Textbook of Organ Transplantation

Textbook of Organ Transplantation

Editors

Allan D. Kirk, MD, PhD, FACS

Professor and Chairman, Department of Surgery
Duke University School of Medicine;
Surgeon-in-Chief for Duke University Health System
Duke University Medical Center
Durham, NC, USA

Stuart J. Knechtle, MD

Professor of Surgery
Emory University School of Medicine
Atlanta, GA, USA

Christian P. Larsen, MD, DPhil

Dean – Emory School of Medicine
Surgeon-in-Chief Emory Healthcare
Emory University
Atlanta, GA, USA

Joren C. Madsen, MD, DPhil

Professor of Surgery
W. Gerald and Patricia R. Austen
Distinguished Scholar in Cardiac Surgery
Massachusetts General Hospital
Boston, MA, USA

Thomas C. Pearson, MD

Emory Transplant Center
Emory University School of Medicine
Atlanta, GA, USA

Steven A. Webber, MBChB, MRCP

James C. Overall Professor and Chair, Department of Pediatrics
Monroe Carell Jr. Children's Hospital at Vanderbilt
Vanderbilt University School of Medicine
Nashville, TN, USA

WILEY Blackwell

This edition first published 2014 © 2014 by John Wiley and Sons, Ltd.

Wiley-Blackwell is an imprint of John Wiley & Sons, formed by the merger of Wiley's global Scientific, Technical and Medical business with Blackwell Publishing.

Registered office: John Wiley & Sons, Ltd, The Atrium, Southern Gate, Chichester, West Sussex, PO19 8SQ, UK

Editorial offices: 9600 Garsington Road, Oxford, OX4 2DQ, UK
The Atrium, Southern Gate, Chichester, West Sussex, PO19 8SQ, UK
111 River Street, Hoboken, NJ 07030-5774, USA

Library of Congress Cataloging-in-Publication Data
Textbook of organ transplantation / editors, Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Thomas C. Pearson, Joren C. Madsen, Steven A. Webber.
p. ; cm.
Includes bibliographical references and index.
ISBN 978-1-118-87014-3 (cloth)
I. Kirk, Allan, editor of compilation.
[DNLM: 1. Organ Transplantation. WO 660]
RD120.7
617.9'54–dc23

A catalogue record for this book is available from the British Library.

Wiley also publishes its books in a variety of electronic formats. Some content that appears in print may not be available in electronic books.

1 2014

Contents

List of Contributors

Michael Abecassis, MD, MBA
J. Roscoe Miller Distinguished Professor
Department of Surgery and
Microbiology-Immunology
Chief, Division of Organ Transplantation
Founding Director, Comprehensive Transplant Center
Northwestern University Feinberg School of Medicine
Chicago, IL, USA

Kareem M. Abu-Elmagd, MD, PhD, FACS
Professor of Surgery
Department of Surgery
Transplant Division
Intestinal Rehabilitation and Transplantation Center
University of Pittsburgh Medical Center
Pittsburgh, PA, USA

Andrew B. Adams, MD, PhD
Assistant Professor of Surgery
Emory Transplant Center
Emory University School of Medicine
Atlanta, GA, USA

Avinash Agarwal, MD, FACS
Assistant Professor of Surgery
Department of Surgery, University of Virginia
Charlottesville, VA, USA

Maria-Luisa Alegre, MD, PhD
Professor of Medicine
University of Chicago
Chicago, IL, USA

Rita R. Alloway, PharmD, FCCP
Research Professor of Medicine
Director, Transplant Clinical Research
Director, Transplant Pharmacy PGY 2 Residency and Fellowship
University of Cincinnati
Cincinnati, OH, USA

Winston A. Ally, PharmD, BCPS
Pharmacy Clinical Coordinator
Solid Organ Transplantation
Director, PGY-2 Solid Organ Transplant Pharmacy Residency
Department of Pharmacy Services
University of Virginia Health System
Charlottesville, VA;
Clinical Assistant Professor
Department of Pharmacotherapy and Outcomes Science
Virginia Commonwealth University School of Pharmacy
Richmond, VA, USA

Estella M. Alonso, MD
Professor of Pediatrics
Department of Pediatrics
Northwestern University Feinberg School of Medicine
Medical Director of Hepatology and Liver Transplantation
Ann and Robert H. Lurie Children's Hospital of Chicago
Chicago, IL, USA

Sandra Amaral, MD, MHS
Co-Director, Pediatric Kidney Transplant Program
Assistant Professor, University of Pennsylvania
The Children's Hospital of Philadelphia
Philadelphia, PA, USA

Douglas J. Anderson, MD
Senior Resident
Department of Surgery
Emory University School of Medicine
Atlanta, GA, USA

Vincent T. Armenti, MD, PhD
Principal Investigator
National Transplantation Pregnancy Registry (NTPR)
Gift of Life Institute
Philadelphia, PA;
Professor of Anatomy and Surgery
University of Central Florida College of Medicine
Orlando, FL, USA

Todd L. Astor, MD
Assistant Professor of Medicine, Harvard Medical School
Medical Director, Lung and Heart-Lung Transplant Program
Pulmonary and Critical Care Unit
Massachusetts General Hospital
Boston, MA, USA

Robin K. Avery, MD
Professor of Medicine
Johns Hopkins University School of Medicine
Infectious Disease Division
Johns Hopkins Hospital
Baltimore, MD, USA

David A. Axelrod, MD, MBA
Section Chief, Solid Organ Transplant Surgery
Dartmouth Hitchcock Medical Center
Lebanon, NH, USA

Agnes M. Azimzadeh, PhD
Assistant Professor of Surgery
University of Maryland School of Medicine
Baltimore, MD, USA

Raul Badell, MD
Chief Resident
Department of Surgery
Emory University School of Medicine
Atlanta, GA, USA

Remzi Bag, MD
McKelvey Scholar
The McKelvey Center for Lung Transplantation
Assistant Professor of Medicine, Pulmonary, Allergy and Critical Care
Emory University School of Medicine
Atlanta, GA, USA

William M. Baldwin III, MD, PhD
Staff, Department of Immunology
Cleveland Clinic
Cleveland, OH, USA

Erik R. Barthel, MD, PhD
Resident in General Surgery
Harbor-UCLA Medical Center
UCLA David Geffen School of Medicine
Los Angeles, CA, USA

Stephen T. Bartlett, MD
Peter Angelos Distinguished Professor and Chairman
Department of Surgery
University of Maryland School of Medicine
Surgeon-in-Chief, University of Maryland Medical System
Baltimore, MD, USA

Lokesh Bathla, MD
Transplant Surgeon
Methodist Specialty and Transplant Hospital
San Antonio, TX, USA

Julia B. Becker, MD
Fellow in Pulmonary and Critical Care Medicine
University of Chicago
Chicago, IL, USA

Lorraine E. Bell, MDCM, FRCPC
Associate Professor of Pediatrics, McGill University
Director, Pediatric Renal Transplant Programme
Director, Pediatric Transition to Adult Care
Montreal Children's Hospital-McGill University Health Centre
Montreal, QC, Canada

Jennifer Berumen, MD
Chief Resident, General Surgery
UC San Diego
La Jolla, CA, USA

Oriol Bestard
Renal Transplant Unit
Nephrology Department
University Hospital of Bellvitge
University of Barcelona
Barcelona, Spain

