, follow recurrent episodes of acute rejection. The clinical symptomatology and treatment of the various forms of intestinal rejection are discussed herein. The histopathological details of intestinal rejection are discussed in detail in Chapter 86.

Acute cellular rejection

The most common form of rejection observed in recipients of an intestinal transplant is acute cellular rejection (ACR). In the earliest published series, up to 60–70% of all patients experienced at least one episode of ACR [1,2,5]. More recent series show that rejection rates can be reduced to as low as 30% when induction therapy is utilized [3,4]. ACR can occur at any time after transplantation, including many years after transplant, but it is usually a complication seen within the early postoperative period. The initial episode of acute rejection is typically seen around 2–4 weeks. More than 70% of all rejection episodes are observed within the first year of transplant [11]. It is widely documented that the presence of a liver graft within the intestinal transplant confers the intestinal graft some degree of protection from developing ACR as compared to intestinal graft alone [2,4,12,13]. There is evidence that the multivisceral graft may provide some protection even in the absence of a liver [3,11].

The severity of ACR is usually graded as mild, moderate, or severe based on pathologic findings [14,15]. Pathological readings of "indeterminate" rejection (suspicious but not clear-cut findings to meet criteria for "mild") need to be correlated with endoscopic and clinical findings and, if necessary, endoscopy and biopsy are repeated for a definitive diagnosis. "Subclinical" rejection is a pathologic diagnosis in the absence of endoscopic or clinical signs. It has to be attended carefully because, if untreated, it has been shown to be associated with inferior outcomes [16].

The length of each rejection episode is directly related to its severity. Mild rejection episodes usually last for about 1 week and for each worsening grade the duration of the episode doubles, with moderate ACR episodes lasting about 2 weeks and severe rejection episodes lasting about 1 month [11]. Prolonged periods of rejection lasting over 45 days are significantly correlated with graft loss from rejection [11].

Symptoms

The initial stages of intestinal graft rejection are usually asymptomatic. Symptoms are typically associated with advanced stages and include increased stoma output, abdominal distension and pain, fever, and sepsis. Stoma output not only increases in volume but also can change its characteristics, becoming watery. Reduced and bloody stoma outputs are late, grave signs. In the most serious cases of exfoliative rejection, gelatinous casts of fibrin and intestinal mucosa are expelled through the stoma. Abdominal pain is acute, persistent, and poorly responsive to pain medications. Abdominal distension is often present in such patients due to ileus, mesenteric, and intestinal wall edema. Fever almost always accompanies the insurgence of ACR, either from the systemic inflammatory response or due to superimposed infection from bacterial translocation. Such symptoms cannot be underestimated and patients

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

experiencing such symptoms should undergo emergent endoscopy, since even a 24-hour delay could significantly affect the outcome. The same symptoms can also be seen during infection episodes, especially viral enteritis; therefore, it is important that diagnosis be made as soon as possible by endoscopy and biopsy.

Diagnosis

The gold standard for diagnosis of ACR is endoscopic evaluation of the bowel mucosa followed by pathological analysis of multiple biopsy specimens [1–5,8,11]. According to the interval of time from transplant to current episode, the patient will receive either endoscopy through the ileostomy or natural orifice endoscopy. The goal is to reach and evaluate the mucosa of the distal ileum, whenever possible, since the ileum is the most affected area during ACR. Indeed, different segments of the gastrointestinal tract develop rejection with different frequency. In a paper describing the relative frequency of rejection in multivisceral transplant organ explant specimens, overall detection of ACR in the small intestine was in 25.5% of cases, 12.2% in the stomach, and 16% in the large intestine. In patients undergoing ACR, the relative frequencies were 80.0% in the small intestine, 38.5% in the stomach, and 33.3% in the large intestine [17]. If the distal ileum cannot be reached, the proximal jejunum can be sampled as an alternate site.

Even when rejection affects the distal ileum, it may leave some areas intact ("skip zones"); therefore ileoscopy should be carried for a good length of intestine (at least 15–20 cm) and multiple biopsies obtained at different levels. Any area of abnormality should be sampled, as should normal-looking mucosa for comparison. On areas where ulcerations are present, a biopsy at the edges of the lesion will yield better results than the center of the ulcer. Diagnostic endoscopy alone can help to rule out gross changes in the bowel mucosa. In patients who can accommodate large scopes, zoom endoscopy of the intestinal mucosa allows for an in-depth evaluation of the intestinal villi and defines alterations in their height, shape of the villous tip, erythema of the mucosa, and friability [18].

Serum citrulline levels, which can also be measured on a dry blood spot, may be useful for the diagnosis of ACR. These levels stabilize at approximately 3 months after transplantation [19,20]. A sudden drop from a stable baseline level or absolute levels below 13–15 μmole/L is strongly associated with episodes of moderate and severe rejection [19,21]. Similar to what we observe with blood urea nitrogen and creatinine in kidney transplantation and liver function tests in liver transplantation, these changes are not pathognomonic, as they can be associated with other causes such as infections or ischemia. They should prompt endoscopy and biopsy to confirm the diagnosis. Calprotectin levels in stools have also been proposed as an alternative non-invasive marker [22].

Recently, analysis of the trend in donor-specific antibodies (DSA) and panel of reactive antibodies (PRA) has been correlated with the presence and response to treatment of acute cellular, as well as mixed cellular, and humoral rejections [23,24].

In search of alternative markers for rejection, more recent studies have been performed both on peripheral blood and on the mucosal biopsies from intestinal transplant recipients [25,26]. In the study of peripheral blood, samples were taken and compared to simultaneous mucosal biopsies during different stages of rejection. The authors showed that there is a significant down-regulation in the expression of several genes implicated in translation-related proteins, with the ribosomal protein L13a (RPL13a) being the most affected during episodes of rejection [25]. The hypothesis is that such events may occur early during the course of rejection and that, therefore, this assay could be used as a potential non-invasive marker for rejection.

In another study, formalin-fixed paraffin-embedded samples were examined in patients with and without biopsy-proven ACR. Significance analysis of microarray (SAM) of the mRNA from such biopsies revealed distinct gene patterns between patients undergoing rejection and patients without rejection. During rejection episodes, there was an over-expression of leukocyte-specific surface markers as well as several chemokines and costimulatory molecules [26].

None of these markers can yet replace pathological analysis of the intestinal mucosa biopsy, which remains the gold standard for the diagnosis.

The differential diagnosis of ACR includes infectious enteritis, whether viral or bacterial, and in such cases the pathology of the intestinal biopsy is of assistance. Testing for viral infections, both systemic including Epstein–Barr virus (EBV) or cytomegalovirus (CMV), respiratory (viral panel for respiratory viruses), and enteroviruses should be performed. Stool specimens should be collected to test for common pathogens such as *Clostridium difficile*, *Cryptosporidium*, *Giardia*, and other parasites.

The final diagnosis of ACR is based on the combination of clinical findings, symptoms, and pathological evaluation of the intestinal biopsy. Once diagnosis has been established, treatment should be started immediately.

Treatment

Empiric treatment of rejection with a bolus of corticosteroids is accepted practice in cases when the patient cannot be readily transferred to the transplant center or when endoscopy is not immediately available.

Treatment of ACR is based on three simultaneous principles: increase in baseline immunosuppression, treatment course with steroids and/or antilymphocyte agents, and antibiotic prophylaxis for opportunistic infections.

First, primary immunosuppressive agents (usually tacrolimus) are increased from baseline levels to levels similar to the immediate post-transplant period (15–20 ng/mL). It has to be noted that tacrolimus levels may rapidly increase during an episode of rejection, due to a more rapid absorption of the drug through a permeable intestinal mucosa as well as a decreased tacrolimus metabolism at the level of the enterocytes.

Second, boluses followed by a weaning cycle of steroids are used to control mild episodes of rejection. For moderate and severe rejection, antilymphocyte agents such as thymoglobulin or alemtuzumab are used, for periods ranging from a few days up to 2–3 weeks, until clinical and histological resolution of the ACR episode. Additional therapies for resistant rejection include the use of antitumor necrosis factor monoclonal antibodies, such as infliximab [27]. In those episodes of rejection where a vascular component is present, and in which there is a suspicion of antibody-mediated rejection (often accompanied by an increase of DSA/PRA), several strategies to decrease humoral response are utilized. These include: the use of rituximab, a monoclonal antibody against the CD20 marker present on B lymphocytes; plasmapheresis, which removes circulating antibodies, coupled with the use of intravenous immunoglobulin (IVIG); and bortezomib [28,29]. Addition of a second baseline immunosuppressive agent such as sirolimus is an option for those patients who may need prolonged higher levels of immunosuppression, as well as for

those in which chronic rejection may be ensuing, because sirolimus inhibits fibroblast proliferation and can possibly slow down fibrosis in a previously injured graft [30].

The third principle of management of ACR is the use of adequate antibiotic coverage. Patients are at a very high risk of developing infections during an episode of ACR not only because the integrity of the intestinal mucosa is altered and bacterial translocation is common, but also because the use of strong immunosuppression will expose the patient to opportunistic infections. Patients being treated with antilymphocyte agents should be covered with empiric antifungal and antiviral therapy to prevent CMV or EBV infection or reactivation. Additional antibacterial therapy is often added and should target the enteric flora, including anaerobe and possible antibiotic-resistant bacteria, such as vancomycin-resistant *Enterococcus* (VRE). It has to be noted that many patients develop sepsis as a first sign of ACR and therefore empiric antibacterial coverage is often started even before final diagnosis of ACR is made.

In those cases where rejection cannot be controlled and where the patient's clinical status is deteriorating, graft enterectomy is a therapeutic option, presenting the following advantages: removal of a non-functional graft that is causing bacterial translocation and infectious complications; a rapid wean off immunosuppression; and the opportunity to prepare for re-transplant when the patient's clinical condition allows [4,7]. In cases of liver–intestine or multivisceral transplantation, removal of the whole graft is not possible; however, removal of the small intestine alone can be performed while the rest of the allograft (liver for liver–intestine grafts and liver–stomach–pancreas for multivisceral grafts), which is generally less susceptible to rejection, can be left in place. Successful re-transplantation of the intestinal component alone can be performed at a later time after graft enterectomy. Lastly, when intestinal graft enterectomy is considered, a useful presurgical procedure embolization of the graft arterial supply by interventional radiology will allow for a decrease in intraoperative blood loss, as well as a clear demarcation of the transplanted graft from the native intestine [31].

Outcomes

Mild rejection episodes usually resolve with short courses of treatment and no residual dysfunction of the intestinal graft. On the other hand, severe ACR episodes, prolonged moderate ACR episodes, and repeated occurrences of ACR have been clearly associated with worse outcomes, both in graft and patient survival [11]. The worst form of severe rejection, exfoliative rejection, results in graft loss in over 50% of cases with a significant increase in patient morbidity and mortality [4,6,7].

Infectious complications are the most common immediate cause of death in patients being treated for ACR. The most common sites of infection are pulmonary (especially in pediatric patients), either viral or bacterial, and central blood stream infections associated with central venous catheters and/or driven by bacterial translocations.

Although an episode of ACR may be successfully treated, medium- and long-term consequences are always of concern: for instance, the incidence of viral infections weeks or months after treatment is quite high and post-transplant lymphoproliferative disorder (PTLD) can develop if there is a reactivation of EBV viremia.

Lastly, ACR can lead to the development of chronic graft rejection, which will be detailed elsewhere in this chapter.

Other forms of acute rejection

Antibody-mediated acute rejection

Antibody-mediated rejection is driven by allospecific antibody and predominantly targets the intestinal graft endothelium. This results in micro- and macrothrombosis and consequent ischemic injury to the graft [32]. High alloantibody levels are found in 18% to 30% of patients waiting for intestinal transplantation [33]. These patients, as well as others who mount de novo donor specific antibodies (DSA) following intestinal transplantation, are prone to develop humoral and mixed cellular/humoral rejections. If a patient was previously sensitized, for instance a patient undergoing re-transplant who lost their graft from previous episodes of rejection, this patient will often have high titers of preformed antibodies or DSA [34,35].

Hyperacute humoral rejection in the operating room presents with sudden congestion of the intestinal graft, discoloration, edema, and loss of arterial pulsatility. The classic hyperacute rejection syndrome that occurs minutes after perfusion of the graft is rare. The few reported cases were associated with discoloration, congestion, and rapid loss of the graft. Interestingly, we have witnessed one such case with documented humoral rejection that responded to treatment with alemtuzumab, rituximab, and plasmapheresis. This patient had an uneventful subsequent course and is well with a perfectly functioning graft 5 years after transplant [36].

The more common syndrome, which is increasingly being recognized, appears several days or a few weeks after transplant and is associated with a rapidly evolving cellular rejection, concomitant rise of PRA and DSAs and characteristic pathologic findings. Accelerated acute rejection can happen a few days after transplant and presents with abdominal distension and tenderness, bloody stoma output or no stoma output, endoscopic appearance of mucosal congestion, and erythema with friability.

Humoral (acute antibody-mediated) rejection is not as well defined in pathological specimens as is ACR, but there is a growing body of histological evidence that antibody-mediated damage at the level of the small- and medium-caliber vessels can contribute to organ damage and either worsen a concurring episode of ACR or alone cause subclinical damage to the graft and lead to chronic rejection. There are no definite clinical signs or symptoms of humoral rejection; however, pathological findings of vascular congestion, deposition of complement components C4d and C3d within the lamina propria of the vessels, or deposition of immunoglobulins along the vessels, can suggest an ongoing process, especially when the patient develops an increased titer of DSA or PRA [34].

A third syndrome, which is being increasingly recognized, is the gradual rise of the antibody levels without evidence of rejection. In the absence of established criteria for treatment, we follow these levels very carefully and treat patients who have been hypersensitized in the past or with a history of repeated rejections.

Treatment of the humoral rejection usually follows concurrent treatment of the episode of ACR, but targeted attack to humoral immunity mechanisms has to be included, with a combination of plasmapheresis, IVIG, and rituximab or bortezomib. Persistence of either cellular rejection or high antibody titers is ominous.

In those rare cases of hyperacute or accelerated acute rejection, graft removal is almost always required; if pharmacological therapy is attempted, it should include aggressive use of antithymocyte agents, in addition to plasmapheresis, rituximab and other agents that target antibody-mediated responses.

Chronic rejection

Approximately 15% of patients receiving an intestinal transplant will develop chronic rejection [4]. Risk factors include the number and length of previous episodes of ACR, especially moderate and severe episodes, viral infections, and previous episodes of PTLD [4,37].

Signs and symptoms are not always easy to detect. Patients usually develop: chronic malabsorption, with increased stool output and occasionally steatorrhea; frequent dehydration episodes requiring intravenous replacement; and repeated episodes of abdominal distension and pain. Upon endoscopy the mucosa may appear normal or near normal, though the intestinal villi are often flat. Intestinal absorption tests will be abnormal in such cases and patients often require parenteral nutrition supplementation. Chronic rejection also leads to the development of strictures in the bowel graft and recurrent episodes of small bowel obstruction.

Radiological studies will show thick, matted loops of bowel with loss of mucosal folds and poor motility with a lead tube appearance of the graft. Encapsulating peritoneal sclerosis has also been described in a few cases, although this finding is usually evident only in the operating room [38]. Most studies of chronic rejection have focused on the histology of explants after death or graft enterectomy [17,37]. This is due to the fact that intestinal mucosal biopsies are too superficial to evaluate the small and medium-sized vessels located in the muscularis mucosae layer of the intestinal wall. Therefore the diagnosis of chronic rejection can be made only indirectly if significant mucosal fibrosis with crypt loss is observed or at the time of the organ removal when the whole thickness of the bowel wall can be evaluated [39].

Some patients will develop only focal areas of intestinal strictures, especially in the distal ileum; in such few selected cases, it is possible to perform partial small bowel resection of only the affected areas and save the rest of the intestinal or multivisceral graft. In many cases, however, removal of the graft will be required. In cases of complete enterectomy, preoperative embolization of the intestinal graft is advisable because it demarcates the graft, facilitates the resection, and helps to reduce blood loss by clearly demarcating native and transplanted bowel [31].

Summary

It is clear that rejection is one of the most significant issues in the management of any intestinal transplant patient. The significant morbidity and mortality associated with the development of rejection episodes results in poor long-term survival rates. Important advancements have been made over the years and rejection rates have improved significantly. It is universally accepted that induction therapy has to be given at the time of transplant, whether with antilymphocyte agents or interleukin-2 receptor inhibitors. It is also clear that a very high index of suspicion must be maintained at all times, not only during the first year after transplant. Definitive diagnosis of any rejection episode requires endoscopy and biopsy; non-invasive markers of rejection, although helpful, have not yet been able to replace histological analysis. Early and aggressive treatment of rejection episodes prevents progression of severity and potential graft loss. Infection complications must be tackled simultaneously with treatment of any episode of rejection. It is yet unclear how chronic rejection can be prevented and how to best treat antibody-mediated rejection episodes. Monitoring and modulation of the recipient humoral response is rapidly becoming a critical issue as compared to the past. DSA/PRA levels, cross-match at the time of transplant, desensitization protocols for presensitized patients, and use of agents like rituximab and bortezomib are all tools that should now become standard of care when treating patients after intestinal transplantation.

CHAPTER 75

Clinical Allograft Rejection Syndromes in Vascularized Composite Allotransplantation

Stefan Schneeberger[1,2] and Gerald Brandacher[2]

Introduction

With the number of hand and face transplants approximating 100, accumulating data indicate that even though the skin, a highly immunogenic tissue, is part of the graft, hands and faces are not irreversibly rejected after transplantation [1–8]. Graft survival at 1 year after such transplantations appears to be consistent with that in other organ transplants. Induction therapy with monoclonal or polyclonal antibodies (as used in most cases) together with a triple maintenance immunosuppression regimen is sufficient to prevent early graft loss [1–8]. However, episodes of acute skin rejection are observed in most patients at rates that appear higher than those associated with other organs and, indeed, these rejection episodes can lead to graft loss: one hand was lost due to late acute rejection (AR) after stopping immunosuppression, and a second was lost in response to "skin inflammation" that was not further specified [1,8,9]. Furthermore, steroid-resistant rejections are frequently observed and require treatment with antithymocyte globulin (ATG), basiliximab, or alemtuzumab [1,8–10]. Scientific reports indicate that the majority of patients demonstrate at least one episode of AR in the first year and that skin was the primary target of the immune response [1–10]. Repeated episodes are observed in some patients beyond the first year after transplantation [1,5–10].

The high frequency and severity of AR in hand transplantation has been attributed to the high immunogenicity of the skin, which forms a major component of the graft. The high antigenicity of the skin can in part be related to the high proportion of potent antigen-presenting cells (Langerhans cells) and keratinocytes, which express MHC I constitutively and MHC II, ICAM-I, and proinflammatory cytokines upon stimulation [11–20]. Also, viral infections, in particular cytomegalovirus (CMV), have been postulated to trigger the episodes [21]. It also has been postulated that the higher incidence of AR reported in hand transplants is due to the ability to visually detect rejection (resulting in an increased positive prevalence). Accessibility of the skin component of a hand allograft enables biopsies to be taken routinely and whenever clinical suspicion warrants histopathologic confirmation. Thus, visual monitoring allows for diagnosis of conditions in hand transplants that may often be missed in organ transplants.

Clinical allograft rejection syndromes are a consequence of an immune response toward one or more of the tissues comprising a vascularized composite allograft (VCA). While skin rejection is most frequently observed after human hand and face allotransplantation, an immune response toward tissues other than the skin has been documented [22–24].

Within the first year post-transplant, approximately 85% of recipients experienced at least one episode of acute skin rejection [1]. The clinical relevance and long-term implications of skin rejection on graft survival and functional outcome remains unknown. An evaluation of over 170 skin biopsies taken from five human hand or forearm transplant recipients revealed that most skin rejections were histologically mild (grade I) [25].

This chapter presents the clinical appearance, diagnosis, and treatment of skin rejection following transplantation of a VCA. Given the low number of transplants performed to date, most data are anecdotal compared to other organ systems. The histologic appearance is covered in greater depth in Chapter 87.

Diagnosis, definition, and mechanisms

Skin rejection

Observations made in the first decade of human hand and face transplantation point toward the skin as a prominent target for rejection [1–10]. More recent findings, however, indicate that also the vasculature of the graft may be affected and proliferation of the myointima can occur [23]. Indeed, these vascular effects may be more consequential with regards to long-term graft survival. Skin rejection usually manifests with maculopapular skin lesions, which can be restricted to small areas or spread over the whole allograft. They vary in color and location and present with or without edema and onychomadesis [5,10,26]. In contrast to solid organ transplantation, rejection of skin-containing VCAs can be diagnosed by visual inspection. In combination with the histopathology of skin biopsies, this allows for rapid diagnosis of rejection, but may also confound the clinical situation as other non-alloimmune processes such as fungal infection and autoimmune diseases can present as a rash. The main histopathologic finding of skin rejection is an immune cell infiltrate, varying in location, distribution, and

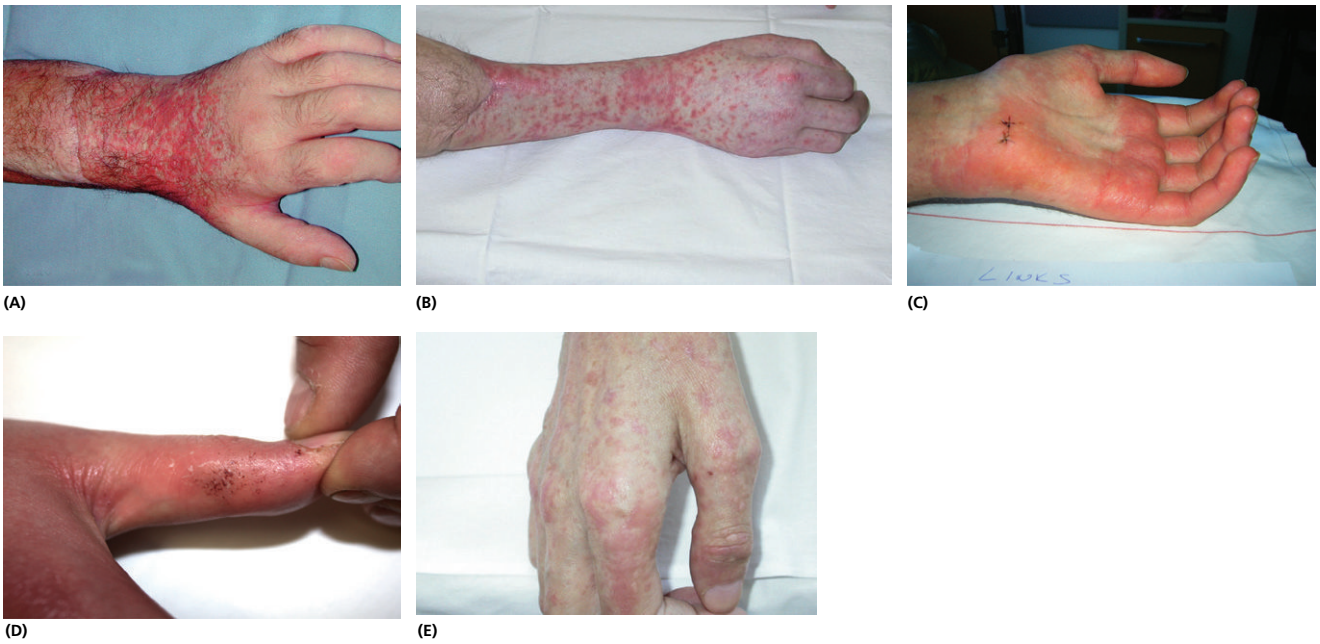

Figure 75.1. The heterogeneity of the appearance of skin rejection in hand transplantation. Very commonly, rejection appears on the forearms with confluent maculopapulous lesions on the dorsum of the forearm (A). Lesion can be heterogeneously scattered over the entire graft (B) or have a specific localization such as the palm of the hand (C) in different types of rejection. Upon mechanical stress and stimulation, rejection may appear on exposed areas (D). Late after transplantation the appearance may differ from rejections early after transplantation and be brighter in color and less prominent (E).

expansion, depending on rejection severity, as well as apoptotic and necrotic cells/tissue in more advanced stages [9,22,26].

The "classic" lesions of skin rejection in hand transplantation affect the dorsal and volar aspects of the forearm and wrist and, in some cases, the dorsum of the hand. The appearance of skin rejection varies interindividually, and even within one patient the presence of rejection can differ from one episode to another one (Figure 75.1). AR has been characterized as a maculopapular erythematous skin rash that may be diffuse, patchy, or focal, with or without burning pain. The location, color, size, and progression of the lesions can differ.

While the palm of the hand and the nails, usually are spared, an "atypical" pattern of rejection involving the palmar skin and the nails has been observed in a series of four patients [10]. In these cases, all patients were young and exposed to repetitive and persistent mechanical stress of the palm. Characteristic features of these rejections included a desquamative rash associated with dry skin, red papules, scaling, and lichenification localized to the palm. Skin lesions were associated with nail dystrophy, degeneration, deformation, or loss. This type of rejection also seems to differ with regard to the heterogenic pattern of rejection on the palmar skin and appendages like nails. The involvement of the nail bed/matrix by rejection leads to weakening/thinning of nail plate followed by loosening of the nail from its bed. Although also observed in conventional types of rejection, resistance to steroids seems to be more frequent in this type of rejection. Histology of the skin and nail bed revealed a lymphocytic infiltrate with predominance of T cells ($CD3^+$, $CD4^+$, $CD8^+$) with small numbers of B cells ($CD20^+$, $CD79a^+$) and a low number of $FOXP3^+$ cells. The lesions persisted over weeks to months, responded poorly to steroid treatment, and were managed with antithymocyte globulin, alemtuzumab and/or intensified maintenance immunosuppression.

Repetitive and significant mechanical stress could not only initiate but also sustain an inflammatory and immune response in the skin of the palm. A neutrophil-mediated induction and acceleration of AR has been described previously and might also be a relevant mechanism in this context [27].

At this point, any erythematous skin rash on a VCA independent of specific appearance size, location, progression has to be considered a skin rejection until proven otherwise. Differential diagnoses include skin infection, pemphigoid, and other skin inflammatory disorders and hyperemia (usually not associated with a rash); a skin biopsy should be performed in any event.

Mechanisms of skin rejection

Based on experimental, clinical, and histologic assessment, AR in VCA seems to be a predominantly cell-mediated immune response directed against the skin—most prominently the epidermis. While the dominance of $CD4^+$ or $CD8^+$ $CD3^+$ T cells has shown some diversity between centers and reports, the phenotype of the cellular infiltrate is dominated by CD3 T cells in any case of skin rejection in VCA [28–30]. Macrophages comprise 10–50% of the infiltrate in mild to moderate skin rejection. In grade IV rejection, $CD68^+$ macrophages are the dominating cell type.

In-depth histopathologic examination of skin biopsies of human hand and face allografts indicates that skin rejection is a dynamic and multistep process. After transmigration through the vessel wall the T cells form a dermal immune cell infiltrate (mainly composed of $CD3^+$ T cells), located in the perivascular areas [29]. Inflammatory cells then spread within the dermis. Guided by a number of cytokines, the cell infiltrate starts to migrate toward the epidermis as rejection progresses. Keratinocytes are known to secrete numerous proinflammatory cytokines when activated [29] and this may further enhance the recruitment and attraction of inflammatory

cells. The induction of apoptosis and necrosis of single keratinocytes, followed by dermal–epidermal separation and finally necrosis of the epidermis, is the final step in the cascade of skin rejection [9,26,29]. In animal models where the size of the graft and the skin defect is limited, regeneration starting at the margins of the graft results in reconstitution of the skin and coverage of the defect [30].

Investigation of adhesion molecules in human hand allografts revealed an up-regulation of E- and P-selectin, which are responsible for leukocyte rolling along the vessel wall, and also ICAM-1 on the vascular endothelium and its counterpart LFA-1 on lymphocytes, which enable cell adhesion to the vessel wall [29]. Expression of all adhesion molecules is particularly up-regulated during severe rejection, indicating that adhesion molecules mediate leukocyte and lymphocyte rolling and adhesion to the vessel wall in the dermis as one of the initial steps in skin rejection [29].

The clinical relevance of antibody-mediated rejection (AMR) in VCA is not well defined [31]. In two different studies and a large set of skin biopsies taken from human hand and face allografts, $CD20^+$ B cells were sparse or absent [29,31,32]. Aggregates of B cells located in the dermis and subcutis were found only in one case of severe allograft rejection [28].

C4d deposition was found in the capillaries of two human hand allograft recipients in the presence of cellular rejection [33], but was also found in the absence of clinical rejection. When analyzed in a large set of skin biopsies, C4d staining was positive in 50% of specimens from six human double hand/forearm transplant recipients showing rejection [29]. Donor-specific alloantibodies (DSA, HLA class I/II) were negative in all cases reported [28,33,34].

Grade I skin rejection

Mild skin rejection represents a particular problem in VCA. While it is commonly observed, its clinical relevance is not well defined. A comprehensive histologic and immunohistochemical analysis of mild rejection revealed a $CD8^+$-prominent cellular infiltrate with sparse $CD20^+$ B lymphocytes and $CD68^+$ macrophages. Adhesion molecules LFA-1, ICAM-1, E-selectin, P-selectin, and VE-cadherin are up-regulated and C4d staining was mainly positive in samples at time points later than 1 year. There was a tendency toward increased indoleamine 2,3-dioxygenase (IDO) expression and more $Foxp3^+$ cells at later time points [25]. A tolerogenic phenotype of a proportion of the infiltrating cells (IDO or Foxp3 expression) was observed during grade I rejection and the percentage of these cells increased at later time points. This observation suggests that regulatory mechanisms are present within the skin of the allograft and may contribute to self-limitation of the alloimmune response [25].

Assessment of skin rejection

When the first hands were transplanted, it was assumed—based on observations in experimental limb transplantation—that the skin might be the primary target for AR. Biopsies of the skin were therefore obtained routinely or whenever clinically indicated. After the first hand transplants had been performed, it became apparent that an erythema with maculopapulous erythematous lesions on the skin represented the macroscopic picture of rejection and correlated well with histomorphologic findings [2–10].

Rejection occurs affecting a heterogeneous pattern of the skin; biopsies taken close to the lesions but not exactly from the affected areas may show normal histology. Therefore, the exact site of skin sampling is of utmost importance. Biopsy specimens are collected as per protocol or whenever clinically indicated. In hand and arm allografts, the forearm or upper arm as sites for taking biopsies are considered anatomically less problematic when compared to the hands. In any case, biopsies need to be taken from the lesions. In face transplant patients, biopsies may be taken from a "sentinel skin flap" often transplanted together with the face. The correlation between skin rejection on a sentinel skin graft and a facial allograft, however, needs to be more convincingly established before biopsies taken from such a distant site can be considered reliable. Histologic and immunohistochemical investigation of skin biopsy samples should be performed according to the 2007 Banff Classification for skin-containing VCA (see Chapter 87).

In summary, the skin seems to be the most evident target for an immunologic response after hand transplantation with early rejection additionally characterized by some minor mononuclear cell infiltration in other compartments, primarily the perineurium and connective tissue. The role of alloantibody remains speculative, but likely to emerge with additional clinical experience. Vascular injury, be it from cellular- or antibody-mediated mechanisms, is concerning both for its prognostic implications and the general inability for it to be assessed directly on biopsy.

Grading of acute skin rejection

Currently, the skin is the component of a VCA routinely monitored for rejection. An erythema comprised of maculopapulous lesions scattered irregularly over the transplanted hand is the clinical feature of AR. So far, such an erythema has always been associated with a mononuclear cell infiltrate as the histologic sign for rejection; in our experience, however, absence of macroscopic lesion does not necessarily indicate normal skin histology. In relation to what has been described previously in kidney transplantation, this is referred to as "subclinical rejection."

The main histologic feature of cellular rejection is a mononuclear cell infiltrate. It first appears in the perivascular space of the dermis. If rejection progresses, the infiltrate spreads to the interphase between dermis and epidermis and/or adnexal structures. A cellular infiltrate within the epidermis is typical for a moderate rejection with the immunologic response reaching the outermost layer. When rejection is not successfully treated at that stage, the inflammatory character of this process shifts toward destructive features; necrosis of single keratinocytes can be observed resulting in focal dermal–epidermal separation. With further progression, necrosis and loss of the epidermis as the ultimate stage of skin rejection is assumed to be irreversible.

The composition of infiltrating cells does not allow for distinction of rejection of a hand transplant from dermatitis; however, when lesions are clinically limited to the graft, rejection can be assumed. In addition, it is rather unlikely that an unspecific dermatitis would occur under immunosuppression.

Rejection of tissues other than skin

Limited information is available about the involvement of components other than the skin in AR. Biopsy samples from bone, vessels, nerves, or muscles have not been routinely obtained clinically. Based on clinical reports, tissues other than the skin are affected to a lesser extent, but this reflects some selection bias with regard to sampling [1,3–6,8,9,22].

Probably the best individual example is the systematic histopathologic assessment of the hand amputated 2.5 years after transplantation in Lyon. Although the hand revealed erosive and necrotic areas over the skin, only mild inflammation in muscles and tendons and no changes in bones and joints were observed [22].

Additional evidence from deep tissue biopsies confirmed a dominance of the immune response toward the skin but also revealed cellular infiltrates in muscle and connective tissue. Infiltrates in larger vessels and a perivascular infiltrate in muscle, tendons and nerves together with a lymphocytic infiltrate in the bone marrow, however, indicate that other compartments can be affected to some extent [22–24]. Potential long-term effects of such limited lymphocytic activity remain to be elucidated and tools other than biopsies are needed for monitoring these compartments. However, in some patients the vasculature, too, has demonstrated hyperplasia of the intima indicating vasculopathy and resulting in loss of the hand in one case [23].

In summary, there is good evidence that a VCA in aggregate induces less immune response than the individual components; this is convincing data supporting the concept that the skin elicits the strongest immune response, and weak evidence that tissue mass has an impact on allograft rejection.

Chronic rejection

A 1-year graft survival of 100% achieved in hand transplantation is better than any outcome achieved in solid organ transplantation. However, this is to be interpreted in light of the fact that in other organs, survival is defined functionally, not by the presence of the graft. For VCA, functional parameters remain to be defined in large part due to the lag involved in re-innervation, and the general lack of intrinsic muscle function in distal graft elements. Nevertheless, well-designed immunosuppression protocols together with the chance of early detection of AR by visual inspection may be responsible for these satisfactory early results. It remains unclear at this point if long-term graft survival may be impacted by the development of VCA vasculopathy and degeneration. Experimental evidence suggests that this is a valid concern.

Unadkat et al. have published a systematic analysis of an orthotopic hind limb allotransplantation model in rats in which multiple AR episodes resulted in development of myointimal proliferation and morphologic signs for chronic rejection (CR) [35]. In this model, repeated AR episodes were treated with cyclosporine A and dexamethasone. At postoperative day (POD) 90 animals had gone through 19 episodes of AR and myointimal proliferation associated with concentric luminal occlusion and perivascular fibroses similar to vasculopathy in cardiac transplantation was observed.

In vascularized bone transplantation, six human vascularized allogeneic knee transplantations were all lost within the first 56 months. A histomorphologic assessment of the latest case resulted in detection of diffuse concentric fibrous intimal thickening and occlusion of graft vessels [36]. Findings are comparable to cardiac allograft vasculopathy (CAV). In cases of bone transplantation, the lack of adequate tools for monitoring rejection might have allowed repeated or ongoing AR of the bone, eventually triggering myointimal proliferation and occlusion of graft vessels.

In hand transplantation, one case was described recently in which unmanageable ischemia in the hand resulted in amputation. The histopathologic assessment of the limb revealed significant myointimal hyperplasia in the graft arteries. Hyperplasia was confluent in all studied arteries restricted to donor vessels.

In solid organs, myointimal proliferation and luminal occlusion of graft vessels—the hallmark for CR—have been observed as early as 1 year after transplantation (e.g. cardiac or kidney). Similar findings in one center, where there was of carefully monitoring patients after hand transplantation with high-resolution ultrasound techniques, gave rise to the hypothesis that graft vessel might be the major target of CR also in VCA. In other centers, however, ultrasound, angiography, and CT-angiography scan together with skin biopsies failed to identify early signs of luminal narrowing or occlusion. In conclusion, myointimal proliferation and impairment of perfusion were observed in a small number of patients after hand transplantation, and careful monitoring of the vasculature after hand and face transplantation remains mandatory. With regard to pharmacologic prevention of CR, a beneficial effect has been described for rapamycin [37]. It therefore may be reasonable to include rapamycin in a long-term immunosuppression protocol.

Management

Prophylaxis of rejection

Clinically applied therapy

Since VCAs are derived from genetically disparate deceased donors, recipients need to be immunosuppressed for life to prevent rejection of the transplant. A unique feature of a VCA is that such grafts, unlike solid organ transplants, are composed of a wider variety of tissue components such as muscle, tendon, nerve, blood vessels, bone, and skin. In particular, due to the fact that the skin is thought to be highly antigeneic, historically, VCA has been considered an immunologic challenge [38].This high immunogenicity of the skin has been mainly attributed to skin-specific antigens in the epidermis as well as the presence and high frequency of antigen-presenting cells (APCs), which could act in an immunostimulatory manner by direct presentation of alloantigens [39]. Thus, broader clinical application of hand allotransplantation has been hampered by particularly strong rejection of the skin component, necessitating long-term high-dose multidrug maintenance immunosuppression. This led to considerable concern for adverse effects of those immunosuppressive drugs that are required to sustain the graft. Such risks include, but are not limited to, infection, diabetes, hyperlipidemia, nephrotoxicity, or malignancy and remain the single most important obstacle to routine application of reconstructive transplantation in the clinic.

The current immunosuppressive protocols applied to hand transplantation are extrapolated from regimens used in solid organ transplantation. An in-depth coverage of maintenance immunosuppressive therapy is also found in Chapter 66. However, no standard immunosuppressive protocol has been established for reconstructive transplantation. The overall amount of immunosuppression required to ensure graft survival is comparable or even slightly higher than for kidney transplantation. However, as aforementioned, the use of maintenance immunosuppression in hand transplantation has resulted in a high graft survival at 1 year after transplantation (in patients compliant with immunosuppressive medication) [1]. Such conventional immunosuppressive strategies rely, for the most part, on agents that halt the robust immunologic attack on the graft in a non-specific manner. According to the International Registry on Hand and Composite Tissue Transplantation the majority of hand transplant patients received either polyclonal (antithymocyte globulins, ATG) or monoclonal (alemtuzumab, basiliximab) antibody preparations as an induction agent, followed by a high-dose triple drug combination for maintenance therapy, including tacrolimus, mycophenolate mofetil (MMF), and steroids [1,40]. The level of tacrolimus was adjusted to 10–15 ng/mL during the first 1–3 months and 5–10 ng/mL thereafter by most centers. With regard to steroid management, prednisone doses were rapidly tapered in the early post-transplant period and

then maintained on lowered doses (5–15 mg/day) for 6 to 12 months in most of the patients. Of the 33 patients included in the most recent report of the international registry, all recipients received tacrolimus as the baseline immunosuppressive agent, 26 received mycophenolate mofetil, and 27 received steroids. During the follow-up period, eight patients were converted from tacrolimus to the mTOR inhibitor sirolimus with the rationale to minimize renal side-effects, improve glycemic control, and to potentially avoid chronic vascular changes (myointimal hyperproliferation) and neurotoxicity [41]. In five cases, steroids were withdrawn; two recipients received steroids and low-dose of tacrolimus and everolimus; and two patients received sirolimus and MMF [1,40]. Of those patients who did not receive induction therapy ($n = 2$) or were not started on triple immunosuppressive regimens ($n = 2$), topical steroid and tacrolimus ointments were applied in addition to systemic immunosuppressive medication. As of now, induction therapy followed by maintenance immunosuppression with at least a dual-drug combination at optimum dose can be considered the most widely used treatment protocol for reconstructive transplantation.

Overall, such conventional regimens have proven sufficient to prevent early immunologic graft loss but were not able to prevent AR so that 85–90% of all hand transplant recipients experienced at least one AR episode within the first year after transplantation. This incidence is significantly higher than what is currently seen in solid organ transplantation, where AR rates are less than 10% in selected series during the first year after renal transplantation [42]. However, this is likely influenced by the fact that the grafts in reconstructive transplantation are visible, and this enables immediate diagnosis of rejection based on even minor changes in appearance. Episodes of AR were always macroscopically characterized by erythematous, maculopapular, heterogeneously scattered cutaneous lesions, that correlated well with the histomorphologic findings of mononuclear cellular infiltrates [43].

The other components of a hand allograft like muscle, nerves, tendon and bone do not seem to be subject to significant damage when episodes of skin rejection occur. However, available information on the involvement of these components is still very limited and more data are needed before a final conclusion can be made that the skin is the sole and prime target of rejection in reconstructive transplantation (see also Section Rejection of tissues other than skin).

Chronic multidrug immunosuppression is expensive and causes substantial long-term costs. Furthermore, due to the amount of daily oral medication required and its resulting high patient burden, such regimens frequently lead to non-compliance. However, considering these obvious downsides of multidrug immunosuppression and its various, sometimes severe side-effects, there is an evident need for novel concepts of systemic immunosuppression in VCA to prevent rejection. In this regard, hand transplantation might offer some unique advantages because continuous monitoring of the graft in contrast to solid organ transplants can be performed by simple visual inspection of the skin, this being the main target of rejection. This allows for directed biopsies and unbiased pathologic confirmation of the earliest stages of AR and subsequent timely intervention, treatment, and precise adjustments of immunosuppression on an individualized basis. When treated adequately and effectively, AR does not seem to impair graft function or long-term survival. Therefore, novel strategies to minimize immunosuppression or even to achieve the ultimate attainable clinical goal of transplantation to induce immune tolerance are particularly appealing in hand transplantation and VCA in general. Studies from our own group demonstrated that a whole limb allograft elicited a less intense alloimmune response than did allografts of each of its individual components, thereby challenging the relative scale of tissue antigenicity [44]. In addition, certain types of VCA contain immunocompetent elements such as bone marrow and lymph nodes that may hasten the rejection processes or result in graft-versus host-disease (GVHD). These factors not only govern the immune reactivity of these allogeneic tissues, but also define potential immunomodulating strategies that are different from those currently used in solid organ transplantation.

Experimental therapy

Historically, routine therapy (as outlined above) has been a non-specific suppressive multidrug regimen, administered to dampen the recipient's immune system. Side-effects of such therapy, however, include an increased risk for opportunistic infections, metabolic disorders, or malignancies. For this reason, research has focused on developing new drugs and biologic agents that aim to specifically target key pathways and receptors during allogeneic T-cell activation, in order to avoid the unwanted negative effect on other immune lineages. This significantly reduces undesirable complications while still enabling graft survival [45].

Furthermore, various modifications have been applied over the years to the immunosuppressive protocols used in hand and face transplantation such as steroid sparing/avoidance attempts, alemtuzumab induction, cell-based immunomodulatory protocols, conversion from tacrolimus to the mTOR inhibitor sirolimus for long-term therapy, or the use of topical steroid and tacrolimus ointments to reduce the overall amount of systemic immunosuppression [46].

Interestingly, a small number of organ recipients have been documented to tolerate their grafts, allowing withdrawal of immunosuppression without promoting rejection [47]. This phenomenon of spontaneous donor antigen-specific immunologic tolerance has given rise to the realization that there is a feasible way to overcome histocompatibility barriers not by means of immunosuppression, but rather immunomodulation or immune regulation. In addition, spontaneous tolerance, achieved in experimental organ transplant models, is often the result of an exhausted host-versus-graft immune response. Such a state of operational tolerance is achieved when the immune response toward the transplant is exhausted because the specific cell clones mediating rejection are deleted. Furthermore, maintenance of engraftment has been postulated to be facilitated when a small number of donor leukocytes persist in the recipient (microchimerism) long term [48]. Such strategies would be particularly appealing for the field of VCA since those transplants, even though significantly improving the quality of life, are not considered life saving and have inherent unique biologic features. Nevertheless, the "risk–benefit balance" in VCA needs to be most carefully addressed, probably even more so than in any other type of solid organ transplantation. To date, several small and large animal studies show highly encouraging results when transplanting vascularized composite allografts without the need for long-term maintenance immunosuppression [49,50]. Strategies applied in these experimental models include the use of total lymphoid irradiation, costimulatory blockade (CD28/B7 and CD154/CD40 pathways), selective depletion of alloreactive recipient T and B cells (e.g. $\alpha\beta$-T cell and CD20-specific monoclonal antibodies), inhibition of lymphocyte trafficking, infusion of

$CD4^+CD25^+Foxp3^+$ regulatory T cells and tolerogeneic APCs, as well as donor bone marrow infusion and chimerism induction [29,51–57]. Indefinite graft survival without the need for long-term systemic immunosuppressive treatment was achieved with the use of an immunomodulatory concept employing donor bone marrow cells in complete MHC-mismatched swine heterotopic hind-limb transplant models [58,59]. This concept has been translated into a novel clinical cell-based treatment protocol for reconstructive transplantation by a joint team at Johns Hopkins University School of Medicine and the University of Pittsburgh [60]. In the initial experience, five patients received alemtuzumab induction and maintenance immunosuppression in the form of tacrolimus monotherapy as well as an infusion of unmodified donor bone marrow cells. This study is currently ongoing but has demonstrated thus far that the protocol is feasible and has allowed reconstructive transplantation in upper extremity amputees with low-dose tacrolimus monotherapy.

Along these lines, Mathes et al. have developed a translational protocol that combines a non-myeloablative induction approach and VCA in a canine model that has led to tolerance to all components of the VCA, including skin, without the need for long-term maintenance immunosuppression [61]. Thus, when considering development of novel therapeutic strategies for minimization or avoidance of maintenance immunosuppression following reconstructive transplantation, cell-based protocols including donor bone marrow or stem cells are promising candidates due to the unique nature of VCA. This trend is further fueled by recent advancements in solid organ transplantation, where both cell-based therapies and non-cell based protocols have resulted in reduction or elimination of long-term immunosuppression [62–64]. VCAs can include vascularized bone and bone marrow and might thereby function as a vascularized bone marrow transplant by itself [65]. Such a graft could be a continuous source of donor-derived stem cells, which have been demonstrated in animal models to favorably modulate the host immune response [66]. In this experimental setting, induction of donor-specific tolerance was attributed to the bone marrow component and to specific immunomodulatory protocols permissive for bone marrow engraftment. This recently led to an intense search of optimal bone marrow-based protocols to prolong VCA survival and to induce donor antigen-specific immune tolerance. Along these lines, Barth et al. developed a non-human primate model utilizing selectively mismatched cynomolgus macaques of facial segment allotransplantation to elucidate the unique pathophysiology, immunogenicity, and immunosuppressive requirements of VCA with addition of concomitant vascularized bone marrow [67]. Heterotopically transplanted facial segment VCA with vascularized bone marrow treated only with tacrolimus and MMF but no radiation or T-cell depletion for induction demonstrated prolonged rejection-free survival (205–430 days), compared to VCA without vascularized bone marrow that experienced early rejection episodes and graft loss by postoperative day 7–15 [67]. While VCA with vascularized bone marrow demonstrated sporadic low-level macrochimerism, AR and CR and graft loss occurred after discontinuation of maintenance immunosuppressive therapy. However, radiologic, phenotypic, histologic, and genotypic evidence supported the persistence of viable donor bone marrow within the transplanted vascularized bone marrow component. Interestingly, vascularized bone marrow in this model prevented allosensitization and the development of IgM and IgG alloantibodies even after withdrawal of immunosuppression [67]. Data from this translational study further indicate an important immunoregulatory role of the vascularized bone marrow component in VCA with the potential to reduce the need for immunosuppressive medication.