Arvind Bhimaraj, MD, MPH, FACC
Assistant Professor of Medicine
Weill Cornell Medical College, NY;
Department of Cardiology
Methodist DeBakey Heart & Vascular Center
Houston Methodist Hospital
Houston, TX, USA

Adam W. Bingaman, MD, PhD
Director, Live Donor and Incompatible Kidney Transplant Programs
Methodist Specialty and Transplant Hospital
San Antonio, TX, USA

Roy D. Bloom, MD
Professor of Medicine
Perelman School of Medicine
University of Pennsylvania
Medical Director
Penn Kidney Pancreas Transplant Program
Philadelphia, PA, USA

Emily A. Blumberg, MD
Professor of Medicine
Perelman School of Medicine
University of Pennsylvania
Philadelphia, PA, USA

J. Andrew Bradley, PhD, FRCS
Professor of Surgery
University of Cambridge
Cambridge, UK

Gerald Brandacher, MD
Associate Professor of Surgery (PAR)
Scientific Director
Reconstructive Transplantation Program
Department of Plastic and Reconstructive Surgery
Johns Hopkins University School of Medicine
Baltimore, MD, USA

Robert A. Bray, PhD
Professor of Pathology
Co-Director, Histocompatibility and Molecular Immunogenetics Laboratory
Department of Pathology
Emory University Hospital
Atlanta, GA, USA

Daniel C. Brennan, MD
Professor of Medicine
Director, Transplant Nephrology
Washington University in St. Louis
School of Medicine
St. Louis, MO, USA

Lori E. Brigham, MBA
President and CEO
Washington Regional Transplant Community
Annandale, VA, USA

Jonathan S. Bromberg, MD, PhD
Professor of Surgery and Microbiology and Immunology
University of Maryland School of Medicine
Baltimore, MD, USA

Kimberly A. Brown, MD
Chief, Gastroenterology and Hepatology
Henry Ford Hospital
Detroit, MI, USA

John C. Bucuvalas
Professor of Pediatrics
Associate Medical Director, Pediatric Liver Care Center
Cincinnati Children's Hospital Medical Center
Cincinnati, OH, USA

Deborah Budge, MD
Associate Director
UTAH Cardiac Transplant Program
Intermountain Medical Center
Salt Lake City, UT, USA

Andrew Bushell, DPhil
Senior Scientist and University Research Lecturer
Transplantation Research Immunology Group
Nuffield Department of Surgical Sciences
John Radcliffe Hospital
Oxford, UK

Chris J. Callaghan, PhD, FRCS
Consultant Transplant and Vascular Access Surgeon
Guy's Hospital
London, UK

Sir Roy Y. Calne, FRS
Emeritus Professor of Surgery
Cambridge University
Cambridge, UK;
Visiting Professor
National University of Singapore
Singapore

Esther-Marie Carmichael, MT(ASCP), CLS, PHM, BSc
Quality Assurance Manager
Keck Hospital of USC, Transplant Institute
Los Angeles, CA, USA

Kelly Carter, MS, RN, NE-BC
Virginia Commonwealth University Health System
Medical College of Virginia Hospitals
Nurse Manager
Pauley Heart Center
Richmond, VA, USA

J. Michael Cecka, PhD
Emeritus Professor
Department of Pathology and Laboratory Medicine;
Director, Clinical Research
UCLA Immunogenetics Center
David Geffen School of Medicine
University of California, Los Angeles
Los Angeles, CA, USA

Linda C. Cendales, MD
Associate Professor of Surgery
Division of Plastic and Reconstructive Surgery and Division of Transplantation (dual appointment)
Director, Vascularized Composite Allotransplantation
Duke University Medical Center
Durham, NC, USA

Ashtar Chami, MD
Assistant Professor of Medicine
Emory Transplant Center
Emory University School of Medicine
Atlanta, GA, USA

Jeremy Chapman, MD, FRCP
Director, Renal Medicine
Centre for Transplant and Renal Research
Westmead Milennium Institute
Sydney University
Westmead Hospital
Westmead, NSW, Australia

Ali H. Charafeddine, MD
General Surgery Resident
Montefiore Medical Centre
Albert Einstein College of Medicine
Bronx, New York, NY, USA

Serban Constantinescu, MD, PhD
Medical Director, Kidney Transplant Program
Associate Professor of Medicine
Temple University School of Medicine
Philadelphia, PA, USA

Damon S. Cooney, MD, PhD
Assistant Professor of Plastic Surgery
Department of Plastic and Reconstructive Surgery
Johns Hopkins University School of Medicine
Baltimore, MD, USA

Matthew Cooper, MD
Associate Professor of Surgery
Medstar Georgetown Transplant Institute
Georgetown University School of Medicine
Washington, DC, USA

Jack G. Copeland, MD
Professor of Cardiothoracic Surgery
Director of Cardiac Transplantation and Mechanical Circulatory Support
UC San Diego
La Jolla, CA, USA

Hannah Copeland, MD
Chief Resident, General Surgery
UC San Diego
La Jolla, CA, USA

A. Benedict Cosimi, MD
Claude E. Welch Distinguished Professor of Surgery
Harvard Medical School
Chief Emeritus
Division of Transplantation
Massachusetts General Hospital
Boston, MA, USA

Guilherme Costa, MD, FACS
Assistant Professor of Surgery
Department of Surgery
University of Pittsburgh
Pittsburgh, PA, USA

Peter J. Cowan, PhD
Professor, Immunology Research Centre
St Vincent's Hospital Melbourne;
Department of Medicine
University of Melbourne
Melbourne, VIC, Australia

John M. Craig, MD
Clinical Assistant Professor of Surgery
University of Tennessee Health Science Center
Baptist Memorial Hospital
Memphis, TN, USA

Josep M. Cruzado
Renal Transplant Unit
Nephrology department.
University Hospital of Bellvitge
University of Barcelona
Barcelona, Spain

Marcelo Cypel, MD, MSc
Assistant Professor of Surgery
Toronto Lung Transplant Program
University Health Network
University of Toronto
Toronto, ON, Canada

Anthony M. D'Alessandro, MD
Professor of Surgery
Director of Liver Transplantation
University of Wisconsin School of Medicine and Public Health
Madison, WI, USA

Gabriel M. Danovitch, MD
Professor of Medicine, Division of Nephrology
Medical Director, Kidney Transplant Program
Department of Medicine
David Geffen School of Medicine at UCLA
Los Angeles, CA, USA

Anthony J.F. d'Apice, MD, MBBS
Professor
Immunology Research Centre
St Vincent's Hospital Melbourne;
Department of Medicine
University of Melbourne
Melbourne, VIC, Australia

R. Duane Davis, MD, MBA
Director of Transplantation
Professor of Surgery
Duke University Medical School and Medical Center
Durham, NC, USA

John M. Davison, MD
Professor Emeritus and Consultant Obstetrician
Institute of Cellular Medicine
Newcastle University
Newcastle upon Tyne, UK

Rowena Delos Santos, MD
Assistant Professor of Medicine
Renal Division
Washington University in St. Louis
St. Louis, MO, USA

Sacha A. De Serres, MD, SM, FRCPC
Research Fellow, Brigham and Women's Hospital and Harvard Medical School
Boston, MA;
Assistant Professor of Medicine
Universite Laval
Quebec, QC, Canada

Patrick G. Dean, MD
Assistant Professor of Surgery
Division of Transplant Surgery
Mayo Clinic
Rochester, MN, USA