Despite these advances, overcoming CR still seems to be a formidable task in most transplant cases for solid organs and continues to limit the best possible long-term outcomes. However, if similar concerns are warranted for VCA, they still need to be determined. Thus far, only a few patients have a follow up beyond the 10-year mark and the incidence of CR in VCA seems to be low in this pioneering cohort. There is only one report in the world series of VCA of graft loss in a patient compliant with immunosuppression that showed vascular lesions such as intima hyperproliferation that are reminiscent of CR in solid organ transplantation. This underscores the importance of close long-term surveillance and standardized follow-up protocols in VCA in particular, with more and more experimental minimization and tolerance-inducing protocols emerging.

Treatment of rejection

Clinically applied therapy

Almost all hand and face transplant recipients to date have experienced AR episodes regardless of their induction or maintenance immunosuppressive treatment protocol. Again these rates of skin rejection are higher than those observed after kidney, liver, or heart transplantation. All episodes of skin rejection encountered and diagnosed clinically were confirmed with skin punch biopsies. Similar to maintenance immunosuppressive regimens, treatment of AR mirrors therapies in solid organ transplantation. Additional coverage of rescue therapy in general can be found in Chapter 67. According to the International Registry on Hand and Composite Tissue Transplantation, treatment of acute skin rejection episodes included high-dose bolused intravenous steroids in 60% of all reported cases. In 30% of the recipients, however, increasing oral steroids was sufficient to reverse rejection. Only in 7.5% of patients, in which rejection episodes were steroid-resistant, treatment consisted of antithymocyte globulins, basiliximab, or alemtuzumab [1]. In addition to systemic treatment, topical application of immunosuppressive ointments (tacrolimus, corticosteroid, or flumix) was performed, taking advantage of the unique possibility of treating skin rejection locally. As under-immunosuppression was thought to be the most important cause for sustained rejection, immunosuppression was increased at the same time in most cases.

When a second rejection episode was encountered, steroids were given intravenously with or without topical ointment in several patients. Alternatively, ATG, basiliximab, or topical drugs were given only in a few patients. In one case of a steroid and ATG resistant rejection, alemtuzumab (Campath-1H, Genzyme, Cambridge, MA, USA) was administered and resulted in full restoration of normal skin histology [6]. Thus far, no graft has been lost due to acute irreversible rejection in the world experience with reconstructive transplantation. The definition of graft function as it relates to a VCA differs from that related to, for example, a heart, where mild degrees of damage would be intolerable clinically.

In hand transplantation most rejections were treated successfully with the modalities described above. In one case, namely the first hand transplanted in France in 1998, progressive AR following non-compliance with immunosuppression led to lichen-like lesions of the skin and progressive loss of function and prompted the patient to request amputation of the hand at 2 years and 4 months after transplantation [22]. Although it has been speculated that

rejection might have been reversible, treatment with a steroid bolus and an anti-CD25 antibody did not prevent progression of rejection. In the second case, a severe "skin inflammation" resistant to "any" treatment resulted in amputation of the hand at 3 years after transplantation [1].

Experimental therapy

Topical application of immunosuppressants has been routinely applied for maintenance immunosuppression as well as treatment of AR in most cases of hand transplantation [1–10]. Interestingly, the first report illustrating the concept of topical/local immunosuppressive therapy appeared as early as 1951, in which Billingham et al. found that topical application of cortisone acetate at a dosage that was ineffective when administered systemically prolonged skin allograft survival in a rabbit model [68]. Further examination of local immunosuppression, however, was then abandoned for almost two decades, with the exception of experimental and clinical studies demonstrating the efficacy of local graft irradiation. With advances in drug delivery systems and a more thorough understanding of both the cellular events during allograft rejection and the pharmacokinetics of target-aimed drug delivery such strategies have recently regained particular interest in the field of reconstructive transplantation.

Several delivery techniques including controlled drug release micro- and nanoparticles or other bioengineered matrices, liposomes, gene transfer and cellular co-transplantation have been used in experimental transplant models to direct immunosuppressive agents and molecules to the site of interest within the graft [69]. Hautz et al. characterized the cellular infiltrate and the mechanisms of cell trafficking in acute skin rejection in skin biopsies taken from human hand and forearm transplants [29]. In this sample set, expression of ICAM-1 and E-selectin correlated closely with the severity of rejection. E-selectin was found predominantly in the endothelium of the vessel wall in both mild and advanced rejection. Endothelial E- and P-selectin are known to mediate tethering and rolling of immune cells along the vessel wall as part of the complex multistep cascade that leads to recruitment of alloreactive T cells and other immune cells to the skin. The concept of therapeutically targeting adhesion molecules has also been pursued in inflammatory skin diseases with, for example efalizumab, which has been applied successfully for the treatment of psoriasis [70]. In a proof-of-concept experimental small animal study this group demonstrated that limb allograft survival is significantly prolonged by local administration of a specific selectin blocker (efomycine M) in combination with amyotrophic lateral sclerosis (ALS) induction and low-dose tacrolimus maintenance therapy. Such a combination of lymphocyte depletion and targeting lymphocyte trafficking in the skin of a VCA seems to be an appealing approach for the treatment of both AR episodes as well as to minimize/spare maintenance immunosuppression. However, one downside of such topical approaches might be that it leaves rejection of other tissue components of VCA undetected and allows progression of an immune response within deeper tissues such as muscle and bone. Although an immunosuppressive agent limited to the graft would be desirable, rejection represents a systemic response and it is unlikely that topical treatment alone would be sufficient to prevent or treat rejection. Therefore, although promising, therapeutic strategies employing topical drug administration to treat acute skin rejection in reconstructive transplantation warrant further evaluation in translational animal models before they can be safely introduced in humans.

The ideal immunosuppression

The ideal situation and ultimate attainable clinical goal in transplant medicine would be the ability to induce donor antigen-specific immune tolerance. This by definition would facilitate avoidance of any type of immunosuppression and could significantly improve long-term graft outcomes [46]. Complete discussions of tolerance from a mechanistic and clinical implementation standpoint can be found in Chapters 11 and 76, respectively. However, tolerance induction has not been routinely achieved thus far and it is not very likely that it will become a clinical reality, broadly available in the near future. Nevertheless, recently introduced innovative protocols appear to provide the opportunity to wean patients from maintenance medication altogether or allow reduction of long-term immunosuppression to minimal levels [62–64]. However, whether such tolerogenic protocols will be ultimately effective in VCA remains to be shown.

For now, clear evidence for superiority of one immunosuppression regimen over another can be derived only from prospective, randomized clinical trials. For hand or face transplantation, a field that is still in its infancy, such data will unfortunately not be available for several decades. Therefore, an immunosuppression regimen needs to be based on the limited experience made in those patients transplanted to date, building on the progress and advances made in solid organ transplantation and data obtained from experimental VCA studies. For those reasons, it is mandatory to implement standardized follow-up protocols and outcome measures to enable comparison of data across institutions and different protocols as well as to continue to pursue multicenter prospective trials despite the limited number of patients enrolled in such trials.

When designing an optimized immunosuppressive protocol for VCA, several differences from organ transplantation need to be taken into account: (1) VCA patients, apart from their amputation or devastating craniofacial tissue loss, are otherwise healthy recipients and usually lacking co-morbidities that might increase the risk of infection and possibly development of malignancy; (2) transplantation of a hand or face is not considered life saving, nor does it positively influence long-term patient survival; (3) the skin component of a VCA is constantly visible and rejection can be detected in most cases by simple visual inspection and biopsies can be taken from lesions under direct vision; (4) repeat acute skin rejection episodes when adequately treated seem not to negatively impact long-term allograft function; (5) the relevance of DSA and AMR at least at this time seems to be less when compared to solid organ transplantation; and (6) virtually all AR episodes thus far in VCA occurred during the first postoperative year.

These factors might be particularly relevant and should be considered with regard to the development and design of novel therapeutic strategies or the ideal protocol for VCA. Hence, based on the world experience with reconstructive transplantation and the available outcome data reported, we make the following recommendations for an immunosuppressive protocol for VCA:

1. An induction therapy with a depletional biologic such as ATG or alemtuzumab may help to prevent early rejection and keep the requirement for maintenance immunosuppression low.
2. Tacrolimus should be part of the immunosuppression regimen during at least the first 2 years because it has demonstrated support of nerve regeneration via its stimulatory effect on the synthesis of axotomy-induced growth-associated protein (GAP-43).
3. During the first 2 years a triple therapy including steroids and mycophenolic acid seems to be effective in preventing AR.

Steroids should be tapered and can finally be withdrawn within that same time period.

4 At 2–3 years after transplantation, calcineurin inhibitors should be replaced with a TOR-inhibitor for their favorable toxicity profile, their antiproliferative and potential protective effect on CR, as well as their antitumor properties.

Summary

In conclusion, when planning the design of new immunosuppression protocols, specific requirements for a VCA mentioned above need to be taken into consideration. Despite the fact that great advances have been made in choosing the most favorable combination of medications from the multitude of available agents to prevent solid organ allograft rejection, the same regimen may not always be optimal when used or attempted in reconstructive transplantation due to the unique biologic/immunologic features outlined in this chapter. In addition, immunosuppression minimization strategies designed for solid organ transplantation should be carefully reviewed and applied with due diligence to VCA.

Because there is no "magic bullet" or breakthrough in conventional immunosuppression on the horizon, we need to continue to optimize combination strategies of the currently available agents and compare data with other centers to create protocols with low toxicity profiles and inhibitory effects on chronic myointimal hyperproliferation and CR. Adherence to these guidelines will ultimately favor the risk–benefit balance of these life-changing transplants and advance this novel era in transplantation.

CHAPTER 76

Clinical Transplantation Tolerance

Tatsuo Kawai, David H. Sachs, and A. Benedict Cosimi
Harvard Medical School and Department of Surgery, Massachusetts General Hospital, Boston, MA, USA

Introduction

Clinical tolerance, defined broadly as the functional acceptance of an allograft without the requirement for ongoing immunosuppression, has been a fundamental goal of transplantation since the initial studies by Medawar that conceptually galvanized the possibility for allotransplantation (see Chapter 11). It is generally and reasonably assumed that the induction of allograft tolerance will improve long-term results of organ transplantation. However, it is only recently that this goal has been prospectively achieved. It is clear that tolerance requires that patients undergo treatments beyond those required to prevent allograft rejection. As such, the short- and long-term risks of those treatments must not outweigh the benefits conferred by tolerance provided by current standard of care. This chapter summarizes the ethical considerations, indications, and strategies for tolerance induction in clinical organ transplantation.

Risk of long-term immunosuppression

Since the first successful human kidney transplantation by Murray et al. in 1956 [1], numerous immunosuppressive regimens have been developed for clinical application. As these more efficacious immunosuppressive drug combinations have successfully prevented or treated acute allograft rejection, short-term survival of organ transplants has significantly improved, resulting in solid organ transplantation becoming the therapy of choice for many end-stage organ diseases [2,3].

However, chronic use of immunosuppressive drugs results in significantly increased risks of cardiovascular disease [4–6], infection [7–9], and malignancies [10–13]. Immunosuppressive medications also cause various side-effects, such as nephrotoxicity, de novo diabetes [14–16], dyslipidemia [17–20], and neurotoxicity [21,22]. Cardiovascular disease has become the most common cause of mortality, accounting for 30–48% of the deaths after kidney transplantation [10]. Infection is also a common complication and remains the second most common cause of mortality after transplantation [7–9]. The risk of many common cancers has been observed to be higher in chronically immunosuppressed transplant patients. Such risk is particularly high in non-melanoma skin cancer and melanoma/leukemia, which are 30-fold and 3-fold higher, respectively, than that of the general population [11,23]. Some studies report that the overall incidence of cancer after kidney transplantation is as high as 40% after 20 years of immunosuppressive therapy, in contrast to a 6% cumulative risk for cancer in an age-matched, non-transplanted control population [13,24]. Because of these morbidities, death with a functioning graft accounts for 16% of graft losses over the first 10 years after kidney transplantation [25]. Chronic nephrotoxicity from calcineurin inhibitor (CNI) treatment is also a serious side-effect, not only for kidney allografts but also for native kidneys in extrarenal transplant recipients. The incidence of chronic CNI nephrotoxicity in non-renal transplant recipients has been reported to be as high as 18%, with half of these patients progressing to overt renal failure requiring replacement therapy within 10 years [26]. Unfortunately, despite these toxicities that accompany the potent immunomodulatory effects of current therapeutic protocols, development of chronic rejection is not consistently prevented. Approximately 15–30% (dependent upon the assay utilized) of renal transplant recipients receiving maintenance immunosuppression eventually develop anti-HLA antibodies [27]. Chronic rejection, often in association with de novo alloantibody detection, accounts for about 20% of graft losses by 10 years after kidney transplantation [25]. In summary, the net effect of these limitations of currently available chronic immunosuppression protocols is an inexorable loss of previously functioning transplanted organs at an annual rate of about 5–7% [28], with no significant improvements of renal graft half-life in the last 10 years [2,3,29] (Figure 76.1).

Rationale of tolerance induction

Induction of tolerance has been considered one strategy to improve the long-term results of organ transplantation. Operational tolerance (defined as the absence of a destructive immune response to a transplanted tissue without ongoing immunosuppression) can be observed in up to 20% of liver transplant recipients following complete immunosuppression withdrawal, 4 to 10 years after the transplant procedure [30,31]. In contrast, such spontaneous tolerance is very rare in kidney transplant recipients and likely less common in heart or lung transplant recipients. These observations have emphasized that additional conditioning or treatment is required for consistent induction of tolerance across major histocompatibility complex (MHC) barriers. In order to justify clinical application, development of such additional conditioning/treatment regimens must utilize approaches with short and long-term risks that do not outweigh the benefits over current standard of care. Presumably, if tolerance could be induced consistently, chronic

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

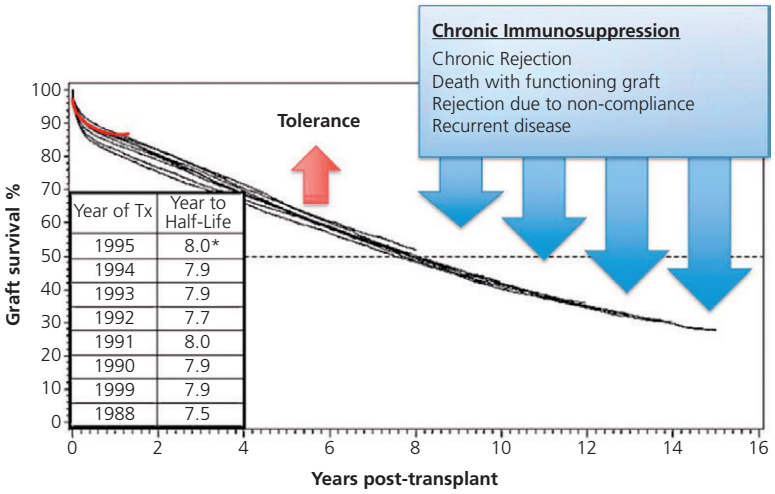

Figure 76.1. Currently available chronic immunosuppression protocols lead to an inexorable loss of functioning transplanted organs at an annual rate of about 5–7% [28], with no significant improvement of renal graft half-life in the last 10 years (lower survival curves, in black). Among the major causes for this graft loss, acute cellular rejection, chronic rejection, and rejection due to non-compliance may all be eliminated if tolerance can be consistently induced (projected survival curve in red). In addition, chronic rejection would be eliminated and the risks of cardiovascular disease, infection, and malignancy should be considerably minimized. * Years to 51.8% survival. (Modified from [36] Meier-Kriesche HU et al. Am J Transplant 2004;4:1289, with permission from Wiley.)

rejection would be eliminated and the risks of cardiovascular disease, infection, malignancy, and other drug-related complications should be considerably minimized. These advantages must be balanced against the potentially increased risks of infection and treatment-related morbidities in the early post-transplant period, which may be higher after administration of the conditioning regimens required for tolerance induction. It must also be weighed cognizant of the potential for recurrent disease in patients whose original disease was autoimmune in nature and for whom post-transplant immunosuppression may carry benefits beyond its requirement for alloimmunity.

In our experience with combined kidney and bone marrow transplantation, discussed below, these requirements appear to be obtainable, indicating that a tolerant state is feasible in some settings. Following our induction regimen, antithird-party responses have been regularly observed to completely recover by 6 months, while donor-specific non-responsiveness persists [32]. In addition, it has been reassuring that no serious infectious complications have been encountered in either non-human primate recipients followed for up to 13 years or in human recipients followed for up to 9 years (unpublished observations). The potential risk of malignancy following tolerance conditioning must also be considered, and this concern is particularly relevant in considering the use of ionizing irradiation during the conditioning regimen. For example, if total body irradiation (TBI) or total lymphoid irradiation (TLI) is included in the induction regimen, as it has been in some of the clinical trials discussed below, the incidence of irradiation-induced malignancy should be compared with the risk of malignancy resulting from long-term immunosuppression. Epidemiologic studies have established that low-dose TBI (2–2.5 Gy) increases the life-time risk of malignancy by a factor of 1.2 over that observed in individuals without prior exposure to irradiation [33]. In contrast, as described above, long-term immunosuppression is associated with a 3- to 30-fold increased risk of cancer [13,24]. Such data would appear to justify the use of low-dose irradiation for tolerance induction. An additional consideration involves strategies using donor bone marrow transplantation (DBMT). Graft-versus-host disease (GVHD) at any level would not be acceptable in organ transplant recipients unless they were simultaneously being treated for malignancy [34,35].

Indications for tolerance induction

Who are the most appropriate candidates for tolerance induction and are there specific contraindications? Because the current graft half-life following deceased-donor kidney transplantation has been unchanged for over a decade, at about 9–10 years [3,36], young kidney transplant recipients may be anticipated to require re-transplantation several times during their lifetime. However, the number of donors is limited and HLA allosensitization by the previous transplants typically makes serial re-transplantation difficult to accomplish. The high prevalence of non-compliance with post-transplant medications that is regularly encountered in pediatric recipients also defines these individuals as highly appropriate candidates for tolerance induction, providing this does not interfere with the follow-up required by the induction protocol. Non-compliant behavior has been reported in 5% to 80% of pediatric allograft recipients, with adolescents having the highest rates [37–40]. As a result, long-term outcomes in the adolescent age group are typically observed to be worse than in other age groups [41,42]. Thus, successful tolerance induction would appear to be highly advantageous for adolescent recipients. Likewise, in view of the significantly increased risk of malignancy in chronically immunosuppressed recipients, patients with a past history or strong family history of malignancy may also represent a group who would achieve additional benefit from tolerance induction. Tolerance induction in patients presensitized to HLA antigens has proved to be exceptionally difficult [43]. In our initial clinical trial, a patient, who had high panel-reactive antibodies (PRA) but no detectable donor-specific antibodies (DSA) by ELISA, developed aggressive humoral rejection within 2 weeks of the transplant procedure [32]. Therefore, we currently exclude any patient with detectible PRA from enrolling into our tolerance induction trials.

Whether patients with high probability of recurrence of their original disease are appropriate candidates for tolerance induction remains to be determined [25]. In the Stanford trial, which enrolled HLA-matched kidney transplant recipients, one patient developed recurrent disease, which led the investigators to discontinue the planned withdrawal of immunosuppression [44]. In our clinical trial, one patient developed recurrence of his original membranoproliferative glomerulonephritis 7 years after immunosuppression had been withdrawn, requiring reinstitution of low-dose immunosuppression. Although there is some possibility that tolerance

induction directed to alloantigens may also suppress autoimmunity, tolerance induction apparently neither enhanced nor prevented the recurrence of the original disease in these anecdotal cases. Currently, no non-human primate (NHP) models have been developed to assess autoimmunity but ongoing studies of mechanistic pathways, such as Tregs (regulatory T cells), may help to evaluate this potential obstacle to tolerance induction.

Strategies for tolerance induction

Since the landmark study by Billingham, Brent, and Medawar that defined a means to achieve neonatal tolerance [45], numerous strategies for induction of tolerance have been developed in rodent models [46–53]. However, only a limited number of these have been successfully translated to NHPs [54–62] and even fewer to humans [32,44,63–66]. The discrepancy in the ease of tolerance induction between rodents and primate models may be attributed to differential expression of MHC antigens, especially class II [67,68], as well as to the presence of heterologous memory T cells in recipients not housed in environmentally controlled conditions [69–71]. Recent studies have emphasized that alloreactive memory T cells can inhibit tolerance induction approaches that utilize costimulatory blockade [72] or mixed chimerism [69]. Nevertheless, at least some recent studies in non-murine models have provided encouraging observations of relatively consistent induction of allograft tolerance in NHP and even in human allograft recipients. Strategies for tolerance induction that, to date, have been extended to clinical transplantation include: (1) profound T-cell depletion, (2) costimulatory blockade, and (3) DBM infusion/transplantation. These strategies appear to depend upon combinations of the three major avenues of tolerance induction: (1) T-cell depletion, (2) anergy, and (3) regulation (Figure 76.2). An example of such a combination of mechanistic pathways is the induction of tolerance through mixed chimerism, in which profound T-cell depletion by anti-T-cell antibodies, which has been reported to expand regulatory T cells [73], has been a necessary part of the non-myeloablative conditioning regimen [74]. Mechanistic studies in clinical trials have also intimated a critical involvement of regulatory T cells in the allograft tolerance induced by transient mixed chimerism [32,75].

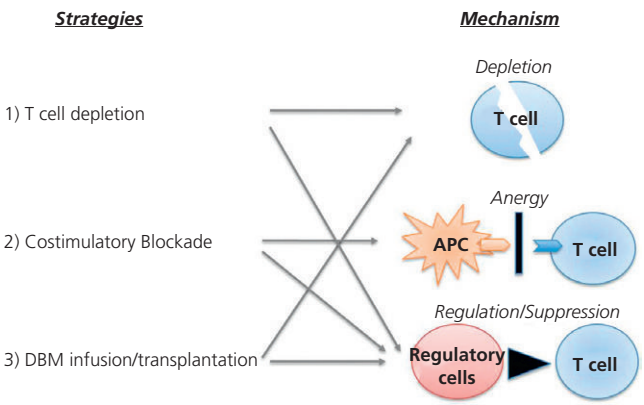

Figure 76.2. Strategies for tolerance induction that have been extended to clinical transplantation include: (1) profound T-cell depletion, (2) costimulatory blockade, and (3) DBM (donor bone marrow) infusion/transplantation. Effective strategies generally depend on combinations of the three major mechanisms of tolerance induction, that is depletion, anergy, and regulation. APC, antigen-presenting cells.

T-cell depletion

Depletion of donor-reactive T cells has been achieved by: (1) irradiation or (2) potent anti-T-cell antibodies or recombinant proteins.

1 Total lymphoid irradiation (TLI). Tolerance induction by TLI was initially studied in the1980s in large-animal models and humans. The Stanford group applied TLI with a cumulative dose of 2800–4500 cGy in canine experiments [76]. Myburgh et al. subsequently demonstrated prolonged renal and liver allograft survival in baboons with a reduced cumulative TLI dose of 1600 cGy [77]. In that study, DBM was also infused in some recipients, but prolonged survival was achieved even in recipients without DBM infusion. The Stanford group subsequently evaluated TLI in a pilot clinical kidney transplant trial, using a cumulative dose of 2000 cGy. Although successful withdrawal of immunosuppression was initially reported in three patients [65], two of these patients eventually lost graft function due to ureteral stenosis and chronic rejection [66]. One-year renal allograft survival of all patients receiving this regimen was 76% [78], which was inferior to graft survival with conventional immunosuppression. The complexity of the regimen as well as failure to show a significantly improved graft survival discouraged further studies with this approach until recently (see below).

2 Anti-T-cell reagents. Anti-CD3 (cluster of differentiation 3) immunotoxin (IT), which is an anti-rhesus CD3 monoclonal antibody (mAb) conjugated with the mutant diphtheria toxin protein (CRM9) [79], has been shown to effectively deplete rhesus monkey peripheral blood and lymph node T cells and prolong renal allograft survival [59,60,80]. However, DSA production was not prevented, ultimately resulting in alloantibody-mediated rejection of the kidneys [60]. A clinical trial based upon this strategy for tolerance induction has been attempted by Calne et al., who suggested that in human renal allograft recipients, a condition called "prope (almost) tolerance" could be achieved consistently after profound T-cell depletion with alemtuzumab (Campath-1H[Genzyme, Cambridge, MA], anti-CD52 mAb) [81,82]. In these patients, who were weaned to low-dose cyclosporine monotherapy, minimal evidence of rejection was observed, but no attempt was made to completely withdraw maintenance immunosuppression. Starzl et al. attempted to induce tolerance in 90 kidney transplant recipients who were treated with alemtuzumab or rabbit thymoglobulin [83]. In these studies, spaced weaning of immunosuppressants was achieved in selected patients, though complete withdrawal was not successful. There was no improvement in patient or graft survival compared with historic controls, and chronic allograft nephropathy progressed at the same rate in both groups [84]. Results with attempted tolerance induction using alemtuzumab have been inconsistent in other trials as well. Kirk et al. encountered acute rejection in their recipients treated with alemtuzumab, despite marked depletion of T cells. These lymphopenic rejections were notable for prominent graft infiltration with monocytes and macrophages [85]. Based on encouraging results in NHP [86], Kirk et al. subsequently added deoxyspergualin (DSG), a potent inhibitor of monocyte activation [87], to their alemtuzumab protocol [88]. However, despite profound T-cell depletion and therapeutic DSG dosing, all patients treated with alemtuzumab/DSG and attempted immunosuppression weaning developed

reversible rejection that was similar in frequency to that seen in patients treated with alemtuzumab alone [88]. Several chemokine gene transcripts were observed to be markedly increased in the biopsies of those allografts, which may have resulted in attracting residual lymphocytes to the kidney graft and led to rejection. Most investigators have now concluded that T-cell depletion alone cannot consistently induce tolerance in humans.

Costimulatory blockade

Among the costimulatory signals that have been identified, blockade of the CD28/CD80-CD86 [89,90], CD40/CD154 [61,62,91], and lymphocyte function associated antigen (LFA)-1/ICAM-1 [92] pathways have been tested in NHP. Although blockade of CD80 and CD86 has not significantly prolonged allograft survival in monkeys [90], blockade of the CD40/CD154 pathway with humanized anti-CD154 mAb (humanized 5c8) induced prolonged allograft survival in over half of recipients after discontinuation of all immunosuppressive treatment [58,61,62]. These encouraging observations suggested that this approach might be promising for human renal transplant trials. However, in the only clinical trial of this regimen, similar immunosuppressive effects were not observed and five of seven patients developed rejection episodes [93]. Further clinical trials of this antibody were suspended when an unexpectedly high incidence of thromboembolic complications was found to be associated with this treatment [94]. The ultimate clinical applicability of anti-CD154 mAb therefore remains questionable at this point.

CTLA4Ig (a protein consisting of the extracellular domain of CTLA4 [cytotoxic T-lymphocyte-associated protein-4] fused to the Fc domain of human IgG1) was designed to target the blockade of CD28/CD80-CD86. This agent only moderately prolonged allograft survival in NHP [95,96]; however, a modified version of CTLA4Ig, LEA29Y (belatacept), in which two amino acids were substituted to provide slower dissociation rates from both CD80 and CD86 ligands, has demonstrated more significant immunosuppressive effects in NHP and humans [97–101] and was recently approved for clinical use. Although the results of LEA29Y have been encouraging, attempts to completely discontinue immunosuppressive treatment following its administration have been unsuccessful [102]. However, belatacept is the first of these new classes of therapeutic agents to be approved for clinical kidney transplantation and its application in clinical tolerance induction trials may be forthcoming. We have recently tested belatacept in place of anti-CD40L mAb in our mixed chimerism conditioning regimen in an effort to develop a clinically applicable costimulatory blockade strategy and the preliminary results have been encouraging (Kawai et al., manuscript in preparation).

In a more complex trial that used costimulatory blockade ex vivo, Bashuda et al. reported successful induction of renal allograft tolerance in three of six monkey recipients who received adoptive transfer of anergized T cells, induced by co-culture with donor alloantigen in the presence of anti-CD80/CD86 antibody [103]. Although induction of allograft tolerance was not consistent, this study represents the first report of renal allograft tolerance induction by adoptive transfer of anergized cells in NHP. However, in their subsequent clinical trial, successful withdrawal of immunosuppression was not accomplished in any of the patients treated with this strategy [104].

Donor bone marrow infusion/transplantation

Strategies using DBM can be divided into those attempting to achieve microchimerism, detectable only by molecular assays, and those striving for mixed chimerism, readily detectable at a macroscopic level. These two approaches appear to operate through different immunologic mechanisms. In the microchimerism approach, DBM has been infused together with conventional immunosuppression, with or without T-cell depletion. Levels of chimerism induced were minimal (<0.1%), and were detectable only by polymerase chain reaction (PCR) analysis (hence the term "microchimerism") [105–108]. In contrast, in the mixed-chimerism approach, either more potent cytotoxic drugs and/or irradiation have been used to provide more complete T-cell depletion, which leads to DBM engraftment and induces higher levels of chimerism, detectable by flow cytometry.

Microchimerism strategy

Attempted tolerance induction by infusion of DBM with antilymphocyte serum (ALS) was first reported by Monaco et al. [46,109] in the 1970s. This strategy was subsequently tested in NHPs [110] and humans [111]. Despite favorable results in NHP studies, immunosuppression was not successfully discontinued in any of the 57 participants in the initial clinical trial. Chimerism in these patients was not evaluated. The concept of microchimerism as an explanation for allograft acceptance in patients treated with conventional immunosuppression, without administration of bone marrow, was first proposed by Starzl et al. in 1992. In that report, the investigators had used sensitive cytostaining and PCR techniques to detect small numbers of donor leukocytes (microchimerism) in 30 recipients of livers or kidneys with long-term stable graft function after all immunosuppression had been discontinued [105]. They hypothesized that responses of coexisting donor and recipient cells lead to reciprocal clonal exhaustion, followed by peripheral donor-reactive clonal deletion [107]. Based on the previous animal studies, as well as Starzl's observations, DBM infusion with conventional immunosuppression has been tested in multiple clinical organ transplant protocols [111–114]. To date, no convincing evidence has been provided to suggest that this approach will have a beneficial effect on patient or allograft survival, although a lower incidence of acute rejection and lower required maintenance immunosuppressive drug dosages have been reported [111–113,115].

Mixed chimerism

In contrast to the myeloablative regimens utilized when DBMT is performed to treat malignancies, the conditioning regimens used for induction of mixed chimerism have generally been non-myeloablative, implying that recipients would recover from the therapy-induced pancytopenia even without engraftment of DBM. The chimerism induced after such non-myeloablative regimens is generally characterized as "mixed chimerism," a state in which both donor and recipient hematopoiesis stably co-exist [47,50,74,116–121]. The presence of lymphohematopoietic elements of both host and donor origin distinguishes such mixed hematopoietic chimerism from full (i.e. 100%) chimerism observed after myeloablative conditioning. The advantages of the mixed-chimerism approach are that the recipient remains more immunocompetent and is less likely to develop GVHD [117].

Mixed chimerism approach in HLA-identical kidney transplantation

Using TLI and DBMT, the Stanford group reported successful induction of stable mixed chimerism and renal allograft tolerance in HLA-identical kidney transplant recipients [44,64]. The protocol consisted of TLI (80–120 cGy × 10), antirabbit thymocyte globulin

(1.5 mg/kg × 5, days 0–4), followed by HLA-matched peripheral blood $CD34^+$ stem cell infusion on day 11. These patients received mycophenolate mofetil (MMF) for 1 month, and cyclosporine starting at day 0 and continued for at least 6 months. All 12 patients receiving this regimen developed persistent mixed chimerism and eight patients were reported to have been completely withdrawn from immunosuppressive medications, with the longest allograft survival exceeding 3 years. Four patients continued to receive immunosuppressive drugs because of recurrence of focal segmental glomerulosclerosis in one, and rejection episodes during the tapering of cyclosporine in the others. To date, this approach has not been successfully applied to HLA-mismatched kidney transplants (see below). A potential advantage of this strategy might be applicability to deceased donor transplantation, because all treatments in the conditioning regimen are initiated after organ transplantation.

At Massachusetts General Hospital, ten patients with renal failure secondary to multiple myeloma who received conditioning with a non-myeloablative regimen and HLA-identical combined kidney and bone marrow transplantation (CKBMT), as well as subsequent donor lymphocyte infusions to provide additional antimyeloma effects, have been observed for periods of 3 to 14 years. The preparative regimen consisted of cyclophosphamide (60 mg/kg × 2), local thymic irradiation 700 cGy, horse antithymocyte globulin (ATG), and a 60-day course of post-transplant cyclosporine administration [34,35,122,123]. All ten patients developed mixed chimerism, which became undetectable by day 100 after CKBMT in four of them. Stable remission of myeloma has been observed in six of the 10 patients. Three patients died after 4 to 7 years, due to recurrence of myeloma, and two surviving patients have required ongoing medical treatment for recurrent myeloma. Of the six patients with stable remission of myeloma, four have successfully discontinued all immunosuppression, while two with stable chimerism have required low-dose immunosuppression to control minor symptoms of chronic GVHD. All kidney allografts were accepted, with no evidence of rejection, although early recurrence of myeloma prevented one patient from completing therapy.

Mixed chimerism in HLA-mismatched kidney transplantation

DBMT with a TLI-based regimen was attempted by the Stanford group in HLA-mismatched kidney transplant recipients [63]. In this clinical trial, three of four recipients developed transient multilineage chimerism, but rejection developed when immunosuppression withdrawal was attempted [63]. These investigators concluded that, despite its successful application to recipients of HLA-identical kidneys, this protocol did not induce allograft tolerance in HLA-mismatched recipients [124].

At Massachusetts General Hospital, based on the studies in NHPs [54–56,125,126] and the experience in HLA-matched CKBMT for myeloma [34,122,123], we have applied a non-myeloablative conditioning regimen to HLA-mismatched kidney transplant recipients [32]. Unlike the situation for myeloma patients, we considered GVHD at any level to be an unacceptable complication for renal transplant recipients without underlying malignant disease. Therefore, ATG, which we had used for the HLA-identical transplants (described above) and which had been used for DBMT in patients with myeloma and lymphoma [127], of whom several experienced GVHD, was replaced with an anti-CD2 mAb (Medi-507). The latter antibody was known to have potent T-cell-depleting properties as well as costimulatory blockade properties [128,129] and had not led to GVHD in patients receiving mismatched DBM for treatment of malignancy [130]. The protocol for recipients of HLA-mismatched allografts was also modified by adding an anti-CD20 mAb (rituximab) to prevent humoral rejection, after the occurrence of an antibody-mediated rejection in one patient (see above). A total of 10 subjects have been enrolled into these studies and maintenance immunosuppression was successfully tapered off in eight subjects by 8–14 months after transplantation. One of these eight subjects developed an episode of acute cellular rejection, which occurred 7 weeks after immunosuppressive therapy had been withdrawn. Following re-institution of immunosuppression, his renal allograft function improved, but has remained compromised and he underwent re-transplantation 3 years later. The clinical courses of the two recipients who were not able to be weaned from immunosuppression as planned were complex. The first developed irreversible humoral rejection during the second post-transplant week, as previously reported [32]. Although this patient was highly sensitized (PRA >40%), pretransplant DSA was not detectable by ELISA. Subsequent Luminex assays suggested that this patient was presensitized to donor HLA specificities. The second unsuccessful clinical course occurred in a patient who developed progressive thrombotic microangiopathy, thought to be the consequence of tacrolimus toxicity, although some element of cellular rejection could not be ruled out. Calcineurin inhibitor immunosuppression was discontinued, but the allograft eventually failed and she was returned to dialysis, 6 months after transplantation. Stable renal allograft function without ongoing immunosuppression has been maintained in the remaining seven patients for follow-up periods to date of 2.5–9 years. Of these seven patients, one patient developed recurrence of his original disease (membranoproliferative glomerulonephritis type 1) after 7 years. Although kidney function remained stable, low-dose MMF was added in an attempt to delay the progression of his recurrent disease. Another of these patients developed antidonor HLA class II antibody shortly after withdrawal of his immunosuppression. Serial biopsies did not show any evidence of chronic rejection until 5 years after discontinuing immunosuppression when the protocol biopsy showed duplication of basement membranes, suggestive of early chronic rejection. Although his kidney function remained stable with no proteinuria, immunosuppressive therapy was instituted after 6 years. These patients, who successfully discontinued their immunosuppression, consistently showed donor-specific unresponsiveness with in vitro immunological assays. However, the mechanism of tolerance induced by this approach has not been fully elucidated. Because the mixed chimerism induced in these patients has been transient, lasting only for 2–3 weeks, the involvement of peripheral tolerance mechanisms has been postulated to maintain the tolerance after the disappearance of chimerism [32,75]. In order to extend clinical applicability of this approach, further clarification of tolerance mechanisms as well as additional modifications of the protocol to decrease morbidity of the procedure are in progress.

Fully allogeneic chimerism in HLA-mismatched kidney transplantation

Direct evidence that persistent donor chimerism permits successful organ transplantation in patients was initially provided in the unique setting of patients who underwent myeloablative HLA-matched bone marrow transplantation for hematologic disorders and years later developed renal failure requiring transplantation. With the kidney donor being the same individual who previously donated bone marrow, kidney transplants succeeded without the

need for immunosuppression, affirming the principle that donor chimerism carried with it tolerance of other tissues and organs transplanted from the same donor [131]. However, as complete replacement of recipient myeloid and lymphoid lineages by donor cells may compromise immunocompetence and incurs the risk of GVHD, full chimerism for induction of allograft tolerance has, until very recently, been considered unlikely to have clinical applicability. However, Leventhal et al. at Northwestern have recently reported use of a conditioning strategy consisting of total body irradiation (200 Gy), fludarabine, and cyclophosphamide, together with administration of donor hematopoietic stem cells, for treatment of eight HLA-mismatched kidney transplant recipients [132]. Although the conditioning regimen was close to myeloablative and all recipients developed fully allogeneic chimerism, no GVHD was reported, purportedly as the result of administration of novel "tolerogenic $CD8^+/TCR^-$ facilitating cells." Although the follow-up period has been brief, the results are striking; multilineage full donor chimerism was achieved in all subjects at 1 month; and, in five of eight patients, it persisted long term, allowing weaning from all maintenance immunosuppression by 1 year. Kidney function has been maintained for 4–18 months without apparent rejection or evidence of GVHD. In the three cases in which tolerance was not successful, weaning was halted with development of membranous nephropathy in one case, presumed rejection in one case, and loss of the renal allograft to thrombosis in the third case, following what was believed to be an episode of sepsis. Considering the fact that this last patient exhibited a high level of chimerism and that the presumed sepsis followed a transient skin rash, it would appear possible that GVHD may have also played a role in the unfortunate outcome for this patient.

These remarkable results reported by Leventhal et al. may be attributable to the addition of a population of bone marrow-derived cells termed "facilitator cells", which include precursor plasmacytoid dendritic cells [133]. In animal models, these cells have been found to improve engraftment and to avoid GVHD, possibly through induction of regulatory T cells [134,135].

Operational tolerance in liver transplantation

Since Calne et al. first reported spontaneous tolerance of liver allografts in swine in 1969 [136], a considerable number of experimental and clinical studies on liver allograft tolerance have been reported. The swine used in these studies were outbred and not typed for MHC antigens. Subsequent data on liver transplantation in MHC-characterized miniature swine demonstrated that such spontaneous tolerance only occurred when the animals were MHC-matched [137], making it likely that Calne's animals, which were farm bred, shared MHC antigens. Nevertheless, the liver is generally considered the most tolerogenic of transplanted organs, with its as yet undefined tolerogenic effects being speculated to be multifactorial. Postulated mechanisms for the tolerance induced by the liver allograft include: (1) soluble MHC class I antigen produced by the liver, which potentially neutralizes graft-specific antibodies or inhibits graft-reactive cytotoxic T cells [138,139]; (2) presence of microchimerism from donor lymphoid cells in the liver transplant, causing a limited graft-versus-host reaction that counteracts the rejection response [105]; (3) clonal deletion/apoptosis of alloreactive cells in the liver after rapid T-cell activation [140–142]; (4) abundant sinusoidal antigen-presenting cells, such as liver sinusoidal endothelial cells, Kupffer cells, and liver dendritic cells (DC), which may present antigen in a tolerogenic manner to naïve T cells [143–145]; and (5) involvement of T regulatory cells, caused to proliferate by the liver [146].

The first large clinical study of liver transplant tolerance was reported from Pittsburgh in 1997 [30]. In this study, 95 recipients (64 adult and 31 pediatric), who were clinically stable for more than 5 years after transplantation, were chosen for withdrawal of immunosuppression. While 18/95 (19%) successfully discontinued immunosuppression for 10 months to 4.8 years, 18/95 (19%) developed rejection during immunosuppression withdrawal. At King's College in London, immunosuppression withdrawal was attempted in 18 adult recipients. Five of 18 recipients (28%) were initially reported to have successfully discontinued immunosuppression for up to 3 years [147], but later studies revealed that only 2/18 remained immunosuppression-free after 10 years [148]. In a study of hepatitis C-positive patients, however, stable long-term (up to 6.5 years) liver function has been reported in 7/34 recipients (20%) [149,150].

In pediatric patients, Kyoto University initially reported that a significantly higher proportion of patients (38%) achieved immunosuppression-free status [151]. However, in their more recent study, with a larger number of patients, approximately 15% (87/581) were reported immunosuppression free [31]. Furthermore, their most recent study revealed a higher incidence of fibrosis in protocol biopsies of immunosuppression-free patients, despite absence of clinical markers of rejection [152]. While studies in Kyoto included relatively older pediatric patients (up to 18 years old with the median age 12), Feng et al. at UCSF attempted to withdraw immunosuppression in much younger liver transplant recipients, (5.5–9.1 months at transplant and 6–11 years at study enrollment) who received parental living-donor liver transplantation [153]. Additional differences from the Kyoto study included longer time from transplant (4 vs. 2 years) and requirement of normal biopsy prior to study entry. Immunosuppression was gradually withdrawn over a minimum of 36 months, and 60% (12/20) of these recipients successfully discontinued their immunosuppression and maintained normal allograft function for a median of close to 3 years. Despite detection of de novo donor-specific antibodies in some tolerant recipients, follow-up biopsies obtained more than 2 years after complete withdrawal of medication showed no significant change compared with baseline biopsies. In this study, although HLA mismatch, sensitization status, and presence of donor-specific antibodies were not relevant to operational tolerance, tolerant patients initiated immunosuppression withdrawal significantly later after transplantation compared with non-tolerant patients (median of 100.6 vs.73 months).

As described above, Starzl et al. reported successful immunosuppression weaning in kidney, liver, and pancreas transplant recipients after profound T-cell depletion by large doses (5 mg/kg) of rabbit thymocyte globulin [83]. In that study, about 70% (14/17) of liver recipients achieved minimized doses of tacrolimus monotherapy. However, this thymoglobulin induction therapy failed to achieve complete immunosuppression withdrawal. Eason et al. attempted to withdraw immunosuppression from 18 patients, 6 months after transplantation, but only one patient successfully achieved immunosuppression-free status, with the majority of patients (14/18) developing rejection. Based on the hypothesis that microchimerism induces allograft tolerance through clonal deletion/exhaustion [105], the Miami group attempted to induce liver allograft tolerance by perioperative infusion of donor bone marrow cells (DBMCs) [113]. Although rejection rates were reported to be significantly lower in the recipients with DBMC, there was no

difference in overall graft survival. In this study, approximately 20% of patients successfully achieved immunosuppression-free status for 1–3 years, regardless of whether or not they had received DBMC.

In conclusion, in contrast to renal allograft recipients, spontaneous induction of tolerance following withdrawal of all immunosuppression can probably be achieved in up to 20% of liver allograft recipients. Long-term consequences of attempted immunosuppression withdrawal in those patients who do not become tolerant remain to be determined. To date, there have been no reported clinical trials attempting to demonstrate or induce operational tolerance in heart or lung transplant recipients.

Biomarkers for tolerance

It would be of great value to identify biomarkers that could accurately identify patients who are already in immunologically tolerant state while still on immunosuppression. Such arrays might help identify which patients can decrease or discontinue immunosuppressive medications and could also provide important insights into the mechanisms of tolerance induction.

Liver transplantation

Most studies of tolerance biomarkers have been carried out on liver transplant recipients because, as described above, the number of recipients who achieve tolerance after discontinuation of immunosuppression is higher for transplantation of the liver than for any other organ. Early studies showed that operationally tolerant recipients had increased numbers of certain lymphocyte subsets, compared to healthy volunteers and recipients maintaining immunosuppression or experiencing rejection. Mazariegos et al. demonstrated increased numbers of plasmacytoid DC precursors (DC2 or $CD11c^{-}CD123^{hi}$) relative to the frequency of monocytoid DC (DC1 or $CD11c^{+}CD123^{-/lo}$) in recipients who achieved immunosuppression-free graft survival [154]. Other studies have shown that operationally tolerant pediatric and adult liver transplant recipients have significantly higher peripheral blood $CD4^{+}CD25^{high}$ T cells and γδT cells (Vδ1/Vδ2 ratio), compared to non-tolerant recipients or healthy individuals [155,156]. A subsequent study also demonstrated a significantly higher level of $FOXP3^{+}CD4^{+}CD25^{high}$ T cells in liver transplant recipients who achieved immunosuppression-free graft survival than in those who developed rejection [157]. More recently, gene-expression profiling of operationally tolerant liver recipients has demonstrated a unique genomic signature set that was preferentially expressed in natural killer, natural killer T, and γδT cells [156,158].

Kidney transplantation

In contrast to the situation in liver transplantation,, it has been difficult to identify tolerance biomarkers for kidney transplantation, because of the scarcity of recipients who achieve spontaneous operational tolerance. Brouard et al. analyzed the blood T-cell repertoire usage in five renal transplant recipients with operational tolerance. They found higher CDR3 length distribution (LD) of Vβ families compared to normal control and stable recipients with conventional immunosuppression. The recipients with low-dose steroid monotherapy also showed similarly high CDR3-LD of TCR Vβ [159]. However, these results have not been reproduced by other groups. The same group subsequently analyzed peripheral lymphocytes of tolerant renal transplant recipients and reported significantly lower absolute counts of B cells, $CD25^{high}CD4^{+}$ cells, and lower levels of Foxp3 transcripts in recipients with chronic rejection than those in tolerant recipients [160]. This group further performed microarray analysis of the peripheral blood in the same five tolerant recipients to identify specific gene expression patterns in tolerant recipients. They identified a 49-gene set specific to tolerant recipients by microarray with 33 of the included genes correctly segregating tolerance and chronic rejection [161]. However, one patient who fulfilled the full clinical description of operational tolerance later developed rejection with antidonor antibody. The authors suggested that the operational tolerance gene-expression signature is likely a metastable rather than permanent status.

More recently, two studies have reported genomic biomarkers of renal allograft tolerance in such individuals. In the first study, sponsored by the Immune Tolerance Network (ITN) and performed in the United States, 25 kidney transplant recipients who had not rejected their graft despite stopping of immunosuppressive medications, were identified and their genetic and cellular signatures were studied [162]. The study found that a set of three B-cell differentiation genes distinguished tolerant from non-tolerant recipients, although not from normal individuals, raising the question of whether non-tolerant recipients showed lower expression of these genes because of ongoing immunosuppression. This B-cell signature was associated with elevated numbers of peripheral blood naïve and transitional B cells in the tolerant recipients. These results were independently verified by another ITN-sponsored study, which was performed in Europe. The European study also demonstrated a bias toward differential expression of B-cell-related genes, which were associated with significantly higher percentages of peripheral blood B and natural killer cells. The study also showed a significantly lower percentage of circulating activated $CD4^{+}CD25^{int}$ cells. Although there was no significant difference in circulating $CD4^{+}CD25^{hi}$ cells, expression of Foxp3 to α-1,2-mannosidase genes was found to be significantly higher in the peripheral blood of tolerant recipients [163]. These studies on biomarkers for renal allograft tolerance have been based on a limited number of patients who achieved operational tolerance of the renal allograft, and further confirmative studies with larger numbers of patients will be required to validate these initial results and to show that there is also a meaningful difference between biomarker expressions in normal versus tolerant individuals.

Summary

Spontaneous cases of allograft tolerance in patients who stopped taking their immunosuppressive medications have been described anecdotally for liver transplants and even for kidneys [159,164,165]. However, it is only during the past 10 years that the goal of intentional induction of allograft tolerance has been brought from animal models to the clinic for both HLA-matched and HLA-mismatched kidney transplantation. Although induction of tolerance by combined kidney and DBMT has thus far been the only effective means of inducing tolerance in the clinic, modifications of current protocols as well as additional approaches should be pursued in both basic laboratory and preclinical studies, to reduce morbidity of the preparative regimen and to make tolerance induction the standard of care in routine organ transplantation.

CHAPTER 77

Recurrent Disease after Kidney and Pancreas Transplantation

Lorna K. Henderson and Philip J. O'Connell
National Pancreas Transplant Unit, University of Sydney at Westmead Hospital, Westmead, NSW, Australia

Introduction

The aim of every transplant program is to achieve long-term patient and graft survival whilst minimizing the adverse effects associated with immunosuppression. Advances in transplant immunosuppression and anti-infective prophylaxis has impacted favourably on short-term outcomes, with early acute rejection rates below 15%, and 1-year graft survival greater than 90% [1]. Despite this, impact on long-term graft function has been disappointing with late allograft failure now major causes of end-stage kidney disease (ESKD). Whilst causes of graft dysfunction are numerous, recurrent disease has been largely ignored as an important contributor.

Better understanding of disease pathogenesis, together with improved diagnostics, has revealed recurrent disease in the kidney to be a much greater challenge to the transplant community than previously appreciated. Reported as the third most common cause of graft failure (after death with a functioning graft and interstitial fibrosis and tubular atrophy), recurrent disease is an important cause of graft dysfunction [2]. Furthermore, data from surveillance biopsy studies suggest that the true incidence of recurrent disease is likely to be much greater, while many patients with slowly deteriorating graft function may never be biopsied and are often incorrectly diagnosed with "chronic rejection." The challenge of recurrent disease lies not only in an accurate diagnosis. For many of the primary glomerulonephritides, recurrence within a graft is unpredictable, with limited therapeutic options available once the diagnosis is confirmed. Moreover, the true impact of recurrent disease on graft survival is unclear in many circumstances. Some may cause a rapid deterioration in graft function with early graft failure, while others appear to have little or no impact on long-term graft survival.

Simultaneous pancreas kidney transplantation (SPK) is the treatment of choice for appropriately selected patients with ESKD due to type 1 diabetes mellitus. Over the past three decades, graft survival for both the pancreas and the kidney have been steadily improving and registry and outcome studies show that patients with type 1 diabetes who receive a pancreas graft with their renal graft have improved survival outcomes compared to those that receive a cadaveric renal graft alone [3–5]. Whilst protecting the renal graft from the recurrence of diabetic nephropathy, the pancreas remains susceptible to recurrent autoimmune disease and it is a recognized cause of graft failure. Although reported to be an uncommon cause of pancreatic failure, true prevalence is unknown, as definitive diagnosis requires a pancreatic biopsy, which is not routinely carried out in most transplant centres.

This chapter will review the aetiology, clinical presentation, and investigation of recurrent disease in the kidney and pancreas grafts after transplantation. Recurrence of specific forms of glomerulonephritis and autoimmune disease in the pancreas is addressed individually, together with a review of current understanding on disease pathogenesis and an evaluation of current therapeutic options.

Recurrent disease after kidney transplantation

Background

Transplantation is the treatment of choice for the majority of patients with end-stage kidney disease, including those with primary or idiopathic glomerulonephritis (GN). However, this therapy does not usually eliminate the underlying cause of renal failure and as such should be regarded as a treatment rather than a cure.

Short-term graft survival has improved substantially in recent years, with a marked improvement in early acute rejection rates [1]. Although the long-term impact has been less impressive [6], overall graft survival has increased and, with this, the likelihood of disease recurrence. Specific discussions of long-term outcomes following kidney and pancreas transplants are found in Chapters 103 and 107, respectively.

Recurrence of primary GN has been considered since the beginnings of successful transplantation [7,8]. Previously thought to be of little significance as a cause of graft failure, prolonged allograft survival, in combination with improved diagnostics, has revealed recurrent GN to be an important factor influencing allograft outcome and survival.

Risk of recurrence and consequent impact on graft survival differs for each category of GN. Reported recurrence rates range from 10 to 20%, with up to 50% losing their graft on long-term follow-up [2,9]. These are likely to be an underestimate, as much

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

disease is subclinical and immunofluorescence and electron microscopy are not routinely performed on allograft biopsy. Furthermore, the introduction of rapid steroid withdrawal or complete avoidance in recent years has resulted in an increased incidence of recurrent GN with a reported tripling of risk of recurrent GN [10].

Epidemiology

To better understand recurrent GN after transplant, it is important to recognize the epidemiology of primary GN leading to native kidney disease. GN is the cause of ESKD in 10% to 25% of patients, with a greater incidence in Caucasian patients and children [11]. High incidence in children is likely due to the low prevalence of diabetic nephropathy as a cause of ESKD, while variance in racial distribution between registries may in part explain differences in type of native kidney disease. For example, the United States Renal Data System (USRDS) includes a larger cohort of Black patients compared with the Australia and New Zealand Dialysis and Transplant Registry (ANZDATA). Lower prevalence of reported GN in Black patients may in part relate to paucity of biopsy information, as well as a higher incidence of hypertensive nephrosclerosis and diabetic nephropathy.

Registry analyses in the US and Australia show the prevalence of recurrence rates following transplant for primary GN varies from 2.9 to 12.1% and is inversely proportional to the recipient's age and directly proportional to duration of follow-up [11]. The Renal Allograft Disease Registry (RADR) was introduced in the USA to better understand the prevalence of recurrent immunological and metabolic diseases and their impact on graft function. Reports confirm an increased risk of recurrent disease with time, rising from 2.8% at 2 years to 9.8% and 18.5% at 5 and 8 years, respectively [12]. Once established, graft survival has been shown to decline more rapidly in patients with recurrent or de novo GN. In a US study, median graft survival with recurrent disease was 1360 days versus 3382 days without recurrence ($P < 0.0001$) [13].

The true incidence of recurrent GN is difficult to establish. Numbers reported within analyses are influenced by the duration of follow-up and whether or not patients with recurrent disease and a functioning graft were included together with those who have lost their graft. Recurrence rates may also be underestimated, as much disease is subclinical. Surveillance biopsies confirm a greater prevalence of certain GN than reported previously [14,15]. Moreover, an accurate diagnosis may be lacking in many patients, in whom recurrent disease is not confirmed histologically or misdiagnosed.

Definition and classification of recurrent disease

Recurrent and de novo glomerular disease may be classified according to clinical and histological criteria (Table 77.1). In order to establish an accurate post-transplant diagnosis of recurrent GN, it is crucial to ascertain a precise primary disease diagnosis, and to exclude donor disease. This requires a biopsy of both the native kidney (or implantation biopsy if GN was not the primary diagnosis) and the transplant kidney. Many cases cited in the literature, do not meet these criteria. As a result, some patients with presumed GN (not biopsy proven), go on to develop biopsy-proven GN after transplant, which is labelled recurrent GN when it may be recurrent or de novo. Furthermore, some patients with deteriorating renal function and proteinuria following transplant may never be biopsied, and are misdiagnosed as "chronic rejection". Implantation biopsies are also informative as they may reveal an unsuspected primary GN in the donor that should be considered when describing subsequent allograft biopsies.

Table 77.1. Classification of recurrent glomerular diseases

Clinical classification	
True recurrent glomerulonephritis	Histology of both the native and transplant kidney confirms the same glomerulonephritis
De novo glomerulonephritis	Biopsy-proven glomerular disease that occurs within the kidney allograft after transplantation that was not present in the native biopsy
Transplant glomerulopathy with unknown primary	Biopsy-proven glomerular disease within the transplant kidney may be recurrent or de novo but histology from native kidney is not available to confirm the diagnosis
Donor glomerulopathy	Biopsy-proven glomerular disease within the kidney allograft after transplant was present in the donor kidney at time of transplant (confirmed by implantation biopsy)
Histological classification	
Recurrence of primary glomerulonephritides	Focal segmental glomerulosclerosis IgA nephropathy Membranous nephropathy Mesangiocapillary glomerulonephritis Anti-GBM disease
Recurrence of secondary glomerulonephritides	Lupus nephritis Henoch–Schönlein purpura Haemolytic uremic syndrome ANCA vasculitis Scleroderma
De novo disease	Haemolytic uremic syndrome Transplant glomerulopathy Anti-GBM disease in patients with Alport's syndrome Membranous glomerulonephritis
Recurrence of metabolic or storage disorders/ glomerular deposition disease	Diabetic nephropathy Oxalosis Cystinosis Amyloidosis Fabry's disease Fibrillary or immunotactoid glomerulonephritis

ANCA, antineutrophil cytoplasmic antibody; GBM, glomerular basement membrane.

For this reason, recurrent diagnosis may be classified in four ways:

1. True recurrent GN: histology of both the native and transplant kidney confirms the same GN.
2. De novo GN: biopsy-proven glomerular disease that occurs within the kidney allograft after transplantation which was not present in the recipient's native kidney biopsy.
3. Transplant glomerulopathy (unknown primary disease): biopsy-proven glomerular disease within the transplant kidney may be recurrent or de novo but histology from the native kidney is not available to confirm the diagnosis.
4. Donor glomerulopathy: biopsy-proven glomerular disease within the kidney allograft after transplant was present in the donor kidney at time of transplant (confirmed by implantation biopsy).

Clinical features

Clinical diagnosis is usually prompted by new-onset haematuria and/or proteinuria. Elevation in serum creatinine often accompanies abnormal urinalysis; however, renal function may be normal or stable at the time of recurrence. Rate of progression of renal disease varies considerably depending on the underlying disease and potential concomitant pathologies such as interstitial fibrosis and tubular atrophy or calcineurin inhibitor (CNI) toxicity, which may also impact on graft function.

The clinical course and severity of recurrent disease often replicates that of the original disease, with the exception of lupus nephritis and vasculitis, which is invariably controlled by transplant

immunosuppression. Timing of recurrence and impact on graft outcome also varies according to the primary disease. Focal segmental glomerulosclerosis (FSGS) may recur within days to weeks from transplantation, while other glomerulonephritides, such as IgA, may not recur until many years from transplant, with little or no deleterious effect on graft outcome.

Extra renal features associated with the primary disease may accompany recurrent disease in the transplant, such as pulmonary involvement in recurrent Wegener's granulomatosis or haemolysis and thrombocytopenia in recurrent haemolytic uremic syndrome (HUS).

Investigation

Urinalysis

New-onset and persistent proteinuria, or haematuria and proteinuria (in the absence of infection or mechanical cause), are suggestive of de novo or recurrent GN and should prompt further investigation. Proteinuria (quantified by either spot or 24-hour protein excretion) is present in up to 45% of transplant recipients and, regardless of underlying cause, is a powerful independent risk factor for graft loss and patient survival [16]. It represents a composite endpoint of many possible pathologies including transplant glomerulopathy, non-specific IF/TA, and tubular proteinuria, as well as glomerular proteinuria from a de novo or recurrent GN. Urinary protein excretion also increases with hyperfiltration, obesity, and hypertension, and from iatrogenic causes such as mTOR inhibitors. Conversely, proteinuria may be rescinded by renin-angiotensin blockade, CNI therapy, and through reduced glomerular filtration rate (GFR) resulting from ischaemia or poor transplant function.

The threshold for pathological proteinuria is less clear for the transplanted kidney compared with native kidneys. Many centres consider 0.5 g/24 hours or higher (which may delay diagnosis and intervention) while others have shown 0.15 g/24 hours is associated with worse outcome [17]. Mounting evidence from protocol and diagnostic biopsy studies suggests a specific disease is responsible for proteinuria in most patients [18]. For this reason, a pre-emptive approach to proteinuria is recommended, allowing early diagnosis and timely management.

Serology

Serology may support diagnosis of recurrent disease, such as with antiglomerular basement membrane (GBM) antibody in Goodpasture's disease and antineutrophil cytoplasmic antibody (ANCA) associated with Wegner's granulomatosis and microscopic polyangiitis. Others such as anti-dsDNA are less informative. Hepatitis B or C antigenaemia is helpful when considering recurrent mesangiocapillary GN (MCGN) or membranous nephropathy. Raised lactate dehydrogenase (LDH) and low haptoglobin together with evidence of microangiopathic haemolysis on a blood film, may support a diagnosis of recurrent HUS, but the absence of these features do not reliably exclude it.

Renal biopsy

Differential diagnosis of post-transplantation GN often poses a diagnostic challenge to pathologists, given the plethora of potential histological findings and often multiple pathologies co-existing within the graft, many with overlapping histological features.

Renal biopsy is crucial for the diagnosis of recurrent GN. Full evaluation of histology includes light microscopy, immunofluorescence, and electron microscopy. Samples should contain at least ten glomeruli and two arteries to reliably represent graft pathology. Some pathological features are often patchy, and two cores of cortex are recommended. Histology should be processed similarly to native biopsies, where light microscopy helps differentiate recurrent from de novo GN, acute rejection, BK virus-associated nephropathy (BKVAN), glomerulitis, CNI nephrotoxicity, and hypertensive nephropathy, while also defining the extent of chronic allograft damage. Periodic acid–Schiff stain defines the basement membrane, silver stain detects the double contours of transplant glomerulopathy and membranous nephropathy, while trichrome stains detect collagen deposition and determines the extent of fibrosis. Light microscopy features, such as reduplication of the glomerular basement membrane, may occur in transplant glomerulopathy, making it difficult to distinguish from recurrent MCGN. The use of immunohistochemistry (to detect immune deposits) and/or electron microscopy (to assess basement membrane and deposits) is often essential to help clarify the diagnosis.

Clinical features and differential diagnosis of recurrent glomerulonephritis

Focal segmental glomerulosclerosis

Background and pathogenesis

Primary FSGS leads to ESKD in a high proportion of adult cases and is the leading cause of acquired renal disease causing ESKD in children [19–22]. The risk of recurrence after transplantation is high, with reports ranging from 20 to 50% [23–25], rising to 80 to 100% in the second transplant if the first was lost due to recurrent FSGS [26]. Without intervention prognosis is poor, with 13–20% grafts failing by 10 years [2] (Table 77.2). Two patterns of clinical presentation are described; the first (and most frequent) occurs within hours to days after transplantation and is characterized by early nephrotic-range proteinuria. The second follows a more insidious course, presenting months or even years from transplant. Risk factors for recurrence include rapid progression to end-stage renal

Table 77.2. Risk of recurrent disease and graft loss

failure with primary disease, young age, Caucasian race, and recurrence in a previous allograft.

Proteinuria is the hallmark of clinical presentation and may precede biochemical evidence of graft dysfunction. Histology is characterized by sclerosis in a segment of the glomerular tuft, along with podocyte effacement and fusion of foot processes on electron microscopy. Light microscopy may be normal in the early stages of disease recurrence and in this circumstance electron microscopy is crucial to confirm the diagnosis (Figure 77.1).

The pathophysiology of primary FSGS remains unclear but emerging evidence suggests a circulating factor plays a role in breaching glomerular permeability. An in vitro assay developed to detect this permeability factor showed that patients with a high level of activity were more likely to develop recurrence [27]. Evidence supporting a role for a circulating factor includes: induction of albuminuria in rats following the transfer of serum from patients with recurrent FSGS [28]; the observation of transient nephrotic syndrome in newborn infants in women with FSGS [29]; and the resolution of disease using therapies known to remove large proteins from the circulation such as plasma exchange or immunoadsorption [30,31]. Identification and characterization of this permeability factor has proved elusive for many years. Its molecular weight is thought to be between 30 and 50 kDa, depending on glycosylation and proteolytic cleavage [32,33]. A protein postulated to alter glomerular permeability, FS permeability factor (FSPS) protein, has been shown to bind with high affinity to galactose and may be eliminated by galactose affinity columns [34]. Serum soluble urokinase receptor (suPAR) has been identified as a circulating factor that may cause FSGS [35]. Elevated concentrations of suPAR were identified in two-thirds of patients with primary FSGS. High serum concentrations of suPAR were associated with recurrence after transplantation and in experimental models suPAR was found to activate podocyte β3 integrin leading to foot process effacement, proteinuria, and FSGS-like glomerulopathy, thereby providing a mechanistic basis for the disease [35]. Whilst this study has provided substantial evidence that suPAR correlates with disease, there have been several other soluble factors proposed as mediators of FSGS in the past. Proof of these findings will come from prospective multicentre studies to diagnose and monitor primary FSGS [36].

Separate studies in humans and experimental animal models of idiopathic nephrotic syndrome (INS) suggest a role for T lymphocyte dysfunction in disease pathogenesis, although treatments targeting T cells (anti-CD3, CNI, anti-CD53) have been largely unsuccessful at preventing or treating FSGS recurrence [31]. Resolution of recurrent FSGS following treatment with the anti-CD20 humanized monoclonal antibody, rituximab, has raised the possibility of B-lymphocyte involvement, although direct evidence is lacking [37]. While a clear trigger underlying disease pathogenesis remains elusive, the role of podocyte injury in disease pathogenesis now seems clear. Podocyte injury certainly appears to be the end point in this complex pathophysiological process, where it is proposed that circulating factor (with or without the involvement of immune cells) interacts with podocytes, leading to loss of nephrin and/or podocin with effacement of the foot processes [31].

Treatment strategies and outcomes

Idiopathic FSGS typically occurs early, with 80% of these cases occurring within the first 4 weeks after transplant [38]. Patients with a primary diagnosis of FSGS should be screened more frequently in the early post-transplant period for proteinuria (Table 77.3). Knowledge of pretransplant proteinuria informs interpretation of proteinuria in the early post-transplant period. Although accepted that the contribution of native kidneys to urine output (and associated proteinuria), declines after transplant, time to disappearance is variable [38].

Evidence supporting the successful treatment of recurrent FSGS has emerged in the last few years. Uncontrolled series and case reports have shown a substantial reduction in proteinuria following plasma exchange [39–41]. Early disease recurrence and initiation of plasma exchange may be associated with response to treatment although proteinuria may recur on cessation of therapy. Relapse may be prevented or reversed with long-term plasmapheresis with or without the addition of cyclosporine or cyclophosphamide. Cyclosporine acts directly on podocytes, blocking calcineurin-mediated dephosphorylization of synaptopodin, stabilizing the cytoskeleton [42]. Though limited by a small population size and historical control group, a non-randomized study achieved complete remission in 90% of patients using a combination of high-dose

Table 77.3. Screening for recurrent disease and potential therapies (adapted from Kidney Disease: Improving Global Outcomes Guidelines)

Disease	Additional Screening*	Minimum screening frequency	Diagnostic tests†	Potential therapies
FSGS	Proteinuria	Daily (1 week) weekly (4 weeks) 3 monthly (1 year) then annually		Plasmapheresis, steroids, cyclosporine, or cyclophosphamide Rituximab‡ ACEI/ARB if proteinuria

§ Recurrence with high anti-GBM titres and cellular crescents on biopsy.

steroids, intravenous followed by oral cyclosporine, and an intensive and prolonged course of plasma exchange, compared with 27% in the control group who received a combination of therapies [43].

Pre-emptive plasmapheresis carried out perioperatively has been reported to reduce recurrence in children [44] and adults [41] although study numbers were small and uncontrolled. Furthermore, this approach is practically challenging with cadaveric transplants and carries the increased risk of hypocoagulation and bleeding peri- and postoperatively.

Rituximab has been used to treat recurrent FSGS refractory to plasmapheresis in a number of case reports. Different regimens have been described in each report with mixed results ranging from complete and persistent remission to no response and early graft failure [45–48]. Randomized controlled studies with sufficient numbers are required before the role of these therapies in modulating disease may be clearly elucidated.

Other novel therapies that may have a role in treating this condition include anti-TNF-α therapy and anti-CTLA4 therapy. Clinical trials are underway evaluating retinoic acid (NCT00098020) and galactose (NCT00814255) to treat primary FSGS in native kidneys.

IgA nephropathy

Background and pathogenesis

IgA nephropathy (IgAN) is the most common GN worldwide [49], leading to ESKD in 30 to 50% of patients after 25 years follow-up and is the most common recurrent GN after transplant [50]. Disease pathogenesis is complex and remains incompletely understood. Current understanding links altered production of abnormally glycosylated IgA1 in patients with primary disease, which cause glomerular inflammation and injury if deposited within the mesangium (Figure 77.2).

A recent review of the literature documented recurrence rates of approximately 30%, although incidence varied between studies, with reports ranging from 9 to 61% [51] (Table 77.2). Differences in duration of follow-up, threshold for biopsy, inclusion of surveillance biopsy, as well as racial and geographical variation, may explain the wide range of recurrence rates between reports. Surveillance biopsy in the absence of clinical signs report recurrence rates in 50 to 60% of patients [52,53].

Clinical presentation is similar to primary IgAN, with microscopic haematuria, low-grade proteinuria, and slow decline in renal function the most common features. Onset may occur early after transplant (implantation biopsy is necessary to exclude IgA within the donor kidney in such circumstances). More commonly, disease recurs from 3 years after transplantation [9]. Once established, disease progression is often benign, at least initially. Indeed, allograft survival for the first 5 years from transplant appears to be better in patients with primary IgAN compared with other disease [54–56]. Reasons are unclear but suggested mechanisms include protective alloreactive IgA anti-HLA antibodies blocking the effects of pathogenic IgG and IgM antibodies on the graft, or protective aberrations in immune function in patients with IgAN [57,58]. Graft survival becomes equivalent or inferior beyond 10 years from transplant when compared with other primary disease. Graft loss from recurrence may in part account for this, with an estimated 9.7% of grafts lost due to recurrent disease at 10 years [2].

Risk of recurrence in a second graft is high (20 to 100%) if the first graft was lost within a few years as a result of recurrent IgAN [51,59,60]. In this situation, alternatives to living donor transplant should be considered. Patients who lost grafts to recurrent IgA beyond 10 years should be regarded as low risk and live donation should not be precluded in this situation. There is no other single

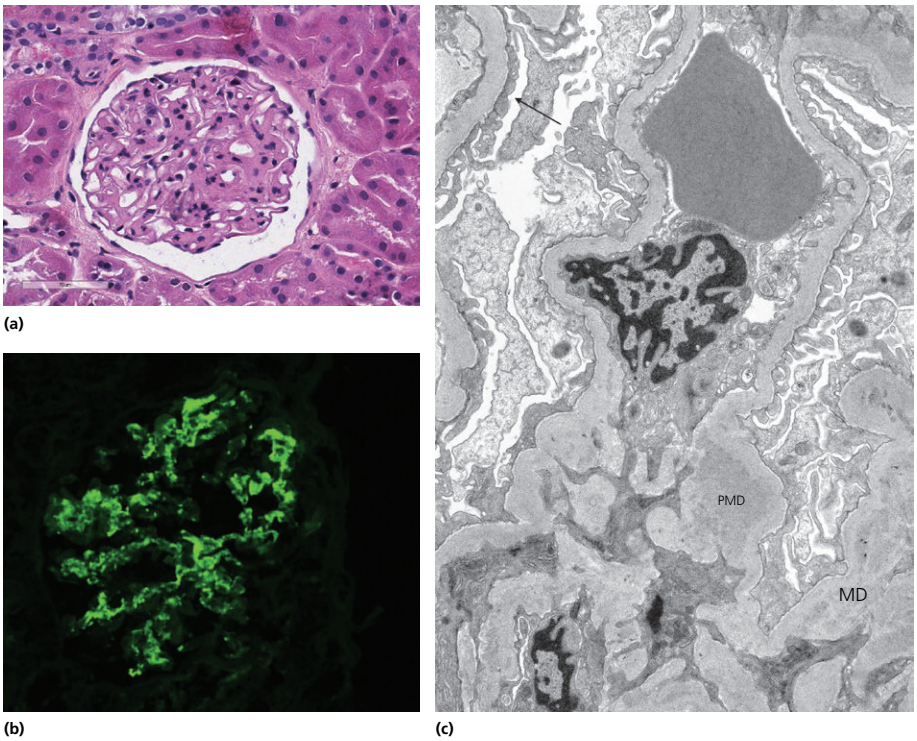

Figure 77.2. Recurrent IgA nephropathy. (A) Light microscopy showing mesangial expansion and mild hypercellularity (H&E). (B) Immunofluorescence demonstrating diffuse mesangial immunostaining for IgA *(immunofluorescence with anti-IgA antibodies marked with fluorescein). predictor for recurrent disease, although recurrence tends to occur with greater frequency in young donors or in those who originally presented with more aggressive disease in the native kidneys. It has been postulated that risk of recurrence is greater in patients receiving a kidney from a live donor; however, this is unsubstantiated and data are conflicting.

Treatment strategies and outcomes

There is no effective therapy to prevent recurrence of IgAN. Treatment should focus on control of blood pressure with renin-angiotensin blockade. Newer immunosuppressive agents appear to have little impact on disease recurrence and reports of lower recurrence rates with mycophenolate mofetil (MMF) are anecdotal and uncorroborated. Although steroid free or rapid steroid withdrawal has been reported not to affect risk of recurrence [61], a recent survival analysis from ANZDATA reported steroid use was strongly associated with a reduced risk of recurrent IgAN [62]. ACE inhibitors and angiotensin receptor blockers reduce proteinuria and may preserve kidney function in recurrent IgAN [63].

Membranous glomerulonephritis

Background and pathogenesis

Membranous nephropathy (MN) is a common cause of nephrotic syndrome in adults, leading to ESKD in up to 50% of patients. Reported to recur in 10 to 30% of patients after transplant [64], accurate assessment of true recurrence rates are hampered by the frequency of de novo MN and the wide variability in threshold for biopsy between centres. Surveillance biopsies suggest that recurrent MN is probably more frequent than previously estimated [14].

Graft survival in patients with idiopathic MN appears to be similar to patients transplanted with different renal diseases (including other GN). Prognosis following recurrent MN after transplantation is less clear, with reports of 60 to 65% of cases progressing to ESKD within 4 years after recurrence [65,66], while others report no significant difference in graft failure, death, or renal function between patients with recurrent MN and those without recurrence [67]. The Australia and New Zealand Dialysis and Transplant Registry reports graft failure from recurrence between 10 to 15% at 10 years [2] (Table 77.2).

To date, there are no clinical or histological factors to reliably predict risk of recurrence. While some groups have reported more frequent recurrence with recipient of live-donor allografts [68,69], others have reported the opposite [70].

Clinical presentation is usually between the first and second year from transplant and is typically heralded by proteinuria (often within nephrotic range) with or without renal dysfunction. Presentation may occur earlier and surveillance biopsies have shown that clinical manifestations of proteinuria or elevated creatinine may be mild or absent in the early stages of disease recurrence [14]. Renal biopsy is characterized by uniform thickening of the glomerular basement membrane (GBM) resulting from immune complex deposits in the outer or subepithelial surface of the GBM. Differentiating recurrent from de novo MN requires an accurate diagnosis of the original renal disease, and review of the recipient's native kidney biopsy may be necessary to assist diagnosis. Clinical clues supporting de novo MN include histological features of transplant glomerulopathy, capillaritis, C4d deposition in the peritubular capillaries, and the presence of donor-specific antibody, all of which

result from either acute or chronic antibody-mediated rejection rather than recurrent idiopathic MN.

Although the pathophysiology of idiopathic MN remains uncertain, there is evidence that circulating autoantibody directed against podocyte enzymes M-type phospholipase-2 receptors, manganese superoxide dismutase, and aldose reductase may play a role in disease pathogenesis. Subepithelial immune complexes, which contain terminal complement, are deposited into podocyte membranes leading to sublytic cellular activation with oxidant and protease production and destruction of the underlying glomerular basement membrane. There is a paucity of data in patients with recurrent idiopathic MN but recent clinical observations have demonstrated the presence of circulating autoantibodies to antiphospholipase A2 receptor, which react with exposed epitopes in the donor kidney [71].

Treatment strategies and outcomes

There is no evidence to support the therapeutic advantage of one immunosuppressive agent over another. Specifically, cyclosporine and MMF (which have been shown to be beneficial in the treatment of primary MN) do not prevent or alter the course of recurrent disease. Reports of rituximab therapy in recurrent MN are few, and limited to case reports or series. Outcomes have been variable and numbers too small to reach any firm conclusion as to its efficacy in achieving partial or complete remission. Non-immunosuppressive therapies include ACE inhibitors and angiotensin receptor blockers to reduce proteinuria, lipid-lowering agents, diuretics to treat symptomatic oedema and anticoagulation for severe nephrotic-range proteinuria.

Mesangiocapillary or membranoproliferative glomerulonephritis

Background and pathogenesis

Mesangiocapillary glomerulonephritis (MCGN) describes a histological pattern of injury rather than a specific disease. Characterized by mesangial hypercellularity, endocapillary proliferation, and double contour formation along the glomerular capillary walls, recurrent MCGN should be distinguished from de novo transplant glomerulopathy, which demonstrates similar histological features. In such circumstances, recurrent MCGN is suggested by the presence of crescents on light microscopy, with strong staining for C3 and the presence of dense subendothelial deposits on electron microscopy [72], while transplant glomerulopathy is supported by the presence of C4d staining and the presence of circulating donor-specific antibodies. Primary MCGN may be idiopathic but more commonly arises from an array of underlying secondary causes including infection (hepatitis B and C the most common infective cause), autoimmune disease (systemic lupus erythematosus, Sjögren's syndrome and rheumatoid arthritis), and dysproteinaemias.

MCGN type I

Disease pathogenesis arises from mesangial and subendothelial glomerular deposition of IgG and C3, presumably representing immune complexes following exposure to endogenous self-antigen (DNA in SLE) or exogenous non-self antigen (hepatitis B or C antigen). As these antigens are not eliminated following transplantation, it is predictable that recurrence rates are high (20 to 50%) [58,73,74], with reports of graft loss in up to 40% of those with recurrence [73,74] (Table 77.2). Clinical manifestations include graft dysfunction, microscopic haematuria, and proteinuria. Risk factors associated with recurrence include severity of histological lesions in the native kidneys, live-related transplants (HLA-identical recipients appear to be at particular risk), HLA-B8DR3, and previous graft loss from recurrent disease (where risk rises to approximately 80%) [73,75]. No formal therapy has been proven useful, although the underlying cause of MCGN type I may influence therapy. Recurrent disease related to hepatitis B antigenaemia may respond to antiviral therapy while liver transplantation has reported short-term success with hepatitis C associated MCGN. Other forms of type I MCGN have been treated with immunosuppression with or without plasma exchange but all therapies have met with limited success.

MCGN type II

Type II MCGN (or dense deposit disease) is confirmed by electron-dense transformation of the glomerular basement membrane and deposition of C3 (and other complement protein) but without IgG deposition. It claims an even greater rate of recurrence at 50 to 100% of grafts, usually presenting with non-nephrotic range proteinuria, haematuria, and gradual graft dysfunction within the first year from transplant. Graft loss to recurrence occurs in 15–30% of grafts beyond 5 years [76] (Table 77.2). Male gender, heavy proteinuria, and cellular crescents on biopsy appear to correlate with worse outcome and higher risk of graft loss. It has been proposed that the superimposition of cellular crescents, interstitial fibrosis, and mesangial proliferation (i.e. severity of disease) better explains the higher risk of recurrence rather than disease subtype itself [75]. Regardless, type II MCGN appears to present with more aggressive histological features than type I, likely explaining the greater risk of recurrence and worse outcome in this group of patients. Immunosuppression and plasmapheresis have been used in case reports but no successful therapy is known.

MCGN type III

Often considered a variant of type I MCGN, histological diagnosis is supported by the presence of both subendothelial and subepithelial deposits. Data on this disease subtype are too sparse to reliably inform recurrence risk or prognosis, suffice to say that transplantation has been successfully performed with recurrence described in one case report at 13 months from transplant with graft loss at 7 years [77].

Thrombotic microangiopathy

Background and pathogenesis

Thrombotic microangiopathy (TMA) is characterized by endothelial injury and is manifested histologically by intimal cell proliferation, thickening and necrosis of the vessel wall with narrowed lumens and thrombi in the glomerular, arteriolar, or interlobular arteries. It is seen typically in the renal biopsies of patients with haemolytic uremic syndrome (HUS) or thrombotic thrombocytopenic purpura. Recurrent disease should be differentiated from de novo TMA following renal transplant that is secondary to infection (e.g. polyoma virus), iatrogenic (related to calcineurin inhibitors, mTORi, or OKT3), or immunological causes (acute humoral rejection).

Recurrent TMA typically occurs in patients who developed renal failure from the non-diarrhoeal form of HUS. It is particularly frequent in patients with autosomal recessive or dominant familial or atypical HUS (aHUS) where the disease arises from mutations or polymorphisms in genes encoding complement regulatory proteins factor H (CFH), membrane cofactor protein (MCP), and factor I (FI). Data are now emerging that patients with mutations

in the complement activating components factor B and C3 are also at risk of recurrence. Circulating complement factor proteins, factor H (the most common mutation), factor I, factor B, and C3, are all produced by the liver, explaining why recurrence rates are so high in these patients following renal transplant. In contrast, MCP is a membrane-associated regulator that limits complement activity at the cell surface. It is ubiquitously expressed and therefore present on endothelial cells within the kidney allograft. For this reason, TMA rarely recurs in patients with MCP mutations.

It is thought that kidney endothelial cells in patients with complement deficiency or anti-CFH autoantibodies with aHUS are more vulnerable to early ischaemic injury, triggering complement activation and thrombotic microangiopathy. Post-transplant viral or bacterial infections that activate complement, and injury that may potentiate inflammation and injury such as acute rejection, may also further increase the risk of triggering recurrent TMA.

Historical reports of HUS patients undergoing renal transplantation quote recurrence rates of 4 to 60%. The low incidence of recurrence in some reports is probably explained by the inclusion of patients who received transplants for HUS following a diarrhoea prodrome and most likely had Shiga-toxin producing *Escherichia coli* (STEC)-associated HUS (Stx-HUS). STEC-released toxins are the cause of Stx-HUS and re-exposure to toxin is required to induce recurrence. As most patients develop neutralizing antibodies to Stx following infection, recurrence is rare.

A review of 118 paediatric patients who received 137 renal transplants after HUS following a diarrhoea prodrome (most of whom were presumably Stx-HUS), found only one had recurrence after transplant. In a separate study of 62 children who were known to have had Stx-HUS, there was no recurrence of HUS and graft survival was superior at 10 years when compared to children transplanted for other causes [78,79].

Conversely, outcome is poor following transplantation for atypical HUS (i.e. STEC infection excluded). A review by Bresin et al. found approximately 60% of patients experienced recurrent disease, 91.6% of which progressed to graft failure. One-year graft survival was 32% for patients receiving a deceased donor kidney transplant and 50% for living donor transplants. The presence of CFH or FI mutations were associated with a high incidence of graft failure (74% and 100%, respectively) [80]. Data from USRDS confirm poor prognosis, reporting survival rates of only 50% at 3 years [81]. Time to recurrence may be within days from transplant up to 2 years, but the majority (60%) present within the first month [79].

Clinical presentation may vary from mild allograft dysfunction, with or without evidence of microangiopathic anaemia and thrombocytopenia, to rapidly progressive graft dysfunction in the absence of extrarenal manifestations. Platelet count should be closely monitored during periods of graft dysfunction in patients with atypical HUS, with a low threshold to assess peripheral blood film (for fragmented cells), haptoglobulin, and lactate dehydrogenase to look for evidence of haemolysis (Table 77.3). Renal biopsy is invariably required to confirm the diagnosis, although caution should be extended in the setting of severe thrombocytopenia.

Treatment strategies and outcomes

There is no evidence to suggest that avoiding agents associated with TMA, such as CNI and mTOR inhibitors, will reduce the risk of recurrence. Some have shown that early use of cyclosporine increased the risk of recurrent TMA [82] while others found no effect [83]. Although some advocate the avoidance of CNI early after transplant if possible [84], recurrent HUS has been reported in patients with CFH or CFI mutations receiving CNI-free immunosuppression. Active treatment strategies include plasmapheresis with fresh frozen plasma (FFP) (to increase levels of factor H and I), IVIG, and rituximab [85,86]. Reports of success are limited to case reports, with variable outcomes. Simultaneous liver and kidney transplant, with perioperative plasma exchange using heparin and FFP, has permitted successful transplantation of a handful of cases with factor H mutations [87–89]. Data have been reported on the successful use of the humanized anti-C5 monoclonal antibody, eculizumab, to treat atypical HUS in native kidneys and rescue therapy for recurrent HUS after transplant. Of five published reports using eculizumab to treat recurrent disease after transplant, four showed complete recovery and one partial recovery [90] (Table 77.3).

ANCA-associated glomerulonephritis

Background and pathogenesis

Advances in early recognition and treatment of ANCA-associated GN have resulted in improved patient survival and progressive renal disease. Despite this, a proportion of patients still progress to ESKD. Providing clinical remission has been achieved and maintained, transplantation is considered safe and the risk of disease recurrence is low. True recurrence rates are unclear, as data remain sparse. A pooled analysis, published in 1999, reported a recurrence rate of 17% with follow-up ranging from 4 to 89 months. Of these, 57% demonstrated renal involvement but only two lost their grafts due to recurrence [91]. In an era of tacrolimus and MMF-based immunosuppression, more recent analysis reported lower recurrence rates of 7%, with 94% graft survival at 5 years [92]. Briganti et al. reported a 10-year incidence of allograft loss of 7.7% in patients with ANCA-associated vasculitis, although not all these grafts were lost to recurrent disease [2] (Table 77.2).

Clinical renal presentation typically involves graft dysfunction accompanied haematuria and proteinuria. Histological features include changes of a pauci-immune necrotizing vasculitis, although acute arteritis may also be present and obstruction from ureteral stenosis resulting from granulomatous vasculitis has been reported.

Other than evidence of clinically active disease prior to transplant, there are no clear predictors of disease recurrence after transplantation. Pretransplant disease course, disease subtype (Wegner's, microscopic polyangiitis, Churg–Strauss), cANCA or pANCA subtype, and pretransplant antibody titres (without clinical disease), type of donor, or duration of follow-up all fail to reliably predict recurrence.

Treatment strategies and outcomes

Current therapies used to treat vasculitis in native kidneys also appear effective in allografts. A pooled analysis and several case series show a good response to cyclophosphamide therapy for the treatment of relapses [93]. Case reports and small case series have also reported successful remission using other treatments including plasma exchange, rituximab, and intravenous immunoglobulin [94–98].

Antiglomerular basement membrane disease

Early case series reported a high rate of recurrence (up to 50%) [99] after transplant. Recurrence of Goodpasture's disease is rare anyway, but current therapies, together with a general policy of delaying transplant until anti-GBM antibodies have been undetectable for

several months, probably explains only one case report of recurrent anti-GBM disease in the last 15 years [100]. Good treatment response was reported with pulse steroid, cyclophosphamide, and plasmapheresis.

Lupus nephritis

Background and pathogenesis

Lupus nephritis leads to ESKD by 10 years in 5 to 10% of patients diagnosed with the disease [101] and accounts for 1 to 2 % of all patients with ESKD who require transplantation [102]. There is no clear consensus on rate of recurrence after transplant. Traditionally thought to be low, more recent data report rates between 2 and 9% [2,103] (Table 77.2). Histological data (including reports from surveillance biopsies) report recurrence rates of 30 to 54%, although graft loss is rare [15,102]. Mean time to recurrence is approximately 3 years but may occur within days from transplant. There are no markers to reliably predict recurrence. In particular, serology and duration of dialysis before transplant are not predictive. Reports on graft survival in patients with lupus nephritis are conflicting. Pooled data have suggested equivalent outcomes in three studies, while six reported worse outcomes in patients with lupus nephritis despite their younger age [103]. Nevertheless, graft loss due to recurrent lupus nephritis is uncommon (2–4%) and more recent data report comparable patient and graft survival when compared with recipients with different underlying disease [102,104] (Table 77.2). The caveat to this is the greater risk of thrombotic events (including graft thrombosis) in lupus patients with known antiphospholipid antibodies.

Treatment strategies and outcomes

Management of recurrent lupus nephritis has not been formally studied. Post-transplant immunosuppression does not routinely differ from standard therapy. There are anecdotal reports on the efficacy of MMF for the treatment of recurrent lupus nephritis; however, these are currently limited to case reports [105,106].

Systemic sclerosis/scleroderma

Background and pathogenesis

Scleroderma renal crisis occurs in approximately 10% of patients with scleroderma, leading to progressive renal disease in many patients despite current therapy. Nevertheless, survival rates have improved in recent years and renal transplantation is an option for those patients who progress to ESKD.

Risk of recurrence was previously thought high, at 20 to 50%, with resultant graft loss occurring in 20% of cases [107]. In contrast, more recent data from the United Network for Organ Sharing (UNOS) report a recurrence rate of 1.9% in 260 patients transplanted between 1987 and 2004 for scleroderma or progressive systemic sclerosis. Graft survival was 79% at 1 year, 57% at 5 years, and 27% at 10 years [108]. Reasons for such disparity in recurrence rates may include publication bias of more complex cases in early case series, while incidence of recurrent disease by UNOS may have been under-reported (not all graft losses were reported and cause of graft loss was unknown in 32% of cases in the UNOS study).

Risk factors for scleroderma renal crisis in the native kidney include use of steroids, disease duration less than 4 years, progressive skin thickening, new-onset anaemia, pericardial effusion, or congestive cardiac failure. No such risk factors have been studied in the renal allograft after transplant and it is not known whether the use of steroids may precipitate recurrent disease in the allograft.

Treatment strategies and outcomes

For those who develop recurrent scleroderma, time to onset is unknown; however, limited data suggest onset is more commonly reported within the first few months to the second year from transplant and late presentation is rare. Management of recurrent scleroderma is not well described. The use of ACE inhibitors to treat hypertension would appear reasonable but there is no evidence clearly demonstrating a beneficial effect in this patient cohort.

Fibrillary glomerulonephritis and immunotactoid glomerulopathy

Fibrillary GN is a recognized histological entity that occurs in approximately 1% of native kidney biopsies in studies from Western countries. It is characterized by glomerular accumulation of randomly arranged fibrils, which differ from amyloid by their size and lack of reactivity with Congo red. In contrast to immunotactoid GN (which is histologically similar), fibrillary GN is rarely associated with underlying systemic disease. Progression to ESKD occurs within several years of diagnosis in approximately 50% of patients and no effective therapeutic intervention has been trialled. A number of these patients have been successfully transplanted. Fibril deposition has been reported in greater than 50% of renal allografts, although recurrent disease appears to follow a relatively benign course [109] (Table 77.2).

Fabry's disease

Background and pathogenesis

Fabry's disease is a rare X-linked glycosphingolipid storage disorder resulting from a deficiency of the lysosomal enzyme α-galactosidase A. It results in gradual accumulation of glycosphingolipids within the lysosomes of various cells and tissues, including renal epithelial cells, leading to proteinuria, renal dysfunction, and eventual ESKD in the majority of affected patients. Renal transplantation is the treatment of choice for these individuals, although data are lacking on the incidence of recurrent disease, graft survival, and the effects of enzyme replacement therapy following transplantation. The US Organ Procurement and Transplantation Network registry study examined 197 renal transplant recipients with Fabry's disease and found 74% had a 5-year graft survival, compared to 64% in patients transplanted for other reasons [110]. Similarly, data from the European Dialysis and Transplant Association/European Renal Association registry found graft survival was similar at 3 years in 33 patients with Fabry's disease compared to other patients with different nephropathies (72% vs. 69%) [111].

Evidence of disease recurrence after transplantation is sparse and limited to case reports, which have shown disease may recur in the kidney within 6 to 8 months from transplant [112], while deposition of glycolipid in tubular epithelial and endothelial cells has been demonstrated up to 14 years after transplant [113]. The presence of these lesions appear insufficient to compromise graft function.

Treatment strategies and outcomes

The introduction of enzyme replacement therapy (ERT), agalsidase-α or agalsidase-β, has been shown to reduce the rate of decline in kidney function in native kidneys; however, it is unclear whether therapy improves graft survival or reduces complications related to Fabry's disease in transplant recipients. A recent European study demonstrated that ERT was safe, well tolerated, and graft function remained stable over the 2-year study period. Whether it impacts on long-term allograft survival is not known [114].

Recurrent disease after pancreas transplantation

Background and pathogenesis

Recurrence of diabetes after pancreas transplantation was reported first by David Sutherland's group in the 1980s. They reported a cohort of ten patients who had been transplanted with the tail of the pancreas from living donors. Five were from HLA-identical twins and five from HLA-identical siblings. There was a prompt return to diabetes when immunosuppression was reduced or stopped. Graft biopsies confirmed disease recurrence with the presence of isletitis and selective β-cell destruction [115–117].