Francis L. Delmonico, MD
President, The Transplantation Society;
World Health Organization
Advisory for Human Transplantation;
Professor of Surgery
Harvard Medical School
Massachusetts General Hospital
Transplant Center
Boston, MA;
Medical Director
New England Organ Bank
Waltham, MA, USA

Anthony J. Demetris, MD
Starzl Professor of Liver and Transplant Pathology
Director, Division of Liver and Transplant Pathology
Department of Pathology
University of Pittsburgh Medical Center
Pittsburgh, PA, USA

Yaozhong Ding, PhD
Associate Professor (retired)
Department of Surgery
University of Maryland School of Medicine
Baltimore, MD, USA

Cinthia B. Drachenberg, MD
Professor of Pathology
Director, Electron Microscopy Laboratory
University of Maryland School of Medicine
Baltimore, MD, USA

Regina Eady
Research Data Informatics Analyst, Senior
Emory University
Atlanta, GA, USA

Bijan Eghtesad, MD
Professor of Surgery
Director, Fellowship Program
Hepato-Pancreato-Biliary/Liver Transplantation Surgery
Cleveland Clinic
Cleveland, OH, USA

Howard J. Eisen, MD
Thomas J. Vischer Professor of Medicine
Chief, Division of Cardiology
Drexel University College of Medicine
Philadelphia, PA, USA

Robert Ettenger, MD
Professor of Pediatrics
Division of Nephrology
Department of Pediatrics
David Geffen School of Medicine at UCLA;
Director of Pediatric Renal Transplant Program
Director, Pediatric Nephrology Fellowship Program
Mattel Children's Hospital, UCLA
Los Angeles, CA, USA

Richard Eliot Fagley, MD
Anesthesiologist and Intensivist
Virginia Mason Medical Center
Seattle, WA, USA

Robert L. Fairchild, PhD
Staff, Department of Immunology
Cleveland Clinic
Cleveland, OH, USA

Konrad S. Famulski, PhD, DSc
Faculty Service Officer
Manager and Lead in Transcriptomics
Alberta Transplant Applied Genomics Centre
Department of Medicine
Division of Nephrology and Transplant Immunology
Edmonton, AB, Canada

Ji Fan, MD
Instructor of Clinical Surgery
University of Miami Miller School of Medicine
Miami Transplant Institute
Miami, FL, USA

Myriam Farah, MD, FRCPC
Clinical Assistant Professor
Division of Nephrology
University of British Columbia
Vancouver, BC, Canada

Douglas G. Farmer, MD
Professor of Surgery
Director, Intestinal Transplant Program
Surgical Director, Pediatric Liver Transplant Program
Dumont-UCLA Transplant Center
David Geffen School of Medicine at UCLA
Los Angeles, CA, USA

Albert Faro, MD
Associate Professor of Pediatrics
Division of Pediatric Allergy, Immunology and Pulmonary Medicine
Washington University School of Medicine
St. Louis, MO, USA

Alton Brad Farris III, MD
Assistant Professor
Director, Laboratory of Nephropathology and Electron Microscopy
Emory University
Atlanta, GA, USA

Carol Farver, MD, MS
Section Head, Surgical Pathology
Director, Pulmonary Pathology
Pathology and Laboratory Medicine Institute
Cleveland Clinic
Cleveland, OH, USA

Sandy Feng, MD, PhD
Professor of Surgery
Division of Transplant Surgery
University of California, San Francisco
San Francisco, CA, USA

Thomas Fishbein, MD
Executive Director, Georgetown Transplant Institute
Professor of Surgery
Georgetown University School of Medicine
Washington DC, USA

Jay A. Fishman, MD
Associate Director
MGH Transplantation Center;
Director, Transplant Infectious Disease & Compromised Host Program
Massachusetts General Hospital;
Professor of Medicine
Harvard Medical School
Boston, MA, USA

Rachel C. Forbes, MD, MBA
Assistant Professor of Surgery
Division of Kidney and Pancreas Transplantation
Department of Surgery
Vanderbilt University
Nashville, TN, USA

Mandy L. Ford, PhD
Assistant Professor
Emory Transplant Center
Department of Surgery
Emory University
Atlanta, GA, USA

Richard N. Formica Jr, MD
Associate Professor of Medicine and Surgery
Director, Transplant Nephrology
Medical Director of Adult and Pediatric Kidney Transplantation
Medical Director of Pancreas Transplantation
Yale University School of Medicine
New Haven, CT, USA

O.H. Frazier, MD
Chief, Transplant Services
Chief, Center for Cardiac Support
Director, Cullen Cardiovascular Research Laboratory
Texas Heart Institute
Houston, TX, USA

Richard Freeman, MD
Professor of Surgery
Dartmouth Hitchcock Medical Center
Lebanon, NH, USA

Alessandrina M. Freitas, MD, MPH
Resident in General Surgery
Department of Surgery
Emory University School of Medicine
Research Fellow
Vascularized Composite Allotransplantation
Emory Transplant Center
Atlanta, GA, USA

John Fung, MD, PhD
Professor of Surgery
Cleveland Clinic Lerner College of Medicine
Case Western Reserve University;
Chairman of Digestive Disease Institute
Cleveland Clinic
Cleveland, OH, USA

Jennifer Garcia, MD
Assistant Professor of Clinical Pediatrics
Division of Gastroenterology, Hepatology, and Nutrition
University of Miami Miller School of Medicine
Miami Transplant Institute
Miami, FL, USA

Sireesha Garikipati, MD
Fellow in Cardiology
University of Texas Medical Branch
Galveston, TX, USA

Edward R. Garrity Jr, MD, MBA
Professor of Medicine
Vice Chair for Clinical Operations
The University of Chicago Medical Center
Chicago, IL, USA

Robert S. Gaston, MD
Co-Director, Comprehensive Transplant Institute
Robert G. Luke Endowed Chair in Transplant Nephrology
University of Alabama at Birmingham
Birmingham, AL, USA

Howard M. Gebel, PhD
Professor of Pathology
Co-Director, Histocompatibility and Molecular Immunogenetics Laboratory
Department of Pathology
Emory University Hospital
Atlanta, GA, USA

Donna George, MS, RN, NEA-BC
Transplant Administrator & Nursing Director
The Hume-Lee Transplant Center
Virginia Commonwealth University Health System
Medical College of Virginia Hospitals
Richmond, VA, USA

John S. Gill, MD, MS, FRCP(C)
Associate Professor, Nephrology
Division of Nephrology
University of British Columbia
St. Paul's Hospital
Vancouver, BC, Canada

Alexandra K. Glazier, JD, MPH
Chair, UNOS Ethics Committee;
Vice-President and General Counsel
New England Organ Bank
Waltham, MA, USA

Denis Glotz
Department of Nephrology and Kidney Transplantation and Research Unit INSERM U940
Hopital Saint Louis
Paris, France

Veronica Gomez-Lobo, MD
Director of Pediatric and Adolescent Obstetrics and Gynecology
MedStar Washington Hospital Center and Children's National Medical Center
Professor of Clinical Obstetrics and Gynecology
Department of Pediatrics, Georgetown University
Washington, DC, USA

Jeremy Goodman, MD, FACS
Assistant Professor of Surgery
Division of Transplant Surgery
University of Alabama at Birmingham
Birmingham, AL, USA

Chad R. Gordon, DO
Assistant Professor of Surgery
Department of Plastic and Reconstructive Surgery
Johns Hopkins University School of Medicine
Baltimore, MD, USA

Michael Green, MD, MPH
Professor of Pediatrics, Surgery and Clinical and Translational Science
University of Pittsburgh School of Medicine
Division of Infectious Diseases
Children's Hospital of Pittsburgh
Pittsburgh, PA, USA

Bartley P. Griffith, MD
Thomas E. and Alice Marie Hales Distinguished Professor in Transplantation
University of Maryland School of Medicine
Division of Cardiac Surgery
Baltimore, MD, USA

Tracy C. Grikscheit, MD, FACS
Assistant Professor of Surgery
Children's Hospital Los Angeles
Division of Pediatric Surgery
Keck University of Southern California School of Medicine
Los Angeles, CA, USA

Josep M. Grinyó, MD
Chief of Nephrology
University Hospital of Bellvitge
University of Barcelona
Barcelona, Spain

Lakshman Gunaratnam
Assistant Professor of Medicine, Microbiology & Immunology
University of Western Ontario
London, ON, Canada

Susan Gunderson, BSN, MHA
Chief Executive Officer
LifeSource
St. Paul, MN, USA

Divya Gupta, MD
Assistant Professor of Medicine
Division of Cardiology
Advanced Heart Failure and Transplant
Emory University School of Medicine
Atlanta, GA, USA

Philip F. Halloran, MD, PhD
Director
Alberta Transplant Applied Genomics Centre
University of Alberta
Edmonton, AB, Canada

Jenny E. Han
Assistant Professor, Division of Pulmonary and Critical Care Medicine
Department of Medicine
Emory University School of Medicine
Atlanta, GA, USA

Steven I. Hanish, MD
Assistant Professor of Surgery
Emory University School of Medicine
Atlanta, GA, USA

Douglas W. Hanto, MD, PhD
Associate Dean for Continuing Medical Education
Continuing Medical Education Office
Professor of Surgery
Washington University School of Medicine in St. Louis
St. Louis, MO, USA

Karen L. Hardinger, PharmD, BCPS
Clinical Professor of Pharmacy Practice
University of Missouri – Kansas City
School of Pharmacy
Kansas City, MO, USA

William Harmon, MD
Professor of Pediatrics
Harvard Medical School;
Pediatric Nephrology
President, Physicians' Organization
Boston Children's Hospital
Boston, MA, USA

Matt Hartwig, MD
Assistant Professor of Surgery
Duke University
Durham, NC, USA

Koji Hashimoto, MD, PhD
Assistant Professor of Surgery
Cleveland Clinic Lerner College of Medicine
Case Western Reserve University;
Digestive Disease Institute
Cleveland Clinic
Cleveland, OH, USA

Peggy B. Hasley, MD, MHSc
Associate Professor of Internal Medicine
Associate Program Director for Ambulatory Medicine
Director, Generalist Track
University of Pittsburgh Medical Center
Pittsburgh, PA, USA

Steven Head, MS
Director
Microarray and Next Generation Sequencing Core Laboratories
The Scripps Research Institute
La Jolla, CA, USA

Timm Heinbokel
Division of Transplant Surgery and Transplant Surgery Research Laboratory
Brigham and Women's Hospital
Harvard Medical School, Boston, MA;
Institute of Medical Immunology
Charité – Universitätsmedizin Berlin
Berlin, Germany

Peter Heining, PhD
Senior Toxicologist
Novartis Pharmaceuticals Corporation
East Hanover, NJ, USA

Lorna K. Henderson, MBChB, MRCP, PhD
Transplant Fellow
National Pancreas Transplant Unit
University of Sydney at Westmead Hospital
Westmead, NSW, Australia

Mitchell L. Henry, MD
Professor of Surgery
Chief, Division of Transplantation
Department of Surgery
The Ohio State University
Columbus, OH, USA

Joanna Hester, PhD
Senior Scientist
Transplantation Research Immunology Group
Nuffield Department of Surgical Sciences
John Radcliffe Hospital
Oxford, UK

J. Mark Hexham, PhD, MSc
Clinical Research Director
Novartis Pharmaceuticals Corporation
East Hanover, NJ, USA

Naim Issa, MD
Assistant Professor of Medicine
Transplant Nephrologist
Division of Renal Diseases and Hypertension
Department of Medicine
University of Minnesota
Minneapolis, MN, USA

Pamala A. Jacobson, PharmD
Associate Professor
University of Minnesota, College of Pharmacy
Minneapolis, MN, USA

Anthony M. Jevnikar, MD, MSc
Professor of Medicine, Surgery, Microbiology & Immunology
Co-Director Multi Organ Transplant Program
University of Western Ontario
London, ON, Canada

Maryl R. Johnson, MD
Professor of Medicine
Medical Director, Heart Failure and Transplantation
University of Wisconsin School of Medicine and Public Health
Madison, WI, USA

Guido Junge, MD, MBA
Vice President and Global Therapeutic Area Head
Infectious Disease and Transplantation
Novartis Pharma AG
Basel, Switzerland

Elizabeth A. Kallenborn, MSN, RN, CCTC
Clinical Manager
Liver Transplant and Hepatology
Thomas E. Starzl Transplantation Institute
University of Pittsburgh Medical Center
Pittsburgh, PA, USA

Bruce Kaplan, MD
Professor of Medicine, Microbiology, Molecular Genetics and Immunology
University of Kansas Medical Center
Kansas, MO, USA;
Adjunct Professor of Medicine
Alberta Applied Genomics and Transplant Center
University of Alberta, Canada

Dixon B. Kaufman, MD, PhD
Ray Owen Professor and Chair
Division of Transplantation
University of Wisconsin School of Medicine and Public Health
Madison, WI, USA

Daniel Kaul, MD
Associate Professor of Medicine
Director, Transplant Infectious Diseases
Division of Infectious Disease
University of Michigan School of Medicine
Ann Arbor, MI, USA

Tatsuo Kawai, MD, PhD
Associate Professor of Surgery
Harvard Medical School
A. Benedict Cosimi Endowed Chair in Transplant Surgery
Massachusetts General Hospital
Boston MA, USA

Marwan Kazimi, MD
Director
Multivisceral and Intestinal Transplantation Program
Division of Transplant Surgery
Transplant Institute
Henry Ford Hospital
Detroit, MI, USA

Desmond Barry Keenan, PhD, MBA
Research Director and Technical Fellow
Closed Loop Development
Medtronic Diabetes
Northridge, CA, USA

Shaf Keshavjee, MD, MSc, FRCSC, FACS
Surgeon-in-Chief, University Health Network
Professor, Division of Thoracic Surgery
Director, Toronto Lung Transplant Program
University of Toronto
Toronto, ON, Canada

Zain Khalpey, MD, PhD, MRCS(Eng)
Surgical Director of Heart Transplant and Mechanical Circulatory Support
Distinguished Tony Marnell Chair in Cardiothoracic Surgery
Surgical Director of Regenerative Medicine
Associate Professor of Surgery
Physiological Sciences & Biomedical Engineering
University of Arizona
Tucson, AZ, USA

Michael S. Kiernan, MD, MS
Assistant Professor of Medicine
Medical Director, Ventricular Assist Device Program
Tufts University School of Medicine
Boston, MA, USA