However, for SPK or pancreas after kidney (PAK) recipients the donors are not HLA-identical and they remain on lifelong immunosuppression. This combination is thought to protect the majority of recipients from recurrent diabetes after pancreas transplantation. The lack of MHC compatibility means that memory autoreactive CD4 and CD8 T cells have limited affinity for the newly transplanted β cells. In addition these diminished autoreactive responses seem adequately suppressed with the combination immunosuppression used to prevent rejection. For the majority of pancreas transplant recipients, the data would seem to support the hypothesis. Once the pancreas survives the early technical complications, the long-term graft survival is excellent. At our institution, the 20-year pancreas graft survival exceeds that of the kidney graft from the same donor, suggesting that autoimmune disease recurrence does not have a major impact on graft survival. Furthermore, long-term graft survival is excellent with normal glucose tolerance tests and HbA1c persisting beyond 10 years with no reduction in function over time [118]. Studies that have looked for autoimmune recurrence after pancreas transplantation have provided mixed results. A retrospective evaluation of pancreas histology, which was a combination of biopsy samples, pancreatectomy, and autopsy results, from a 100 pancreas transplant recipients, showed no definitive evidence of autoimmune recurrence [119]. In HLA-mismatched pancreas grafts isletitis was identified in 19% of grafts but was only seen in the context of associated graft rejection. Although disease recurrence could not be ruled out, none of these patients developed recurrent diabetes [119,120]. In a follow-up publication of 200 pancreas transplants by the same group, they failed to identify a single case of recurrent autoimmune diabetes provided the graft was mismatched for MHC and the recipient remained on immunosuppression [117]. Hence in their experience, disease recurrence was seen primarily in patients who received HLA-identical segmental pancreas graft from a sibling and minimal or no immunosuppression.

More recently, evidence of autoimmune disease recurrence has been demonstrated as a cause of graft loss in a small number of pancreas transplant recipients. Initially, there was a report of two cases of histologically proven autoimmune induced recurrent diabetes [121]. The two patients received HLA-mismatched pancreas grafts and were maintained on cyclosporine, azathioprine, and prednisolone. After initial good graft function, the pancreas graft failed whilst maintaining good renal graft function 2 years and 29 months after transplantation [121]. Histology showed isletitis without rejection and selective loss of β cells consistent with autoimmune destruction. A second study looked at the association of major islet autoantigens and pancreas graft outcome [122]. They looked at islet autoantibodies in 110 recipients and followed 75 of these sequentially for up to 11.2 years (median follow-up 6.3 years). They found that pancreas graft survival was not associated with the presence of GAD or IA-2A antibodies prior to transplantation. The majority (59%) of patients remained persistently autoantibody negative after transplantation; 34% of patients had stable or declining levels of autoantibodies after transplantation and it was not a predictor of loss of function. However, in five cases (7%) there was an increase in IgG1 antibody titre and graft function was lost in four of these patients, suggesting that in a minority of patients increasing titres of islet autoantibodies was a strong predictor of graft failure and return to insulin [122].

The most definitive proof of recurrence of diabetes was provided by researchers at the University of Miami. Using very sophisticated studies in a small number of individuals they were able to confirm recurrent autoimmunity as a cause of graft loss. In three individuals they showed: hyperglycaemia without rejection, the presence of isletitis with selective β-cell loss, the persistence or reappearance of islet autoantibodies, and the presence of circulating islet autoreactive CD4 and CD8 T cells at the time of graft loss [123–125]. The assays used to identify islet-specific autoreactive T cells are difficult to perform and the technology is available only in one or two research laboratories worldwide. Hence, it is not suitable as a routine screening test. Nevertheless, these studies show definitively that autoimmune disease recurrence does occur in HLA-mismatched pancreas transplants despite immunosuppression. Whilst the condition is thought to be relatively uncommon, there are suggestions it may occur in up to 5% of recipients [126]. Further work is required to more accurately determine the size of the problem and to validate diagnostic markers that would point to the diagnosis prior to loss of function.

Clinical features

The clinical feature suspicious of autoimmune recurrence is loss of c-peptide in the absence of rejection (Table 77.4). In SPK patients this is relatively easy to confirm as rejection is diagnosed by monitoring renal function and renal biopsy is standard of care for diagnosing rejection. In patients who have received a pancreas transplant alone or a PAK transplant this is more difficult as pancreas rejection can occur in the absence of kidney rejection and a pancreas biopsy is necessary to determine whether autoimmune recurrence or pancreas rejection is the cause.

Investigation

The early features of autoimmune diabetes is isletitis with mononuclear cells and selective loss of β cells [127]. With time there may be variable loss of other cell types such as α cells but this is variable and the loss of β cells is constant. In addition, the acinar tissue and blood vessels are normal without a cellular infiltrate. By contrast, rejection consists of a mononuclear cellular infiltrate within all compartments of the pancreas (acinar, islets, and vascular) with or

Table 77.4. Features of recurrent type 1 diabetes after pancreas transplantation

	Features in recurrent type 1 diabetes
Incidence	Uncommon Up to 5% of transplants
Clinical features	Gradual loss of c-peptide and recurrence of diabetes in absence of rejection
Pathology	Isletitis with selective loss of β cells with normal acinar and vascular histology
Diagnosis	Reappearance or increase in titre of anti-GAD and anti-IA2 antibodies Pancreas biopsy
Treatment	None shown to be of benefit Maximize immunosuppression if under immunosuppressed

without an endoluminal vasculitis. Whilst a mononuclear infiltrate of islets can occur in pancreas rejection, there is not a selective loss of β cells and other compartments of the pancreas, such as acinar tissue, are similarly involved [119].

Whilst definitive proof of autoimmune recurrence relies on a histological diagnosis, there are other laboratory features that are suggestive of this possibility. Loss of function from recurrence of disease is gradual and there is a progressive loss of c-peptide over months to years [125]. In addition, the reappearance or increase in titre of anti-GAD and anti-IA2 antibodies has been shown to be associated with recurrence. However, the data regarding this is limited and it is not clear whether autoimmune diabetes can recur in the absence of autoantibodies and many patients remain disease free despite the persistence of autoantibodies. Hence, diagnosis depends on longitudinal measurement of the titre of autoantibodies over time—something that is not done routinely.

Treatment strategies and outcomes

There is no effective treatment of autoimmunity associated with type 1 diabetes. Various immunosuppressive and short-term depleting T-cell therapies have been tried but none have been shown to be more than transiently effective [128,129]. There has been a small trial of autologous haematopoietic stem cell transplantation at the time of presentation of type 1 diabetes [130]. Whilst there was evidence of benefit, the long-term outcomes and a proper evaluation of the risks have yet to be undertaken. Translating this to a transplant setting has not been done and would be more difficult as there would be substantial additional risks for patients already on long-term immunosuppression.

Because the diagnosis of recurrent diabetes after pancreas transplantation has been limited to case reports, it is very difficult to say anything definitive about treatment. The patients are already on immunosuppression and this should be reviewed and optimized to ensure that adequate immunosuppression is achieved. This is a reasonable approach because the initial reports were in transplants from HLA identical siblings, where immunosuppression was minimized or abolished. Some centres have treated the patients with T- and B-cell-depleting antibodies upon diagnosis. Whilst it was reported that there was temporary abolition of autoreactive T cells and stabilization of c-peptide, there was eventual recurrence of autoreactive T cells and ultimate loss of function. Given the potential risks involved with such an approach it could not be recommended as routine therapy.

Summary of recurrent diabetes after pancreas transplantation

Recurrent type 1 diabetes after pancreas transplantation can occur and is responsible for loss of function and return to diabetes after successful transplantation. It should be suspected in patients who have a progressive loss of c-peptide months to years after transplantation in the presence of stable renal graft function. A reappearance or increase in titre of anti-GAD and anti-IA2 antibodies should raise the suspicion of the diagnosis, which would then be made on pancreas biopsy. The actual prevalence is not really known although it is uncommon. Clearly this is an area requiring ongoing investigation and research.

Concluding remarks

Despite overall progress in renal and pancreas transplant research, our understanding of the pathogenesis of recurrent disease, and its true prevalence in both organs, remains unclear while therapeutic interventions are limited.

Part of this problem lies in our poor understanding of primary disease in the native organ. However, rather than being seen as a deterrent, perhaps this should be regarded as a unique opportunity to provide insight into native disease in the setting of different persistent immunosuppressive regimens. Furthermore, the advent of new molecular methods, originally targeted to allow non-invasive monitoring of allograft pathology, provide the chance to apply techniques such as gene microarray, proteomics, and metabolomics to study the aetiology and pathogenesis of primary disease that may recur in the graft.

Collaboration is required to better inform the true prevalence of recurrent disease, risk of recurrence, and impact on graft survival. Given the relative rarity of many of the diseases in question, large multicentre trials are necessary if any hope of progress in prevention and therapeutic intervention is to be achieved.

CHAPTER 78

Recurrent Disease after Liver Transplantation

Samir Parekh and James R. Spivey
Emory University School of Medicine, The Emory Transplant Center, Atlanta, GA, USA

Introduction

For many patients with chronic liver disease, orthotopic liver transplantation (OLT) offers the best, if not only, hope for survival and long-term quality of life. For some patients, liver transplantation cures the offending disease, offering the recipient a chance for life without concerns about disease recurrence. For others, recurrence of the original disease, or manifestation of previously unidentified disease processes, present ongoing postoperative challenges. In this chapter, we limit our discussion to disease recurrence acknowledging that, in some cases, such as the differentiation of ischemic ductal disease from recurrent primary sclerosing cholangitis, or the development of de novo autoimmune disease, diagnosis may not be so precise. Much space has been devoted to recurrent hepatitis C commensurate with the effort required to manage these patients in the outpatient clinic and perhaps motivated by a consistently lower survival rate in these patients. On the other hand, the once feared recurrence of hepatitis B might soon become a footnote in transplant history. This chapter covers the common diseases with substantial recurrence risk to liver transplant recipients, and describes their differential diagnosis and treatment. It complements Chapter 70 covering the clinical identification and management of liver allograft rejection, and provides clinical context to the more in-depth discussion of liver transplant histopathology found in Chapter 82.

Viral disease

Hepatitis C

Recurrence of hepatitis C virus (HCV) infection is the leading cause of allograft failure and death in HCV patients undergoing OLT [1]. Forman reviewed over 11 000 OLT cases from the United Network for Organ Sharing (UNOS) database and compared outcomes of HCV+ patients with HCV– patients. Liver transplantation in HCV+ patients was associated with higher death and allograft loss rates than HCV– patients in this analysis, in contrast to other, smaller studies at various centers [2–5]. Outcomes for retransplantation for recurrent HCV infection are lower than for primary transplantation [6,7], leading some centers to refuse retransplantation, especially if renal dysfunction exists. Outcomes following retransplantation of HCV+ patients compared with HCV– patients may not differ when the degree of liver dysfunction and patient performance status are similar and when HCV+ patients are transplanted promptly upon development of allograft dysfunction [8].

Viral kinetics

Recurrence of HCV infection after OLT usually occurs quickly and in essentially every case when the patient is viremic at the time of OLT. HCV RNA levels drop significantly in the anhepatic phase and for a short time after reperfusion [9]. Up to 90% of patients become viremic within 1 week after OLT, while peak viral loads are often not realized for up to 7–8 weeks. Mean viral loads in transplant patients are higher than those seen prior to transplantation due to immunosuppression. Gane *et al.* [10] noted many years ago that pulsed corticosteroids for acute cellular rejection were associated with higher viral loads and more severe histologic disease.

Disease course

Once allograft infection occurs, the clinical course is variable. Approximately 5–7% of patients will develop an ominous fibrosing cholestatic hepatitis, a term applied first to allograft infection with recurrent hepatitis B. These patients usually display high viral loads and relentless hepatonecrosis and jaundice. Histologic findings include centrilobular ballooning hepatocyte degeneration, cholestasis, and a characteristic paucity of lobular inflammation (Figure 78.1). The aggressive course and poorer outcomes associated with this type of disease represent perhaps the best evidence of a direct cytopathic effect of the virus on the hepatic allograft [11]. Most patients develop lobular hepatitis within 3–6 months after OLT. Approximately 25% of patients experience an aggressive recurrence of disease that leads to allograft cirrhosis or advanced fibrosis within 3–5 years. Ciccorossi et al. [12] correlated high viral load at 1 week after OLT with poorer outcomes. Sreekumar et al. [13] noted that higher HCV RNA levels at 4 months after OLT ($>10^9$ copies/mL or >log 1 meq/mL) were associated with higher grades of inflammation and stages of fibrosis at 1 and 3 years post-OLT. Approximately two-thirds of patients will experience a somewhat less aggressive but variable course, with little or slower fibrosis progression. A typical course includes mild lobular hepatitis within the first few months after allograft infection (Figure 78.2) followed by the appearance of more significant portal infiltrates and chronic active hepatitis (Figure 78.3). Patients with recurrent HCV infection after OLT often display significant impairment in quality of life and physical functioning [14]. Histologic evidence of recurrent HCV infection is often confused with, or obscured by findings of acute cellular rejection [15]. More obvious evidence of HCV recurrence is often evident after treatment of acute cellular rejection and resolution of its associated histologic findings. Table 78.1, and the

sections that follow, summarize these and other factors that may predict more severe HCV recurrence.

Recipient factors and virus characteristics

Recipient factors associated with worse outcomes for HCV after OLT include pretransplant viral load and, in some studies, recipient age, gender, ethnicity, and HCV genotype [1,10,12,16]. Of these variables, high pretransplant viral load may represent the highest risk for graft loss and mortality [1]. Virus characteristics such as genotype and viral heterogeneity may have a role in disease severity after transplantation, but these findings have little practical application. Quasispecies noted pre-OLT do not necessarily persist after OLT, leading to further uncertainty about the significance of their existence [17]. Genotype 1b may be associated with more severe HCV infection after OLT [10] but other studies have shown no such discrepancy [3,18,19]. In a small study, genotype 4 was not associated with different outcomes when compared with outcomes of patients with other genotypes, but fibrosis development was more rapid and severe in the patients with genotype 4 [20]. A separate study from Australia, however, suggested that patients with genotype 4 have inferior outcomes [21]. Heterogeneity of patient cohorts and immunosuppression regimens make data comparison difficult with regard to these variables.

Donor factors

No donor factor has a stronger proclivity for more severe recurrence of HCV than donor age. Donor age greater than 50 years, and especially greater than 65 years, has been shown unequivocally to lead to worse outcomes for these patients, both in Europe and in North America and whether or not the donor is living or deceased

Table 78.1. Risk factors for more severe recurrence of hepatitis C virus (HCV)

Factor	Strength of evidence
Pretransplant	
Donor age (linear for age >35)	+++
Living donor	+
Donor/recipient HLA matching	+
Genotype 1B	+
HIV coinfection	+++
Female gender	+
Epoch (more recent)	+
Donor steatosis	+
Operative	
longer cold ischemic time (>12 h)	++
Donor genetic factors	+
Post-transplant recipient	
Advanced age (>50 years)	+++ (patient/graft survival)
Non-white race/ethnicity	+++ (patient survival)
Biliary tract complications	++
Viroiogic variables	
Higher pretransplant viral load	+++
Higher post-transplant viral load	+++
Immunosuppression	
OKT3, pulsed corticosteroids	+++
Short time to recurrence	+++
Treated cytomegalovirus infection	+++

Adapted from [49] Watt et al. (2009), with permission from John Wiley and Sons Ltd.

[22–24]. Donor organ steatosis has been blamed for more frequent and earlier HCV recurrence after OLT [25] but the effects of donor steatosis must be analyzed independently of prolonged ischemia time and associated organ reperfusion injury [26].

Other factors

It is fair to say that for the patient with HCV infection to have a favorable outcome after liver transplantation, a number of complications must be absent or averted. Excessive immunosuppression must be avoided. Yet acute cellular rejection, which does not generally adversely affect outcomes in non-viral patients, is associated with poorer outcomes in patients with HCV infection [27]. Just how to achieve optimal immunosuppression in the patient with HCV infection is a challenge for all transplant providers and a topic of much debate. Immunosuppression in these patients is covered in more detail later. Cytomegalovirus (CMV) infection, another factor directly related to immunosuppression levels, is associated with more rapid progression of recurrent disease, although its association with graft survival is not clear [28,29]. Although difficult to separate from reperfusion injury and prolonged ischemia times, biliary complications may contribute to poorer outcomes in patients with HCV. One carefully performed retrospective review of over 700 patients from two institutions showed that although biliary complications adversely affected 1-year graft survival rates, the combination of biliary complications and HCV did not, thereafter, affect fibrosis rates [30].

Treatment challenges

Sustained clearance of HCV infection through treatment was at first expected to be tenuous in the patient undergoing subsequent immunosuppression therapy but sufficient data exist to prove that sustained viral responses (SVR) are durable when achieved before and after OLT [31–33]. A persistent portal hepatitis in some patients rendered virus-free after transplantation has led to concerns about persistent virus in liver tissue [34]. However, modern assays for viral quantitation and viral detection as well as appropriate follow-up must be employed to determine the significance of such findings [35]. Some investigators have made a strong case for early treatment of recurrent HCV regardless of fibrosis score, noting the risk for progression of fibrosis and portal hypertension [36]. Since some patients with HCV infection do not progress rapidly after OLT and given the concerns about treatment-mediated chronic rejection and autoimmune phenomenon (see later), other programs initiate therapy when documented disease progression compels treatment [37,38]. Such reports of dire outcomes associated with antiviral therapy usually include only small numbers of patients and, while calling for caution, have not dissuaded the transplant community from taking an aggressive approach to treatment. At this time, the accepted treatment regimen of HCV after transplantation is standard of care (SOC) therapy with pegylated interferon and ribavirin as direct acting antiviral agents are only just being introduced to these patients. Treatment is less well tolerated by these patients compared with the general population and dose reductions, especially because of anemia, are much more common. Rates of SVR vary widely but are approximately 30% across many studies and are only rarely seen when treatment is not continued for at least 48 weeks [39]. As recently as 2005, no prospective randomized trials of post-OLT HCV treatment had been conducted. In a multicenter study, Chalasani et al. performed two randomized controlled trials, a prophylaxis trial and a treatment trial, to evaluate the safety and efficacy of peginterferon alfa-2a in the treatment of HCV recurrence after OLT. Peginterferon alfa-2a treated patients had significantly lower HCV RNA levels and more favorable changes in hepatic histologic features than untreated controls. However, only two treated patients in the prophylaxis trial (8%) and three patients in the treatment trial (12%) achieved a sustained virologic response. In the prophylaxis trial, eight patients (31%) in the peginterferon alfa-2a group and nine patients (32%) in the untreated group were withdrawn prematurely; whereas in the treatment trial, 10 patients (30%) in the peginterferon alfa-2a group and six (19%) in the untreated group were withdrawn prematurely. The incidence of acute rejection was similar in the treated and untreated groups in both the prophylaxis (12% versus 21%; $P = 0.5$) and treatment (12% versus 0%; $P = 0.1$) trials [40]. The importance of IL28B status and response to treatment after OLT is uncertain. A recent study from Barcelona suggests that successful treatment of patients for HCV infection after OLT may be influenced by the IL28B status of both recipient and donor [41].

Concerns about treatment-induced allograft rejection exist but the data are conflicting [42]. In one study, interferon-induced rejection, when it occurred, was easily treated [43]. In a French study of 70 treated patients, 21% developed rejection, five mild, nine moderate and one severe, during IFN-based therapy. Almost all responded to treatment of rejection and there were no allograft losses [44]. Previous history of rejection prior to interferon therapy and use of pegylated interferon were significantly associated with rejection. Finally, Berardi et al. have described de novo autoimmune hepatitis attributed to antiviral therapy with interferon and ribavirin in 9 of 44 patients despite viral clearance [45]. The occurrence of autoimmune and/or plasma cell hepatitis will be expanded in the following section.

The emergence of new viral-specific agents to include boceprevir and telaprevir offer the potential for less morbid and more effective therapeutic options. While data regarding these and other agents post-transplant are sparse at present, the use of more targeted antivirals will certainly occupy a substantial part of the future of HCV disease recurrence.

Plasma cell hepatitis

Ward and others have raised concern about the occurrence of de novo plasma cell hepatitis in patients with HCV after OLT [46]. It is unclear if this is a variant of autoimmune disease or a peculiar type of allograft rejection. These questions have focused attention on a broader challenge: the accurate interpretation of liver allograft biopsy findings in patients with HCV. Differentiation of acute rejection from HCV recurrence is difficult when the two processes share characteristics including periportal hepatitis and lymphocytic cholangitis. Effective treatment of acute cellular rejection may simply make residual findings of HCV more obvious. These challenges were brought nicely into focus by Demetris and Sebagh [47]. Their editorial in 2008 concentrated on the importance of the finding of centrilobular necroinflammatory activity and its association with acute and chronic rejection, the presence of plasma cell infiltrates, and the possible importance of autoimmune phenomena. The presence of autoimmune phenomena in patients with HCV in the general population is well described, including cryoglobulinemia and vasculitis, production of autoantibodies and serum rheumatoid factor, Sjögren's syndrome, glomerulonephritis, and B-cell lymphoma [48]. In the liver transplant patient, the use of steroids in some programs has approached anathema although experience clearly shows that corticosteroids often provide benefit in HCV+ liver transplant patients with autoimmune features. Nevertheless, some HCV+ transplant patients with autoimmune features will likely experience more aggressive disease and realize worse outcomes. The inconsistent nature of the post-transplant course, biopsy findings, and response to corticosteroids and antiviral therapy in HCV+ allograft recipients calls attention to the heterogeneous nature of these patients and the pitfalls of treating them all in the same way. Nevertheless, a general treatment algorithm is useful [42,49].

Immunosuppression considerations

Tacrolimus and HCV antibody testing were introduced at roughly the same time in the early 1990s. Since that time, there has been intense interest in the effects of immunosuppression on the severity of recurrence of HCV after OLT. Berenguer et al. [50] reported in 2000 that the fibrosis progression rate of HCV infection after liver transplantation has increased in more recent years, suggesting that perhaps changing immunosuppression may affect outcomes in these patients. Two groups have suggested, based on *in vitro* data, that cyclosporine may have inhibitory effects on HCV [51,52]. This notion has not been strongly supported by clinical data. By 1998, Wiesner [53] showed that patients with HCV infection receiving tacrolimus had significantly lower 5-year mortality rates than patients receiving cyclosporine. More recently, Irish examined the UNOS/OPTN (Organ Procurement and Transplantation Network) database and noted that in 8809 patients receiving either cyclosporine or tacrolimus between 2000 and 2007, with a median follow-up time of 5 years, patients receiving cyclosporine were more likely to develop allograft failure and death within 2 years post-transplant [54]. The authors point out the need to examine survival beyond 1 year when examining the effects of different types of immunosuppression. Some transplant programs convert patients with HCV infection to cyclosporine from tacrolimus when initiating antiviral therapy. In the time of direct acting agents (DAAs), such conversion may be justified because the interactions of cyclosporine and the DAAs will be much easier to manage, but only highly successful antiviral therapy may justify the switch away from tacrolimus. Manousou et al. [55] prospectively compared single-drug therapy with tacrolimus and triple-drug therapy with tacrolimus, azathioprine, and short-term prednisone, and noted slower fibrosis progression in the patients treated with triple-drug therapy. A single-center study by Jain et al. [56] prospectively compared tacrolimus and prednisone with tacrolimus, prednisone, and mycophenolate (MMF) and noted no differences in graft or patient survival, rejection, or rate of HCV recurrence based on biochemical changes and histologic findings. More recently, McKenna et al. [57], in a retrospective analysis, showed slower fibrosis progression in a cohort of sirolimus patients than a control group of patients not exposed to sirolimus. Conversely, Watt et al. [58] analyzed over 26 000 patients in the Scientific Registry of Transplant Recipients (SRTR) database including over 12 000 patients with HCV infection, and noted an association between sirolimus use and an increased risk of death and graft loss after liver transplantation in patients with HCV infection not seen in patients without HCV. The authors concluded that tacrolimus was associated with superior outcomes and that sirolimus should be used sparingly in recipients with HCV infections. In the multicenter HCV3 trial, patients were prospectively randomized to three arms: tacrolimus/corticosteroids; tacrolimus/corticosteroids/MMF; and a steroid-free arm using tacrolimus/MMF and daclizumab induction [59]. After 2 years, the steroid-free arm proved safe and was also associated with fewer patients with diabetes mellitus but there was no difference between the groups with regard to severe recurrence of HCV. Steroid avoidance in these patients is therefore feasible. On the other hand, given that acute cellular rejection (ACR) is to be avoided, and in consideration of de novo autoimmune disease, steroids should not be assiduously avoided.

In conclusion, interest in the importance of immunosuppression with regard to the severity of HCV infection progression after transplantation remains high, but few conclusions can be drawn at this time.

Hepatitis B

The early experience with liver transplantation for hepatitis B virus (HBV) infection was not encouraging as recurrence of the virus was usual, often with predictably unacceptable results. The term fibrosing cholestatic hepatitis, now more often associated with HCV after OLT, was first used to describe some cases of post-transplant HBV infection. The difference in outcomes of patients with or without measurable HBV DNA prior to OLT also became obvious once reliable and sensitive assays became available. Liver transplant programs were especially wary of transplanting patients with ongoing replicative HBV infection until Samuel et al. [60] demonstrated the effectiveness of passive immunoprophylaxis of such patients with hepatitis B immunoglobulin (HBIg). Their European multicenter trial of 334 patients showed a viral recurrence rate of 36% in treated patients versus 75% in untreated patients. Soon thereafter, teams from the Universities of Virginia and California San Francisco demonstrated the improved reliability of HBIg when used in higher and fixed doses sufficient to maintain threshold hepatitis B surface antibody (HBsAb) levels [61,62]. Using these dosing regimens and with compulsive attention to antibody monitoring, programs began to demonstrate only rare viral breakthrough including patients with hepatitis B E antigen (HBeAg) positivity prior to OLT. Over time, although effective, the use of HBIg proved expensive and inconvenient. The eventual emergence of evidence that intramuscular administration of HBIg is as effective as intravenous infusion did little to distract the transplant community from these concerns [63,64]. As oral drugs such as lamivudine and adefovir became

Table 78.2. Diagnostic criteria for recurrent autoimmune liver disease after liver transplantation

	Diagnostic Criteria	Exclusion Criteria
Autoimmune hepatitis	• Elevated transaminases • Hypergammaglobulinemia • Compatible histopathology – Portal inflammation – Lymphoplasmacytic inflammatory infiltrate – Interface hepatitis • Response to steroids	• Viral hepatitis • Drug-induced liver injury • Acute cellular rejection
Primary biliary cirrhosis	• Elevated alkaline phosphatase (variable) • Persistence of serum AMA (not required) • Histopathology – Typical: Florid duct lesion (granulomatous cholangitis) – Compatible: Lymphoplasmacytic portal infiltrates or lymphocytic cholangitis	• Acute or chronic rejection • Drug-induced liver injury • Biliary obstruction
Primary sclerosing cholangitis	• Cholangiogram with intra- and/or extrahepatic biliary stricturing, beading and irregularities of bile ducts • > 90 days post-LT • Histopathology – Fibrous cholangitis – Fibro-obliterative lesions with or without ductopenia, biliary fibrosis or cirrhosis	• Acute or chronic rejection • Hepatic artery thrombosis/stenosis • Anastomotic strictures • Nonanastomotic strictures <90 days post-LT • ABO incompatibillity

AMA, antimitochondiral antibody; LT, liver transplantation.

available, they were combined with HBIg to reduce the risk of HBIg breakthrough [65]. Lamivudine alone was not as effective in preventing HBV recurrence after OLT [66]. Nevertheless, in patients treated with lamivudine and HBIg, scattered cases of successful withdrawal, or ill-advised discontinuation of HBIg, did not result in recurrent viremia. The use of emtricitabine/tenofovir disoproxil fumarate (FTC/TDF) in patients with coinfection with HIV and HBV has been highly effective and provided sufficient encouragement for investigators to consider prospective HBIg withdrawal protocols. Teperman et al. [67] treated 40 patients transplanted for HBV for 24 weeks with HBIg and FTC/TDF. Once viral suppression was documented, patients were randomized 1 : 1 to continue both drugs or to have HBIg withdrawn. Forty-eight weeks after randomization, no patient experienced viral breakthrough. Stravitz et al. [68] simply stopped HBIg after 6 months of therapy in 21 patients, and initiated FTC/TDF, again with excellent results and an estimated savings of $12 469 per year per patient compared with monthly intramuscular HBIg and lamivudine.

More recently, liver transplant programs have begun to replace HBIg early after OLT with either tenofovir or entecavir with increasing confidence.

Autoimmune disorders

Autoimmune hepatitits

Autoimmune hepatitis (AIH) is a chronic necroinflammatory liver disease of unknown etiology characterized by the presence of circulating autoantibodies, hypergammaglobulinemia, and histologic evidence of lymphoplasmacytic interface hepatitis. Treatment with immunosuppression, most commonly prednisone and azathioprine, is effective in preventing disease progression; however, up to 10% of patients fail medical therapy and require liver transplantation. AIH is a relatively uncommon indication for liver transplantation, accounting for 2–3% of pediatric and 4–5% of adult liver transplants performed in Europe and the United States [69]. Overall outcomes with liver transplantation are very favorable, with 5-year and 10-year patient survival rates of approximately 75% [69].

Despite the use of immunosuppressive agents post-transplantation, AIH can recur at rates ranging from 12% to 46% [1]. The wide variation of reported recurrence rates is likely the result of different diagnostic criteria, immunosuppressive regimens, length of follow-up and performance of per protocol liver biopsies. In a study by Gautman et al. [70] reviewing 25 publications, AIH recurrence was found in 23% of patients after a median interval of 26 months. Although AIH can recur in the early post-transplant period, most cases occur after 12 months, and the frequency tends to increase with time after transplantation.

As there is no one specific diagnostic marker of the disease, the diagnosis of AIH is based on a constellation of features, which also holds true for AIH recurrence (Table 78.2). The American Association of the Study of Liver Diseases (AASLD) has put forth the following diagnostic criteria for AIH recurrence:

1 Elevation of serum AST or ALT levels;
2 Persistence of autoantibodies;
3 Hypergammaglobulinemia;
4 Compatible histopathologic findings;
5 Exclusion of alternative etiologies; and
6 Responsiveness to steroids [69].

Defining AIH recurrence may often be a diagnostic dilemma as hypergammaglobulinemia and autoantibodies may persist after transplantation, without necessarily implying recurrence. As such, studies have pointed to histopathology as the most appropriate diagnostic marker of AIH recurrence. Compatible histologic evidence of recurrent AIH includes portal and/or lobular hepatitis in the presence of lymphoplasmacytic infiltrates, and the absence of histologic changes suggestive of alternative diagnoses. Histologic features of AIH recurrence appear to precede clinical or laboratory evidence of disease and may be found despite normal liver biochemistries, suggesting post-transplant protocol biopsies may be beneficial in identifying AIH recurrence early [71,72].

While the pathogenesis remains undefined, several studies have identified risk factors for developing AIH recurrence; however, most risk factors have not been validated and remain controversial. Transplant recipients positive for HLA DRB1*03 or HLA DRB1*04 have been identified as a risk factor in some but not all studies [71,73–77]. HLA-DR locus mismatching between donor and recipient has also been found to be a risk for recurrence [70,76]. In contrast to type 2 AIH, type 1 AIH incurred a sevenfold increased rate of recurrence based on a review of 89 cases [74,77–79]. Not only are patients undergoing transplantation for AIH at

higher risk of both acute and chronic rejection, but acute cellular rejection may also be associated with an increased risk of disease recurrence [72,80]. Increased severity of explant inflammation has been found to be a strong predictor of recurrence, in addition to high serum levels of IgG prior to transplantation [72,81]. While differences in transplant immunosuppressive regimens have been implicated, a systematic review of 13 studies reported no significant difference in disease recurrence between primary immunosuppression with either cyclosporine or tacrolimus [70]. Discontinuation of corticosteroids in patients with AIH following transplantation remains controversial. Several studies have associated disease recurrence with discontinuation of steroids, therefore supporting low dose steroid maintenance after transplantation [74,78]. Conversely, others have demonstrated successful withdrawal of steroids without impact on recurrence, but these studies lacked protocol liver biopsies and silent disease may have been missed [82,83].

The mainstay of treatment for AIH recurrence remains intensification of immunosuppression; however, randomized controlled trials are lacking. Most patients respond to reintroduction or increasing dosages of corticosteroids [73,75,78]. Optimization of calcineurin inhibitor levels and the addition of azathioprine or mycophenolate may provide added benefit. In the setting of a immunosuppressive-unresponsive course, substituting tacrolimus for cyclosporine or replacing sirolimus for calcineurin inhibitors may be efficacious [84,85]. Given the risk of allograft loss, discontinuation of corticosteroids after successful treatment of AIH recurrence is not recommended. For the most part, recurrent AIH can be effectively treated with immunosuppression and has limited impact on graft or patient survival. Some patients will progress to cirrhosis, allograft failure, and need retransplantation, although the true frequency of graft loss resulting from recurrence remains to be determined [86].

Primary biliary cirrhosis

Primary biliary cirrhosis (PBC) is a cholestatic autoimmune liver disease characterized by highly specific antimitochondiral antibodies (AMAs) and lymphocytic cholangitis of small- and medium-sized bile ducts that may eventually lead to biliary cirrhosis. Ursodeoxcholic acid (UDCA) has been shown to prolong survival, free of liver transplantation; however, approximately one-third of patients do not respond to therapy, and a proportion of these patients will require liver transplantation. In the 1980s, PBC was the leading indication for liver transplant, but the number of patients requiring transplant for PBC has declined by 20% in the last decade, possibly in part because of increased use of UDCA [87]. Outcomes following transplant for PBC are excellent, with 5-year patient survival rates of up to 85% [81].

Recurrent PBC (rPBC) was first described in 1982 and subsequent studies have reported prevalence rates ranging widely from 9% to 35% [88–96]. The average time to recurrence ranges between 3 and 5.5 years [88–90,95,96]. The rate of recurrence appears to increases over time with a cumulative incidence rate of 21–37% at 10 years and as high as 43% at 15 years [88,89,95].

Unlike PBC of the native liver, laboratory features of rPBC are not reliable diagnostic markers (Table 78.2). The majority of patients will have normal or clinically insignificant elevations of liver enzymes at the time of diagnosis [89,90,95,96]. In addition, AMA levels follow an unpredictable course post-transplant, as levels may decline, remain elevated, or re-emerge after becoming undetectable [97,98]. There does not appear to be a correlation between the presence of serum AMA and the development of rPBC. The diagnosis of rPBC relies heavily on liver biopsy and histologic analysis. The diagnostic hallmark of rPBC is the florid duct lesions of granulomatous cholangitis which are present in approximately 60% of initial diagnostic biopsies [89]. Other less specific features include lymphoplasmacytic portal infiltrate or lymphocytic cholangitis, and it has been suggested that these features may be predictive of eventual disease recurrence [91,93,94,97,99]. Although often challenging, differentiation between histologic changes of rPBC from other causes of bile duct damage, including acute and chronic rejection, ischemic cholangiopathy, or drug hepatotoxicity, is important.

Risk factors for rPBC remain poorly understood, and while several studies have sought to identify risk factors, findings have been conflicting. Some of the common risk factors identified are increased donor and recipient age, male recipient gender, increased warm and cold ischemia times, and HLA mismatching [76,88,89,95,96]. Multiple studies have demonstrated an increased risk of disease recurrence with the use of tacrolimus compared with cyclosporine-based regimens. Tacrolimus also has been associated with a significant reduction in time to recurrence, up to 50% in one study [88–90,99]. On the other hand, a systematic review including 16 original studies with a total of 1241 patients who received transplantations for PBC found an overall rPCB rate of 16% after a median time of 46.5 months. While there was a trend toward increased recurrence with tacrolimus compared with cyclosporine, statistical significance was not reached. Furthermore, thus far cyclosporine-based immunosuppression has not been shown to influence long-term survival following liver transplantation for PBC compared with tacrolimus [89,96]. No studies have identified a clear correlation between use of azathioprine, MMF, or corticosteroids and rPBC.

Although no established treatment guidelines exist, UDCA is widely used to treat rPBC given its proven pretransplant efficacy, minimal adverse effects, and the opportunity to initiate therapy in the early stages of disease. The assessment of UDCA efficacy is challenging, as many patients with rPBC have normal or near normal liver enzymes; however, Guy et al. [100] found an improvement in alkaline phosphatase levels among 75% of patients with rPBC treated with UDCA. Similarly, Charatcharoenwitthaya et al. [89] demonstrated 52% of patients with rPBC normalized liver enzymes with UDCA treatment compared with only 22% of those untreated. These sample sizes were small and there are no conclusive data that UDCA influences patient or graft survival.

Fortunately, rPBC appears to have little impact on patient or graft survival; however, rPBC can lead to graft failure in rare circumstances and require retransplantation. In a study of PBC patients transplanted in Birmingham, UK, 5.4% of all graft losses were attributable to recurrent disease. The median time from diagnosis of recurrence to graft loss was 7.8 years (range 22–181 months) [86].

Primary sclerosing cholangitis

Primary sclerosing cholangitis (PSC) is a chronic cholestatic liver disease characterized by inflammation and fibrosis of both intrahepatic and extrahepatic bile ducts leading to the formation of duct obliteration and biliary cirrhosis. PSC is a disease without any proven medical, endoscopic, or surgical therapies to impact disease progression. OLT remains the only curative therapy for patients with end-stage liver disease due to PSC, and the disease currently accounts for approximately 4–5% of adult liver transplantations

performed in Europe and the United States [101]. Similar to PBC, post-transplant outcomes for PSC are excellent, with 5-year patient survival rates of approximately 80% [102–104].

Recurrence of PSC after OLT was first described by Lerut in 1988 [105] and is now a well-established entity, with recurrence rates of 20–25% within 5–10 years following transplantation [102,106,107]. The diagnosis of rPSC can be challenging, and while there are no gold standard criteria, the most widely accepted definition of rPSC was proposed by the Mayo Clinic in 1999:

1 Confirmed diagnosis of PSC before OLT;
2 Cholangiography showing evidence of intrahepatic and/or extrahepatic biliary stricturing, beading and irregularities as least >90 days following transplant; and/or
3 Histologic finding of fibrous cholangitis and/or fibro-obliterative lesions with or without ductopenia, biliary fibrosis, or cirrhosis;
4 Exclusion of alternative diagnoses (hepatic artery thrombosis or stenosis, ductopenic rejection, ABO blood type incompatibility between donor and recipient, solitary anastomotic stricture, ischemic strictures, bacterial or fungal cholangitis with strictures, and CMV or cryptosporidium infection) (Table 78.2) [102].

Several risk factors for rPSC have been reported including, recipient age, male gender, donor–recipient gender mismatch, HLA DRB1*08, active ulcerative colitis prior to liver transplantation, especially requiring steroids, episodes of acute cellular rejection, steroid-resistant acute cellular rejection, steroid-resistant acute cellular rejection requiring OKT3, presence of cholangiocarcinoma, maintenance corticosteroids, and use of extended donor criteria grafts [107–115].

The impact of rPSC on graft survival remains controversial. Campsen et al. [106] found the median survival time before retransplantation for rPSC was 39.1 months. In an analysis of 3309 patients from the UNOS database transplanted for PSC, Maheshwari et al. [116] found a higher retransplantation rate and lower survival when compared with patients transplanted for PBC, which became apparent 7 years after OLT. The being said, most published studies have failed to demonstrate that rPSC has an impact on patient survival [106,107,111–115]. As for the native liver, there is no established medical therapy for rPSC. Although many centers use UDCA, there are no established data that UDCA is beneficial in the treatment of rPSC. The focus of treatment in rPSC remains symptomatic relief of biliary strictures, and patients with graft failure caused by recurrent disease should be considered for retransplantation.

Alcoholic liver disease

Alcoholic liver disease (ALD) is the second most common indication for liver transplantation in the Western world, accounting for approximately 20% of primary transplants performed [117]. Liver transplantation for ALD remains a controversial topic which stems from public perceptions that ALD is a self-inflicted disease with a risk of post-transplant recidivism or non-compliance, all in the setting of an increasing demand for donor organs. In fact, approximately 95% of patients with alcoholic end-stage liver disease are never formally evaluated for liver transplantation [118]. Although initial reports indicated poor post-transplant patient survival (20% at 3 years), more recent data suggest similar if not better survival than for those who undergo transplantation for other indications, with 1 and 5 year survival rates of 86% and 74%, respectively [119,120].

Unfortunately, alcoholism is a disease of relapses and remissions, and recurrence of disease post-transplant due to recidivism is frequent. There is significant variation in the reported rates of alcoholic relapse following OLT, ranging from 10% to 90% [121]. This high variability is the result of differing definitions of alcohol relapse, and the difficulty of obtaining accurate data regarding alcohol use from patients. Much of the data deriving recidivism rates are based on a definition of relapse as any alcohol use, instead of more appropriately distinguishing between occasional lapses or slips from harmful or addictive drinking [122]. It is estimated that 20% of patients transplanted for ALD resume harmful drinking, whereas most patients remain abstinent or consume only small amounts of alcohol occasionally [123,124]. This is an important distinguishing factor, as heavy drinking has been associated with a decrease in long-term patient survival [125]. Although early studies did not suggest an impact of recidivism on patient or graft survival, these studies were small in size with short periods of follow-up [126,127]. With longer follow up, there is increasing evidence of poorer outcomes in patients who return to drinking due to recurrence of ALD [125,128,129]. Pfitzmann et al. [130] demonstrated a significantly reduced patient survival in subjects who resumed abusive drinking compared with those who remained abstinent or had occasional "slips." Recurrent ALD was responsible for the majority of deaths (87.5%) among patients who resumed abusive drinking. Whereas patients transplanted for ALD who remain abstinent most commonly die from cardiovascular disease or malignancy, recurrent ALD accounts for the majority of deaths among recipients who resume abusive drinking after transplantation [128,129].

Several factors have been associated with alcohol relapse after transplantation (Table 78.3). One such factor that remains heavily debated is the time period of abstinence prior to transplant. Longer periods of abstinence are associated with lower rates of post-transplant recidivism, but no one optimal time period has been established [131,132]. In the United States, 85% of transplant centers require at least 6 months of abstinence from alcohol use before being considered for transplant listing, the "6-month rule" [133]. Nevertheless, studies have indicated that 6 months of abstinence alone is an inadequate predictor of relapse post-transplant, and it may take up to 5 years to achieve true predictive sobriety [131,132,134]. Drinking patterns pretransplant have been shown to have a role in risk of relapse, with a history of alcohol abuse carrying a lower risk than alcohol dependence [131]. Inadequate social support has been consistently linked to alcohol recidivism, the most common being lack of a spouse or poor marital relationship

Table 78.3. Risk factors for alcohol relapse after liver transplantation

Lower Risk	Higher Risk
• Diagnosis of alcohol abuse • Good social support • History of good adherence to treatments, medications and appointments • Lower risk for psychosocial risk factors – Mood disorders under treatment – Substance abuse amenable to rehabilitation	• Diagnosis of alcohol dependence • Poor social support • Pattern of non-adherence • Higher risk psychosocial risk factors – Psychotic disorders – Personality disorders

Reproduced by permission of Robert Weinrieb, MD.

[130,131,135]. Other risk factors for alcohol relapse after transplantation include younger age, non-adherence with alcoholism treatment, medication non-compliance, family history of alcoholism, polysubstance abuse, and the presence of psychiatric co-morbidities (personality disorder, psychotic disorder, depressive disorder) [136–138]. Unfortunately, studies have led to mixed conclusions regarding risk of relapse, and no one predictor thus far can reliably identify recidivism.

Given the poor long-term outcomes associated with a relapse to heavy drinking post-OLT, it is imperative for transplant centers to take necessary steps to prevent recidivism. This begins at the transplant evaluation stage, with careful psychosocial assessment for risk of relapse by social workers and trained mental health specialists. Those patients at risk for recidivism should be referred for appropriate substance abuse or psychiatric counseling and treatment before proceeding with transplantation. Following liver transplantation, detecting recidivism can be quite challenging. Several strategies have been suggested to monitor and identify alcohol use post-OLT, including biochemical markers, psychiatric interviews, questionnaires, and screening tools [122,139,140]. Many transplant centers have mental health specialists who follow patients post-transplant to provide ongoing relapse prevention and support. No single method for identifying recidivism is truly specific; therefore a combined use of methods is suggested to increase the detection of relapse. When relapse of alcohol use is identified, prompt implementation of a treatment plan should be sought; however, there is a paucity of data in the literature regarding the treatment of recidivism post-OLT. Weinrieb et al. [141] demonstrated the difficulty of engaging patients in treatment for recidivism with a failure to recruit participants into a trial of naltrexone for patients with alcoholism post-OLT. Not only did patients feel they did not require treatment, but they were also unwilling to take potentially hepatotoxic medications. Bjornsson et al. [142] were able to implement a successful transplant alcohol treatment program, including assessment by a skilled psychiatrist, encouragement to participate in motivational enhancement, and the use of an abstinent contract. This resulted in a decreased alcohol relapse rate of any drinking over a 4-year period (22% versus historic control of 48%). Although alcohol relapse post-OLT poses significant hurdles, transplant centers must try to implement programs to prevent, identify, and treat recidivism in order to limit recurrent ALD.

Non-alcoholic fatty liver disease

Non-alcoholic fatty liver disease (NAFLD) is the most common cause of chronic liver disease in the developing world, affecting approximately one-third of the general population [143]. NAFLD encompasses a spectrum ranging from benign bland hepatic steatosis to steatosis accompanied by varying degrees of necroinflammation and fibrosis, or non-alcoholic steatohepatitis (NASH). An estimated 3% of individuals from developed countries have NASH, and up to 20% of these individuals may progress to cirrhosis [144,145]. Furthermore, up to one-third of patients with NASH will die from complications of liver disease or require OLT. NAFLD is associated with obesity, dyslipidemia, and diabetes mellitus and is considered to be the hepatic manifestation of the metabolic syndrome [146]. NAFLD accounts for 5–10% of OLT per year, and the disease is ultimately expected to surpass HCV infection as the leading indication for OLT in the future [147,148]. In general, post-transplant outcomes are good and similar to that of other indications, with 1- and 5-year patient survival rates of 86% and 71%, respectively [149].

The first reported case of recurrent fatty liver disease following OLT was in 1992, and multiple subsequent studies have confirmed that recurrence of NAFLD is common [150]. Incidence of post-transplant NAFLD recurrence has ranged from 25% to 60%, although most studies have been small with limited follow-up [151–155]. In a prospective histologic study, Maor-Kendler et al. [155] reported 60% of recipients with NASH had steatosis grade 2 or higher post-OLT, with half of these patients meeting histologic criteria for NASH. Another study similarly demonstrated 70% of patients developed recurrent steatosis at a mean follow-up of 18 months, with 25% having NASH and almost 20% having stage II or greater fibrosis [156]. Comparatively, a recent study found lower rates of recurrence with the probability of developing recurrent steatosis at 1-, 5-, and 10-years post-OLT to be 8%, 25%, and 33%, respectively [149]. It has previously been suggested that approximately 10% of patients undergoing OLT for NASH have recurrence that leads to cirrhosis and approximately half of these patients will develop graft failure, although more recent studies have not demonstrated graft loss due to NASH recurrence [157,158].