S. Joseph Kim
Division of Nephrology
Toronto General Hospital;
University Health Network and the Institute for Health Policy, Management and Evaluation
Faculty of Medicine
University of Toronto
Toronto, ON, Canada

Allan D. Kirk, MD, PhD, FACS
Professor and Chairman, Department of Surgery
Duke University School of Medicine;
Surgeon-in-Chief for Duke University Health System
Duke University Medical Center
Durham, NC, USA

Michelle M. Kittleson, MD, PhD
Assistant Clinical Professor of Medicine, UCLA
Director, Heart Failure Research
Director, Post-Graduate Education in Heart Failure and Transplantation
Cedars-Sinai Heart Institute
Los Angeles, CA, USA

Andrew Klein, MD, MBA, FACS
Director, Comprehensive Transplant Center
Esther and Mark Schulman Chair of Surgery and Transplant Medicine
Professor and Vice Chair
Department of Surgery
Cedars-Sinai Medical Center
Los Angeles, CA, USA

Christina L.M. Klein, MD
Assistant Professor of Medicine
Medical Director, Pancreas Transplant
Director, High Risk Kidney Transplant
Washington University in St. Louis
St. Louis, MO, USA

Stuart J. Knechtle, MD
Professor of Surgery
Emory University School of Medicine
Atlanta, GA, USA

Jon A. Kobashigawa, MD
DSL/Thomas D. Gordon Chair in Heart Transplantation Medicine
Director, Advanced Heart Disease Section
Director, Heart Transplant Program
Cedars-Sinai Heart Institute
Los Angeles, CA, USA

Chatchai Kreepala, MD
Clinical and Research Fellow
Alberta Transplant Applied Genomics Centre
Department of Medicine
Division of Nephrology and Transplant Immunology
University of Alberta
Edmonton, AB, Canada

Jill C. Krisl, PharmD
Transplant Pharmacy Fellow
Department of Surgery
Division of Transplantation
University of Cincinnati
Academic Health Center
Cincinnati, OH, USA

Aleksandra Kukla, MD
Assistant Professor of Medicine
Transplant Nephrologist;
Medical Director of Pancreas Transpant Program
Division of Renal Diseases and Hypertension
Department of Medicine
University of Minnesota
Minneapolis, MN, USA

Sunil M. Kurian, PhD
Staff Scientist
Laboratory of Functional Genomics
Department of Molecular and Experimental Medicine
The Scripps Research Institute
La Jolla, CA, USA

Keren Ladin, PhD, MSc
Director
Research on Ethics, Aging, and Community Health
Tufts University;
Assistant Professor
Department of Occupational Therapy
Tufts University
Medford, MA;
Department of Public Health and Community Medicine
Tufts University School of Medicine
Boston, MA, USA

Alan Langnas
Chief, Section of Transplant Surgery
University of Nebraska Medical Center
Omaha, NE, USA

Dianne LaPointe Rudow, ANP-BC, DNP, CCTC
Associate Professor
Department of Health Evidence and Policy
Director, Zweig Family Center for Living Donation
Medical Director of Liver and Kidney Donor Program
Recanati/Miller Transplant Institute
The Mount Sinai Medical Center
New York, NY, USA

Christian P. Larsen, MD, DPhil
Dean – Emory School of Medicine
Surgeon-in-Chief Emory Healthcare
Emory University
Atlanta, GA, USA

E. Clinton Lawrence, MD
Director, Andrew J. McKelvey Lung Transplant Center
Emory Transplant Center
Emory University Hospital;
Augustus J. McKelvey Professor of Lung Transplantation Medicine
Emory University School of Medicine
Department of Medicine
Division of Pulmonary, Allergy and Critical Care Medicine
Emory University
Atlanta, GA, USA

Daniel J. Lebovitz, MD
Associate Director, Critical Care
Akron Children's Hospital
Akron, OH;
Director, PICU
MetroHealth Medical Center
Cleveland OH;
Medical Director
Lifebanc
Cleveland, OH, USA

Sung-Gyu Lee
Professor of Surgery
Hepato-Biliary Surgery and Liver Transplantation
Department of Surgery
Asan Medical Center
University of Ulsan College of Medicine
Seoul, Korea

W.P. Andrew Lee, MD
The Milton T Edgerton, MD, Professor and Chairman
Department of Plastic and Reconstructive Surgery
Johns Hopkins University School of Medicine
Baltimore, MD, USA

Soyoung Lee, MD
Research Fellow
Massachusetts General Hospital
Boston, MA, USA

Jason R. Lees, PhD
Assistant Professor
Department of Microbiology and Immunology
Uniformed Services of Health Sciences
Bethesda, MD, USA

Carmen Lefaucheur
Department of Nephrology and Kidney Transplantation and Research Unit INSERM U940
Hopital Saint Louis
Paris, France

Henri G.D. Leuvenink, PhD
Associate Professor
Principle Investigator, Experimental Transplantation
Surgical Research Laboratory
Department of Surgery
University Medical Center Groningen
Groningen, The Netherlands

Matthew H. Levine, MD, PhD
Assistant Professor of Surgery
Division of Transplant Surgery
Perelman School of Medicine
University of Pennsylvania
Philadelphia, PA, USA

Xian C. Li, MD, PhD, ASCI
Director
Immunobiology & Transplantation Research
Houston Methodist Hospital
Texas Medical Center
Houston, Texas

Sundus A. Lodhi, MD,
Assistant Professor
Transplant Nephrology
Emory University
Atlanta, GA, USA

Marc I. Lorber, MD
Sr. Vice President and Chief Medical Officer
XenoLung Clinical Development
Lung Biotechnology, Inc
United Therapeutics Corporation
Silver Spring, MD, USA

Richard S. Luskin, MPA
President and CEO
New England Organ Bank
Waltham, MA, USA

G. Marshall Lyon, MD, MMSc
Associate Professor of Medicine
Director of Transplant Infectious Disease
Emory University School of Medicine
Atlanta, GA, USA

Joren C. Madsen, MD, DPhil
Professor of Surgery
W. Gerald and Patricia R. Austen
Distinguished Scholar in Cardiac Surgery
Massachusetts General Hospital
Boston, MA, USA

Joseph F. Magliocca, MD
Assistant Professor of Surgery
Emory University School of Medicine
Atlanta, GA, USA

Sayeed Malek, MD
Clinical Director, Division of Transplant Surgery
Brigham and Women's Hospital
Harvard Medical School
Boston, MA, USA

Roslyn B. Mannon, MD
Professor of Medicine and Surgery
University of Alabama at Birmingham
Birmingham, AL, USA

James F. Markmann, MD, PhD
Professor of Surgery
Harvard Medical School;
Chief, Division of Transplantation
Massachusetts General Hospital
Boston, MA, USA

Benjamin M. Martin, MD
Senior Resident, Department of Surgery
Emory University School of Medicine
Atlanta, GA, USA

Paulo Martins, MD, PhD
Instructor, Harvard Medical School
Clinical Fellow, Massachusetts General Hospital
Boston, MA, USA

Allan B. Massie, PhD
Department of Surgery
Johns Hopkins School of Medicine
Baltimore, MD, USA

Virginia A. McBride, RN, MPH
President
AMVAT Consulting
Grand Junction, CO, USA

Kenneth R. McCurry, MD
Staff Surgeon
CCF
Cleveland Clinic
Cleveland, OH, USA

Gwen McNatt, MS, RN, CNN, FNP-BC
Director, Operations
Kovler Organ Transplantation Center and Infectious Disease
Northwestern Memorial Hospital
Chicago, IL, USA

Mandeep R. Mehra, MD
Brigham and Women's Hospital
Harvard Medical School
Boston, MA, USA

Aneesh K. Mehta, MD
Assistant Professor of Medicine
Assistant Director of Transplant Infectious Diseases
Emory University School of Medicine
Atlanta, GA, USA

Edward A. Meister, PhD
College of Medicine
Division of Nephrology
University of Arizona
Tucson, AZ, USA

Michael H. Mengel, MD
Associate Professor
University of Alberta
Edmonton, AB, Canada

Diana Metes, MD
Associate Professor of Surgery and Immunology
Starzl Transplantation Institute
Department of Surgery and Department of Immunology
University of Pittsburgh School of Medicine
Pittsburgh, PA, USA

Charles M. Miller, MD
Professor of Surgery
Cleveland Clinic Lerner College of Medicine
Case Western Reserve University;
Director, Liver Transplant Program
Digestive Disease Institute
Cleveland Clinic
Cleveland, OH, USA

Marta I. Minervini, MD
Assistant Professor of Pathology
Department of Pathology
University of Pittsburgh Medical Center
Pittsburgh, PA, USA

Saeed Mohammad, MD, MS
Assistant Professor
Department of Pediatrics
Northwestern University Feinberg School of Medicine
Ann and Robert H. Lurie Children's Hospital of Chicago
Chicago, IL, USA

Deok-Bog Moon
Professor of Surgery
Hepato-Biliary Surgery and Liver Transplantation
Department of Surgery
Asan Medical Center
University of Ulsan College of Medicine
Seoul, Korea

Christian Morath, MD
Department of Medicine
Division of Nephrology and Hypertension
University of Heidelberg
Heidelberg, Germany

Michael J. Moritz, MD
Chief, Transplant Services
Lehigh Valley Health Network
Allentown, PA;
Professor of Surgery
University of South Florida
Morsani College of Medicine
Tampa, FL, USA

Tim Morris
Director, Research Informatics
Research and Woodruff Health Sciences IT
Emory University
Atlanta, GA, USA

Cathi L. Murphey, PhD
Director, Histocompatibility and Immunogenetics Laboratory
Southwest Immunodiagnostics, Inc.
San Antonio, TX, USA

Michael A. Nalesnik, MD
Professor of Pathology
Department of Pathology
University of Pittsburgh Medical Center
Pittsburgh, PA, USA

Jung-Man Namgoong
Clinical Instructor of Surgery
Hepato-Biliary Surgery and Liver Transplantation
Department of Surgery
Asan Medical Center
University of Ulsan College of Medicine
Seoul, Korea

Brian J. Nankivell, MD, PhD, FRACP
Transplant Physician
Department of Renal Medicine
Westmead Hospital
Sydney, NSW, Australia

Peter Neuhaus, MD, PhD
Chairman of General, Visceral, and Transplantation Surgery
Experimental Surgery and Regenerative Medicine
Charité – Campus Virchow, Universitätsmedizin Berlin
Berlin, Germany

David C. Neujahr, MD
Medical Director
Andrew McKelvey Adult Lung Transplant Program
Emory University Transplant Center
Assistant Professor of Medicine, Pulmonary, Allergy and Critical Care
Emory University School of Medicine
Atlanta, GA, USA

Kenneth A. Newell, MD, PhD
Professor of Surgery
Emory Transplant Center
Emory University School of Medicine
Atlanta, GA, USA

Silke Niederhaus, MD
Assistant Professor of Surgery
University of Maryland Medical System
Division of Transplantation
Baltimore, MD, USA

Seigo Nishida, MD
Department of Surgery, Division of Transplantation
University of Miami
Miami, FL, USA

Douglas J. Norman, MD
Professor of Medicine
Director, Transplant Medicine
Director, Laboratory of Immunogenetics and Transplantation
Oregon Health & Science University
Portland, OR, USA

Rupert Oberhuber, MD

SECTION 1

History/Introduction

Introduction

Allan D. Kirk
Duke University Medical Center, Durham, NC, USA

To understand organ transplantation is to understand all of modern medicine, and to practice organ transplantation is to comprehend the fundamental challenges of advanced healthcare delivery in general.

Although these introductory statements are biased by a lifetime of study and admiration of this field, they are not wholly derived of hyperbole. Indeed, when considered objectively, there are few serious students of medicine that would argue the principles they espouse.

Consider the most fundamental diagnosis of medicine: alive or dead. The objective determination of death has been conceived in large part in pursuit of ethical grounds for organ donation; the concepts of brain death are unarguably intertwined with clinical organ donation, and the transplant clinician must understand this most critical of states as much as anyone in any field. Similarly, beyond knowing what constitutes a living individual, the transplant professional is continuously defining where the individual resides by objectively demonstrating that most of *what* we are exists as parts in support of *who* we are. From a utilitarian standpoint, the vast majority of a person is replaceable! This concept is experienced in transplantation as a matter of fact, and the transplant professional's proximity to it provides a unique vantage point relative to other specialties. At a more granular level, the transplanter (a term used to avoid distinguishing between scientists, surgeons, non-surgeons, and the numerous combinations thereof ubiquitous in the field of transplantation) uses biological definitions of individuality, namely molecular histocompatibility, as a daily tool of the trade. This fundamental biological characteristic has arisen through the study of transplantation and is as central to transplantation as brain death is to organ donation. From these high level examples, it is clear that the practicing transplanter more regularly deals in rather heady biological concepts than many other professions. That same characteristic applies to the most difficult of ethical concepts, as transplanters, more than any other specialists, must grapple daily with very practical applications of beneficence, justice, and utility.

Beyond the high-level concepts discussed above, the delivery of transplantation has emerged in such a way as to solidify its location in the core of the day-to-day details of medical practice. The nature of transplantation has always been to treat those with end stage illness, and while the etiology of the disease in question may be organ system specific, the consequences of any organ disease requiring transplantation become systemic in end stage. As such, transplanters have always had to treat the entire patient simply as a matter of practicality. The patient in fulminant hepatic failure not infrequently has critical brain, cardiopulmonary and renal dysfunction, as well. While these resolve when the underlying liver failure is reversed (in a way so dramatic as to have been unimaginable before the advent of liver transplantation), the transplanter must understand these systems exceptionally well just to get the patient to the operation; he or she cannot be overly focused on an organ of choice. Similarly, given the complexity of post-transplant immunomodulatory management, the transplanter's need to maintain a role in primary care and rehabilitation eclipses that of most subspecialties. As the need to stay involved for immune management has combined with improving life spans of transplant recipients, the understanding of long-term health maintenance required of the transplanter far exceeds that required of any other subspecialist. The transplant surgeon knows far more about medical management of diabetes and hypertension than the general surgeon, and the transplant physician understands surgical complications and wound healing much better than their non-transplant counterparts. Additionally, patients with transplants get the same diseases as patients without transplants, and thus, any illness arising in a transplant recipient will (or at least should) involve a transplanter at some level. A reciprocal effect of the growth and success of transplantation has impelled transplantation to be a core aspect of almost all subspecialties. One cannot consider himself or herself a fully trained cardiologist, endocrinologist, gastroenterologist, intensivist, hepatologist, nephrologist, pediatrician, pulmonologist, or surgeon without at least rudimentary knowledge of transplantation.