Several risk factors have been associated with NAFLD recurrence following OLT. Not surprisingly, most of these risk factors are closely linked to the metabolic syndrome and include obesity, diabetes, dyslipidemia, and hypertension pre- or post-OLT [156, 159,160]. It is possible that post-OLT immunosuppression may also impact disease recurrence, because corticosteroids, calcinuerin inhibitors, and sirolimus can be associated with an increase in obesity, hypertension, and insulin resistance; however, no one particular immunosuppression regimen has been implicated in NAFLD recurrence. There is increasing evidence that steroid avoidance or minimization of calcineurin inhibitors are safe and reduce the frequency of metabolic complications post-OLT [161,162]. It is yet to be determined whether these strategies may lead to a decreased incidence of NAFLD recurrence.

The diagnosis of recurrent NAFLD is similar to that of the native liver. Liver biochemistries remain non-specific and up to one-third of patients with recurrent NASH may have normal liver enzymes [156]. While radiologic imaging may detect the presence of steatosis, it cannot differentiate from other causes of fatty liver or determine severity. Thus, liver biopsy may be useful to confirm the diagnosis, determine extent of disease, and exclude other causes. Unfortunately, similar to NAFLD of the native liver, there is no pharmacotherapy proven to be efficacious and safe for the treatment of NAFLD recurrence. The mainstay of treatment focuses on modification of those conditions associated with the metabolic syndrome. This includes weight loss through lifestyle modifications, as well as strict medical management of diabetes and dyslipidemia. It is anticipated that current promising treatments for NAFLD in the native liver will translate into treatments for recurrent NAFLD, but thus far data are lacking on the prevention and treatment of recurrent disease.

Hepatocellular carcinoma

Hepatocellular carcinoma (HCC) is the sixth most common solid organ malignancy, and the third leading cause of cancer-related mortality worldwide [163]. For the most part, HCC almost exclusively occurs in the setting of underlying cirrhosis and is most commonly associated with HCV infection in the United States and HBV infection worldwide. It is projected that the incidence of HCC

will continue to rise in the United States over the ensuing decades as a consequence of the high prevalence of HCV and NASH [164]. In recent years, significant advances have been made in the treatment of HCC, including development of locoregional ablation therapy and use of chemotherapeutic agents like sorafenib; however, surgical treatment remains the mainstay of curative therapy for HCC. Eighty percent of patients presenting with HCC are unresectable due to extent of tumor burden or underlying poor functional hepatic reserve in the presence of cirrhosis [165]. Therefore, liver transplantation is the optimal surgical treatment for most patients, providing complete tumor excision as well as removal of the diseased liver.

Initial transplantation for HCC was performed in the setting of large, unresectable, and advanced-staged HCC, resulting in very disappointing outcomes with poor patient survival rates due to high HCC recurrence rates [166,167]. The landmark study by Mazzafero et al. [168] in 1996 demonstrated much improved survival for patients transplanted with early HCC and defined specific patient selection criteria to optimize transplant outcomes. These criteria, now known as the Milan criteria, include the presence of a single lesion $\leq$5 cm or up to three lesions all $\leq$3 cm, no macrovascular invasion, and no extrahepatic spread. Adhering to these criteria resulted in similar outcomes to other benign indications for OLT, with a 5-year patient survival rate of 70% and a HCC recurrence rate of 8%. The positive impact of the Milan criteria was confirmed in an analysis of the UNOS database that included 985 patients transplanted for HCC between 1987 and 2001. In this study, Yoo et al. [167] demonstrated a dramatic improvement in post-OLT patient survival following the adoption of the Milan criteria (5-year survival: pre-Milan criteria 25% versus post-Milan 61%; $P = 0.001$). More recently, some transplant centers have challenged the Milan criteria as being too restrictive and advocated for expansion of the criteria to enable more patients to undergo OLT, without incurring an increased risk of HCC recurrence or decreased patient survival. The most established of these expanded criteria comes from the University of San Francisco (UCFS criteria), which allow transplant for a solitary HCC up to 6.5 cm in diameter or up to three nodules, none larger that 4.5 cm with a cumulative diameter up to 8 cm [169]. The reported 5-year patient survival rate using this model was 75%, with an HCC recurrence rate of 11%. Still, the use of expanded criteria has not been universally accepted and remains a debated topic that warrants more prospective investigation.

The reported incidence of recurrent HCC post-OLT has been variable, ranging from 6% to 56%, most likely the result of differences in patient selection criteria for transplantation [170–173]. HCC recurrence after OLT most commonly involves the liver graft, although initial presentation with extrahepatic recurrence has also been reported in 10–43% of cases [174–181]. The extrahepatic sites of HCC recurrence most commonly involve the lungs and bone, but also can be found in abdominal lymph nodes, adrenal glands, and peritoneum. Mechanisms that may attribute to HCC recurrence include the presence of microscopic malignant foci in lymph nodes or distant organs at the time of transplant, as well as hematogenous or peritoneal tumor seeding during transplantation. While the risk of recurrence appears to be highest within the first 2 years post-OLT, late recurrence beyond 5 years has also been reported [174–181].

Although the incidence of HCC recurrence may vary between transplant centers, several recipient and tumor-specific prognostic factors for tumor recurrence have been identified. The most powerful predictor of HCC recurrence is the presence of macro- or microvascular invasion which portend a poor prognosis [182,183]. Tumor size greater than 5 cm, total number of lesions, and bilobar disease are also associated with increased risk of recurrence and are likely surrogates of microvascular invasion [184–186]. Similarly, poor tumor differentiation is a predictor of microvascular invasion, and an independent risk factor for tumor recurrence; however, assessment of tumor grade requires percutananous liver biopsy, which is not without the risk of biopsy tract tumor seeding which can occur in up to 3% of cases [187–190]. The value of determining tumor histology warrants further investigation, as it has been suggested that poor differentiation is a better predictor of recurrence than being within or outside Milan criteria [191]. There have been a number of studies that have attempted to identify surrogate molecular markers for microvascular invasion and recurrence without the risk of tumor seeding. The most widely used marker is serum alfa-fetoprotein (AFP), which has been associated with HCC recurrence; however, its use is limited as 30–40% of HCC patients have normal AFP levels [192]. Numerous other molecular biomarkers targeting cell proliferation, cell adhesion and extracellular matrix, angiogenesis, cell surface markers, and transcription factors are being investigated.

Locoregional ablation therapy has been proposed in order to slow progression of HCC while awaiting OLT to avoid drop-out (i.e. removal from the transplant waiting list due to progression beyond transplant criteria). For this purpose, intention to treat analyses suggest that such bridge therapy is effective for patients with anticipated transplant waiting times longer than 6 months, but there are differing results on whether locoregional therapy results in decreased recurrence and improved survival after OLT [193–197]. Locoregional therapy may also be used for down-staging of tumors initially found outside Milan criteria, thereby allowing OLT. There is evidence that down-sizing tumor burden to within Milan criteria can be done successfully without incurring an increased risk of HCC recurrence. Furthermore, tumor response to down-staging may be a useful predictor of post-OLT outcomes and assist with patient selection for transplantation [193,194,198]. Historically, adjuvant chemotherapy has not been proven to be beneficial for the treatment of HCC pre- or post-OLT; however, the multikinase inhibitor, sorafenib, has recently demonstrated a significant improvement in overall survival for patients with advanced HCC [199]. Whether an agent such as sorafenib has the ability to reduce the risk of HCC recurrence post-OLT and in what setting needs to be addressed with further investigation.

Immunosuppression is commonly associated with an increased risk of malignancy post-OLT, and it may be an influential factor in HCC recurrence and tumor progression. Vivarelli et al. [200] observed a direct relationship between higher cumulative doses of cyclosporine during the first year post-OLT and a lower rate of 5-year HCC recurrence-free survival. This observation was confirmed in a retrospective analysis of 70 patients transplanted for HCC, which found post-OLT HCC recurrence was statistically associated with higher cyclosporine levels [201]. A subsequent publication by the same group identified higher doses of both cyclosporine and tacrolimus as independent risk factors for HCC recurrence after OLT [202]. Similarly, steroids may also have an adverse role in the recurrence of HCC, and it has been suggested that early withdrawal of steroids post-OLT may decrease the risk of disease recurrence [209]. M-TOR (mammalian target of rapamycin) inhibitors have drawn considerable interest in the setting of HCC. In addition to potent immunosuppression activity, m-TOR inhibitors have demonstrated a potential anticancer effect related to

impairment of vascular endothelial growth factor (VEGF) production. Sirolimus was shown to induce cell cycle arrest and blocked proliferation of an HCC cell line [203]. In a matched case-controlled study, the 3-year recurrence-free survival was 30% higher for patients maintained on sirolimus post-OLT compared with those on standard treatment tacrolimus [204]. Further promising clinical data were presented by Toso et al. [205] who analyzed the Scientific Registry of Transplant Recipients in the United States to determine whether the type of immunosuppression used influenced survival after OLT in HCC patients. The authors concluded that sirolimus-based maintenance therapy was associated with improved survival. Despite these findings, there is no definitive link between one specific immunosuppression regimen and recurrent HCC following OLT; however, available data would suggest minimizing calcineurin inhibitor dosage or switching to an m-TOR inhibitor is beneficial for patients at high risk of HCC recurrence.

There are very few published data to help guide the most efficacious and cost-effective strategy to monitor for HCC recurrence after OLT, and surveillance protocols vary among transplant centers [206]. Once identified, the reported 5-year survival rate for recurrent metastatic HCC following OLT is 13–35% [175–181]. Unfortunately, limited treatment options for HCC recurrence are currently available, as many patients present with established disseminated disease. Although the data are limited, aggressive surgical intervention may be considered in a select group of patients with localized recurrence. Regallia et al. [175] first reported on a small group of post-transplant patients who underwent surgical resection for isolated recurrence in the liver, lung, bone, and skin. These patients had a 4-year survival rate of 57%, compared with 14% for patients with unresectable disease who did not undergo surgical intervention. A more recent study from Mount Sinai Medical Center reported a similar advantage, with patients who underwent radical surgical resection for localized HCC recurrence having an improved survival [181]. By multivariate analysis, surgical treatment was independently associated with prolonged survival, in addition to the absence of bony metastasis as well as time to recurrence of >1 year post-OLT. Based on experience in the pretransplant HCC population, other potential treatments for HCC recurrence following liver transplantation include use of locoregional ablation therapy or chemotherapy with agents such as sorafenib; however, sufficient data are lacking in the post-OLT setting to draw any firm conclusions. Finally, radiation therapy can be utilized as a treatment option for symptomatic palliation of extrahepatic disease, primarily bone metastasis [207,208]. Reducing the incidence of HCC recurrence and its associated mortality after liver transplantation requires careful consideration of pretransplant factors and post-transplantation immunosuppression, as well as the use of a multidisciplinary approach to patient care that includes hepatology, transplant surgery, radiology, and oncology.

Conclusions

Liver transplantation remains the mainstay for the treatment of most end-stage liver diseases. Unlike other transplanted organs, where rejection is the fundamental problem influencing survival, the liver is much more influenced by recurrent viral and autoimmune diseases. Clinicians must therefore remain constantly aware of the risk of disease recurrence, and familiarize themselves with the diagnostic maneuvers and treatment options available to accurately diagnose and manage these myriad diseases. Immune management should go hand in hand with use of viral specific therapies to achieve optimal results and minimize the need for retransplantation.

CHAPTER 79

Recurrent Disease after Heart Transplantation

Jignesh K. Patel and Jon A. Kobashigawa
Cedars-Sinai Heart Institute, Los Angeles, CA, USA

Introduction

The risk of recurrent disease following cardiac transplantation generally relates to the etiology of the underlying condition for which transplantation was carried out. Fortunately, for the vast majority of heart transplant recipients this risk is limited. Dilated cardiomyopathy and coronary artery disease are the two most common indications for heart transplantation. The majority of cases of dilated cardiomyopathy are idiopathic, post-viral, or familial, and these conditions do not affect the post-transplant course. In a small portion of cardiomyopathy cases the etiology is infiltrative and, for some of these (particularly myocarditis, sarcoid, or Chagas disease), there is a finite risk of recurrence. The most common cause of allograft dysfunction in the long term and a principal cause for limiting graft survival after cardiac transplantation is the development of what may be considered a form of recurrent disease, cardiac allograft vasculopathy (CAV), a process with many similarities to native non-transplant atherosclerosis. Approximately half of all heart transplants are performed for end-stage disease due to coronary artery disease. However, the immune system has a critical role in the development of CAV and the process thus is a manifestation of chronic allograft rejection.

In cardiac transplantation, mortality in the first year is predominantly dictated by increased risk of rejection and infection associated with the concomitant need for augmented immunosuppression (see Chapter 105). However, after the first year, a principal determinant limiting long-term allograft survival is the development of CAV. This phenomenon was first noted in experimental animal models of cardiac transplantation, which demonstrated a time-dependent development of coronary intimal thickening with histologic features similar to atherosclerosis. CAV was noted clinically in early transplants when histologic evaluation of coronary arteries of transplanted hearts revealed extensive disease in vessels that had appeared normal angiographically at the time of transplantation. Despite the introduction of cyclosporine in the 1980s, which had a significant impact in reducing allograft rejection rates and improving survival, there appeared to be no corresponding decrease in the prevalence of CAV [1].

Registry data suggest a constant annual mortality rate of 4% per year after the first year (Figure 79.1). In the 3 years after transplant, acute rejection is responsible for up to 9% of deaths [2]. After 3 years, the incidence of death due to acute rejection declines significantly. Up to 20% of deaths after the first year are attributed to non-specific allograft failure for which a precise cause has not been identified. These cases likely represent undiagnosed allograft rejection or sequelae of recurrent or low-grade rejection such as small vessel CAV or restrictive physiology, and in many cases the processes leading to graft failure remain poorly understood. After the first year following transplantation, allograft failure may result from antibody-mediated rejection and CAV. Approximately 10% of deaths between 1 and 3 years after transplant are attributable to CAV, with the prevalence increasing thereafter to 20% at 3 years, 30% at 5 years, and 45% at 8 years after transplant. The impact of newer immunosuppressive regimens has been limited on CAV, with only a small decrease of approximately 2–4 percentage points in the cumulative incidence of CAV in patients who underwent transplant between 2001 and June 2009 compared with those between April 1994 and 2000 (Figure 79.1).

Pathology

Non-transplant atherosclerosis is characterized by a chronic inflammatory process affecting the vessel wall with accumulation of macrophages, T cells, and smooth muscle cells. Ross et al. [3] postulated that the process represented a response to injury of the endothelium. The process is believed to be reflected in CAV, although the initial injury to the endothelium is believed to be as a result of a number of factors attributable to transplantation including ischemia–reperfusion injury, the immune response, donor factors, and traditional risk factors for atherosclerosis.

The pathology of CAV differs somewhat from non-transplant atherosclerosis in many other ways (see Chapter 83) (Table 79.1). In CAV, the disease tends to be more diffuse, with concentric narrowing of vessels including frequent involvement of not only the large- and medium-sized vessels, but also the microvasculature [4]. The concentric and diffuse nature of CAV generally limits its detection by angiography [4], and is better appreciated by intravascular ultrasound (IVUS). However, many patients may have the more typical focal lesions seen in non-transplant atherosclerosis, although the lipid component may be highly variable and calcification appears late if at all [5]. The correlation between coronary calcification and CAV has been debated. Early studies have suggested an association between coronary calcium score assessed by electron-beam computed tomography and severity of disease noted by coronary angiography or IVUS [6,7]. More recent data suggest coronary calcification may not correlate with the severity of CAV. In a recent study [8], 4 of 11 patients with severe CAV by coronary

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

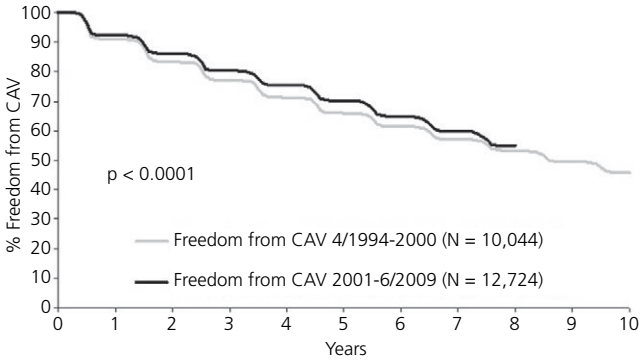

Figure 79.1. Freedom from cardiac allograft vasculopathy for adult heart recipients (Transplants: April 1994–June 2009). Reproduced from [2] Stehlik et al., *Journal of Heart and Lung Transplantation* 2011;30:1078–1094 with permission from Elsevier. Copyright © 2011, Elsevier.

Table 79.1. Typical features of non-transplant atherosclerosis and cardiac allograft vasculopathy

Non-transplant atherosclerosis	Cardiac allograft vasculopathy
Mostly epicardial vessels affected	Panvascular disease including microvasculature
Slow progression	Rapid progression
Lesions eccentric	Lesions concentric
Generally lipid-rich	Generally lipid-poor
Calcification common	Calcification sparse
Compensatory dilatation (Glagov phenomenon)	Arteries constrict

angiography had a calcium score of 0. The diagnostic accuracy of the test was less than 60%. The authors postulate that coronary calcification seen in patients with CAV may represent pre-existing disease or de novo traditional coronary atherosclerosis.

The concentric intimal thickening is comprised predominantly of smooth muscle cells and extracellular matrix, and the internal and external elastic laminae are generally intact. The disease thus not only affects the intima, but the media and adventitia frequently also undergo fibrous infiltration. Consequently, compensatory remodeling of the artery is attenuated (the Glagov phenomenon seen in non-transplant atherosclerosis) and the artery may even undergo constriction [9]. Generally, the contribution to luminal loss tends to occur from intimal hyperplasia in the first year and then by constrictive remodeling thereafter [10,11].

Immune mechanisms contributing to CAV

Adaptive immunity

As a highly vascular organ with significant endothelial exposure to recipient blood, the transplanted heart represents a major antigenic stimulus, and the principal determinant of the recipient immune response is the recognition of foreign major histocompatibility antigens. Antigenic recognition (covered in depth in Chapter 5) by circulating host T lymphocytes and dendritic cells results in a robust immune response that leads to production of a variety of cytokines including interleukins, γ-interferon (INF-γ), and tumor necrosis factor α (TNF-α). These cytokines subsequently allow development of effector mechanisms including cytotoxic T cells, infiltrating macrophages, and antibody production (covered in depth in Chapters 5–7). Although this immune response is mainly responsible for allograft dysfunction seen in acute rejection, it likely has an equally important role in the development of CAV, a process that is a recognized component of most syndromes of chronic rejection seen in some form not only in the transplanted heart, but also in renal, lung, and liver allografts. Indeed, a substantial amount of the fibrotic degeneration seen in other allografts likely relates to some extent to ischemic atrophy downstream of vessels with progressive vasculopathy. In transplanted lungs chronic rejection presents as obliterative bronchiolitis and in liver allografts the equivalent process is known as vanishing bile duct syndrome.

Direct allorecognition, with recognition of foreign human leukocyte antigen (HLA) antigens on donor cells by recipient dendritic cells, is predominantly responsible for acute rejection. In contrast, indirect allorecognition, when donor antigens are internalized, processed, and presented as peptides by host dendritic cells, likely contributes to chronic rejection and the development of CAV [12,13]. Severe CAV is positively correlated with degree of HLA mismatch and production of donor-specific antibodies (see Chapters 6 and 36) [14]. Both symptomatic and asymptomatic antibody-mediated rejection predispose to the development of CAV.

Conventional immunosuppressive therapy is mainly targeted at T cells to prevent acute cellular rejection, and the use of calcineurin inhibitors (particularly tacrolimus) and mycophenolate mofetil (MMF) has been associated with a significant decline in rejection rates in the recent era [15]. However, these agents have had a modest effect on the development of CAV in heart transplant recipients [2]. While the agents are effective at suppressing the production of many Th-1 cytokines and limiting T-cell activation in general, the processes that lead to antibody production appear to be less affected [16]. Following solid organ transplantation, a significant portion of patients continue to make antibodies to the allograft. Anti-HLA antibody production in recipients has been associated with a higher mortality [17] and CAV [18,19]. Thus, alloimmune insults distinguish CAV from general progressive atherosclerotic vascular disease, and likely contribute to the accelerated course of CAV.

Production of non-HLA antibodies likely also contributes to the development of CAV (see Chapter 36). These antibodies do not appear to contribute to the development of native cardiomyopathies. The presence of circulating anti-endothelial antibodies has been shown to correlate with CAV [20]. The development of antibodies to the intermediate filament vimentin, a protein characteristic but not restricted to endothelial cells, has been particularly associated as an independent risk factor for the development of CAV [21]. Vimentin is diffusely expressed in the intima and media of normal and diseased coronary arteries. Therefore, injury early following transplantation, for example by ischemia and reperfusion, may lead to release of vimentin into the circulation. The protein may then be taken up by antigen-presenting cells (APCs) and presented as an autoantigen, as it is not normally exposed to the immune system. Interestingly, these antibodies do not seem to mediate complement-mediated cytotoxity to endothelial cells in vitro, a process associated with hyperacute rejection. Anti-vimentin antibodies may therefore exert a more subtle form of low-grade damage in a process consistent with the chronic progressive course of CAV development. Also, transplant patients on tacrolimus compared with cyclosporine, and MMF compared with azathioprine appear to develop fewer anti-vimentin antibodies [22,23].

In addition to vimentin, other antibodies against various antigens of the endothelial cells, such as angiotensin II type 1 receptor, and anti-major histocompatibility complex class I chain-related A (MICA) or B, have been found in solid organ transplant recipients

and associated with poor graft outcome [24,25]. MICA antigens are HLA-related polymorphic glycoproteins expressed on the surface of human endothelial cells, epithelial cells, and fibroblasts. The expression of MICA is induced by stress. These proteins act as ligands for the activating receptor NKG2D on natural killer (NK) cells and $CD8^+$ T cells. The observation that MICA is expressed on endothelial cells but not on lymphocytes may explain some cases of graft loss in patients with a negative cross-match to donor lymphocytes.

The presence of anti-MICA antibodies and MICA expression in endomyocardial biopsies of the allograft has been correlated with acute heart allograft rejection [26]. Antibody production against MICA antigens can induce complement-dependent cytotoxicity [27]. MICA antibody production in heart-transplant recipients has been associated with both acute rejection and the development of CAV [28].

Innate immunity

Although conventional immunosuppressive agents are able to efficiently target the adaptive immune system, these agents largely spare the innate immune system. An intact innate immune response may contribute both to stimulation of the adaptive response and to the future development of CAV (see Chapter 7). Perhaps the best-studied components of the innate immune system are the toll-like receptors (TLRs), a family of transmembrane proteins expressed on a variety of cells including epithelial cells, dendritic cells, macrophages, and T and B lymphocytes. TLRs, some of the most conserved components of the immune system throughout evolution, bind to conserved ligands on microbial pathogens such as lipopolysaccharide on Gram-negative bacteria. However, TLRs are also thought to be activated both by exogenous and by endogenous ligands [29]. Ischemia–reperfusion injury following donor heart engraftment leads to release of a number of endogenous ligands, including products of direct tissue injury such as the extracellular matrix polysaccharide hyaluronan. Hyaluronan has been demonstrated to activate dendritic cells predominantly by binding to TLR [30]. Other components of ischemia–reperfusion injury that may lead to activation of the innate immune system include heat shock protein 70 [31] and allograft inflammatory factor-1 (AIF-1). Activation of TLRs initiates an inflammatory cascade, which likely contributes to both acute allograft rejection and the development of CAV. In heart transplant recipients, expression profiles of AIF-1, TLR-2, and interleukin-18 were correlated with biopsy-proven allograft rejection in both peripheral blood and biopsy tissue [32]. Transplant recipients with endothelial dysfunction – as measured by compromised coronary flow reserve – demonstrate increased mRNA transcript levels for TLR-4, surface expression of TLR-4, and increased expression of downstream components of TLR signaling such as B7-1, interleukin-12, and TNF-α compared with controls [33].

Endothelial activation

Endothelial cells likely have a key role in mediating both acute and chronic rejection [34]. Endothelial injury and dysfunction appears to be the sentinel event leading to the development of CAV [35] as the endothelium forms the initial interface between donor and the host circulating lymphocytes and maintains a barrier to prevent entry of inflammatory cells into the interstitium. Endothelial cells are also highly responsive to cytokines [36], and express Class II antigens particularly in the microvasculature [37,38] and coronary arteries. They also act as APCs [39,40]. In vitro, endothelial cells from human coronary arteries are able to stimulate allogeneic T cells [41].

Endothelial cell hyperpermeability is a proposed mechanism of increased lipid infiltration into the vessel walls of allografts [42], contributing to the development of CAV. Vascular endothelial growth factor (VEGF) is a potent inducer of vascular permeability and its expression is up-regulated in human heart allografts, particularly after acute rejection [43]. Its presence has therefore been associated with the development of CAV [44,45].

Allograft vascular endothelial cells express HLA Class II antigens and adhesion molecules such as intercellular adhesion molecule 1 (ICAM-1) and vascular cell adhesion molecule (VCAM) [46,47]. The expression of these molecules on endothelium reflects ongoing endothelial activation. These molecules are not typically expressed on endothelium of normal hearts.

Although expression of adhesion molecules on endothelium is also a feature of non-transplant atherosclerosis, the induced expression of HLA antigens appears to be unique to the transplant endothelium. A consequence of endothelial activation is that co-culture of these cells in vitro with $CD4^+$ T cells results in their proliferation and production of interleukin-2 [46]. Chronically activated donor endothelium may therefore provide a sustained stimulus to recipient lymphocytes to maintain a chronic immunologic response. Allografts expressing ICAM-1 and HLA-DR on vascular endothelium have been shown to develop transplant vasculopathy [48] but there is also evidence that a certain polymorphism of ICAM-1 detected in donor hearts may protect from the development of CAV [49] and this may relate to an allelic change that renders decreased ICAM-1 binding to B cells.

Endothelial activation may be caused by a number of factors, and likely distinguishes the phenotype of accelerated CAV from native atherosclerosis (Figure 79.2). Cytokines released from inflammatory cells following an episode of acute rejection may precipitate endothelial activation, and development of CAV has been correlated with the frequency of acute allograft rejection episodes [50]. Other triggers of endothelial activation include injury by endothelial-specific T lymphocytes or generation of recipient antibodies, such as anti-vimentin antibodies, to donor endothelium. Ischemia–reperfusion injury at the time of transplantation also causes endothelial activation. Human endothelial cells subjected to hypoxia experimentally do show up-regulation of ICAM-1 [51]. In animal models, the induction of adhesion molecules on allograft endothelium prior to transplantation has also been shown to be associated with the subsequent development of CAV [52]. In humans, the assessment of circulating soluble ICAM-1 following transplantation has been suggested to be a marker for the subsequent development of CAV [53]. IFN-γ has a central role as it activates macrophages, augments inflammatory cell recruitment, and amplifies immune responses [54]. Even in the setting of ongoing acute rejection, the absence of IFN-γ prevents development of CAV [55].

Integrins and chemokines

There is evidence that integrins and chemokines also contribute to transplant vasculopathy. Studies imply a correlation between sustained expression of the vitronectin receptor (integrin α-V,β-3) and progression of CAV by IVUS [56]. Myocardial ischemic injury at the time of transplant is associated with up-regulation of α-V,β-3, tissue factor, and activation of the matrix metalloproteinase system [57]. Interestingly, the mode of donor death may also determine integrin regulation. Intracranial bleeding as a cause of donor death

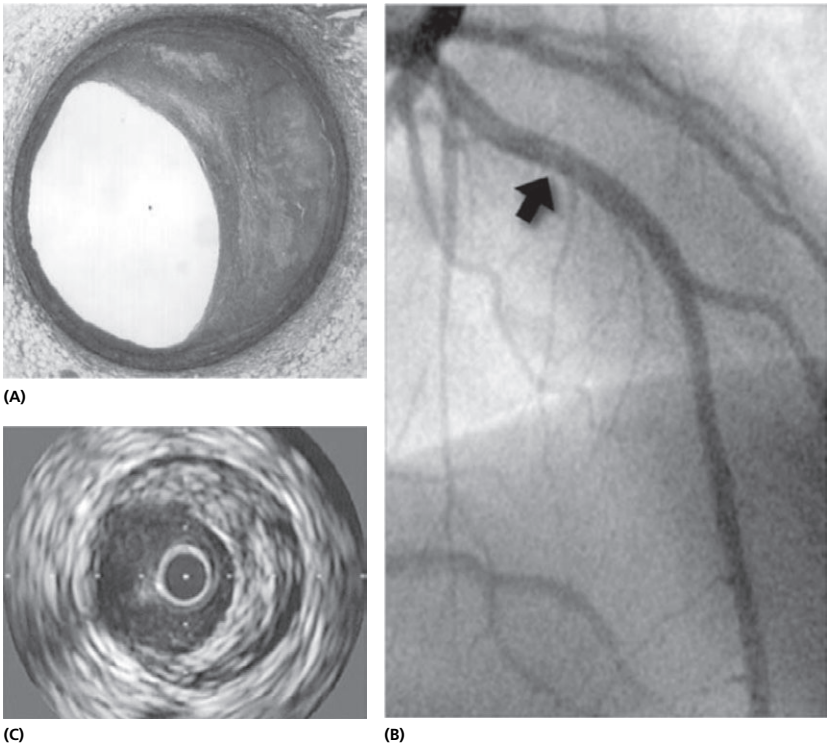

Figure 79.2. Concentric or eccentric subintimal proliferation in CAV seen histologically (A) are underestimated in lesion severity angiographically (B) but are better appreciated by IVUS (C). Reproduced with permission from [219]: Patel JK, Kobashigawa JA. Cardiac allograft vasculopathy. In: Ahsan N, ed. *Chronic Allograft Failure: Natural History, Pathogenesis, Diagnosis and Management*. Austin: Landes Bioscience, 2008:65 (Figure 3).

has been associated with the development of CAV [58] after heart transplant and this appears to correlate with systemic activation of α-V,β-3 [59]. Cytomegalovirus (CMV) infection, strongly associated with transplant vasculopathy, may involve an angiogenic response that results from endothelial proliferation and migration. This CMV-induced angiogenic response may occur as a result of viral binding to and signaling through the beta 1 and beta 3 integrins and the epidermal growth factor receptor, via their ability to activate the phosphatidylinositol 3-kinase and the mitogen-activated protein kinase signaling pathways [60].

Besides facilitating endothelial cell interactions, lymphocyte integrins can also act as costimulatory molecules during antigen presentation. In experimental models, blockade of ICAM-1 and leukocyte function associated antigen-1 (LFA-1) interactions induces allograft tolerance [61], and significantly abrogates CAV development [62].

Expression of the chemokine RANTES, a chemokine that selectively chemoattracts T lymphocytes, NK cells, monocytes, and eosinophils, has been shown to be expressed in human CAV [63]. In an animal model, sustained RANTES production was required for both monocyte recruitment and the development of intimal thickening and this required the presence of $CD4^+$ cells [64]. In humans, the presence of elevated peripheral blood levels of the CCR3 chemokine ITAC/CXCL11 is associated with severe CAV [65]. In this study, the CCR3 chemokine ligand ITAC/CXCL11 localized on the endothelial surface of CAV lesions, and underlying infiltration of inflammatory mononuclear cells expressed CCR3. In a mouse model, blockade of chemokine receptors CCR1 and CCR5 attenuated development of CAV [66]. In a rat model, there is evidence to suggest that the protective effect of statins may occur partly through modulation of chemokines and their receptors [67]. Both low and high doses of simvastatin significantly decreased the CAV score, inhibited recruitment of T lymphocytes and macrophages, reduced levels of intragraft monocyte chemoattractant protein 1 (MCP-1), RANTES, and interferon-inducible protein 10 (IP-10) and down-regulated expression of chemokine receptors CCR2 and CCR5.

A typical feature of a CAV lesion is the subintimal proliferation of smooth muscle cells. Initially, these were thought to be derived from the donor. However, in gender-mismatched cardiac allografts, Y-chromosome in situ hybridization has revealed the presence of recipient-derived smooth muscle cells, suggesting an important role for host-derived stem cells in the development of CAV [68,69].

Coagulopathy

One of the distinguishing features of CAV is the diffuse nature of the disease, affecting not only the arterial network, but also the capillary network and the venous system [70], suggesting that this is truly a panvascular disease. Cardiac microvasculature is normally highly resistant to thrombosis. However, in the first month following cardiac transplantation, endomyocardial biopsies begin to show evidence of microvascular fibrin deposition and this subsequently significantly correlates with the development of CAV [71]. Microvascular thrombosis also results in acute myocardial cell damage from ischemia. Troponins, sensitive markers for myocardial damage, are indeed elevated in transplant patients with evidence of microvascular fibrin deposition on endomyocardial biopsies [72]. Furthermore, patients with persistently elevated troponins in the first year had a significantly higher likelihood of developing graft failure or severe CAV. In the first month following cardiac transplantation, troponins are elevated, presumably due to the ischemia–reperfusion injury occurring at the time of transplantation. However, in some patients, troponins remain persistently elevated in the following months and this appears to correlate with ongoing microvascular thrombosis presumably relating to a more persistent thrombogenic insult such as allograft rejection. Time-dependent

factors may contribute to microvascular injury, with ischemia–reperfusion injury being important early following transplantation, and development of antibodies or cytokine-dependent endothelial cell activation being more important later on. The early events may serve to propagate chronic injury, for example by release of endothelial cell antigens such as vimentin during ischemia–reperfusion injury to which a humoral response is subsequently mounted.

The risk for vascular thrombosis depends upon the balance between procoagulant factors and endogenous fibrinolytic activity. A decrease in fibrinolytic activity would prevent removal of fibrin and, in a prothrombotic microvasculature, would facilitate further production of thrombin and fibrin. Both increased plasma fibrinogen concentration and decreased plasma fibrinolytic activity have been associated with increased arterial intimal thickening in cardiac transplant patients [47,73]. An increased incidence of angiographic coronary artery disease in transplant patients with lower levels of tissue plasminogen activator (t-PA) on endomyocardial biopsies has been observed [47]. These patients developed earlier and more aggressive disease than those patients with normal t-PA levels within the arteriolar microvasculature. Circulating levels of t-PA and plasminogen activator inhibitor-1 (PAI-1) also correlate with development of CAV [74].

Development of CAV may also relate to abnormalities of the coagulation system following transplantation. Microvascular antithrombin depletion early after transplantation has been associated with the subsequent development of CAV [75]. Grafts with recovery of antithrombin expression appear to be less prone to CAV. The mechanisms leading to change in antithrombin expression are unclear but may include cytokine release after rejection or changes in the expression or availability of molecules that bind antithrombin, such as heparan sulfate proteoglycan molecules [76]. Ischemia and reperfusion may lead to release of enzymes from recruited neutrophils including neutrophil elastase and heparanase. Decreased antithrombin binding due to resulting loss of heparan sulfate would then lead to generation of thrombin, a process that would lead to further loss of heparan sulfate proteoglycan, thereby sustaining a prothrombogenic milieu within the microvasculature.

Influence of non-immune factors in the development of CAV

Although the alloimmune response is the predominant factor that determines graft outcome both in the short term and in the long term, a number of other non-immune determinants contribute to the development of CAV. Temporally, the immune response may be important in the early phases of CAV, while non-immune factors may dictate the severity of CAV late after transplantation [77].

Donor-related issues

Profound physiologic derangements accompany cadaveric organ procurement. Catastrophic central nervous system injury is often accompanied by periods of labile blood pressure and the need for prolonged inotropic support is not infrequent (see Chapter 20). Circulating neuroendocrine hormonal levels may be increased while levels of other hormones may decrease [78]. Inflammatory markers including cytokines and adhesion molecules may be up-regulated leading to apoptosis and cardiac dysfunction [79]. Organ procurement and transport contribute to ischemic injury, and further perturbations take place following engraftment and reperfusion. Spontaneous or atraumatic intracranial bleeding occurs in about 40% of brain-dead donors and is associated with poor short-term outcomes and development of CAV at 5 years [80].

Endothelial injury during ischemia–reperfusion may produce changes critical to the subsequent development of CAV in the ensuing years [81]. Early changes include endothelial cell desquamation and retraction allowing increased permeability. Hypoxia can induce a number of endothelial genes including VEGF, basic fibroblast growth factor (b-FGF), and platelet-derived growth factor (PDGF) [82–84]. PDGF and b-FGF induce intimal smooth muscle proliferation and migration and VEGF stimulates endothelial proliferation and enhances vascular permeability [85]. Angiotensin II is also a potent mitogen for smooth muscle cell proliferation and, experimentally, its inhibition has been shown to be effective in inhibiting the development of CAV [86,87]. Angiotensin-converting enzyme (ACE) expression is increased during vascular injury and, experimentally, its inhibition has been shown to ameliorate CAV. ACE inhibitors may therefore also be of some potential value as preventive agents [86].

In a large multi-institutional analysis with long-term follow-up [88], risk factors for fatal CAV included older donor age, male donor, younger recipient age, earlier date of transplant, ischemic etiology, history of recipient cigarette use, history of gouty arthritis, black recipient, and positive donor CMV serology. In an earlier study [89], risk factors identified for the earlier onset of CAV included many that are common to native atherosclerosis including older donor age, donor male sex, donor hypertension, recipient male sex, and recipient black race. The actuarial incidence of severe coronary artery disease was 9% at 5 years, and was associated with a particularly high mortality. In a multicenter retrospective analysis of cardiovascular risk factors in heart transplant recipients, hypercholesterolemia and diabetes mellitus were associated with nonfatal major adverse cardiac outcomes, whereas high creatinine and body mass index were associated with graft loss [90]. Interestingly, in this study no co-variates were identified to be significant for CAV. Studies have suggested an increased risk of CAV progression with donor-transmitted coronary disease [91,92], and the presence of native coronary disease predicts a 3–5 times greater relative risk for cardiac events including myocardial infarction, heart failure, and sudden death [93,94]. However, other studies suggest that CAV is multifactorial and that atherosclerotic plaque in the donor heart may not necessarily progress to CAV [95]. Using serial IVUS measurements, Li et al. [96] demonstrated that pre-existing donor atherosclerotic lesions do not accelerate the development of CAV either at the site of pre-existing donor atherosclerosis or elsewhere within the same artery.

Hyperlipidemia

Ischemic cardiomyopathy is a common cause of end-stage heart disease and about half of all heart transplants are performed for patients with this diagnosis. The majority of these patients have a history of hyperlipidemia as a major contributor to their disease, and after transplant hyperlipidemia is a widely observed phenomenon [97]. A number of factors contribute to post-transplant hyperlipidemia. Steroids increase apolipoprotein B production and also contribute to post-transplant obesity. Cyclosporine increases hepatic lipase activity and decreases lipoprotein lipase activity [98], resulting in impaired very-low-density lipoprotein (VLDL) and low-density lipoprotein (LDL) clearances. The use of tacrolimus has been associated with a minimization of lipid abnormalities [99,100].

Hyperlipidemia is a well-established risk factor for non-transplant atherosclerosis. Both clinical and experimental observations suggest that it is an important contributor to CAV [101–103]. In one study, elevated lipid values 6 months following transplantation had a strong predictive value for the development of CAV at 3 years [102]. In another study, post-transplant elevation of LDL at 1 year was the only predictor for the development or progression CAV by IVUS [104]. In early experimental studies, rabbits fed a high cholesterol diet following cardiac transplantation develop accelerated CAV [105]. Hyperlipidemia likely compounds the effect of endothelial activation observed after transplantation. Greater intimal thickening, more intimal angiogenesis, and a greater accumulation of T cells is seen in transplanted vasculature compared to native vessels in animals exposed to the same level of hyperlipidemia [106,107]. The net effect of immunosuppression on CAV, however, may depend upon its ability to suppress the allogeneic immune response and prevent smooth muscle proliferation regardless of the effect of the agent on the lipid profile so that in the case of proliferation signal inhibitors, their effect on attenuating CAV development occurs despite a significant elevation in serum lipids with the use of these agents [108].

Interestingly, one class of drugs of particular benefit in cardiac transplantation appears to be effective not only at significantly reducing hyperlipidemia, but also decreasing the alloimmune response. Treatment initiated within 2 weeks of transplantation with a hydroxymethylglutaryl co-enzyme A (HMG Co-A) reductase inhibitor (statin) is associated not only with decreased development of coronary intimal thickening, but also a lower frequency of hemodynamically compromising rejection episodes and improved survival [109]. These agents appear to have an immunosuppressive effect that may be at least as important in cardiac transplantation as their lipid-lowering activity. Statins appear to have pleiotropic effects. They have been shown to decrease cytokine production and improve coronary endothelial function in patients [110], inhibit IFN-γ induced MHC class II expression in human vascular endothelial cells [111], decrease cytotoxicity of NK cells [109,112], decrease post-transplant hypercoagulability by inhibiting monocyte tissue factor [113], and modulate chemokine and chemokine-receptor function (see earlier).

Hypertension

Hypertension is a well-established risk factor for non-transplant coronary atherosclerosis. Hypertension is common following heart transplantation, and is attributed to the use of corticosteroids, frequent associated weight gain, and calcineurin inhibitors. Prevalence of hypertension increases after transplant from 74% at 1 year to 98% at 10 years [114]. Studies confirming the link between post-transplant hypertension and CAV have been sparse [115], with most studies being unable to confirm an association [89,90,116].

However, there are data to suggest a therapeutic benefit with regard to decreased CAV with the use of antihypertensive agents. In one study [117], patients randomized to diltiazem demonstrated a significant decrease in coronary artery luminal diameter by **quantitative coronary angiography** (QCA) compared with baseline at 1 and 5 years. At 5 years there was also a significant difference in freedom from both death and CAV. In a rat heterotopic transplant model, amlodipine was shown to significantly decrease the development of allograft vasculopathy [118]. In vitro, calcium channel blockers have been shown to stabilize endothelial cell function, inhibit platelet aggregation, and decrease the release of platelet-derived growth factors [119].

One study demonstrated that the use of calcium channel blockers or ACE inhibitors was associated with a significant decrease in intimal thickening at 1 year by IVUS [120]; the benefit was seen with the use of calcium channel blockers either alone or in combination with ACE inhibitors. As recipients were treated with any calcium channel blocker or ACE inhibitor, it was determined that there was a class effect. Another study suggested that the benefit of calcium channel blockers and ACE inhibitors was synergistic on the development of transplant vasculopathy as determined by IVUS at 1 year [121].

In an experimental transplant model, the angiotensin receptor blocker losartan was noted to be superior to enalapril in preventing allograft vasculopathy [122]. The effect of angiotensin receptor blocker on attenuating neointimal proliferation of smooth muscle cells may be due to decreased differentiation of peripheral mononuclear cells into a smooth-muscle phenotype [123] or involve inhibition of peroxisome proliferator-activated receptor gamma (PPAR-γ) [124].

Diabetes

More than 30% of adult heart recipients are diabetic 1 year after transplantation [114]. Predominant factors contributing to the development of new-onset diabetes after transplantation include increased pretransplant body mass index [125] and immunosuppressive therapy, corticosteroids and calcineurin inhibitors in particular [126]. In a retrospective analysis, pretransplant glucose intolerance, family history of diabetes, and the need for insulin more than 24 hours after transplantation was associated with post-transplant diabetes [127]. Corticosteroids are associated with the greatest risk of developing new-onset diabetes after transplantation. Higher doses of prednisolone also have been found to be a risk factor for the development of new-onset diabetes in heart transplant recipients [127]. Tacrolimus appears to be more diabetogenic than cyclosporine [126,128]. However, glycemic control, as determined by hemoglobin A1c measurement, was found to be a more important factor associated with the severity of CAV than cumulative doses of diabetogenic immunosuppressive agents in one study [129]. In an analysis of 20,000 heart transplant recipients in the United Network for Organ Sharing (UNOS) database, diabetes was associated with an increased risk of CAV [130].

Most heart transplant recipients are markedly insulin-resistant and demonstrate many of the features of compensatory hyperinsulinemia, including the atherogenic and proinflammatory profiles [131,132]. Insulin resistance and a proinflammatory state are associated with the development of CAV despite the use of statin therapy [133]. The use of immunosuppressive drugs and factors such as post-transplant obesity are major contributors to insulin resistance syndrome, which appears to correlate with the development of CAV [134].

Cytomegalovirus

Human CMV is ubiquitous, with a wide global distribution (see Chapter 94). Exposure to CMV increases with age such that by the age of 60, most have evidence of prior exposure. Fortunately, in the majority with a well-developed competent immune system, CMV poses little threat, with most infections causing only mild subclinical disease. However, in immune-compromised patients – for example, patients with AIDS, cancer patients undergoing chemotherapy, and organ transplant recipients – CMV infection can be life-threatening, leading to systemic viremia, hepatitis,

pneumonitis, retinitis, colitis, and other manifestations. In heart transplant recipients, CMV infection has been associated with development of CAV. Several clinical studies have shown an association between evidence of CMV infection and subsequent development of CAV [135–139]. CMV infection occurs in 25–50% of cardiac transplant recipients. CMV infection increases with the use of anti-lymphocyte induction therapy and with acute rejection episodes [1]. In earlier studies, the 5-year survival rate was about 70% in patients without CMV compared with about 30% in those with CMV infection [136].

The mechanisms by which CMV infection contributes to CAV are unclear. Endomyocardial biopsy studies demonstrate that CMV disease in heart transplant recipients have a greater degree of severe angiographically demonstrable coronary artery disease, intimal thickening, vascular smooth muscle cell proliferation, and significant perivascular inflammation when compared with patients without CMV disease [140]. CMV infection after transplant is associated with chronic endothelial dysfunction [141,142] through a pathway that results in impaired endothelial nitric oxide production [143].

In animal studies, in rat aortic allograft models, CMV infection at the time of transplantation results in neointimal proliferation [144]. Endothelial cell infection leads to up-regulation of adhesion molecules on both infected and non-infected cells and may be mediated by a paracrine effect from interleukin-1 beta production [145]. In co-culture experiments, CMV infection of T cells induces production of IFN-γ and TNF-α, which, through a paracrine effect, are then able induce expression of Class I and II antigens, VCAM-1 and ICAM-1. CMV infection may also contribute to neointimal proliferation by inhibition of apoptosis of smooth muscle cells [146].

Clinical assessment

Due to cardiac denervation, symptoms resulting from CAV may not occur until the disease is very advanced and beyond therapeutic intervention. Most programs therefore use a surveillance strategy to monitor the development of CAV. Although invasive strategies with coronary angiography and IVUS have been traditionally used, non-invasive methods have become increasingly popular in recent years. Non-invasive strategies have typically involved stress testing, which is limited because these techniques depend upon the presence of hemodynamically significant lesions. Dobutamine stress echocardiography (DSE) has been used for detection of CAV with variable sensitivity and specificity and is predictive of adverse cardiac events [147,148]. The method may be limited by the presence of resting wall motion abnormalities in cardiac allografts and abnormalities in certain parameters such as Doppler tissue imaging, which may not be attributable to CAV [149,150]. However, quantitative techniques and use of myocardial contrast [151,152] appear to improve the ability of DSE to detect CAV even in the absence of significant angiographically detectable disease [153].