Transplant pharmacology similarly has driven pharmacology in general. The concept of therapeutic immune suppression derives from transplant applications and the first clinically approved monoclonal antibody (muromonab) and engineered biologic (daclizumab) were introduced in transplantation. As transplant pharmacology is with rare exception, poly-pharmacy, the role of the clinical pharmacist has been a long-standing feature of transplant care delivery, a model that many other areas have since adopted.

The means by which transplantation has been practiced is turning out to be prophetic for healthcare's ongoing evolution. Transplantation has always been a multidisciplinary craft, as evidenced by the inclusive nature of the depiction of the first successful transplant (see Figure 1.5, Chapter 1). From the start of the field, surgeon and non-surgeon physicians, nurses, allied health professionals, and basic scientists have mingled with a symbiotic fluidity that has typically exceeded that in other fields of medicine. Transplantation has not *become* a team sport, it *always has been* a team

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

sport, and as such has stood as a tested example of the way forward for healthcare delivery. At a higher hierarchical level, transplantation has long ago adopted means of healthcare delivery that are just now emerging as vogue: elements of accountable care networks, capitated payment plans, pay for performance agreements, public/private partnerships, and rationing algorithms have been in place for transplantation for decades, and again, other fields of medicine can look to transplantation as a source for data on how these health services models are likely to perform.

In a similar vein, transplantation has led the way in terms of keeping track of outcomes on a local and national level, using these data to provide objective means of charting the future. The limited availability of donors and the life-or-death nature of the diseases treated, no doubt, have stimulated the desire to measure and improve the field. While other fields may have differences in the degree of these basic restraints (scarcity and severity) at some level they are applicable, and the model of transplant clinical databases has much to teach other areas of medicine. Transplantation has been aggressive in reporting its complications, and this has led to fundamental revelations in the biology of cancer, infectious diseases, metabolic syndrome, and numerous conditions. Basic physiology has also derived incalculably from the natural experiment of organ replacement.

With all this said, the breadth and depth of content implied by a textbook aiming to cover organ transplantation as a whole might be considered daunting. However, it is no more so than the challenges routinely faced in our field: replacing one person's heart with that of another, operating within the Venn diagrams of allo- and protective immunity, ethically allocating scarce donor organs, paying for it all . . .

Thus, this textbook has been created with the opening sweeping statements at its heart. It is not meant to cover everything to its maximal depth (there are texts dedicated exclusively to each of most of the topics covered in this text), but rather is designed to provide a reasonable introduction to most of what transplanter's do. It is arranged with topics presented in an order that a clinician might encounter them. Basic concepts are presented first, moving from requisite historical and general scientific concepts to transplant-specific biology and the fundamental principles of alloimmunity and immune modulation. Beginning, as do all transplants, with donor considerations, the clinical sections of the text then proceed through pre-operative, operative, and post-operative topics. Each of these sections contain chapters specific to the major organ systems presented in order of clinical volume: kidney, liver, heart, lung, pancreas and islet, intestinal and multivisceral, and in selected areas, vascularized composite transplantation. Within the pre-operative section, specific chapters related to the complex management of critically ill patients with end stage organ disease are presented, including intensive care and artificial life support devices. A technique for each major operation is presented in the operative section, acknowledging that there are numerous ways to do everything. The goal is to provide the fundamental starting point for the surgeon, and a reasonable idea of the scope of a procedure for the non-surgeon. The postoperative section includes organ specific post-transplant management, including acute and chronic management issues, as well as substantial attention to immune management and its consequences, particularly infectious and malignant complications. Rejection, being a central diagnosis driving much of a patient's post-operative care, is presented in two ways: from its organ-specific histopathological definition, and from an organ-specific clinical management vantage. The postoperative section ends with current accountings of long-term outcomes for each transplanted organ type.

We have chosen to provide a specific section dedicated to pediatric transplantation. While much of the biology and conduct mirrors that of adult transplantation, there are numerous areas, particularly related to indications, technical nuances and complications that clearly are unique to children. Indeed, the pediatrician will find the pediatric section to be a very satisfactory primer for transplantation in children in and of itself, complete with its own introductory comments.

As discussed above, the infrastructure and organizational requirements, ethical principles, and administrative guidelines for transplantation are exceptional examples of similar issues now facing the healthcare community at large. As such, the Textbook closes with sections dealing with these issues, both to provide the student of transplantation with transplant-specific knowledge of "how things get done", and to provide the general student of an example of how they might be done in other fields.

The overall goal of this textbook is to bring together a reasonable representation of modern transplantation in all its complexity into a single place. It is anticipated that there are several settings in which such a reference work will be useful. For the graduate or medical student, resident, or allied health trainee, this will serve as a centralized touchstone to help them orient their thoughts and prepare for rotations in transplantation. For non-transplant professions whose practice involves the care of patients awaiting or following a transplant, such as cardiologists, endocrinologists, gastroenterologists, hepatologists, nephrologists and pulmonologists, this will provide sufficient information to help in following patients and understanding when referral is prudent. Indeed, there are two chapters specifically directed toward the concerns of the community physician. For the established transplanter, the knowledge here will be useful when considering aspects of transplantation not typically encountered: for example information about heart transplantation for a kidney transplanter; clinical information for the basic scientist (or vice versa); or background information about a topic to aid in the interpretation of an article in the primary literature. Finally, for the transplant unit or hospital administrator, the content herein will provide substantial subject matter information helpful in organizing and staffing transplant cost centers, and understanding the contribution margins and risks derived from clinical transplant practices.

This first edition has emerged slowly, hindered somewhat by the substantial inertia of its scope. At some point, completeness has given way to practicality, and it is hoped that this same property will aid in its continuation–it is not, and may never be, "done". As the Textbook will be published in an electronic format, it will allow for continuous updates, and it is planned that approximately 10% of the content will be updated annually, making this a perpetually current resource. It will not replace the primary literature, but will be a constant source of information on which to base readings from the primary literature. Future enhancements linking the Textbook directly to the primary literature, particularly journals published by Wiley-Blackwell, are underway, and should provide a new paradigm for textbook utility.

CHAPTER 1

A Brief History of Clinical Organ Transplantation

Sir Roy Y. Calne
Professor Emeritus, Cambridge University, Cambridge, UK

Introduction

Transplantation is one of the most visible and influential medical accomplishments of the twentieth century. Arising from technical advances and insights of the early twentieth century, the concept that transplantation was technically feasible gave rise to earnest investigations into its physiological barriers by a small number of visionary investigators driven by recognized clinical problems. From their descriptions of the genetic and immunological basis for graft rejection and the pioneering work of the first transplant surgeons, the clinical practice of transplantation rapidly became interwoven into the fabric of clinical care, not only from a practical standpoint but also as an example of the immense possibilities and challenges inherent in advanced medical practice. Multiple concepts now taken for granted in modern medical practice, such as immunosuppression, monoclonal antibody use, and indeed the concept of death as a definable state, have their origins in transplantation. Numerous modern ethical quandaries also trace their roots to problems introduced by transplantation.

The history of transplantation has been the subject of numerous books, and while its in-depth treatment is not practical in this text, it is important to make evident the major contributions that brought the field to where it stands currently: a prime example of the power of science and medicine combined for a common good. This chapter will provide the reader with a reasonable orientation to the history of the field, referring to more definitive works when necessary and to other chapters in this text. In doing so it will serve as an important introduction to the subject of organ transplantation in general. Throughout this textbook, more specific historical references will be introduced in individual chapters.