Myocardial perfusion imaging (MPI) has the advantage of detecting perfusion associated with both large epicardial vessels and the microvasculature. MPI reliably identifies patients at risk for subsequent cardiac events in cases of CAV, with a high negative predictive value [154–156]. Measurement of quantitative myocardial blood flow and reserve by positron emission tomography (PET) may be particularly useful in the determination of microvascular allograft vasculopathy as a marker for early disease and to monitor disease progression [157].

Ultrafast computerized tomography (CT) has been used to detect coronary calcification and may be useful in the detection of CAV [158], but still does not provide detailed information about the vessel lumen or wall. CT angiography (CTA) has become an increasingly useful tool in the non-invasive assessment of coronary disease. Development in the field with 64-slice, dual source, and ECG gating technologies has allowed detailed luminal and extraluminal evaluation of coronaries with significant decrease in radiation exposure. Diagnostic accuracy for detection of CAV is comparable to IVUS [159], and CTA may also allow detailed evaluation of plaque composition [160]. Serial CTA follow-up may be a reasonable alternative to conventional invasive coronary angiography in many patients [161].

Magnetic resonance imaging (MRI) is a very promising technology for evaluation of cardiac structure and function. In heart transplantation, it may be useful in the evaluation of acute allograft rejection, allowing simultaneous assessment of cardiac function and early contrast enhancement and myocardial edema as non-invasive correlates for biopsy proven rejection [162]. ^{31}P magnetic resonance chemical shift imaging with measurement of phosphocreatine to adenosine triphosphate ratio has been shown to predict angiographic CAV [163]. Quantification of myocardial strain and perfusion reserve by MRI has also been shown to correlate with CAV [164] and may be particularly useful for assessment of microvascular disease.

Invasive methods have traditionally been the standard for assessment of CAV. Coronary angiography requires the ability to compare normal segments of the vessel with diseased segments. However, the panvascular nature of CAV often results in underestimation of disease because of the absence of a reference segment in which the normal diameter of the vessel can be assessed. The presence of minimal luminal irregularities on angiography often suggests the presence of early disease and is therefore commented upon. Comparison with prior studies may help determine progression of disease but requires the use of comparable angiographic views and magnification at each study for precise evaluation. This methodology also allows use of computer-assisted QCA, improving the sensitivity of detection of CAV. However, QCA still does not allow evaluation of the vessel wall and may miss early disease where compensatory dilatation of the vessel may occur to preserve luminal area. Interestingly, coronary angiography has allowed some estimation of the presence of microvascular disease. Distal pruning on angiography frequently suggests diffuse small vessel involvement. The presence of coronary collaterals with myocardial blush has been interpreted as a correlate for microvascular disease [165]. Transplant patients generally have microcirculatory aberrations as determined by Thrombolysis in Myocardial Infarction (TIMI) myocardial perfusion grade, and severity appears to correspond to both epicardial disease and survival [166]. More recent quantitative assessment of angiographic myocardial blush has been shown to be predictive of survival in transplant recipients and may help with the identification of early CAV in patients with impaired perfusion reserve but without angiographically evident atherosclerosis [167].

While coronary angiography is the gold standard for the assessment of coronary artery disease, conventional coronary angiography generally underestimates the extent of disease because lesions are frequently concentric due to subintimal cellular proliferation. In contrast, IVUS allows direct imaging of the vessel wall to determine the extent of intimal and medial disease (Figure 79.2). Quantitative assessment of intimal and medial area by planimetry allows assessment of even early plaque burden

not appreciable angiographically. Sequential images are usually obtained by automated catheter pull-back to determine the extent of disease along a vessel wall. Several studies have confirmed that IVUS is more sensitive than angiography in detecting CAV [168–170]. Serial IVUS assessment allows determination of the percentage change in atheroma volume, with considerable statistical power to detect small changes. The technique is therefore routinely used to assess efficacy of newer treatment regimens in reducing the development of CAV. IVUS studies suggest that the most rapid rate of progression of intimal thickening occurs during the first year, followed by slow but inexorable progression over time [171]. The progressive development of intimal thickening as recognized by IVUS is predictive of development of angiographically apparent CAV. Rapidly progressive CAV, defined as an increase of $\geq$0.5 mm in maximal intimal thickness within the first year after heart transplant, is associated with a significantly increased risk of all-cause death, myocardial infarction, and the subsequent development of angiographically severe CAV [171,172]. The performance of IVUS at 1 and 12 months after heart transplant is therefore increasingly used to identify patients at high risk for future cardiovascular events, and may aid in allowing therapeutic adjustment of immunosuppression. More recently, IVUS techniques have been developed to allow assessment of plaque composition using radio frequency analysis [173,174]. This approach, known as virtual histology, is a promising development which may allow not only quantification of plaque burden but also determination of changes in plaque composition which may be of prognostic value [173,175].

Despite these promising developments, IVUS has several limitations: it is highly invasive, requires anticoagulation, use of expensive single-use catheters, and evaluation is mainly limited to the major epicardial vessels. Catheter-induced coronary vasospasm is also a particular concern in heart transplant recipients due to persistent endothelial dysfunction.

Determination of coronary flow reserve with intracoronary Doppler flow measurement may be useful in assessing CAV, although the clinical importance of this information has yet to be determined and non-invasive methods using PET myocardial perfusion imaging or echocardiography may provide similar information more easily. Intracoronary flow velocities are determined using a Doppler transducer mounted on a guide wire. Pharmacologic intervention with adenosine or dipyridamole allows measure of maximal coronary flow and calculation of flow reserve. Coronary flow reserve has been shown to be reduced in patients with CAV and deteriorates with increasing time after transplantation [176,177]. Measurement of coronary flow reserve reflects changes in the microvasculature as well as the epicardial vessels and it correlates with plaque burden assessed by IVUS [178].

Unfortunately, the definitions of CAV are diverse, and there are no uniform international standards for the nomenclature of this entity. However, a consensus document commissioned by the International Society of Heart and Lung Transplantation Board has been published, which is based on best evidence and clinical consensus derived from critical analysis of available information pertaining to angiography, IVUS, microvascular function, cardiac allograft histology, circulating immune markers, non-invasive imaging tests, and gene-based and protein-based biomarkers [179]. This document represents a working formulation for an international nomenclature of CAV, similar to the development of the system for adjudication of cardiac allograft rejection by histology (Table 79.2).

Table 79.2. Recommended nomenclature for cardiac allograft vasculopathy

ISHLT CAV_0 (Not significant): No detectable angiographic lesion
ISHLT CAV_1 (Mild): Angiographic left main (LM) <50%, or primary vessel with maximum lesion of <70%, or any branch stenosis <70% (including diffuse narrowing) without allograft dysfunction
ISHLT CAV_2 (Moderate): Angiographic LM <50%; a single primary vessel $\geq$70%, or isolated branch stenosis $\geq$70% in branches of two systems, without allograft dysfunction
ISHLT CAV_3 (Severe): Angiographic LM $\geq$50%, or two or more primary vessels $\geq$70% stenosis, or isolated branch stenosis $\geq$70% in all three systems; or ISHLT CAV1 or CAV2 with allograft dysfunction (defined as LVEF $\leq$45% usually in the presence of regional wall motion abnormalities) or evidence of significant restrictive physiology (which is common but not specific; see text for definitions)

Definitions
(a) A **primary vessel** denotes the proximal and middle 33% of the left anterior descending artery, the left circumflex, the ramus and the dominant or co-dominant right coronary artery with the posterior descending and posterolateral branches
(b) A **secondary branch vessel** includes the distal 33% of the primary vessels or any segment within a large septal perforator, diagonals and obtuse marginal branches or any portion of a non-dominant right coronary artery
(c) **Restrictive cardiac allograft physiology** is defined as symptomatic heart failure with echocardiographic E to A velocity ratio >2 (>1.5 in children), shortened isovolumetric relaxation time (<60 ms), shortened deceleration time (<150 ms), or restrictive hemodynamic values (right atrial pressure >12 mmHg, pulmonary capillary wedge pressure >25 mmHg, cardiac index <2 L/min/m^2)

Pharmacologic therapy

The impact of immunosuppressive agents on the development of CAV is complex (see Chapters 98–102). The indirect effects of long-term steroid therapy on lipid metabolism have already been described. Cyclosporine further enhances this effect although substitution of cyclosporine for tacrolimus appears to attenuate the rise in serum lipids [100]. The number and severity of episodes of acute rejection contributes to CAV [50,77] and even asymptomatic antibody- mediated rejection appears to be a risk factor for the development of allograft vasculopathy [180]. More effective immunosuppressive regimens may therefore have a beneficial impact on the development of allograft vasculopathy.

Although tacrolimus has been shown to be superior to cyclosporine in preventing chronic rejection on liver transplantation [181], data in cardiac transplant patients remain limited. This is despite demonstrated improvements with tacrolimus in hypertension and lipid profiles in comparison to cyclosporine [100], although rates of diabetes are demonstrably higher with tacrolimus. Five-year results of a randomized study comparing tacrolimus with microemulsion cyclosporine revealed comparable outcomes with respect to the development of CAV [182].

MMF, an inhibitor of the de novo pathway for purine biosynthesis, has been shown to be more effective at reducing cardiac allograft rejection and post-transplant mortality [183]. It may also be more effective at reducing allograft vasculopathy [184]. This effect may be related at least in part to its ability to reduce B-cell responses, as patients treated with MMF developed lower antivimentin titers that correlated with the lower incidence of CAV by IVUS. In comparison to azathioprine, MMF has been shown by IVUS to reduce intimal thickness [185], although rates of CMV infection, a risk factor for CAV, appear to be increased with the use of MMF [186].

The availability of proliferation signal inhibitors (PSI) sirolimus and everolimus represents a major advance in the management of CAV. These agents are a class of anti-proliferative agents shown to inhibit smooth muscle cell proliferation in vitro and in experimental animal models of vascular injury, a key component in the development of CAV. The agents are clinically effective in reducing in-stent restenosis in native coronary artery disease [187,188]. In a randomized clinical trial involving 136 patients [189], the use of sirolimus in de novo heart transplantation was associated with decreased development of CAV at 2 years compared to patients receiving azathioprine. In a subsequent sentinel multicenter study [190], over 600 patients were randomized to everolimus or azathioprine within 72 hours of transplantation. IVUS demonstrated that the average increase in maximal intimal thickness at 12 months was significantly smaller with everolimus than azathioprine. This finding was significant as it has been noted that an increase in maximal intimal thickness at 1 year is associated with higher post-transplant mortality at 5 years [172].

Treatment

Clinically apparent disease is associated with a poor prognosis and therefore prevention is an important strategy in addressing transplant vasculopathy. In addition to the use of anti-proliferative immunosuppressants, agents used in the treatment and prevention of native coronary disease are also utilized in CAV. Aspirin is widely used because of its widely established use in non-transplant coronary disease and may have an important role in preventing thrombosis in the setting of persistent endothelial dysfunction and prothrombotic milieu seen in CAV. Control of hypertension and hyperlipidemia has already been discussed. The use of statins is particularly important as it also helps prevent allograft rejection. In contrast to native atherosclerosis, vitamin C and E supplementation may be beneficial in decreasing CAV [191].

Once clinically apparent disease is apparent, a number of approaches are available to relieve ischemia. For focal disease, percutaneous coronary intervention (PCI) with balloon angioplasty has been successful, although restenosis is particularly common in the transplant setting [192], especially with the use of cutting balloon techniques [193]. Stenting has helped to address this problem and the use of drug-eluting stents has significantly attenuated restenosis rates [194,195]. No studies are available to show whether PCI alters the prognosis of CAV and because many patients with significant disease are asymptomatic, intervention often presents a dilemma. Furthermore, patients who develop in-stent restenosis after PCI appear to develop accelerated disease in the non-intervened vessels and may be at higher risk for myocardial infarction or death [196], suggesting that a heightened immune response contributes to progression of CAV as a panvascular phenomenon [197].

Patients with multi-vessel focal disease with adequate distal target vessels may be candidates for coronary artery bypass surgery (CABG). Efficacy is difficult to determine as relatively small numbers have been reported, reflecting the many patients who do not have adequate targets and the preferential use of PCI. Surgical revascularization appears to be a safe option with reasonable outcomes for the select patients with CAV with suitable targets [198,199].

Retransplantation may be the only consideration for many patients with advanced CAV not amenable to PCI or CABG. Survival rates reported after retransplantation have been consistently lower than those after primary transplantation. In one, the 1-year actuarial survival rate of those patients who underwent retransplantation specifically for CAV approached 1-year survival rates following primary transplants [200]. This study also showed that patients having a second heart transplant do not have an increased risk for development of CAV in the second donor heart. Recent data suggest that patients undergoing retransplantation for CAV or chronic graft failure appear to have acceptable long-term outcomes with a median survival over 10 years [201].

Cardiac transplantation for infiltrative cardiomyopathies and risk of recurrence

A number of infiltrative diseases may lead to end-stage heart disease with a requirement for transplantation. These include cardiac sarcoidosis, myocarditis (giant-cell, lymphocytic, eosinophilic, or viral), autoimmune diseases such as lupus and amyloidosis. In many cases, the diagnosis is only made upon histology of the explanted heart. For most conditions, post-transplant outcome is comparable with those patients undergoing heart transplantation for other conditions despite documented cases of recurrence of disease noted on endomyocardial biopsies [202].

Cardiac sarcoidosis

There are a few case reports of recurrent cardiac sarcoidosis in the transplanted heart, with many occurring several years after transplantation [203–207]. A case series of four patients transplanted for sarcoid heart disease has been reported, with no evidence of post-transplant recurrence [208]. Although data are sparse, the risk of recurrence of cardiac sarcoid appears to be significantly lower than the risk of recurrence of pulmonary sarcoidosis after lung transplantation, where the recurrence rate is as high as 50%. Recurrence of disease following cardiac transplantation is treated with augmentation of immunosuppression, particularly corticosteroids.

Giant-cell myocarditis

Giant-cell myocarditis causes irreversible fulminant left ventricular dysfunction with associated conduction abnormalities and congestive failure. Response to immunosuppressive therapy is poor [209] and cardiac transplantation is the only viable treatment option. The histologic hallmarks of giant-cell myocarditis include a polymorphous inflammatory response with numerous multinucleated giant cells and extensive myocyte necrosis in a geographic pattern. In the Giant Cell Myocarditis Registry, of 38 patients receiving a heart transplant for giant-cell myocarditis, there were nine recurrences of disease in the allograft. Due to the high risk of recurrence, concern has been expressed that recurrence of giant-cell myocarditis in the allograft might be a contraindication for cardiac transplantation. In one series of five patients from the Cleveland Clinic [210], one patient developed recurrence early after transplant in conjunction with an episode of cellular rejection with subsequent resolution with treatment. Despite the increased rate of recurrence, patients with giant-cell myocarditis are considered for transplantation as without this option mortality remains high. Interestingly, while the condition appears to respond poorly to immunosuppressive treatment, its recurrence post-transplant appears to be amenable to augmentation of immunosuppressive therapy. This might be the result of detection of the disease at an earlier stage than in the native heart, or the immunosuppression milieu in the allograft. The favorable response to therapy suggests that the likelihood of

recurrence of giant-cell myocarditis should not be considered a barrier to transplantation.

Chagas disease

Chagas disease, caused by the parasite *Trypanosoma cruzi*, is an important cause of cardiac disease in endemic areas of Latin America. It is now being diagnosed in non-endemic areas because of immigration and is a more frequent cause of presentation with end-stage heart disease in the United States. There is also a significant reservoir of the parasite in raccoons in the United States, although autochthonous transmission is rare [211]. It is also becoming an issue of concern as a transmissible organism during organ donation, requiring establishment of appropriate screening strategies in potential donors. This is further complicated as serology may be unreliable and accurate diagnosis depends on tissue samples, histology, or polymerase chain reaction (PCR) assays. Typical cardiac manifestations of Chagas disease include dilated cardiomyopathy, congestive heart failure, arrhythmias, cardioembolism, and stroke.

Chagas disease is the third leading indication for cardiac transplantation in Brazil, representing 15–20% of cases [212]. The recurrence rate of Chagas disease is around 40% [212,213], although there is some evidence that in the most recent era, with minimization of immunosuppression, close surveillance, and initiation of appropriate therapy, rates are much lower [212]. In an analysis of 107 heart transplants for Chagas disease between 1985 and 2010 in Sao Paulo, Brazil [212], the hospital mortality was 17.7% (n = 19) and causes of death were infection (n = 6; 31.5%), graft dysfunction (n = 6; 31.5%), rejection (n = 4; 21.1%), sudden cardiac arrest (n = 2; 10.5%) or ABO incompatibility (n = 1; 5.3%). Late mortality occurred in 27 (25.2%) patients. The main causes of death were rejection (n = 6; 22.2%), infection (n = 6; 22.2%), lymphoma (n = 4; 14.8%), sarcoma (n = 2; 7.4%), pericarditis (n = 2; 7.4%), and reactivation of Chagas disease in the central nervous system (n = 1; 7.1%). Early experience was associated with higher rates of malignancy attributed to higher immunosupression [214]. Improvement in survival and a decrease in reactivation rate has been associated with lower immunosuppression, particularly steroid weaning [212] and avoidance or minimization of MMF [215,216]. Patients with a history of rejection and malignancy are at higher risk of reactivation [216]. Current strategies for monitoring for reactivation rely on PCR testing of blood and this technique is also useful for monitoring treatment efficacy [217]. Episodes of parasitemia, myocarditis, or Chagas disease reactivation are treated with benznidazole in a 5 mg/kg/day dosage for 60 days. Nifurtimox is another option for reactivation and high-dose allopurinol has been used based on an anecdotal report [214,218].

Conclusions

CAV is an important complication that limits the long-term survival of cardiac allografts. The disease has many similar features to native non-transplant coronary atherosclerosis, although there are also several unique features in both pathology and distribution. Development of CAV requires several contributing factors including risk factors associated with conventional atherosclerosis, ischemia–reperfusion injury at the time of transplant, host alloimmune response, hemostatic factors, and the modulating effect of post-transplant medications. Clinical presentation of CAV is frequently atypical due to surgical denervation. Diagnosis and monitoring of disease depends mostly on invasive techniques, although recent advances in non-invasive techniques may decrease the need for routine invasive evaluation in the future. Given the relatively poor prognosis of CAV, prevention remains an important strategy. A greater understanding of its pathology has offered more promising immunosuppressive regimens such as PSI. A greater awareness of the role of antibody-mediated rejection in the development of CAV may allow the development of strategies particularly focused on abrogating the humoral response. In the meantime, patients with established symptomatic disease have conventional revascularization techniques available to them for palliation, and retransplantation may be a consideration for select patients.

For the relatively few who undergo cardiac transplantation for an infiltrative process, the risk of recurrent disease appears to be greatest for Chagas disease and giant-cell myocarditis. Close surveillance for recurrence of disease and prompt therapy appears to allow satisfactory outcomes in these patients.

CHAPTER 80

Recurrent Disease after Lung Transplantation

Todd L. Astor
Harvard Medical School, Boston, MA, USA; Pulmonary and Critical Care Unit, Massachusetts General Hospital, Boston, MA, USA

Introduction

Lung transplantation has become the definitive therapy for many different types of advanced lung disease. Although advances in surgical technique (see Chapter 59) and donor organ preservation have led to improvement in early post-transplant survival, infections (see Chapters 93 and 94) and bronchiolitis obliterans syndrome (BOS; see Chapter 72) have remained major impediments to long-term survival. Therefore, a great deal of attention and research has centered on these allograft-related complications.

However, little consideration has been given to the potential for recurrence of native lung disease as an etiology of allograft dysfunction following lung transplantation. Recurrence has been reported for a number of lung diseases following lung transplantation, resulting in a spectrum of outcomes ranging from incidental biopsy findings to graft failure and death (Box 80.1). In this chapter, we survey the evidence supporting the recurrence of native lung disease following lung transplantation, examine the variable impact of recurrent native disease on allograft function, explore the pathogenesis of recurrent disease, and discuss the potential implications of recurrent disease on the decision to perform transplantation.

Sarcoidosis

Sarcoidosis is a multi-organ granulomatous disease of unclear etiology. The development of sarcoidosis most likely begins with presentation of an unknown antigen by macrophages or dendritic cells to naïve T lymphocytes (primarily $CD4^+$), resulting in a polarized Th1 immune response. This ultimately leads to the formation of granulomas, characterized by epithelioid histiocytes and multinucleated giant cells mixed with $CD4^+$ lymphocytes. The diagnosis of sarcoidosis requires the exclusion of a number of alternative diagnoses, and generally requires a combination of clinical, radiographic, and/or histologic findings involving multiple organ systems [1].

The lung is the most commonly affected organ in patients with sarcoidosis [2,3]. Granulomas can occur in the parenchyma as well as the airways, and therefore can lead to both restrictive and obstructive lung physiology [4,5]. Severity of pulmonary disease can range from isolated radiographic findings in the absence of symptoms to end-stage lung disease requiring lung transplantation. Therapy for pulmonary sarcoidosis currently includes the stepwise use of corticosteroids [6,7], steroid-sparing agents (methotrexate, azathioprine, leflunomide, mycophenolate) [8–11], and biologic agents capable of blocking tumor necrosis factor (infliximab) [12,13].

Lung transplantation has become the definitive therapy for patients with severe refractory lung disease secondary to sarcoidosis. Between 1995 and 2010, a total of 783 total lung transplant procedures (236 single lung transplant and 547 double lung transplant) were performed for patients with sarcoidosis, representing 2.6% of all indications for transplant. The survival half-life following lung transplantation for sarcoidosis is 5.3 years, compared to 7.4 years for cystic fibrosis, 6.3 years for alpha-1 antitrypsin deficiency, 5.3 years for chronic obstructive pulmonary disease (COPD), 4.5 years for idiopathic pulmonary fibrosis, and 4.9 years for idiopathic pulmonary arterial hypertension [14].

Sarcoidosis is the most common native lung disease to recur in the lung allograft, with a reported incidence of 30–80% following lung transplantation [15–22]. Although several early reports described the findings of non-caseating granulomas on biopsy specimens from patients following lung transplantation for sarcoidosis [18–20], none of the patients in these reports had symptoms or radiographic findings consistent with sarcoidosis. Interestingly, one of the reports described a patient with recurrence of sarcoidosis granulomas in the transplanted allograft, as well as recurrence in a second contralateral allograft following retransplantation for obliterative bronchiolitis [20].

Martinez et al. [21] published the first case report of a lung transplant recipient with symptoms and computed tomography (CT) scan findings, in addition to biopsy pathology, consistent with a diagnosis of sarcoidosis. The patient in their report presented with dyspnea and fatigue 13 months following lung transplantation, and a high resolution computed tomography (HRCT) scan demonstrated upper lobe micronodular infiltration. A subsequent bronchoscopic lung biopsy revealed non-caseating granulomas. The patient's symptoms and radiographic abnormalities resolved following treatment with oral corticosteroids, but the finding of non-caseating granulomas persisted in biopsies performed 3, 6, and 9 months later.

Since then several reports have described a total of 31 cases of recurrent sarcoidosis following lung transplantation. Milman et al. [17] published the long-term outcomes of seven patients receiving single lung allografts for pulmonary sarcoidosis. These patients were followed for a median of 31 months post-transplant (range 12–136 months). Only one of the patients had radiographic findings consistent with pulmonary sarcoidosis. Three patients had

Box 80.1. Reports of recurrent native lung disease following lung transplantation

- Sarcoidosis [15–22]
- Lymphangioleiomyomatosis [47–53]
- Langerhans cell histiocytosis [79–81]
- Bronchioloalveolar carcinoma [100–105]
- Emphysema secondary to alpha-1 antitrypsin deficiency [140,141]
- Pulmonary alveolar proteinosis [122,123]
- Desquamative interstitial pneumonia [148–150]
- Giant cell interstitial pneumonia [153]
- Diffuse panbronchiolitis [155]
- Pulmonary capillary hemangiomatosis [160,161]
- Williams–Campbell syndrome [164]

pathologic evidence of sarcoidosis in the allograft, revealed in biopsies performed at 2, 5, and 6 months post-transplant, respectively. Ionescu et al. [15] described a series of eight patients with recurrent sarcoidosis following lung transplantation. Histologic evidence of sarcoid granulomas was identified during the first 6 months in two cases, between 6 and 12 months in two other cases, and between 1 and 2 years in the other four cases.

The cumulative findings in these reports suggest that recurrence of sarcoidosis is most often diagnosed by the incidental finding of non-caseating granulomas on transbronchial biopsies. Clinical signs and symptoms are often absent and, when present, are generally less severe than in primary disease. Radiographic findings are uncommon, but may include lymphadenopathy, solitary or military nodules, and diffuse reticulonodular infiltrates [23,24]. Graft dysfunction related to the appearance of granulomas is rare. It is possible that the mild form of recurrent disease, compared to the original native disease, may be a result of the effects of post-transplant immunosuppressive therapy. Interestingly, acute rejection has been reported at a much higher rate in the presence of recurrent sarcoidosis [15,16,18,21,24]. Based on this observation, it has been proposed that rejection and sarcoidosis may share some common immunologic pathways [17,21,25].

It is not completely known if recurrent sarcoid granulomas in the transplanted lung is derived from recipient or donor cells, or both. Donor-acquired sarcoidosis has been proposed, in which sarcoidosis in the lung allograft is thought to originate from donors with undiagnosed sarcoidosis [16]. However, there are few data supporting the likelihood that significant sarcoidosis could develop in "normal" recipients following transplantation of organs from donors with known sarcoidosis. Heatly et al. [26] reported the transplant of a lung allograft from a donor with pulmonary sarcoidosis (unknown at the time of transplant) into a recipient with primary pulmonary hypertension and no known history of sarcoidosis. During a follow-up period of 16 months post-transplant, there was no evidence of histologic, radiologic, or clinical evidence of pulmonary sarcoidosis involving the transplanted lung. Ionescu et al. [15] performed polymerase chain reaction (PCR) DNA analysis of lung samples from the native lung, allograft lung, and recurrent sarcoid granuloma (in the allograft) in three lung transplant recipients with recurrent sarcoidosis, and demonstrated an increase in the percentage of recipient DNA in the epithelioid cell clusters within the granulomas. Milman et al. [22] used fluorescence in situ hybridization (FISH) to analyze immune cells in recurrent granulomas from the allograft of a female lung transplant recipient with sarcoidosis who received an allograft from a male donor, and demonstrated that the immune cells in the granulomas were X-chromosome positive and Y-chromosome negative. These results suggest that the recurrent granulomas originate in the recipient, and likely result from the infusion of recipient macrophages into the allograft, rather than a response of donor histiocytes to a recipient antigen.

Lymphangioleiomyomatosis

Lymphangioleiomyomatosis (LAM) is a rare idiopathic disease primarily affecting women of reproductive age, although it has been reported to develop in a small percentage of men in association with tuberous sclerosis [27–29]. LAM is characterized by smooth muscle proliferation and thin-walled cyst formation in the lungs, kidneys, liver, spleen, uterus, ovaries, and retroperitoneal lymphatics. The lung is the most commonly affected organ, and dysfunction results from smooth muscle proliferation and cyst formation in the lung parenchyma, airways, vessels, and lymphatics [30]. Symptoms include progressive dyspnea, pneumothoraces from ruptured cysts, chylothoraces from occluded lymphatics, and pulmonary hemorrhage. HRCT scan demonstrates evenly distributed thin-walled cysts of varying sizes [31]. Histology is characterized by cysts surrounded by proliferating smooth muscle-like spindle cells, which can be identified by immunostaining for melanoma-related marker (HMB-45) [32].

LAM has a very slow and progressive natural history, with an approximately 70% 10-year survival rate [30]. Therapeutic strategies have revolved around preventing further proliferation of the smooth muscle-like cells, in the past primarily involving surgical or medical reduction of estrogen production [27,28,33–35]. More recently, the discovery of tuberous sclerosis genes *TSC1* and *TSC2* in LAM have led to the successful use of the mammalian target of rapamycin (mTOR) inhibitor, sirolimus, in the treatment of LAM [36–42].

Despite advances in the understanding and treatment of LAM, lung transplantation remains the only definitive therapy. A total of 308 lung transplant procedures (101 single, 207 double) were performed for patients with LAM between 1995 and 2010, representing 1% of all lung transplants performed [14]. The actuarial survival rates following lung transplantation for LAM based on published US and European data have been reported as 79–86% at 1 year, 73–76% at 3 years, and 65% at 5 years [43,44]. Postoperative LAM-related complications include significant pleural adhesions and bleeding, chylothorax, and pneumothorax of the native lung [43,45,46].

Recurrence of LAM has been demonstrated in the allograft following lung transplantation in at least seven published reports [47–53]. Early reports of LAM recurrence were primarily based on findings at autopsy. However, as LAM is generally characterized by an obstructive pattern of pulmonary function testing, recurrence following lung transplantation may be misdiagnosed as BOS.

O'Brien et al. [48] reported the first case of recurrent LAM following lung transplantation in a 38-year-old woman who underwent right single lung transplantation for pulmonary LAM. One month following lung transplant surgery, the patient's lung function began to decline, and an open-lung biopsy revealed evidence of moderate acute cellular rejection and lymphocytic bronchiolitis. There was no evidence of LAM on the biopsy, or on subsequent transbronchial biopsies. Despite intensification of immunosuppressive therapy, the patient's lung function did not significantly improve, and the patient eventually died 18 months later from invasive aspergillosis. The autopsy did not reveal evidence of acute

Figure 80.1. The lung shows replacement of the normal alveolar interstitium by muscle-like spindle cells and slit-like lymphatic spaces (A). An HMB-45 immunostain highlights the infiltrating spindle cells. The findings are diagnostic of lymphangioleiomyomatosis (B) H&E, original magnification x250. Courtesy of Dr. Richard Kradin.

rejection or obliterative bronchiolitis, but did demonstrate nodular proliferation of spindle cells blended with smooth muscle, consistent with a histologic diagnosis of LAM. These findings suggested that LAM may have had a significant role in the earlier loss of allograft function.

The challenge of clinically differentiating LAM from BOS was also highlighted in a report by Bittman et al. [50,51]. The authors described a 31-year-old woman who underwent right single lung transplantation for pulmonary LAM, and developed a significant decline in lung function 1 year following transplant. An open lung biopsy revealed bronchiolitis obliterans, but at that time no histologic evidence of recurrent LAM was reported. During the next several months, her lung function continued to decline, presumably from progressive obliterative bronchiolitis. She presented 3 years post-transplant with a pneumothorax on the side of the right allograft, and died of related complications. As expected, the postmortem examination revealed histologic evidence of significant bronchiolitis obliterans, but also demonstrated proliferation of smooth muscle cells that stained strongly positive for HMB-45. Moreover, the original open lung biopsy was reanalyzed with immunohistochemical staining, revealing evidence of smooth muscle proliferation with positive HMB-45 staining. These histologic findings, along with the clinical sequela of a pneumothorax, highlight the potential clinical significance of recurrent LAM in this patient.

Recurrent LAM has also been described following living-donor lobar transplantation. Chen et al. [52,53] described a 20-year-old woman with pulmonary and abdominopelvic LAM who underwent living-donor lobar transplantation, and subsequently developed recurrent chylous pleural effusions and pneumothoraces within the first year post-transplant. HRCT findings demonstrated emphysematous changes and pulmonary infiltrates, and a transbronchial biopsy of the left lung revealed histologic evidence of LAM. Sirolimus therapy was substituted for azathioprine, and continued along with tacrolimus. The patient's symptoms, HRCT findings, and pulmonary function testing subsequently improved, and remained stable during the next 2 years.

We have recently performed a bilateral retransplantation for a patient with recurrent LAM [54]. The patient is a 34-year-old woman who had pulmonary and abdominopelvic LAM and initially underwent living-donor lobar transplantation. HRCT performed 6 years later first detected the appearance of multiple bilateral lung cysts, consistent with a diagnosis of recurrent LAM. Her lung function gradually deteriorated, presumably from a combination of recurrent LAM and bronchiolitis obliterans syndrome, and 9 years post-transplant she eventually underwent bilateral lung retransplantation. Histologic analysis of her explanted lobar allografts revealed muscle-like spindle cells and slit-like lymphatic spaces, and HMB-45 immunostain confirmed the infiltrating spindle cells, consistent with a diagnosis of LAM (Figure 80.1A,B). Evidence of patchy obliterative bronchiolitis was also seen, consistent with concomitant chronic rejection. Sirolimus was initiated approximately 5 months post-transplant to prevent recurrence of LAM in the new allografts. Although recurrent pulmonary LAM has not subsequently been detected in a 2-year follow-up period, a significant increase in hepatic and renal LAM lesions occurred during this interval.

The origin of recurrent LAM lesions in the lung allograft has been debated. Early reports utilizing non-isotopic in situ hybridization (NISH) with probes of the human Y and X chromosomes suggested that the cells were of donor origin [46,50]. However, it was then discovered that recipient LAM cells were often tightly associated with cells of donor origin, resulting in misinterpretation of the NISH signals. Subsequent analysis using simultaneous NISH and immunohistochemical staining revealed that the LAM cells actually originated from the recipient, not the donor [51]. Karbowniczek et al. [47] utilized microsatellite marker fingerprinting and *TSC2* mutational analysis to demonstrate that recurrent LAM cells in an allograft from a patient receiving a single lung transplant for LAM originated from the native lung and lymph nodes. These findings supported the hypothesis that LAM cells may actually migrate or metastasize either from the native lung and lymphatics, or from abdominopelvic foci.

The recognition that LAM can recur in the lung allograft, coupled with the common current practice of routine allograft surveillance with transbronchial biopsies, has created an opportunity for early therapeutic intervention. The discovery of *TSC2* mutation in LAM has invoked a significant role for the mTOR pathway in the pathogenesis of LAM. This finding has led to the use of sirolimus, an inhibitor of the mTOR pathway, in the treatment of LAM cell proliferation [36–42]. Chen et al. [52,53] reported the successful use of sirolimus in treating chylous effusions and declining lung function in a patient with recurrent LAM following lung transplantation. Three other reports demonstrated that initiation of sirolimus therapy resulted in significant improvement in lesions associated with retroperitoneal and recurrent pulmonary LAM in

lung transplant recipients [55–57]. We have successfully utilized sirolimus to prevent pulmonary recurrence of LAM in a patient following retransplantation for recurrent LAM in the original allografts [54]. However, progression of hepatic and renal LAM occurred despite sirolimus therapy.

Pulmonary Langerhans cell histiocytosis

Pulmonary Langerhans cell histiocytosis (PLCH) is a rare disease characterized by the infiltration and accumulation of Langerhans cells, bone-marrow derived dendritic cells, within the alveolar airspaces and interstitium [58]. Although Langerhans cell histiocytosis (LCH) can effect extrapulmonary organs such as bone, skin, and pituitary gland (particularly in children), most afflicted adults have isolated pulmonary disease [59–61]. PLCH is very strongly associated with cigarette smoking; 90% of patients with PLCH are active smokers at the time of diagnosis [59,60,62,63]. Patients with PLCH may present with mild dyspnea or cough or, in some instances, spontaneous pneumothoraces. Many patients are asymptomatic and are diagnosed by incidental findings on a chest radiograph. HRCT scan of the chest reveals the characteristic finding of a combination of cysts and nodules in predominantly upper- and mid-lung zone distribution [64–66]. Transbronchial biopsies have a very low sensitivity in the diagnosis of PCLH, and therefore surgical biopsy is generally required to make a diagnosis [67]. Histologic analysis reveals lesions with LCH cells, readily identified by characteristic kidney bean-shaped nuclei, immunohistochemical staining for CD1a, and the presence of Birbeck granules (cytoplasmic inclusion bodies) evident on electron microscopy [68–70].

The clinical course of PLCH is quite variable. Some patients spontaneously improve without any therapy, while others develop progressive disease despite potent immunosuppressive therapy. In light of the strong association between PLCH and cigarette smoking, smoking cessation is considered to be an essential intervention. Indeed, smoking cessation alone has been shown to be effective at reducing the disease manifestations in several published reports, although worsening of disease despite this behavioral modification has also been described [71–73]. Corticosteroid therapy is reserved for symptomatic patients with predominantly inflammatory lesions, although few data exist in the literature supporting evidence of a clear benefit [60,74,75]. Although potent systemic chemotherapeutic cytotoxic drugs such as cyclophosphamide, methotrexate, vinblastine, and etoposide have been utilized in the treatment of multisystem LCH, the role of these agents in the treatment of PLCH is unclear [76–78].

Lung transplantation has become the final therapy for a small number of patients with PLCH who have developed progressive refractory respiratory failure, primarily from severe cystic lung destruction and/or severe pulmonary hypertension [58,79–81]. Although many transplant centers have limited experience in the lung transplantation of patients with PLCH, there are few published data concerning short and long-term post-transplant outcomes. Dauriat et al. [58] conducted a retrospective multicenter study in France, including 39 patients who underwent lung transplantation (15 single-lung transplant, 15 double-lung transplant, 9 heart–lung transplant) for end-stage PLCH. All but two of the patients were current or former cigarette smokers. Most of the patients had moderate to severe preoperative pulmonary hypertension, and approximately one third had extrapulmonary involvement of LCH. The post-transplant survival rates for the patients in this study are 76.9% at 1 year, 63.6% at 2 years, 57.2% at 5 years, and 53.7% at 10 years. Although survival data for more common indications for transplant at these centers were not presented, these survival rates are comparable to data reported in the International Society for Heart and Lung Transplantation Registry during this same period [82]. In addition, there were no differences in survival rates related to the type of transplant procedure performed (i.e. single, double, heart–lung). The incidences of acute cellular rejection and bronchiolitis obliterans syndrome reported for this cohort were also similar to accepted rates in the general lung transplant population.

Clinical and radiographic evidence of PLCH, with or without concomitant histologic confirmation, has been reported following lung transplantation [79–81]. Gabbay et al. [79] described the first case of a patient with symptomatic recurrent PLCH following lung transplantation, a 32-year old-man with a history of diabetes insipidus (presumably from pituitary LCH) and progressive pulmonary failure. A surveillance lung biopsy performed at 24 and 30 months post-bilateral lung transplant revealed infiltration of Langerhans cells, interstitial fibrosis, and aggregates of Langerhans cells around terminal bronchioles. During this same period, the patient developed dyspnea and a progressively restrictive pattern of pulmonary function testing, and HRCT demonstrated findings consistent with interstitial fibrosis. The patient had been a lifelong non-smoker prior to transplant, and did not smoke after transplant. Interestingly, during this same period the patient's diabetes insipidus worsened, requiring increased therapy with nasal desmopressin. Following addition of cyclophosphamide to his maintenance immunosuppression of cyclosporine and prednisolone, his symptoms, lung function, and diabetes insipidus all improved. In this same report, the authors also mentioned four other patients who had undergone transplantation for PLCH at their center; only one of those patients demonstrated findings of Langerhans cells on biopsy.

Habib et al. [81] reported a case of recurrent PLCH in a 27-year-old Asian male who underwent bilateral lung transplantation. The patient smoked cigarettes preoperatively, but did not resume smoking following transplant. Approximately 2 years post-transplant, his respiratory function deteriorated, accompanied by HRCT findings of widespread cystic changes in the mid and lower lung zones of both lungs. This uncharacteristic distribution of disease in the lower lung fields (as opposed to the characteristic upper lung zone predominance normally associated with LCH) was also noted in the native lungs of this patient. Histologic analysis of a transbronchial biopsy specimen from the right lower lobe revealed clusters of interstitial, peribronchiolar, and perivascular Langerhans cells. Chemotherapy consisting of doxorubicin, vincristine, and etoposide was not tolerated, and the addition of cyclophosphamide to the maintenance immunosuppression regimen was ineffective.

Etienne et al. [80] related their single-center experience regarding recurrence of PLCH following lung transplantation, reporting the outcomes of seven patients who underwent lung transplantation for PLCH (six single lung, one heart–lung). Five of the patients did not demonstrate evidence of recurrence, and were alive and well at time intervals ranging from 15 to 90 months. Two patients developed recurrence of LCH in their lung allografts, in each case highlighted by radiologic, histologic, and spirometric abnormalities. Both patients had resumed smoking cigarettes, at 3 and 6 months post-transplant, respectively.

The largest single report of recurrence of PLCH following lung transplantation was described in the French multicenter study previously mentioned [58]. In this study, eight of the 39 patients

transplanted for PLCH (20.5%) developed recurrence of disease, although two of these patients were the same patients reported previously by Etienne et al. [80]. Except for these two patients, only one other patient in the cohort had resumed smoking post-transplant. Recurrence was notably more common in patients with extrapulmonary involvement than those with isolated pulmonary disease (41.7% versus 11.1%).

Although these reports were limited to a total of 10 patients with recurrent PLCH in the lung allograft(s), the findings highlight some interesting observations regarding the pathogenesis of LCH recurrence following lung transplantation. First, only 3 of the 10 patients with recurrence had resumed smoking following transplant. Therefore, it does not appear that smoking alone is responsible for disease recurrence. As previously discussed, there is a very strong association between smoking and the development of pretransplant PLCH. It has been proposed that tobacco injures the bronchiolar epithelium resulting in modification of specific cell surface antigens, recruitment of Langerhans cells, and an increase in the presentation of antigens by Langerhans cells to $CD4^+$ T lymphocytes [59,83]. One could argue that the relatively low rate of PLCH recurrence following lung transplantation may be in large part due to the low incidence of smoking recidivism in this subgroup of patients. Second, extrapulmonary involvement of LCH appears to be an important risk factor for the development of recurrence post-transplant. This observation suggests that recurrence of disease possibly results from the repopulation of the donor allograft by recipient Langerhans cells. It is conceivable that this process may be augmented by bronchiolar epithelial injury from tobacco and/or other environmental stimuli (i.e. respiratory viruses).

Despite the possibility of recurrence of PLCH following lung transplantation, the incidence of clinically significant disease is relatively low. Lung transplantation should therefore remain a viable therapeutic option for patients with refractory progressive lung failure secondary to PLCH, particularly for those patients with significant secondary pulmonary hypertension. Patients should be counseled repeatedly regarding abstinence from smoking following lung transplantation. Surveillance of the lung allograft should include pulmonary function testing, HRCT, and transbronchial biopsy. Surgical lung biopsy should be performed in cases of suspected recurrence if transbronchial biopsy is non-diagnostic. Patients with extrapulmonary LCH should be monitored even more closely for evidence of recurrent disease.

Bronchioloalveolar carcinoma

Bronchioloalveolar carcinoma (BAC) is a rare form of pulmonary carcinoma characterized by growth of well-differentiated neoplastic cells along the walls of alveoli without destruction or invasion of the pulmonary architecture, or lymphatic or systemic metastases [84,85]. BAC therefore represents an in situ carcinoma, although tumors with BAC features and areas of invasion are more common, classified as adenocarcinomas of mixed subtype [84,86,87]. BAC represent only 5% of all non-small cell lung cancers, but as many as 20% of all non-small cell lung cancers are adenocarcinomas with mixed BAC subtype [86,87]. BAC most commonly presents as a solitary nodule, often discovered incidentally on a chest radiograph or HRCT. BAC can also present as multiple nodules or diffuse parenchymal disease, although the latter form usually has features of the mixed adenocarcinoma and BAC type. The nodules of BAC most commonly appear as ground glass opacities on HRCT, although areas of consolidation are also frequently observed [88–92]. Treatment of isolated BAC tumors usually involves sublobar or lobar surgical resection, and multifocal BAC usually requires sublobar resection of all foci, with or without systemic chemotherapy [85,93–96]. The discovery that epidermal growth factor receptor (EGFR) mutations are much more common in BAC than in other lung cancers has led to the use of EGFR-tyrosine kinase inhibitors (TKI) in the treatment of patients with advanced or recurrent BAC [97–99].

Lung transplantation has become a therapeutic modality for a small number of patients with recurrent or unresectable BAC, particularly those with diffuse pneumonic disease [100]. BAC has been considered a controversial indication for lung transplantation because of the significant risk for recurrence [101–105]. The most significant experience in performing lung transplantation for patients with BAC exists at the University of Alabama Lung Transplant Program. Garver et al. [104] from that center initially reported a small series of patients who received lung transplantation for treatment of advanced BAC. Four of seven patients who received single or double lung transplantation developed recurrence of BAC in the allograft(s), although two of these patients enjoyed initial recurrence-free periods of 39 and 48 months. The same group subsequently reported the results of a study to determine whether lung transplantation would provide curative therapy for patients with BAC [100]. Eight patients with confirmed BAC underwent lung transplantation, although it is unclear whether any of these patients were also included in the original report. Six of the eight patients had recurrence of BAC after transplantation, with the time of recurrence ranging from 12 to 75 months post-transplant. Two of the six patients had localized recurrence; one of these patients underwent left lower lobectomy and right middle and lower lobe wedge resections, and the other patient required a left lung pneumonectomy. Four of the six cases of recurrence involved a diffuse pattern of recurrent disease. Two of these four patients died of pulmonary failure, a third underwent retransplantation and died shortly after, and the fourth was still alive at 39 months post-transplant with recurrent disease. Despite the very high rate of recurrence in this small cohort, the 5-year survival rate was 52%, a rate similar to the total 5-year survival rate at the authors' transplant center. However, based on the high recurrence rate of 75% in the original cohort, the authors decided to terminate the study.

The origin of recurrent BAC tumors in the lung allograft has been a topic for debate. Most reports of multifocal BAC support a monoclonal origin of tumor followed by spread via intra-alveolar, lymphatic, or aerosolization routes [101,106,107]. In the cohort of patients reported by the University of Alabama group, analysis of the recurrent tumors in the allografts of three of the patients revealed similar radiographic and histologic characteristics when compared with the original tumors. Subsequent PCR amplification of microsatellite DNA showed similar fragments in the recurrent tumor compared with the original tumor in all three patients [103,104]. These findings support the hypothesis that recurrent BAC after transplantation originates from recipient neoplastic cells. This hypothesis was further supported in a published case report of a transplant recipient with BAC, in which the authors reported the results of molecular fingerprinting on DNA extracted from original and recurrent tumors [101]. Analysis of 15 highly polymorphic loci revealed that the neoplastic cells were similar in the primary and recurrent tumors.

Lymphatic spread has been the mechanism most commonly proposed for the recurrence of BAC following lung transplantation. However, because most of the cases of recurrent BAC following

lung transplantation have not demonstrated evidence of lymph node metastases, either at the time of transplant or at the time of resection of recurrent tumors, this explanation does not seem plausible. It is therefore possible that contamination of the allograft may occur as a result of aerosolization of neoplastic cells from the native lungs. In light of this possibility it has been proposed that meticulous surgical technique and airway irrigation have a vital role in preventing recurrence of BAC following transplantation [101,102]. Despite these advances in the understanding of BAC and peri/post-transplant surgical management of patients with BAC, lung transplantation remains a controversial therapeutic modality for this indication.

Pulmonary alveolar proteinosis

Pulmonary alveolar proteinosis (PAP) is an uncommon lung disease characterized by the accumulation of surfactant protein in the alveolar spaces. The pathogenesis of PAP remains poorly understood, although significant advances in potential therapies have occurred during the past decade. PAP likely involves a combination of abnormal production of surfactant by type II pneumocytes, and impaired clearance of surfactant by alveolar macrophages [108–112]. PAP generally occurs as one of three different types of disorders:

1 A congenital group of diseases resulting from mutations in the genes expressing surfactant proteins and/or granulocyte–macrophage colony-stimulating factor (GM-CSF);
2 In association with certain chemical or mineral dust exposures, or in the setting of certain hematological malignancies and immunodeficiency disorders; or
3 Idiopathic, or primary PAP, with no obvious etiology.

This latter idiopathic form is the most common presentation, accounting for almost 90% of all cases of PAP [111,113]. Whole-lung lavage is generally the only effective therapeutic modality, indicated primarily for the treatment of the idiopathic form of PAP [114–116]. GM-CSF is believed to have a significant role in the pathogenesis of PAP, and autoantibodies to GM-CSF have been discovered in most adult patients with the idiopathic form. These findings have led to the use of exogenous GM-CSF as a therapeutic approach to PAP, but the reported efficacy of this approach has been variable [116–120].

Lung transplantation rarely has been performed for progressive lung failure secondary to PAP [121–125]. Recurrence of PAP in the allograft following lung transplantation has been described [122,123]. Parker et al. [123] reported a case of recurrent PAP in a 44-year-old woman 3 years following bilateral lung transplantation for PAP. At that time she presented with fatigue and dyspnea, and chest radiograph revealed new infiltrates. Histologic analysis of transbronchial biopsies revealed alveolar air spaces filled with eosinophilic dense flocculent material, along with the presence of scattered foamy macrophages and cholesterol clefts. Electron microscopy confirmed the presence of surfactant accumulation.

Santamaria et al. [122] subsequently described fatal recurrent PAP in a child who had undergone heart–lung transplantation for PAP secondary to lysinuric protein intolerance (LPI). The patient was a 3-year-old boy who had previously been diagnosed with LPI, a rare genetic disorder caused by the defective plasma membrane transport of cationic amino acids. Pulmonary manifestations, primarily characterized by severe PAP, began more than 1 year prior to transplant. Attempts at therapy with whole lung lavage and GM-CSF were unsuccessful, and the child eventually underwent successful heart–lung transplantation. Eighteen months after transplantation, he developed severe dyspnea and hypoxemia, presumed to be secondary to a severe viral pneumonia. However, subsequent transbronchial biopsy revealed the presence of PAP in the allograft, with no evidence of infection or rejection. Neither therapy with whole-lung lavage nor GM-CSF therapy led to any improvement, and the child eventually died 26 months after transplantation.

The pathogenesis of recurrent PAP following lung transplantation is poorly understood. The presence of circulating antibodies directed against GM-CSF has been proposed as a potential mechanism in the development of PAP, and could be an explanation for recurrence in the allograft. A second hypothesis is that PAP results from a defect in bone marrow-derived monocytes, such as a dysfunctional GM-CSF receptor. In this scenario, lung transplantation may not be beneficial because immature alveolar macrophages, unable to clear surfactant effectively, would continue to be ineffective following transplantation [122,126–128].

Previous published reports describing the development of de novo PAP in lung transplant recipients have provided some insight into the mechanism behind recurrence of native PAP [129,130]. Yousem et al. [129] described three patients who developed PAP following lung or heart–lung transplant, despite lacking evidence of PAP prior to transplant. The authors hypothesized that repeated allograft injury resulting from primary graft injury, rejection, and infections, in addition to the use of chronic corticosteroid therapy, may have resulted in excessive surfactant production in the alveolar spaces. Gal et al. [130] identified a patient who developed de novo PAP 66 days after undergoing single lung transplantation for pulmonary fibrosis. The diagnosis of PAP was based on the persistent finding of amorphous, acellular, finely granular material in bronchoalveolar lavage (BAL) fluid. The patient died 35 months later from progressive BOS and cytomegalovirus pneumonitis. Autopsy examination of both lungs confirmed the presence of PAP in the native lung, but not the allograft. The authors suggested that immunosuppressive medications might have impaired alveolar macrophage function, and ability to clear surfactant. They also concluded that careful examination of BAL fluid might be the most sensitive method in diagnosing PAP following lung transplantation.

Emphysema secondary to alpha-1 antitrypsin deficiency

Alpha-1 antitrypsin deficiency (ATD) is a genetic disorder that effects almost 3.4 million individuals worldwide, and may account for up to 2% of all cases of COPD in the United States [131,132]. The most frequently affected organs are the liver and lung. Liver disease, which often progresses to cirrhosis, occurs most likely as a result of the accumulation of an altered form of alpha-1 antitrypsin protein [133]. Lung disease, primarily in the form of panlobular emphysema beginning in the fourth or fifth decade, is a result of a reduction in circulating alpha-1 antitrypsin protein. Emphysema likely results from a protease–antiprotease imbalance, leading to unopposed proteolytic enzyme activity. An increase in inflammatory conditions also seems to be an important co-factor, and cigarette smoking probably plays the most important part in the ultimate development of lung disease [134,135]. Treatment of alpha-1 ATD has focused primarily on alpha-1 antitrypsin replacement therapy, in the form of intravenous human plasma-derived therapy, inhalation therapy, recombinant therapy, or synthetic elastase inhibition [136–139].

Lung transplantation has been a successful treatment modality for patients with advanced emphysema secondary to alpha-1 ATD. Almost 2000 lung transplant procedures (728 single, 1225 double) have been performed for patients with alpha-1 ATD since 1995, representing approximately 6.5% of all transplants [14]. Patients undergoing lung transplantation for alpha-1 ATD have a post-transplant survival half-life of 6.3 years, second only to patients with cystic fibrosis (7.4 years) [14].

Indeed, lung transplantation addresses the emphysematous damage to the native lungs. However, it does not treat the etiology of the lung disease, the systemic deficiency in alpha-1 antitrypsin. It would therefore seem likely that recurrent emphysema following lung transplantation would be quite common. However, there were no published reports of recurrent emphysema secondary to alpha-1 ATD until 2002, when Glanville et al. [140] reported two patients with postmortem histologic findings of alpha-1 ATD in the lung allografts. Neither of these patients was suspected of having recurrent disease prior to the autopsy findings.

Mal et al. [141] subsequently published a report of recurrent emphysema in the allograft of a patient with alpha-1 ATD 10 years following single lung transplantation. At that time a chest CT revealed findings of emphysema in the allograft, and during the next 2 years the patient had a progressive deterioration in lung function. Interestingly, the patient had experienced a number of episodes of acute rejection in the first 18 months post-transplant, and had resumed smoking cigarettes approximately 3 years prior to the CT findings of emphysema. The authors hypothesized that the initial inflammation associated with repeated acute rejection, coupled with the resumption of smoking, may have triggered the recurrence of the emphysema. In addition, a high level of elastase activity was found in the BAL fluid and serum of the patient. Prior studies have demonstrated that high levels of unopposed elastase activity are present in BAL fluid obtained from lung transplant recipients during periods of significant inflammation associated with allograft rejection or infection [142,143].

In light of the potential role for increased unopposed elastase activity in lung transplant recipients with alpha-1 ATD, it has been proposed that supplementation of alpha-1 antitrypsin following lung transplantation may be beneficial [142–145]. As suggested by Mal et al. [141], replacement therapy with alpha-1 antitrypsin may be particularly helpful in patients with BOS. BOS is associated with an increased concentration of neutrophils in the airways and parenchyma, potentially resulting in a significant increase in elastase-mediated injury. Many lung transplant programs have adopted a practice of intravenous replacement of alpha-1 antitrypsin for patients with signs of BOS. Some centers even initiate alpha-1 antitrypsin replacement therapy for all alpha-1 ATD patients shortly after transplant surgery, although at present there is little conclusive evidence to support this practice.

Other lung diseases recurring after transplant

There have been a number of published case reports describing recurrence of native lung disease in the pulmonary allograft, in most cases involving very uncommon indications for lung transplant.

Desquamative interstitial pneumonia

Desquamative interstitial pneumonia (DIP) is a rare interstitial pneumonia characterized by the accumulation of large numbers of macrophages in the alveolar spaces, likely in response to injury to the alveolar epithelium. DIP has a strong association with cigarette smoking, but other types of drugs and inhaled agents have also been linked to the development of disease. Although most patients with DIP improve with immunosuppressive treatment, a small number develop irreversible pulmonary fibrosis and require lung transplantation [146,147].

Recurrence of DIP in the allograft following lung transplantation has been reported [148,149]. King et al. [148] described a 50-year-old woman with DIP who underwent a left single lung transplant. One month following transplant the patient developed progressive cough and dyspnea in the absence of radiographic findings, and a thoracoscopic lung biopsy demonstrated evidence of DIP. Despite repeated therapy with high dose corticosteroids, her condition continued to deteriorate, and she eventually died of respiratory failure. Autopsy findings confirmed the presence of diffuse DIP in the allograft. Verleden et al. [149,150] subsequently published a second case of recurrent DIP following lung transplantation. In this case, however, DIP did not recur in the allograft until 1 year post-transplant, confirmed by the characteristic histologic findings noted on transbronchial biopsy. In contrast to the refractory course (ultimately leading to death) reported by King et al. [148], the patient in this report completely recovered following a prolonged course of increased corticosteroids.

Giant cell interstitial pneumonia

Giant cell interstitial pneumonia (GIP) is a rare form of interstitial pneumonia associated with exposure to certain hard metals, characterized by the alveolar accumulation of mineral particles and enlarged multinucleated macrophages [151,152]. Frost et al. [153] reported a case of recurrence of GIP in the allograft of a patient who had undergone single-lung transplantation for GIP secondary to cobalt exposure. The interesting observation in this case was that the patient did not have any further exposure to cobalt following lung transplantation to explain the recurrence of disease. Furthermore, eventual autopsy analysis of the allograft revealed characteristic findings of GIP, but no evidence of inorganic particles. The authors hypothesized an autoimmune etiology for the recurrent disease. It is conceivable that inorganic particles in the existing native lung or from an extrapulmonary source may have served as a stimulus for the autoimmune response.

Diffuse panbronchiolitis

Diffuse panbronchiolitis is an uncommon complex genetic lung disease almost exclusively affecting East Asians, with a strong association with Class I HLA-B54 and HLA-A11. It is characterized by chronic inflammation in respiratory bronchioles, and chronic bacterial infections in the airways and sinuses. Pulmonary function testing reveals a pattern of airway obstruction and hyperinflation. Histologic analysis of lung tissue reveals lymphocytes and foamy macrophages around respiratory bronchioles. The use of macrolide therapy has dramatically improved the prognosis of patients with diffuse panbronchiolitis, although the mechanism of action is poorly understood. Some patients do not respond to therapy and progress to lung failure, rarely necessitating consideration for lung transplantation [154].

Only one case of recurrence of diffuse panbronchiolitis has been reported following lung transplantation. Baz et al. [155] described a patient who developed recurrence of diffuse panbronchiolitis 10 weeks after bilateral lung transplantation, resulting in a very rapid deterioration in allograft function. Therapy with erythromycin was

initiated, and allograft function significantly improved within a few weeks. Although this was an isolated single report of a rare indication for lung transplantation, the findings may support the use of macrolide therapy in patients following lung transplantation for diffuse panbronchiolitis.

Pulmonary capillary hemangiomatosis

Pulmonary capillary hemangiomatosis (PCH) is a rare etiology of pulmonary hypertension characterized by uncontrolled capillary proliferation in the pulmonary interstitium and vascular and alveolar walls. HRCT findings include centrilobular nodular opacities, septal lines, pleural effusions, and lymphadenopathy, although similar findings occur with pulmonary veno-occlusive disease. PCH is a rapidly progressive disease, and lung transplantation remains the only treatment [156–159].

Few published data exist concerning lung transplantation for PCH, but recurrence of disease has been described. The first report of PCH following lung transplantation occurred in a patient 3 months after undergoing bilateral lung transplantation for another indication (emphysema) [160]. The authors hypothesized that the de novo occurrence of PCH resulted from uncontrolled angiogenesis as a result of an infectious or inflammatory trigger.

Lee et al. [161] subsequently reported the only published case of recurrence of native PCH following lung transplantation. The authors described a patient who developed clinical and histologic findings consistent with recurrent PCH 6 months following bilateral lung transplantation for an original diagnosis of PCH. Interestingly, her early postoperative course had been complicated by recurrent acute cellular rejection, bronchiolitis obliterans, and organizing pneumonia. The patient died 8 months after transplant, and autopsy analysis revealed extensive bilateral findings consistent with PCH with associated veno-occlusive disease. The authors postulated that the recurrence of PCH resulted from recurrent early allograft injury, leading to the recruitment to the lung of circulating endothelial cells with a genetic predisposition to abnormal proliferation.

Williams–Campbell syndrome

Williams–Campbell syndrome is a very rare disorder affecting children, characterized by a deficiency of cartilage in the subsegmental bronchi resulting in airway collapse and bronchiectasis. The clinical course is quite variable; some children rapidly progress to respiratory failure, and others survive into adulthood suffering from recurrent infections and airway obstruction [162,163]. Although there is no known treatment, there has been only one report in the literature involving lung transplantation for this disorder. Palmer et al. [164] described a 28-year-old male who underwent bilateral lung transplantation for respiratory failure secondary to Williams–Campbell syndrome. Although the patient initially did well, his post-transplant course was complicated by severe proximal bronchomalacia of the mainstem bronchi, leading to recurrent infections and death 1 year following transplantation. The authors postulated that although the cartilage deficiency in this syndrome typically involves distal airways, there may have been a more subtle decrease in cartilage in the proximal airways, leaving them susceptible to the effects of post-transplant airway ischemia. Impaired bronchial perfusion post-transplant has been linked to the development of bronchomalacia associated with obliterative bronchiolitis [165]. Based on the airway complications encountered in this case, the authors recommended that bilateral lung transplantation not be considered for this indication, but suggested that perhaps *en bloc* bilateral lung transplantation may be a viable option.

Conclusions

Recurrence of native lung disease has been reported for several types of native lung disease following lung transplantation (Box 80.1). Sarcoidosis is the most common etiology for recurrent disease following transplantation, with a rate of recurrence as high as 80%. However, most of the cases of recurrence are limited to incidental biopsy findings, with little obvious impact on graft function. This mild nature of recurrent disease compared with the primary native disease may in large part be related to the use of post-transplant immunosuppressive agents. BAC commonly recurs following lung transplantation, with a reported recurrence rate as high as 75%. Despite the significant amount of morbidity and surgical intervention resulting from recurrence, post-transplant survival outcomes for patients with BAC are comparable to other indications. LAM and PLCH may also commonly recur following transplant, and, as a result of the obstructive physiology associated with these diseases, may often be misdiagnosed as BOS. Alveolar proteinosis and DIP are very rare indications for transplant, but may have a high incidence and potential for recurrence. Recurrence of emphysema from alpha-1 antitrypsin deficiency may be underappreciated, but may become more prevalent as recipients survive for longer post-transplant periods.

The potential for recurrence of native lung disease highlights the importance and utility of post-transplant allograft surveillance. Routine chest radiography and HRCT may identify specific findings consistent with recurrent disease, particularly in the cases of BAC, PLCH, and LAM. Radiographic patterns of recurrent disease most often mimic those of the native pretransplant findings. Pulmonary function testing may detect an obstructive defect characteristic of diseases such as sarcoidosis, LAM, PLCH, and emphysema, although these diagnoses may be difficult to distinguish from allograft rejection or infection based on pulmonary function testing alone. Transbronchial or surgical biopsies remain the gold standard for confirmation of recurrent disease, highlighting another benefit for the practice of post-transplant surveillance lung biopsies.

The pathogenesis of most types of native lung disease recurrence following transplantation remains poorly understood. In cases of sarcoidosis and LAM, in situ hybridization and immunohistochemical studies have demonstrated that recurrent disease likely results from infiltration of recipient immune cells into the allograft. The association between extrapulmonary involvement of LCH and recurrence of PLCH following transplant also supports a possible mechanism of metastases and infiltration of recipient immune cells (Langerhans cells). Recurrent BAC possibly results from aerosolization of neoplastic cells from the native lungs, perhaps at the time of transplant. In the cases of recurrent PAP, DIP, and GIP, few published data exist regarding the mechanism of recurrence, although it has been proposed for both diseases that abnormal recipient immune cells (monocytes/macrophages) may have a significant role. A similar mechanism may occur in the recurrence of PCH involving recruitment of recipient circulating aberrant endothelial cells. Recurrent emphysema from alpha-1 antitrypsin deficiency likely results from a lack of the protective effect of a deficient proteinase in the face of ongoing inflammation in the allograft (i.e. secondary to BOS).

The recognition that native lung diseases may recur following transplant affords the opportunity for using prophylactic and/or

early treatment interventions. mTOR inhibitor drugs may be effective at preventing or treating recurrence of LAM following transplant. Augmentation of immunosuppression or systemic chemotherapy may be effective in treating recurrent PLCH and sarcoidosis. Replacement therapy with alpha-1 antitrypsin may help to prevent the onset or progression of recurrent emphysema. The incidence and impact of smoking recidivism following lung transplantation has not been as well-studied as alcohol recidivism following liver transplantation. However, abstinence from, or cessation of, cigarette smoking may play a significant part in preventing recurrence of PLCH, DIP, and alpha-1 antitrypsin deficiency-related emphysema. Precise transplant surgical technique and careful irrigation of native airways may help prevent aerosolization and contamination of the allograft with neoplastic cells.

Given the potential for recurrence of certain native lung diseases following lung transplantation, one may question whether transplant should be considered as a therapeutic option for these indications. Although in some of these diseases the rates of recurrence may be quite high, with a few exceptions, the incidence of significant graft dysfunction and morbidity secondary to recurrence is relatively low. BAC represents the most important exception, as recurrence is quite common and necessitates radical, often recurrent, surgical intervention. In light of this likelihood, BAC remains a controversial indication for lung transplant. It is important to again point out, however, that despite the morbidity associated with recurrence of BAC, post-transplant survival rates have been comparatively good.

In conclusion, native lung disease may recur following lung transplantation, with variable impact on allograft function. Recurrence of lung disease has been most often described for less common indications for lung transplantation. In most cases, the possibility of recurrence should not preclude transplant as a therapeutic modality. However, the transplant recipient and transplant physician or surgeon should be aware of the potential for, and clinical signs of, recurrent disease. Specific prophylactic behavioral and medical therapies and early treatment interventions should be implemented in the appropriate clinical settings.

CHAPTER 81

Histopathological Syndromes of Kidney Allograft Rejection and Recurrent Disease

Alton Brad Farris, III[1] and Michael H. Mengel[2]

[1] Department of Pathology and Laboratory Medicine, Emory University, Atlanta, GA, USA

[2] Department of Laboratory Medicine and Pathology, University of Alberta, Edmonton, AB, Canada

Introduction

Renal transplantation has been conducted with increasing success for nearly five decades [1]. Since the first successful renal transplant in 1954 [2], immunosuppression has become progressively more effective in preventing and treating acute rejection episodes, particularly those occurring less than 1 year post-transplantation. However, challenges still exist in treating late cellular and antibody-mediated rejection (AMR), as well as in preventing chronic rejection and recurrent disease [1].

Renal biopsies offer a useful diagnostic aid for clinicians, often leading to changes in the treatment plan in up to approximately 40% of patients. Renal biopsies lead to a decrease in immunosuppression levels in around 20% of patients [3–5]. Most renal allograft biopsies involve the analysis of routine light microscopic findings; however, ancillary techniques (i.e. fluorescence and electron microscopy (EM)) are crucial to renal allograft biopsy analysis, and new tools such as molecular assessments are rapidly emerging. Renal biopsies are important at all time points in the life of an allograft: before transplantation, when pretransplant donor biopsies are employed in triaging available organs; early after transplantation, when allograft rejection is important; and late after transplantation, when considerations include chronic rejection, recurrent and/or de novo disease, and infection [3]. This chapter provides the reader with an understanding of the major types of graft rejection, other relevant disorders in renal allografts, and the types of de novo and recurrent disease that can occur.

Graft rejection

Before the establishment of the Banff classification in 1991 by Dr. Kim Solez and others, no unified diagnostic criteria for diagnosing rejection were available; diagnoses were rendered based on local experience and individual pathologists' judgment [6–12]. Since the early 1990s [9], consensus criteria have been developed and constantly refined by panels of experts, initially for renal allograft pathology and then for the pathology of other allograft organs [9]. Renal allograft rejection can typically be attributed to either cellular- or antibody-mediated (humoral) rejection mechanisms, or a combination of the two [5,13].

Acute rejection refers to a relatively rapid deterioration of renal function due to immunologic injury on the allograft, typically within days. Although the term "acute" is used, an episode of acute rejection can occur from hours to years after transplantation, but typically evolves over a shorter period of time [14]. In contrast, chronic rejection refers to a slow deterioration of renal function through smoldering injury to the renal allograft, typically evolving and occurring over the space of months to years [14]. Furthermore, the term "chronic" is used when respective morphologic changes of structural remodeling in the allograft are seen (e.g. intimal arterial fibrosis or glomerular basement double contours). While these processes differ in regard to their typical clinical characteristics, their diagnosis relies on examination of an allograft biopsy.

As defined in the Banff 1997 criteria, an "adequate" biopsy is one with at least 10 glomeruli and two arteries, and a "minimal" sample is one with seven glomeruli and one artery. At least two cores are recommended. Alternatively, it is suggested that at least two separate areas of cortex be on the same core. For evaluation of renal allograft biopsies, it is best if there are seven slides containing multiple sequential 3–4 μm sections stained with the following stains: three with hematoxylin and eosin, three with periodic acid–Schiff (PAS) or silver stains, and one with a trichrome stain [7,15]. Furthermore, since C4d staining is currently part of the Banff classification, C4d is typically performed using fluorescence or immunohistochemistry [8]. Biopsies are scored according to histologic criteria, with pathologic lesions scored semi-quantitatively in all morphologic compartments of the kidney, and, following the thresholds of certain criteria, cases are fitted into consensus Banff diagnoses (Tables 81.1 and 81.2). It should be noted that variation in histologic grading can be substantial, showing limitations in interobserver agreement and providing opportunities for future refinements and technical improvements in the process [16]. As the effector mechanisms involved in rejection are active in other immune-mediated renal diseases, some clinical correlation of the histologic findings may at times be required.

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

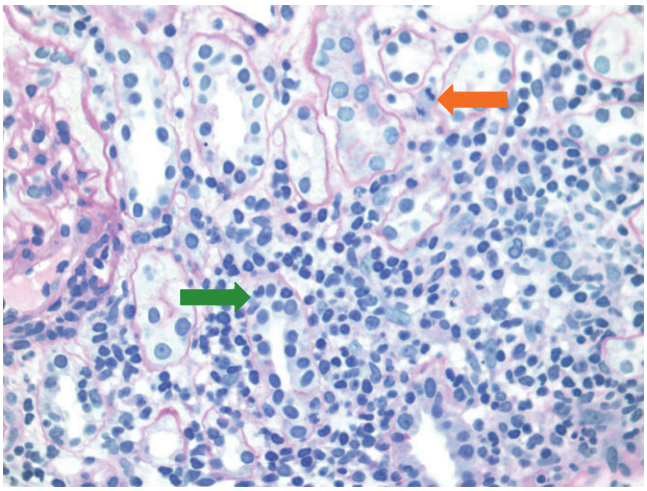

Figure 81.1. Interstitial inflammation and tubulitis. Interstitial inflammation with an "activated" infiltrate displays conspicuous mitotic activity (orange arrow) and tubulitis (green arrow) in acute cellular rejection, type 1.

Cell-mediated rejection

Cell-mediated rejection (CMR), under most circumstances, is conducted by effector T cells originating from the lymphoid organs and infiltrating the allograft, leading to an inflammatory response (covered in detail in Chapter 5). Thus, the term "cell-mediated rejection" typically refers to T-cell-mediated rejection (TCMR). The T cells are thought to be reactive against donor alloantigen [14,17]. The interstitium is permeated by this cellular infiltrate, eventually leading to tubulitis lesions (i.e., the infiltration of T cells between tubular epithelial cells), an early hallmark of many rejection episodes (Figure 81.1) [5,18]. Most of the cells in the interstitium are composed of $CD4^+$ and $CD8^+$ T cells and $CD68^+$ monocyte–macrophages. Eosinophils may also be present, possibly indicative of a worse outcome [13,19]. Tubules may also display increased HLA-DR expression [20]. However, although tubulitis is frequently considered fairly specific for TCMR, recent data suggest that tubulitis is the consequence rather than the cause of epithelial injury [21]. Furthermore, tubulitis can be observed in other disease of renal allograft and also in native kidneys.

Acute tubulointerstitial rejection consists of interstitial edema with a mononuclear infiltrate accompanied by tubulitis lesions. For a diagnosis fulfilling the criteria for tubulointerstitial acute CMR under Banff criteria (Table 81.1), the interstitial infiltrate and tubulitis are given an "i" and "t" score respectively (as shown in Table 81.2). Acute CMR, type IA, consists of renal allografts displaying tubulitis reaching a threshold of "moderate" severity (t2, or 5–10 inflammatory cells/tubular cross-section) when accompanied by a "significant" inflammatory infiltrate (i2 or i3, >25% of the non-scarred cortical parenchyma affected). If the severity of tubulointerstitial rejection process is greater, consisting of more intense tubulitis (t3), then a designation of acute CMR, type IB, can be made, which has been shown to be associated with a worse prognosis. Such more severe tubulointerstitial acute CMR is primarily characterized by multifocal rupture–destruction of tubular basement membranes, putatively indicating irreversible destruction of nephrons [8,22].

In the category of tubulointerstitial rejection, a "gray zone" exists in which either only tubulitis (t1, 2, or 3) is present without a substantial interstitial infiltrate (having only i0 or i1) or an interstitial infiltrate is accompanied by only mild tubulitis (t1). Such cases are termed "borderline" or "suspicious" for acute CMR [8]. The interpretation of such lesions is controversial and often depends on the center or the study protocol. Some centers interpret these borderline cases as rejection while others do not [5]. A recent study using gene expression analysis with borderline cases revealed that one third of these cases present with a molecular phenotype identical to "true" TCMR cases, while two thirds were similar to cases showing no evidence of rejection [23]. Past studies have indicated that conservative therapy may be appropriate in some of these cases [24]. Therefore, ultimately it is hoped that further research and guidelines will clarify the significance of the borderline category and ultimately contribute to the elimination of this ambiguous gray zone [23].

Plasma cell-rich forms of rejection may be present, displaying marked numbers of interstitial plasma cells. In addition, some cases may have prominent edema. In the past these forms of rejection have often been associated with a more aggressive course and may portend a worse prognosis. However, most of these cases were described prior to robust antibody testing and screening for polyomavirus, and thus may actually represent other underlying entities like AMR and polyomavirus nephritis (PVAN). In some of these cases C4d deposition in peritubular capillaries (PTCs) may be detected; however, the AMR component in many of these cases may be attenuated, late in their course, and co-exist with the cellular component. Also, PVAN frequently presents a plasma cell-rich interstitial infiltrate, edema, and tubulitis and thus represents a challenging differential diagnosis. When present, plasma cell-rich infiltrates must also be distinguished from post-transplant lymphoproliferative disorder (PTLD) by staining for kappa and lambda light chains and, with this testing, for potential clonality of the plasma cells [25–27].

In addition, vessels may be infiltrated by inflammatory cells, leading to undermining of the endothelium, a process variably referred to as endothelialitis, vascular rejection or, more accurately, endarteritis (Figure 81.2) [5]. If mild to moderate endarteritis is present (designated v1), a rejection episode is designated acute CMR, type IIA under Banff criteria. If severe (v2) arteritis is present, a designation of acute CMR, type IIB can be rendered [8]. These cases have been shown to be associated with a worse prognosis than Banff type IIA cases [28]. Cases with transmural arteritis and/or arterial fibrinoid change (considered v3) are given a designation of acute CMR, type III; however, it is generally recognized that such lesions may often have an antibody-mediated component [5,8]. It is important to note that the term "vascular rejection" is also frequently used in the context of pure AMR particularly in the xenograft literature. Studies have indicated a worse prognosis for cases with endarteritis, but it must be noted that most of these studies were carried out prior to sensitive antibody testing [29].

Data presented at the 2011 Banff meeting indicated that cases with "isolated v-lesions" (i.e. endarteritis in the absence of significant tubulointerstitial inflammation or capillaritis) might actually represent a heterogeneous group of disease processes. Results from a retrospective multicenter case cohort study were presented. After the exclusion of AMR cases, two additional types of isolated v-lesion cases were identified: those associated with TCMR and those with delayed graft function. Thus, a more differentiated diagnostic and tailored therapeutic approach toward cases with endarteritis seems warranted [30].

Table 81.1. Banff classification for renal allograft pathology: diagnostic categories summarized with updates

Category	Features
1	**Normal**
2	**Ab-mediated changes (± Cat. 3, 4, 5, 6)**
	Acute/active ABMR; all three features must be present for diagnosis[a,b]
	1 Histologic evidence of acute tissue injury, including one or more of the following:
	• Microvascular inflammation (g > 0[c] and/or ptc > 0)
	• Intimal or transmural arteritis (v > 0)[d]
	• Acute thrombotic microangiopathy, in the absence of any other cause
	• Acute tubular injury, in the absence of any other apparent cause
	2 Evidence of current–recent antibody interaction with vascular endothelium, including at least one of the following:
	• Linear C4d staining in peritubular capillaries (C4d2 or C4d3 by IF on frozen sections, or C4d > 0 by IHC on paraffin sections)*
	• At least moderate microvascular inflammation ([g + ptc] > 2)[e]
	• Increased expression of gene transcripts in the biopsy tissue indicative of endothelial injury, if thoroughly validated[f]
	3 Serologic evidence of donor-specific antibodies (HLA or other antigens)
	Chronic, active ABMR; all three features must be present for diagnosis[a,g]
	1 Morphologic evidence of chronic tissue injury, including one or more of the following:
	• Transplant glomerulopathy (cg > 0)[h], if no evidence of chronic TMA
	• Severe peritubular capillary basement membrane multilayering (requires EM)[i]
	• Arterial intimal fibrosis of new onset, excluding other causes[j]
	2 Evidence of current–recent antibody interaction with vascular endothelium, including at least one of the following:
	• Linear C4d staining in peritubular capillaries (C4d2 or C4d3 by IF on frozen sections, or C4d > 0 by IHC on paraffin sections)*
	• At least moderate microvascular inflammation ([g + ptc] > 2)[e]
	• Increased expression of gene transcripts in the biopsy tissue indicative of endothelial injury, if thoroughly validated[f]
	3 Serologic evidence of donor-specific antibodies (HLA or other antigens)
	C4d staining without evidence of rejection; all three features must be present for diagnosis[j]
	1 Linear C4d staining in peritubular capillaries (C4d2 or C4d3 by IF on frozen sections, or C4d > 0 by IHC on paraffin sections)*
	2 g = 0, ptc = 0, cg = 0 (by LM and by EM if available), v = 0; no TMA, no peritubular capillary basement membrane multilayering, no acute tubular injury (in the absence of another apparent cause for this)
	3 No acute cell-mediated rejection (Banff 97 type 1A or greater) or borderline changes
3	**Borderline changes: "suspicious" for acute T-cell-mediated rejection (± Cat. 2, 5, 6)**
	No arteritis but present are tubulitis (t1, t2, or t3) with minor interstitial infiltration (i0 or i1) or interstitial infiltration (i2, i3) with mild tubulitis (t1)
4	**T-cell-mediated rejection (± Cat. 2, 5, 6)**
	• Acute TCMR
	IA. Significant interstitial infiltration (>25% of parenchyma affected, i2 or i3) and foci of moderate tubulitis (t2)
	IB. Significant interstitial infiltration (>25% of parenchyma affected, i2 or i3) and foci of severe tubulitis (t3)
	IIA. Mild to moderate intimal arteritis (v1)
	IIB. Severe intimal arteritis comprising >25% of the luminal area (v2)
	III. "Transmural" arteritis and/or arterial fibrinoid change and necrosis of medial smooth muscle with accompanying lymphocytic inflammation
	• Chronic active T-cell-mediated rejection
	"Chronic allograft arteriopathy" (arterial intimal fibrosis with mononuclear infiltration of fibrosis, formation of neointima)
5	**Interstitial fibrosis and tubular atrophy (IFTA), no evidence of specific etiology**
	(Graded according to IFTA; may also have non-specific vascular and glomerular sclerosis)
	I. Mild IFTA (<25% of cortical area)
	II. Moderate IFTA (25–50% of cortical area)
	III. Severe IFTA/loss (>25% of cortical area)
6	**Other**
	Changes not due to rejection – acute or chronic – ay include cg or cv lesions, ± Cat. 2, 3, 4, 5

Source: Sis et al. 2010 [8] and Haas et al. 2014 [36]. Adapted with permission from John Wiley and Sons.

Ab, antibody; ABMR, antibody-mediated rejection; C4d+, C4d deposition in peritubular capillary endothelium according to Table 81.2; Cat., category; EM, electron microscopy; cg, Banff chronic transplant glomerulopathy score; g, Banff glomerulitis score; i, Banff interstitial inflammation score; IFTA, interstitial fibrosis and tubular atrophy; ptc, Banff peritubular capillaritis score; TCMR, T-cell-mediated rejection, ± may coincide with; v, Banff arteritis score.

*In lieu of C4d deposition, ABMR can be diagnosed if either at least moderate microvascular inflammation is present ([g+ptc] ≥ 2]) or if there is a valid gene transcript measurement of increased endothelial injury.

[a]For all ABMR diagnoses, it should be specified whether the lesion is C4d-positive (C4d2 or C4d3 by IF on frozen sections; C4d > 0 by IHC on paraffin sections) or without evident C4d deposition (C4d0 or C4d1 by IF on frozen sections; C4d0 by IHC on paraffin sections.

[b]These lesions may be clinically acute, smoldering, or subclinical. Biopsies showing two of the three features, except those with donor-specific antibodies and C4d without histologic abnormalities potentially related to ABMR or TCMR (C4d staining without evidence of rejection; see footnote k, below) may be designated as "suspicious" for acute/active ABMR.

[c]Recurrent/de novo glomerulonephritis should be excluded.

[d]Arterial lesions may be indicative of ABMR, TCMR, or mixed ABMR/TCMR. "v" lesions are only scored in arteries having a continuous media with two or more smooth muscle layers.

[e]In the presence acute T-cell-mediated rejection, borderline infiltrates, or evidence of infection, ptc ≥2 alone is not sufficient to define moderate microvascular inflammation and g must be ≥1.

[f]At present the only validated molecular marker meeting this criterion is ENDAT expression, and this has only been validated in a single center (University of Alberta). The use of ENDAT expression at other centers or other test(s) of gene expression within the biopsy as evidence of ABMR must first undergo independent validation as was done for ENDAT expression by Sis et al. [8].

[g]Lesions of chronic, active ABMR can range from primarily active lesions with early transplant glomerulopathy (TG) evident only by electron microscopy (cg 1a) to those with advanced TG and other chronic changes in addition to active microvascular inflammation. In the absence of evidence of current/recent antibody interaction with the endothelium (those features in section 2), the term active should be omitted; in such cases donor-specific antibodies may be present at the time of biopsy or at any previous time post-transplantation.

[h]Includes glomerular basement membrane (GBM) duplication by electron microscopy only (cg1a) or GBM double contours by light microscopy.

[i]≥Seven layers in one cortical peritubular capillary and ≥5 in two additional capillaries, avoiding portions cut tangentially.

[j]While leukocytes within the fibrotic intima favor chronic rejection, these are seen with chronic TCMR as well as chronic ABMR, and are therefore helpful only if there is no history of TCMR. An elastic stain may be helpful as absence of elastic lamellae is more typical of chronic rejection and multiple elastic lamellae are most typical of arteriosclerosis, although these findings are not definitive.

[k]The clinical significance of these findings may be quite different in grafts exposed to anti-blood-group antibodies (ABO-incompatible allografts), where they do not appear to be injurious to the graft and may represent accommodation, and anti-HLA antibodies where more clinical outcome data are needed.

Table 81.2. Banff scores based on quantitative criteria (data from [7] and [36])

Lesions	Abbreviation	Banff score			
		0	**1**	**2**	**3**
Interstitial inflammation[a]	**i**	Interstitial mononuclear inflammatory cells in <10% of non-scarred cortex	Interstitial mononuclear inflammatory cells in 10–25% of non-scarred cortex	Interstitial mononuclear inflammatory cells in 26–50% of non-scarred cortex	Interstitial mononuclear inflammatory cells in >50% of non-scarred cortex
Tubulitis[b]	**t**	No tubulitis	1–4 mononuclear inflammatory cells/tubular cross-section	5–10 mononuclear inflammatory cells/tubular cross-section	>10 mononuclear inflammatory cells/tubular cross-section or two areas of tubular basement membrane destruction accompanied by i2/i3 inflammation and t2 tubulitis elsewhere in biopsy
Intimal arteritis[c]	**v**	No arteritis	Subendothelial mononuclear inflammatory cells involving <25% of luminal area	Subendothelial mononuclear cells involving >25% of luminal area, no necrosis	Transmural inflammation and/or arterial fibrinoid necrosis with mononuclear cells
Glomerulitis[d]	**g**	No glomerulitis	Mononuclear cells in <25% of glomeruli	Mononuclear cells in 26–75% of glomeruli	Mononuclear cells in >75% of glomeruli
Peritubular capillaritis[e]	**ptc**	Absent or <10% of cortical PTCs with inflammatory cells	3–4 luminal inflammatory cells in ≥10% of cortical PTCs	5–10 luminal inflammatory cells in ≥10% of cortical PTCs	>10 luminal inflammatory cells in ≥10% of cortical PTCs
Transplant glomerulopathy[f]	**cg**	Double contours in <10% of capillary loops in most severely affected glomerulus	Double contours in 10–25% of capillary loops in most severely affected glomerulus	Double contours in 26–50% of capillary loops in most severely affected glomerulus	Double contours in >50% of capillary loops in most severely affected glomerulus
Mesangial matrix increase[g]	**mm**	No mesangial matrix increase	Present in up to 25% of non-sclerotic glomeruli	Present in 26–50% of non-sclerotic glomeruli	Present in >50% of non-sclerotic glomeruli
Interstitial fibrosis	**ci**	Interstitial fibrosis in 0–5% of cortex	Interstitial fibrosis in 6–25% of cortex	Interstitial fibrosis in 26–50% of cortex	Interstitial fibrosis in >50% of cortex
Tubular atrophy	**ct**	No tubular atrophy	Tubular atrophy in up to 25% of cortical tubules	Tubular atrophy in 26–50% of cortical tubules	Tubular atrophy in >50% of cortical tubules
Arterial fibrous intimal thickening[h]	**cv**	No arterial fibrous intimal thickening	Arterial fibrous intimal thickening with 1–25% luminal narrowing	Arterial fibrous intimal thickening with 26–50% luminal narrowing	Arterial fibrous intimal thickening with >50% luminal narrowing
Arteriolar hyalinosis[i]	**ah**	No arteriolar hyalinosis	Mild–moderate hyalinosis in at least one arteriole	Moderate–severe hyalinosis in more than one arteriole	Severe hyalinosis in many arterioles
Peritubular capillary basement membrane multilayering*	**ptcml**	1–2 basement membrane layers in PTCs assessed by electron microscopy	3–4 basement membrane layers in PTCs assessed by electron microscopy	5–6 basement membrane layers in PTCs assessed by electron microscopy	>6 basement membrane layers in PTCs assessed by electron microscopy
Total Interstitial inflammation[j]	**ti**	No or trivial (<10% of parenchyma)	10–25% of cortical parenchyma	26–50% of cortical parenchyma	>50% of cortical parenchyma
Arteriolar hyaline thickening[k]	**aah**	No lesions typical of CNI arteriolopathy	1 arteriole, not circumferential	>1 arteriole, not circumferential	Any number of arterioles, circumferential
C4d in PTCs by Immunofluorescence (IF)[k]	**C4d (IF)**	0% of biopsy area, considered Negative	1 < 10% of biopsy area with linear, circumferential stain in PTC, considered Minimal/Negative	10–50% of biopsy area with linear, circumferential stain in PTC, considered Focal Unknown	>50% of biopsy area with linear, circumferential stain in PTC, considered Diffuse Positive
C4d in PTCs by Immunohistochemistry (IHC)[k]	**C4d (IHC)**	0% of biopsy area with linear, circumferential stain in PTC, considered Negative	1 < 10% of biopsy area with linear, circumferential stain in PTC, considered Minimal/Unknown	10–50% of biopsy area with linear, circumferential stain in PTC, considered Focal Positive	>50% of biopsy area with linear, circumferential stain in PTC, considered Diffuse Positive

[a] Note if "remarkable" number of eosinophils, neutrophils, plasma cells and denote with asterisk.
[b] Applies to tubules no more than mildly atrophic.
[c] Note number of arteries present and number affected; indicate infarction and/or interstitial hemorrhage with asterisk.
[d] Complete or partial occlusion of ≥1 glomerular capillary by leukocyte infiltration and endothelial cell enlargement.
[e] Comment on composition (mononuclear cells and neutrophils) and extent (focal ≤50%; diffuse >50%).
[f] This refers to most severely affected glomerulus; note number and percent sclerotic. Also, cg1a denotes no GBM double contours by light microscopy but GBM double contours by electron microcopy (EM) with endothelial swelling and/or subendothelial electron lucent widening, and cg1b can denote ≥1 double contours in ≥1 non-sclerotic glomerulus, confirmed by EM if available].
[g] This refers to at least a moderate increase, which is an increase by an average of >2 mesangial cells in the mesangial interspace between adjacent capillaries in at least two adjacent capillaries.
[h] This is characterized by features of chronic rejection (fibrointimal thickening/neointima formation ± breach of internal elastic lamina or presence of occasional mononuclear or foam cells, ± breaks in elastic lamina).
[i] Indicate arteriolitis with an asterisk.
[j] Alternate scoring for interstitial inflammation not always used diagnostically.
[k] Alternate scoring for hyaline arteriolar thickening (not always used diagnostically) due to calcineurin inhibitors (CNI).

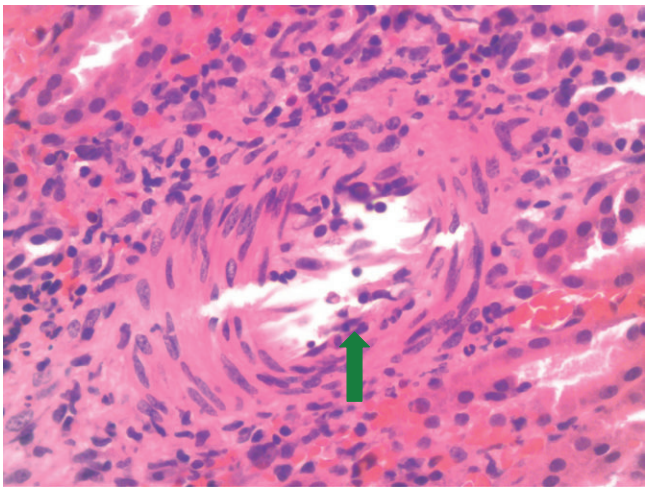

Figure 81.2. Arteritis. With endarteritis in a case of acute cellular rejection, type 2, mononuclear cells can be observed underlying the endothelium (green arrow).

Interstitial fibrosis and tubular atrophy (IFTA) is the non-specific final common pathway in both chronic CMR and AMR as well as in other forms of graft deterioration [31]. However, the only accepted diagnostic criteria for chronic CMR under Banff criteria is chronic allograft arteriopathy, consisting of arterial intimal fibrosis with mononuclear infiltration of fibrosis and formation of a neo-intima [8]. With IFTA, the renal tubules become smaller, acquire wrinkled thickened tubular basement membranes, and are infiltrated by inflammatory cells. Inflammation in areas of IFTA is currently not considered for the Banff i score by convention; however, recent studies have shown the importance of inflammation in areas of fibrosis, suggesting a role in chronic rejection and ultimate graft deterioration, at least as a robust prognostic marker [32–34]. A scoring system has been proposed to score total interstitial inflammation [the ti-score] and is currently under review for its interobserver reproducibility and clinical utility [11,35]. To determine the importance of inflammation in sclerotic areas and the ti score, a Banff working group on T-cell CMR was formed to assess these issues as well as the significance of "borderline" infiltrates [36].

After treatment, there is a decrease in the inflammation associated with acute CMR, in particular after early CMR with less IFTA. However, up to approximately 50% of biopsies taken 1–2 months after acute CMR show continued inflammation. In these biopsies, inflammation primarily remains in areas of fibrosis. Inflammatory cells may remain in the intima in some cases, sometimes embedded within a loose matrix, possibly representing a precursor to transplant arteriopathy [13]. This observation stresses the difficulties with the discrimination between injury-related inflammation and infiltrates mediating acute rejection.

Antibody-mediated rejection

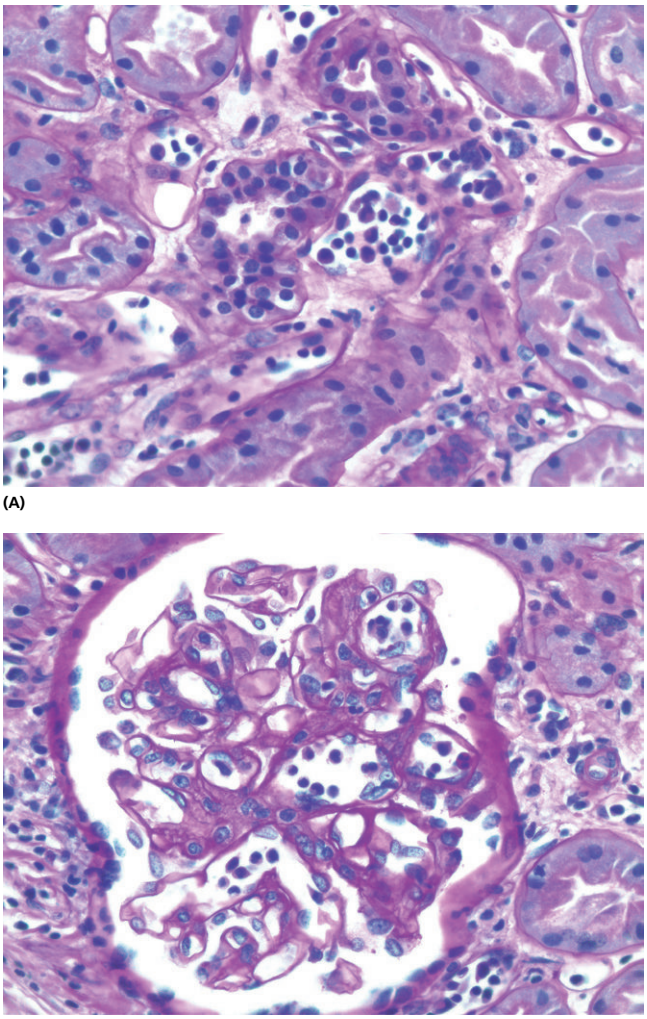
With the exception of hyperacute rejection mediated by pre-existing unrecognized donor-specific antibodies (DSAs) [37,38], for much of the five decades since the first kidney transplant, T cells were thought to be the major determinant in graft rejection. However, over approximately two decades it has become clear that much graft injury occurs through antibody-mediated (humoral) rejection, primarily directed against donor HLA [14]. Consequently, in 2001, AMR was introduced as a diagnostic category into the Banff classification [6]. AMR contributes to both early and, in particular, to late graft loss [39,40]. Antibody causes injury through the action of complement, producing tissue injury and coagulation and the recruitment of neutrophils and macrophages, culminating in endothelial injury. Edema results from the release of histamine from mast cells. Endothelial cell adhesion molecules (e.g. E-selectin, intracellular adhesion molecule 1, and vascular adhesion molecule 1) are up-regulated through the action of complement. Eventually, the membrane attack complex, C5b-9, leads to endothelial cell lysis. This process is complex and may not always be dependent on complement as AMR mediated by natural killer (NK) cells independent of complement has been described [3,14,41,42].

Clinically, two AMR phenotypes can be identified: phenotype 1 occurring in sensitized patients with pre-existing DSA early post-transplantation after incomplete desensitization; and phenotype 2 observed late post-transplantation after de novo development of DSA, frequently in the setting of non-compliance. Morphologically, acute AMR has three main patterns:

1. Type/Grade I, an acute tubular necrosis-like (ATN) minimal inflammation pattern;
2. Type/Grade II, a pattern containing PTC and/or glomerular inflammation (= microcirculation inflammation) (Figure 81.3), sometimes accompanied by thrombi; and
3. Type/Grade III, vascular fibrinoid necrosis (v3).

According to current Banff consensus criteria, in addition to one of these morphologic patterns of injury, two other criteria are required for the diagnosis of AMR: the identification of a DSA and the presence of the complement split product component C4d in the endothelium of PTCs (Figure 81.4) [8]. Ultrastructurally, peritubular and glomerular capillary endothelium shows signs of injury with cell enlargement, loss of fenestrations, detachment from basement membranes, lysis, and apoptosis [43].

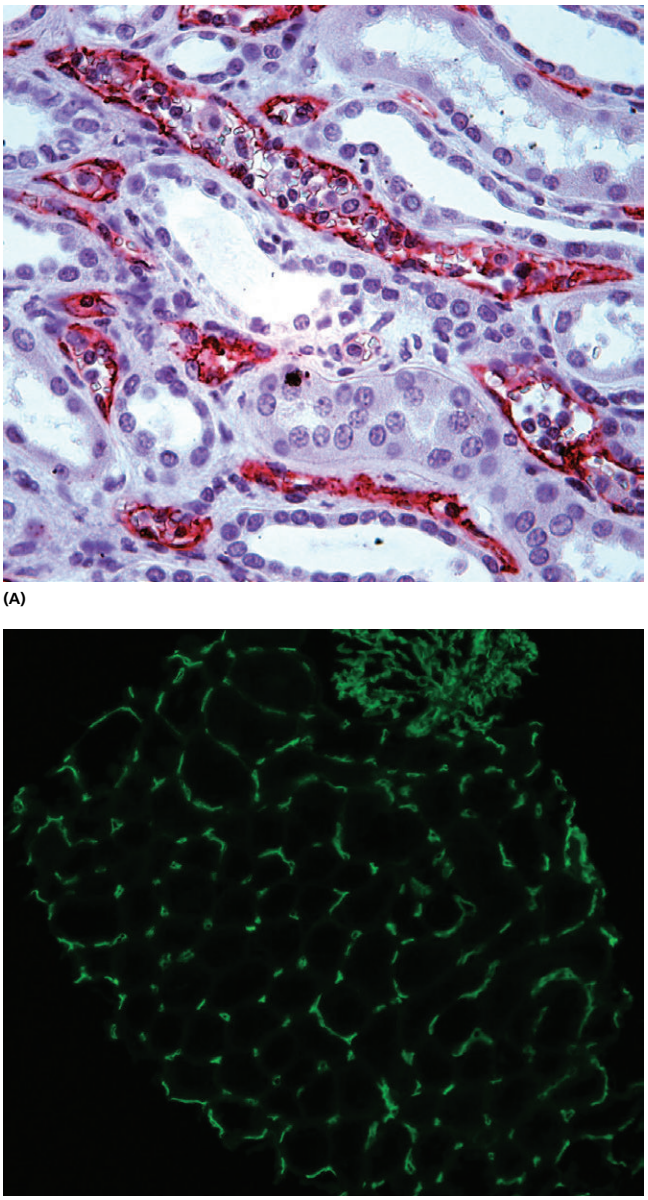
Chronic antibody-mediated rejection (CAMR) is characterized by structural remodeling primarily in the microcirculation of the kidney, but also in larger arteries (intimal hyperplasia) with secondary IFTA and eventual decline in renal allograft function. Clinically, CAMR may be accompanied by proteinuria [13,44]. In the microcirculation, renal glomerular basement membranes undergo reduplication, developing "double contours" in a process termed transplant glomerulopathy [44]. Under Banff criteria, for a diagnosis of CAMR there must be morphologic signs of chronic remodeling, C4d in PTC endothelium, and a documented DSA [8]. Morphologic signs of chronic antibody-mediated injury accepted as evidence of CAMR include: glomerular double contours (Figure 81.5), PTC basement membrane multilayering, IFTA, and fibrous thickening in arteries [8]. At least two of four of these morphologic signs of injury are typically recommended for a CAMR diagnosis [5]. Glomerular and PTC basement membrane multilamination are considered to be the most valuable evidence in the diagnosis of chronic renal allograft rejection [45]. In addition, as in acute AMR, there is typically glomerulitis and peritubular capillaritis present in most biopsies with CAMR. These findings can be interpreted as signs of ongoing disease activity and thus progression. Glomerular inflammatory cells are mostly composed of $CD68^+$ monocytes with fewer numbers of $CD3^+$ T cells, and occasionally neutrophils. PTCs contain C4d in CAMR, and C4d staining may also be seen as a non-specific finding in glomeruli with double contours. It is likely that CAMR occurs in multiple stages, a concept that has been demonstrated in non-human primate models [46]. It has been postulated that CAMR is initiated by the production of DSA, followed by deposition of C4d in PTCs,



(A)

(B)

Figure 81.3. Acute antibody-mediated rejection. In acute antibody-mediated rejection both (A) peritubular capillaritis and (B) glomerulitis can be seen.



(A)

(B)

Figure 81.4. C4d staining. (A) C4d stain in acute antibody-mediated rejection demonstrates a linear, circumferential staining of the peritubular capillary endothelium using both (A) immunohistochemistry (with a red chromogen) and (B) immunofluorescence (with a green fluorophore).

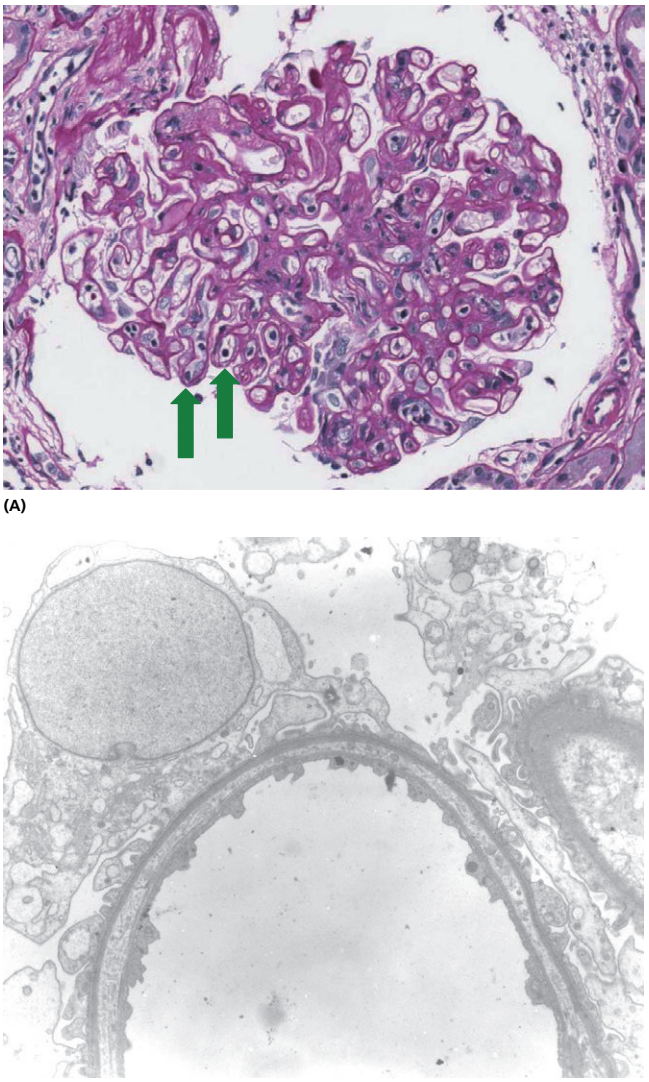
and subsequent acute and then chronic morphologic signs of microcirculation injury, eventually leading to graft dysfunction. C4d and DSA may be intermittently present throughout this process. These stages can occur within months or be spread over years in humans, mostly depending on the compliance and immunosuppressive status of the patient [13,47].

In regards to AMR, attention has recently been drawn to C4d-negative AMR. These cases have DSA and morphologic evidence of antibody-mediated injury but lack C4d positivity in PTC endothelium. Negativity for C4d in AMR can be explained by various mechanisms: complement independent antibody-mediated injury; lack of sensitivity and reproducibility of the staining methods; arbitrary criteria for defining "positivity"; or time-dependent degradation of C4d deposits in the microcirculation. Molecular studies identified a subset of cases with DSA and morphologic features of antibody-mediated injury showing increased expression of endothelial cell associated transcripts as a sign of endothelial cell activation and stress [48]. These data suggest that 50–60% of AMR cases are missed by current Banff criteria due to C4d-negativity. AMR in the absence of C4d deposition has now been added to the Banff diagnostic armamentarium after data was gathered by a topic-specific Banff Working Group [30,36,49].

AMR may co-exist with CMR, in particular in non-compliant patients [13]. The presence of a substantial interstitial inflammatory infiltrate and tubulitis tends to favor acute CMR. Mononuclear tubulitis is found in 30–80% of cases of acute AMR and is thought to represent a concurrent TCMR component [5,50–52], and HLA-DR expression is also thought to denote cases with concurrent T cell and AMR [5,53].

Accommodation

A peculiar scenario related to AMR has been termed accommodation. Accommodation refers to the presence of PTC C4d deposition



(A)

(B)

Figure 81.5. Transplant glomerulopathy. Transplant glomerulopathy in chronic antibody-mediated rejection can be demonstrated with both (A) light microscopy, in which glomerular basement membrane duplication can be appreciated (green arrows), and (B) electron microscopy, in which the glomerular basement duplication is more evident.

in the absence of other evidence of antibody-mediated injury, and is thought to represent a process of endothelial cell adaptation to antibody and complement over time. In these cases, DSA may be detectable; however, there are no morphologic signs of tissue injury. Signs of acute or chronic TCMR or AMR are absent; more specifically, there is no ATN-like minimal inflammation, no glomerulitis (g0), no chronic transplant glomerulopathy (cg0), no peritubular capillaritis (ptc0), and no PTC basement membrane multilamination (<5 layers by EM). These cases are considered to be "C4d deposition without evidence of active rejection" under current Banff criteria and are considered indeterminate if there are simultaneous borderline changes [8]. Accommodation is often described in the setting of ABO-incompatible allografts. The long-term significance of these relatively rare cases is still under investigation [13,54,55].

Atypical rejection syndromes

Novel immunosuppression regimens can lead to novel patterns of rejection. For example, alemtuzumab (CAMPATH-1H) leads to pronounced lymphocyte depletion [56–58]. Acute CMR with a predominance of monocytes (i.e. an acute monocytic rejection) has been described with lymphocyte depletion with alemtuzumab. In these cases, much of the interstitial infiltrate accounting for the rejection stains for CD68, which correlates with the renal dysfunction and tubular stress, measured with HLA-DR staining. However, in these cases, T cells did not correlate with renal dysfunction or HLA-DR staining [56].

Studies recently have included protocols for simultaneous bone marrow and kidney transplantation in attempts to induce tolerance to the transplanted organ. In such patients, HLA-mismatched renal transplants have been conducted, and maintenance immunosuppression has been withdrawn in some of the patients with relative preservation of renal function [59]. In many of these patients, a capillary leak or engraftment syndrome has been observed around 10 days after a simultaneous kidney/bone marrow transplant preceded by a non-myeloablative conditioning regimen. In this "engraftment syndrome," PTCs are congested with mononuclear cells and red blood cells, accompanied by acute tubular injury (ATI). Immunohistochemistry shows that the cells are mostly $CD68^{+}MPO^{+}$ mononuclear cells and $CD3^{+}CD8^{+}$ T cells, the latter with a high proliferation index ($Ki67^{+}$). Fluorescence in situ hybridization (FISH) showed that the cells in PTCs are derived from the recipient, correlating with chimerism studies showing that this is the time period at which there is a decline in circulating donor cells and recovery of recipient circulating cells. EM shows PTC endothelium injury in these cases [59,60]. Others have performed combined kidney and bone marrow transplants without this phenomenon, and the etiology of the syndrome remains undefined [61].

In sensitized patients bearing a high risk for AMR despite desensitization, inhibition of the complement cascade has been tested as a treatment option. Early biopsies from patients treated with eculizumab were diffusely C4d-positive but did not show morphologic signs of AMR including lack of endothelial cell activation by EM. The fact that complement component C5 as the target of eculizumab is downstream of C4d explains the diffuse positivity for C4d, while the lack of respective pathology suggests that eculizumab simultaneously protects the endothelium. However, a few patients developed AMR despite eculizumab, in particular chronic AMR with transplant glomerulopathy (TG) [62]. This highlights the fact that complement inhibition alone does not prevent the development of chronic antibody-mediated microcirculation injury. Furthermore, these observations also illustrate the limitations in the diagnostic reliability of C4d and DSA in this setting and emphasize the need for the refinement of the respective diagnostic criteria.

Other important disorders observed in allografts

A variety of disorders should be considered in the differential diagnosis of rejection (Box 81.1), including a variety of infections, drug effects, and anatomic problems [7]. Acute tubular injury/necrosis (ATI/ATN) is also a common finding, as discussed later [7].

Infection should be excluded before a diagnosis of acute rejection is made [7]. Pyelonephritis may be present in allografts. Pyelonephritis typically has a more prominent neutrophilic component to the inflammatory infiltrate, sometimes displaying neutrophilic

casts (Figure 81.8). Clinical correlation with urinalysis and urine culture may be useful in such cases [5]. In addition, a variety of viral infections may be present in renal allografts, some of which are discussed later [7].

Drug effects may cause changes in renal allografts. For example, the calcineurin inhibitor immunosuppressive agents are important in this regard (Figure 81.6), as discussed later. Acute interstitial nephritis may be present in renal allografts and may often be drug-induced.

Urinary tract anatomic problems can be present in renal allografts, examples of which include obstruction and/or reflux and urine leak. In spite of the fact that surgical techniques have improved over the past decades, leading to a lower incidence of technical complications, some anatomic problems still can be caused by problems with surgical technique, including misplacement of ureteral sutures, insufficient ureteral length, and ureteral or renal pelvis laceration. Most ureteral complications occurring after the first week are related to ureteral ischemic injury. In some of these circumstances, the dysfunctional anastomosis may lead to reflux and/or leakage [5,63–66]. The related morphologic features in transplant biopsies are identical to those in native kidneys with similar problems. Focal dilatation of tubules with cast formation and occasional rupture of the tubular basement membrane can be seen, which is then accompanied by a focal inflammatory response.

Vascular problems may also be present, including anastomotic defects leading to renal artery stenosis [7,67–70]. Vascular problems are caused by intimal injury during procurement, anastomotic stenosis, excessive trauma, and renal vein narrowing, compression, or twisting. These problems may be complicated by a hypercoagulable state from disorders such as factor V Leiden disorder, antiphospholipid antibody disorder, and nephrotic syndrome [13].

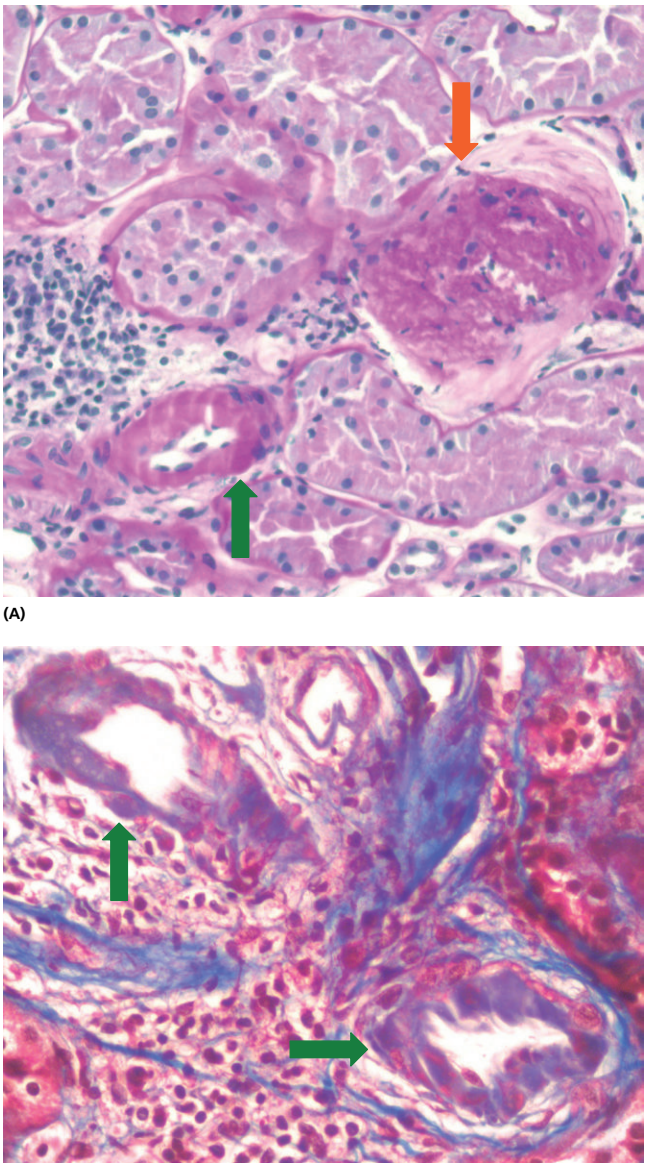

Figure 81.6. Arteriolar hyalinosis. Arteriolar hyalinosis of the type associated with chronic calcineurin inhibitor toxicity can be readily observed on both (A) PAS and (B) trichrome stains (green arrows). The hyalinosis focally has a nodular quality. A sclerotic glomerulus is also present (orange arrow).

Transplant renal artery stenosis may be caused by atherosclerosis, intimal flaps, kinking, and chronic rejection later in the life of the allograft; the arterial stenosis may result in refractory hypertension due to increased renin production [71–73]. Vascular thrombosis may cause renal dysfunction and injury to the renal parenchyma [7,71–73]. Lymphoceles may also be present as a result of incomplete lymphatic anastomosis, leading to mild inflammation that may fulfill the criteria for "borderline/suspicious" for acute CMR and be erroneously attributed to CMR [74–76].

Non-specific histologic changes may be present and must be distinguished from rejection. Venulitis is not considered to be pathognomonic for rejection in kidney allografts. Furthermore, the subcapsular region often contains IFTA, inflammation, and

glomerulosclerosis; however, findings in subcapsular region must be interpreted with caution because subcapsular injury or "healing in" is a rather common non-specific finding in renal allografts, which is not considered pathognomonic of rejection [5,7].

Acute tubular injury

The epithelium of the nephron is the crucial determinant of kidney function and outcome [77–79]. However, the fact that biopsies from acutely injured non-functioning kidneys frequently show "normal" histology or non-specific injury feature like loss of brush border, epithelial necrosis, and cellular degeneration highlights the limited ability of light microscopy to assess, in particular, the early potentially reversible stages of epithelial injury. Furthermore, the continuous process of nephron dedifferentiation from acute reversible injury to chronic irreversible atrophy represents a morphologic challenge to determine the exact turning-point when an injured tubule becomes atrophic. Therefore, significant research efforts are underway for identifying in situ injury markers enhancing light microscopy in assessing epithelial injury (e.g. Kim-1, vimentin, and integrin-beta 6) [80,81]. Elegant molecular, mechanistic, and imaging data are available demonstrating that epithelial cells show a highly stereotyped response to any kind of injury [82,83]. This includes the re-expression of embryonic and developmental pathways; and with this, epithelial cells assume a more mesenchymal phenotype as a sign of dedifferentiation, which often represents a transient state [84,85]. The expression of the mesenchymal phenotype frequently co-localizes with increased inflammation and matrix production in the adjacent interstitium. However, there is no convincing evidence, at least in kidney allografts, that the source of fibrosis is a migrated dedifferentiated epithelial cell, but rather an adjacent residential interstitial cell (i.e. there is no evidence for true epithelial-to-mesenchymal-transition (EMT)). Rather, this process may simply represent an epithelial-to-mesenchymal phenotype (EMP) [86]. Thus, in situ markers for epithelial injury will be clinically very useful in kidneys with early stages of injury as a reflection of potentially reversible injury and in kidneys with later stages as a reflection of epithelial dedifferentiation and atrophy.

Polyomavirus nephritis

Current drug regimens can lead to such profound immunosuppression that viral infection can be a problem. Clinically, these patients can present with features of renal dysfunction identical to those seen in rejection. The polyomavirus BK virus is a particular problem in this regard, accounting for around 80% of cases of PVAN. The polyomavirus JC virus, which may account for up to almost 20% of cases, can also cause PVAN; however, cases caused by JC virus are typically milder. PVAN results in a tubulointerstitial nephritis and preferentially infects the renal tubular epithelium, producing nuclear inclusions in many cases (Figure 81.7). The inflammatory infiltrate often has numerous plasma cells. Plasma cell tubulitis may sometimes be seen [13]. Immune complex deposits can be seen along tubular basement membranes. Eventually IFTA results in advanced stages, which are associated with an inferior prognosis [13,87–89]. It has been postulated that acute CMR and polyomavirus may co-exist; however, the differential diagnosis of these two entities is difficult [90].

Immunohistochemistry, typically directed against the polyomavirus SV40 large T antigen, can be used to detect virally infected cells and thus confirm the diagnosis. Although some morphologic changes in the way of tubulointerstitial inflammation are typically present in polyomavirus nephritis [91], a low threshold for performing the SV40 stain is recommended given the threat of polyomavirus nephritis/nephropathy, particularly when mild inflammatory infiltrates or a "borderline" pattern are seen [87,92]. Virally infected cells may also be detected with in situ hybridization or EM, which can display paracrystalline arrays of viral particles [13,87–89].

Adenovirus

Adenovirus may infect renal allografts. Infections are very rare (<1% of transplants), typically presenting in the 1–3 months after transplant, although the condition may be under-diagnosed. Patients may be febrile and may present with hematuria from hemorrhagic cystitis. Histologically, tubular necrosis may be appreciated (Figure 81.7); and granulomatous inflammation may be present. Tubular epithelial cells may appear smudgy and contain basophilic intranuclear inclusions. Immunohistochemistry can be helpful in diagnosing the virally infected cells [13,93–95].

Cytomegalovirus

Cytomegalovirus (CMV) infection, although frequent in solid organ recipients, may rarely be seen as nephritis in renal allografts. Patients are often profoundly immunocompromised and typically present with flu-like symptoms and renal dysfunction. Allograft CMV infections have become less common with prophylaxis using drugs such as ganciclovir. CMV inclusions may be seen very rarely in the tubular epithelium and also in glomerular capillary and/or PTC endothelial cells (Figure 81.7). This may be accompanied by interstitial inflammation. Special stains, such as immunohistochemistry for CMV, are available to aid in the identification of infected cells [13,96–98].

Calcineurin inhibitor toxicity

Calcineurin inihibitors (e.g. cyclosporine and tacrolimus) are instrumental in preventing rejection in renal allografts [17]; however, calcineurin inhibitors can cause both acute and chronic nephrotoxicity. Acute toxicity can be associated with tubular injury necrosis with isometric vacuolization of the proximal straight tubules. Afferent arterioles can display smooth muscle cell necrosis with eventual hyalinization. Uncommonly, thrombotic microangiopathy (TMA) can develop. Chronically, the damage to smooth muscle cells caused by calcineurin inhibitor toxicity leads to more extensive hyaline deposits, which often have a beaded appearance and protrude into the adventitia (Figure 81.6). The interstitium may also display striped fibrosis and tubular atrophy [99].

However, none of these histologic features are specific for calcineurin inhibitor toxicity, and can be observed frequently in kidneys from patients who have never received calcineurin inhibitors [100]. Thus, the actual contribution of calcineurin inhibitors to renal allograft loss as well as a reliable risk–benefit analysis of calcineurin inhibitors is still a matter of ongoing debate.

Post-transplant lymphproliferative disease

PTLD is a disorder in lymphoid proliferation in the post-transplantation setting, typically due to the profound immunosuppression and associated Epstein–Barr virus (EBV) reactivation. PTLD may be seen in both solid organ or bone marrow transplant patients. Eventually, frank lymphoma may result, leading to a reported mortality of 40–60%. Most (85–90%) cases of PTLD are of B-cell origin, expressing CD20. Many cases are driven by EBV, and EBV seronegativity prior to transplantation is a risk factor for the development of PTLD. Morphologically, most of these cases are

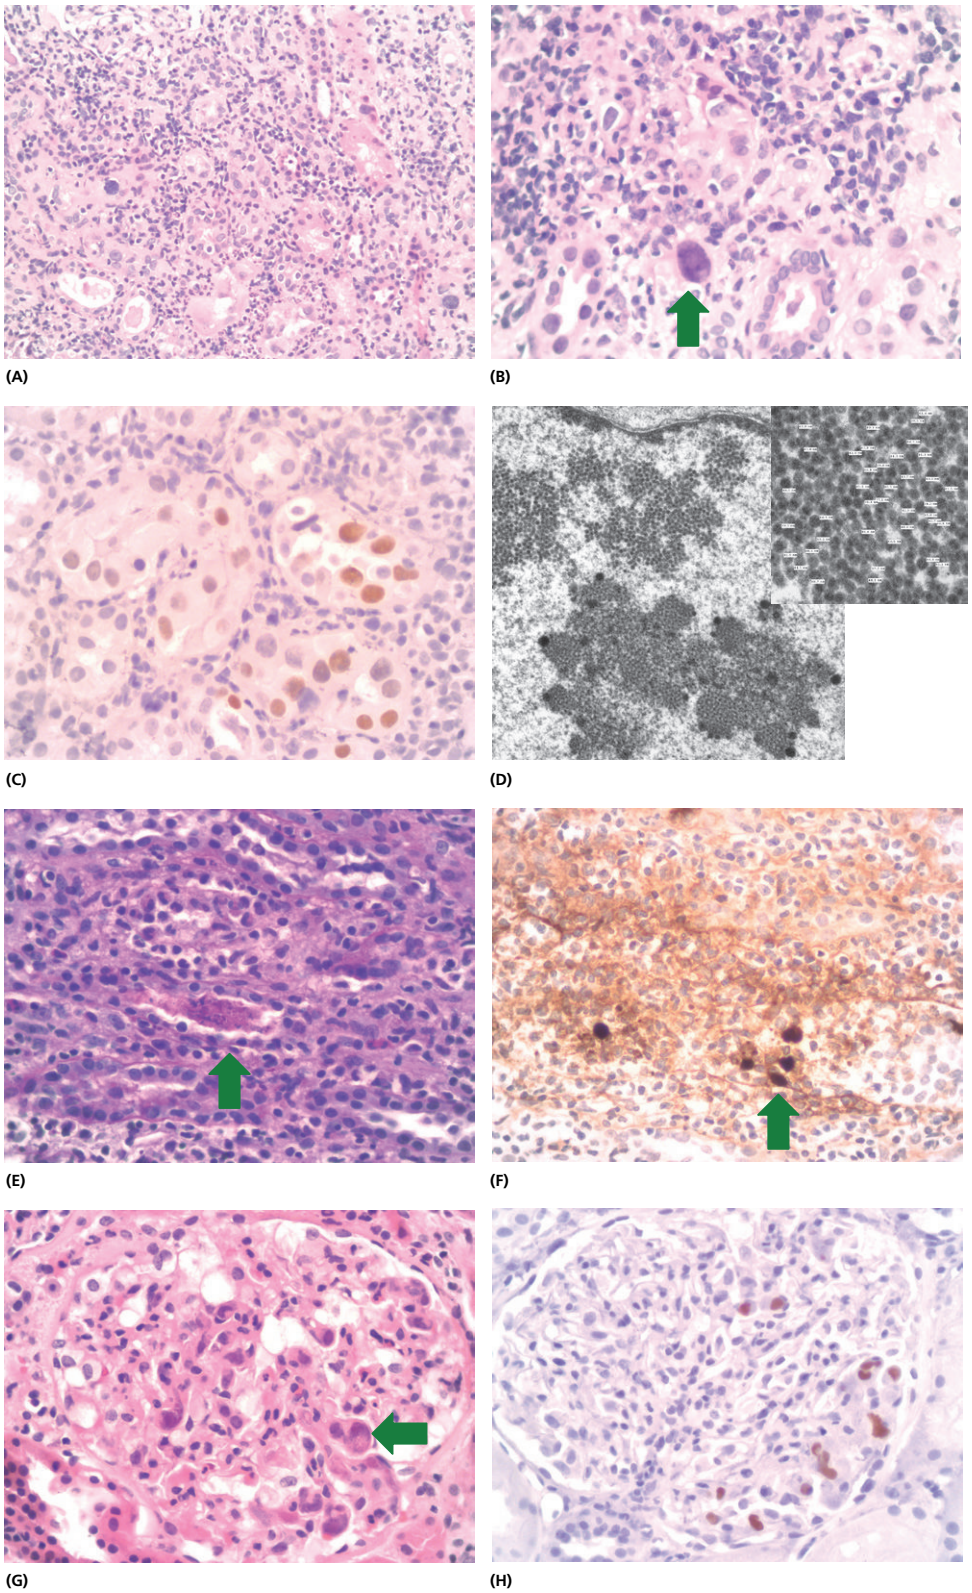

Figure 81.7. Viral nephritis. In polyomavirus nephritis, there is often (A) a dense lymphoplasmacytic infiltrate; and (B) markedly enlarged tubular epithelial cells can be seen (arrow). (C) SV40 immunohistochemistry can be used to confirm that the cells are infected by polyomavirus, and (D) the polyomavirus virions can be seen on electron microscopy measuring approximately 40–50 nm (inset). (E) In adenovirus nephritis, necrotic material can often be appreciated in the renal tubules (arrow); and (F) adenovirus immunohistochemistry can confirm the presence of adenovirus (arrow). (G) Cytomegalovirus viral inclusions may sometimes be seen in glomeruli (arrow), which can be confirmed with positivity staining using cytomegalovirus immunohistochemistry (H).

composed of "activated" mononuclear cells with enlarged nuclei, prominent nucleoli, and frequently evident mitotic activity. Immunohistochemistry may be useful in looking for the presence of B- or T-cell antigens and the EBV-associated antigens (such as the EBV-latent membrane protein), and in situ hybridization maybe useful in looking for EBV-encoded RNA (EBER). Classification of PTLD has been established by individuals working under the auspices of the World Health Organization (WHO), and PTLD under this WHO classification fits into four major categories: early lesions; polymorphic PTLD (plasmacytic hyperplasia and infectious mononucleosis-like PTLD); monomorphic PTLD (B, T, and NK cell); and classic Hodgkin lymphoma [13,101]. PTLD is treated with a reduction in immunosuppression, antiviral drugs, anti-CD20 (rituximab, if of B-cell phenotype), chemotherapy, and radiation.

Recurrent and de novo disease

With successes in the treatment of acute graft rejection, allografts have lasted longer and recurrent disease has become an important contributor to renal allograft deterioration (Table 81.3). Detailed investigation has indicated that the majority of cases have an identifiable cause of renal allograft deterioration, consisting of both alloimmune and non-alloimmune mechanisms. Glomerular pathology includes recurrent disease in a substantial number of patients [102]. Clinically relevant proteinuria may eventually be present in approximately 40% of kidney transplant recipients with the most common cause being CAMR; however, rejection-associated causes are closely followed by post-transplant glomerulonephritis [103,104].

Studies have indicated that recurrent renal disease may be the third leading cause of graft failure in patients with glomerulonephritis. Important examples of renal disease that have a prominent impact on graft survival include recurrent focal segmental glomerulosclerosis (FSGS) [105–107], atypical hemolytic uremic syndrome (HUS) [103], lupus nephritis [108], and membranoproliferative glomerulonephritis (MPGN) [103,109,110]. Other noteworthy diseases that may recur after transplantation include membranous glomerulonephritis (MGN), antiglomerular basement membrane (GBM) disease, antineutrophil cytoplasmic antibody (ANCA) [13,111], and post-infectious glomerulonephritis [112].

In general, recurrent and de novo diseases present with identical morphologic features and clinical symptoms, as in native kidneys. The C4d stain routinely performed in allograft biopsies can serve as a screening test in this regard. Granular C4d deposition by immunofluorescence and immunohistochemistry (particularly along the glomerular basement membrane) raises the possibility of de novo or recurrent glomerulonephritis. Mesangial C4d is a normal finding by immunofluorescence [13]. Some diseases recur relatively fast; however, others such as diabetic glomerulopathy may take years to manifest recurrent disease [13,111].

Immunofluorescence and EM are crucial in making a diagnosis of recurrent disease (Figure 81.8). Features of recurrent disease may be superimposed upon acute or chronic allograft rejection or drug toxicity, and by this represent a differential diagnostic challenge. Recurrent disease should be distinguished from de novo disease; thus, knowledge of the primary disease is important in recognizing and interpreting relevant pathologies in renal allografts because the morphologic features are identical in recurrent and de novo diseases. However, this distinction is frequently impossible as only a minority of renal allograft recipients undergo biopsies of their native kidney disease. In general, recurrent disease is favored if there is an early onset (<6 months).

Primary FSGS may recur rapidly (within minutes) after transplantation, resulting in profound proteinuria, extensive podocyte foot process effacement often in a minimal change-like disease picture, and eventually producing segmental sclerosing lesions [105,106]. Recurrence is five times more likely in children than in adults [13]. Some cohorts have shown the same histologic pattern

Table 81.3. Recurrent diseases (data from [102,103])

Disease	Recurrence rate (% of recipients)	5–10 year graft loss (% of recipients)	Comments
Disease primarily affecting glomeruli			
FSGS	20–40	20	Typically accompanied by proteinuria and may display collapsing features
MPGN, type I	20–33	High	
MPGN, type II (DDD)	67–100	34–66	
MGN	10–30	50	IgG4 is the dominant subclass compared to IgG1 in de novo MGN
IgA nephropathy/HSP	7–30	3–16	Crescentic GN may be present
Lupus nephritis	Up to 30	<5	Podocytopathy or FSGS may be present
Anti-GBM disease	<5	Rare	
Pauci-immune crescentic GN (ANCA associated)	0–20	10	
Fibrillary GN	50	20	
Immunotactoid glomerulopathy	Rare	Uncertain	
Systemic/metabolic disease			
Diabetic nephropathy	>50	5	
HUS (Idiopathic D-)	33–82	90	
Amyloidosis, AL type	10–30	35	
Amyloidosis, AA type	<10	5	
MIDD	70–85	>50	
Fabry disease	Low	Rare	Enzyme replacement therapy has decreased incidence
Primary hyperoxaluria	90–100	80–100	
Cystinosis	Rare	0	
Sickle cell nephropathy	Rare	Not available	

ANCA, antineutrophil cytoplasmic antibody; DDD, dense deposit disease; FSGS, focal segmental glomerulosclerosis; GBM, glomerular basement membrane; GN, glomerulonephritis; HSP, Henoch–Schönlein purpura; HUS, hemolytic uremic syndrome; MGN, membranous glomerulonephritis; MIDD, monoclonal immunoglobulin deposition disease; MPGN, membranoproliferative glomerulonephritis.

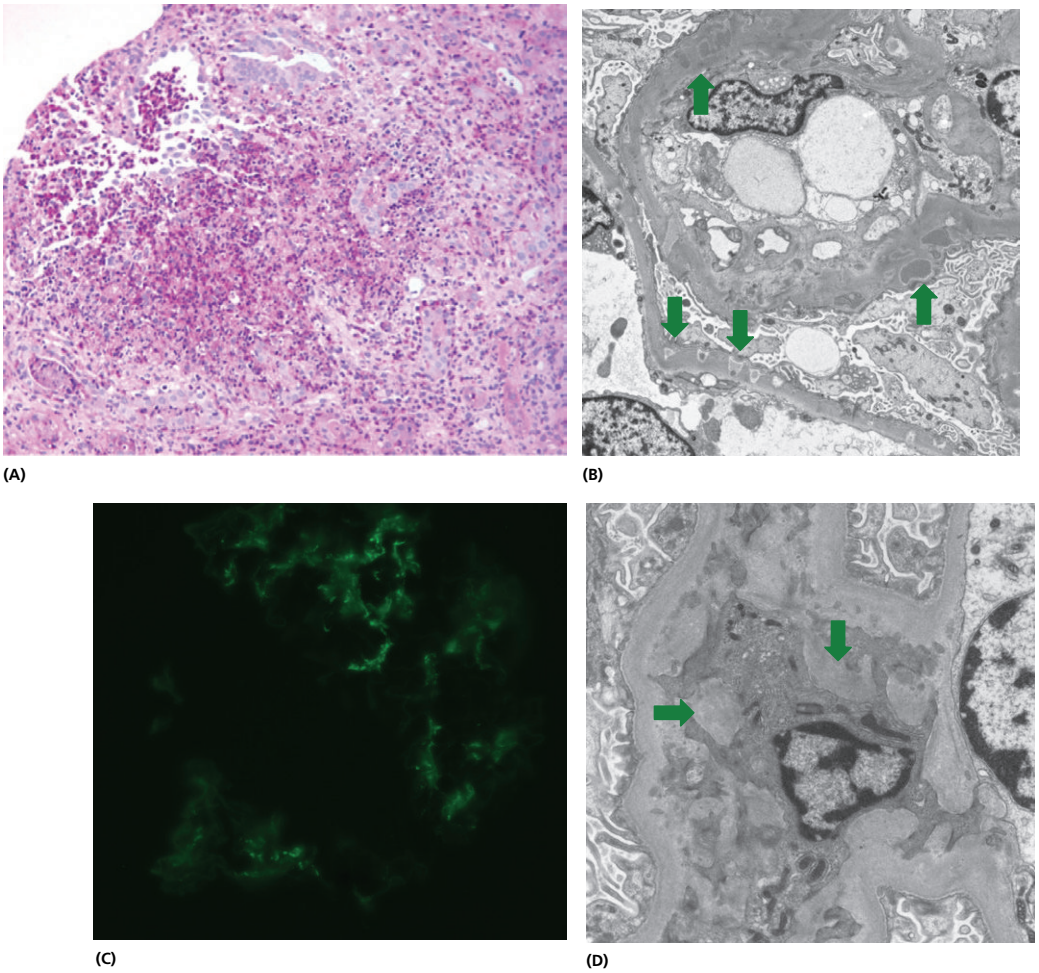

Figure 81.8. Examples of non-rejection disease, including recurrent/de novo glomerulonephritis. (A) In transplant pyelonephritis, there is often a dense inflammatory infiltrate composed of a predominance of neutrophils. (B) Electron microscopy in de novo membranous glomerulonephritis demonstrates numerous subepithelial immune-type deposits (arrows). In a case of recurrent IgA nephropathy (C) IgA immunofluorescence shows a granular mesangial staining pattern; and (D) electron microscopy shows electron dense immune-type deposits (arrows) closely apposed to reactive-appearing mesangial cells.

according to the Columbia classification [113] of FSGS in the FSGS recurrence [105]; however, other studies have failed to show this fidelity [106]. Attempts have been made to treat some cases with intense plasma exchange, displaying promising results in some [13,103,107,114].

FSGS may also occur as a de novo disease. It may sometimes have a collapsing pattern with glomerular capillary loop collapse and overlying podocyte hypertrophy. De novo FSGS is also associated with proteinuria. The collapsing pattern has been attributed to severe vascular disease and calcineurin inhibitor toxicity. The de novo and collapsing patterns have 5-year graft survival rates of approximately 60% and 50%, respectively [13,115–117]. FSGS is also seen frequently as a secondary lesion to various glomerular pathologies and hypertension occurring in allograft recipients.

Glomerular basement double contours in transplants (i.e. transplant glomerulopathy) most often represents a manifestation of CAMR. In approximately 30–40% of the cases with glomerular basement double contour, no C4d and DSA can be detected at time of biopsy [118]. In these cases, recurrent or de novo glomerular disease has to be taken into consideration. The most relevant entities in this regard are TMA and MPGN, in particular in the setting of underlying viral hepatitis [119,120]. MPGN typically has immunoglobulin and C3 deposits seen by immunofluorescence, prominent electron-dense subendothelial deposits on EM, and negative C4d in PTCs [13].

MGN recurs in about 30% of cases with severe proteinuria being present as early as 1 week after transplantation [13,121]. In MGN, glomerular basement membrane thickening, vacuolization, or spike formation may be present, together with the characteristic EM and immunofluorescence findings of MGN (Figure 81.8) [13]. Some MGN in allografts may represent a peculiar result of humoral rejection and may have concurrent C4d deposition [13,122–125].

In recurrent lupus nephritis, mesangial hypercellularity or sclerosis may be present, and crescent formation and fibrinoid necrosis may be seen. Segmental sclerosis or prominent podocyte injury may sometimes be present [13,108].

IgA nephropathy/Henoch–Schönlein purpura (HSP) is a recurrent disease that may manifest in the allograft. As in native kidneys with IgA nephropathy, there may be varying degrees of mesangial hypercellularity and crescent formation, and characteristic fluorescent microscopy and EM changes can be demonstrated (Figure 81.8) [13,126–128].

Serologic investigation may be important in the investigation of recurrent ANCA or anti-GBM-mediated disease. Serum and/or urine protein electrophoresis may be important in diagnosing recurrent or de novo immunoglobulin deposition diseases or amyloidosis [13].

An anti-GBM type disease may develop in allografts transplanted into recipients with Alport syndrome as their original disease. In this disorder, antibodies develop against the α-3, α-4, or α-5 chains of collagen type IV of the kidney allograft because the recipient was never exposed to these collagens before. Patients with Alport syndrome with relatively large deletions of *COL4A5* are thought to be more susceptible to anti-GBM disease development. Patients with Alport syndrome with X-linked disease targeting the NC1 domain of *COL4A5*, and other patients with Alport syndrome have autosomal recessive disease targeting the NC1 domain of either *COL4A3* or *COL4A4*. About 3–5% of patients with Alport syndrome develop de novo anti-GBM disease after kidney transplantation; approximately 75% of cases occur in the first year after transplant, and about 90% of grafts fail within months after onset. This anti-GBM disease is manifested by hematuria. Microscopically, there is cellular crescent formation and/or fibrinoid necrosis in >80% of glomeruli. By immunofluorescence, strong IgG staining along the GBM is seen. Plasmapheresis is typically the treatment of choice; immunosuppressive agents such as cyclophosphamide, high-dose corticosteroids, antithymocyte globulin, and mycophenolate mofetil have also been used [13,129–135].

Some metabolic and other familial diseases may recur in renal transplants. For primary hyperoxaluria, liver transplantation may be curative and make the need for kidney transplantation unnecessary. Excretion of oxalate may stimulate disease recurrence [13]. Fabry disease has a decreased recurrence rate with the development of enzyme replacement therapy. In cystinosis, macrophages containing cystine crystals may accumulate in the interstitium or glomerular mesangium; cysteine may also deposit in other organs [13]. Familial, atypical, or non-shiga toxin HUS has a high recurrence rate for complement factor H and I mutations; 20% recurrence for CD46 mutation [13,136,137]. Sickle cell nephropathy may also recur in renal transplants [13,138].

Future directions in biopsy assessment

Improved biopsy assessment can be expected to result from new developments in molecular and image analysis techniques. Significant progress has been made in applying "omics" technologies to allograft biopsies [77,78]. The molecular phenotype of renal allograft biopsies is already widely defined and understood. The next step will be further validation of its clinical utility (i.e. the identification of those areas and disease where molecular assessments are superior to histopathology). In addition, further refinement of turn-around times, development of reporting formats for high-dimensional "omics" data, and reduced costs are necessary to make molecular biopsy assessment a clinically feasible adjunct to histopathology. Thus, a new Banff working group has been formed to validate molecular markers and develop consensus guidelines for their use [36].

In addition, the advent of digital microscopy (i.e. whole slide scanning) offers significant potential for further improvements in assessment of biopsy results. Digital files of scanned histologic biopsy sections offer unprecedented detail and richness of image information, which allows significant information to be extracted by computer-based image analysis techniques. For example, assessment of interstitial fibrosis will very likely be automated in the next couple of years. Studies over the prior decade have demonstrated the utility of such an approach. Several applications require accurate measurement of interstitial fibrosis [139–161], including research focused on therapeutic inhibition of interstitial fibrosis and comparison of renal allograft protocol biopsies [162–165]. Furthermore, the combination of multicolor immunofluorescence techniques with digital microscopy and tailored image analysis algorithms will allow for quantitative and reproducible assessment of inter-related proteins representative of relevant immunopathologic pathways operating in the biopsy.

Conclusions

Kidney graft rejection and recurrent disease are important to recognize in renal allografts. In particular, AMR and glomerular disease are relevant because they represent the two major causes for late renal allograft loss [39,40,102]. In 80% of all kidney allografts with dysfunction and IFTA in the biopsy, an underlying disease process causing the chronic tissue injury can be identified [102]. It is important to expect the biopsy to reveal a specific diagnosis. Non-specific terms trying to summarize numerous pathomechanisms into one "pseudo-entity" like chronic allograft nephropathy (CAN) are obsolete [12]. Common histologic features like IFTA and interstitial inflammation are mostly non-specific epiphenomena of an underlying specific disease. The detailed understanding of the morphologic features and their integral interpretation with corresponding serologic, laboratory, and clinical features is crucial for making appropriate therapeutic decisions. Recent developments in assessing molecular phenotypes from allograft biopsies have shed important insights into the pathogenesis of some changes in renal allografts; and it is anticipated that molecular assays will continue to make even greater advances in our evaluation and understanding of these changes, complementing histology [36,77–79], and possibly eventually alleviating the need to perform some biopsies.