The concept of transplant surgery

The idea of organ transplantation is a surgical concept based on an understanding of anatomy and the physiological requirements of an organ to stay viable and fulfil its biological role. Its origins relate to intuitive concepts of like replacing like that date back hundreds of years, including the oft cited Catholic miracle of Cosmos and Damian. However, its serious pursuit arose independently from work conducted in a number of European countries in the early twentieth century, the products of which led to the kidney as the chief candidate for speculations on organ transplantation. Kidney failure was a relatively common fatal condition, the physiological role of the kidney was understood and the kidneys were well defined anatomically. Importantly, it was recognized that one well-functioning organ was sufficient to maintain an individual in good health for a normal lifespan. The kidney's essential anatomical connections, namely a single artery and vein and a urinary drainage vessel, were apparently sufficient for it to perform its physiological role. Nerves, lymphatic and fascial connections, although important, did not seem to be essential. At the beginning of the twentieth century, Alexis Carrel (Figure 1.1) devised a method of joining blood vessels together surgically [1], a technique that became the subject of his 1912 Nobel Prize in Physiology or Medicine. Carrel himself used this technique to show that a kidney could be removed and transplanted and would function after restoration of the arterial in-flow and venous out-flow, provided these surgical procedures were undertaken expeditiously, since a prolonged period without a blood circulation led to irreversible damage from ischaemia.

In cats and dogs Carrel and Guthrie proved the technical feasibility of the operation and also observed that moving a kidney from an animal to another site in the same animal could result in long-term survival of the kidney and the animal after removal of the opposite kidney [2]. However, transplanting a kidney from one individual to another, after a short period of satisfactory kidney function, was soon doomed to failure. Carrel recorded this observation, but at that time there was no explanation for the fairly rapid failure of what are now called renal allografts [3]. Priority for the transplantation of a kidney in a human patient has been claimed and disputed by a number of surgeons and their historians. Transplants to the brachial or femoral vessels of human kidneys or animal kidneys to humans were described. The early claims and a critical discussion of these unsuccessful experiments can be found in Dr. Francis Moore's book *Transplant* [4]. None of them functioned for a long period of time and with hindsight the procedures were premature in relation to the knowledge that was gradually accumulating from Carrel and Guthrie's experiments.

Transplant biology

In the 1940s and 50s, Morten Simonsen in Denmark and William Dempster in London independently described experiments similar in nature to those of Carrel and Guthrie and long-term, life-sustaining function of autografts was confirmed. However, experimental allografts were shown to fail universally and a second kidney transplanted from the same donor to the same recipient was destroyed almost instantaneously. These observations were the culmination of many years of painstaking research by Simonsen and Dempster, who also reported on the use of cortisone in renal

allograft recipients. Both workers described histological changes that occurred in renal allografts. The renal cortex became infiltrated with neutrophils, eosinophils, macrophages, lymphocytes and pyronin-positive plasma cells, and these inflammatory changes were accompanied by necrosis of nephrons. Both Simonsen and Dempster felt that it was likely that the cells originated from the grafted organ and were in fact a graft-against-host reaction [5,6]. Subsequently, using a newly developed isotope labelling technique it was shown by Porter and Calne that most of the infiltrated cells came from the recipient [7].

At the time that these experiments were being performed by Simonsen and Dempster in canine renal allografts, Peter Medawar (Figure 1.2) and his colleagues had studied the biology of rejection of skin grafts in rabbits and mice. The first set of grafts became infiltrated with leukocytes after a few days, the graft becoming necrotic after 7–10 days. A second set of grafts from the same donor were usually destroyed immediately and never achieved a capillary circulation. They were called 'white grafts'. The immune nature of skin graft rejection was proved beyond doubt by Medawar's group [8], and from their experiments it seemed likely that kidney grafts between identical twins would behave like skin grafts between identical twins and, provided the surgery was satisfactory, would be accepted without any immune reaction. From this scientifically established basis reciprocal skin grafting should differentiate identical from non-identical cattle twins, and Medawar and his colleagues were confident that this would be straightforward. However, they were astonished, and presumably initially disappointed, when the non-identical cattle twins accepted skin grafts in the same way that grafts were accepted between identical cattle twins [9]. They became aware of studies of non-identical cattle twins by Ray Owen who had observed that non-identical cattle twins frequently had blood groups of more than one type, circulating in apparently healthy animals [10]. This would be equivalent to a human having some red cells Group A and some Group B, which was know not to occur because of natural antibodies. Owen described the unusual status of their red cells blood groups as 'chimeric' from the fanciful resemblance to the mythical ancient Greek animal with organs derived from different species (Figure 1.3).

Medawar and his colleagues, Billingham and Brent, then set about performing a series of carefully controlled experiments between inbred strains of mice. The individuals of each strain after many sibling matings would be regarded as identical or 'isologous' individuals, so skin grafts were accepted between members of each inbred strain. However, grafts from a given strain transplanted into individuals of a different strain would be rejected, by what was later called the 'allograft' reaction.

Based on these observations in the cattle twins, Medawar's group found that injecting cells from one inbred strain into the foetus of another strain, although a formidable technical achievement, resulted in some survivors, which were then rendered 'tolerant' to grafts from the strain that donated the tissue (Figure 1.2B) [11]. They later found that this tolerance could also be reproduced with neonatal animals, where the technical challenges were still grave but less demanding than in the foetus. This discovery of 'specific immunological tolerance' was awarded the Nobel Prize in Medicine or Physiology and was a fundamental advance in immunology and also raised the practical question of whether the plasticity of the developing foetal immunological system could be reproduced in an adult, at least temporarily while a graft was performed, although it would be important that normal immunity would later be restored. Another factor of importance observed by Medawar's group was that if lymphocytes were included in the donor inoculum they

(C)

Figure 1.2. (A) Sir Peter Medawar, who won the 1960 Nobel Prize in Physiology or Medicine for (B) his studies into the biology of acquired immunological tolerance [11]. (C) The description of 'runt disease', a primary demonstration of the concept of graft-versus-host disease.

could react against the recipient, causing a wasting illness which they called 'runt disease' [12]. This was an example of a graft-versus-host reaction, which was subsequently recognized to be extremely important in bone marrow transplantation, and also relevant in some organ transplants, particularly the liver where many lymphocytes are transplanted together with the donor liver.

In the early 1950s, David Hume performed a series of carefully observed clinical kidney grafts, joining the renal artery and vein to the femoral vessels of the recipient, bringing the ureter through the skin [13]. Despite no serious attempt to impair the immunity of the recipients, some of the grafts functioned and one continued to produce urine for nearly 5 months. When it failed the kidney was found to have both cellular infiltration and severe arteriolar narrowing typical of what later was called 'chronic allograft rejection'. The investigators wondered if these somewhat less severe rejections in human kidneys than those observed in animal experiments was

Figure 1.3. The chimera, a creature from Greek mythology referenced in Homer's *Iliad*, which is amalgam of a lion, snake and goat and has become a recognized symbol of transplantation. Apulian plate, 350BC, Musee Louve.

due to the fact that the patients all suffered from uraemia, which was both generally debilitating but also possibly impaired the normal activity of the immune system.

Concurrently, experimental studies were also performed at the Peter Bent Brigham Hospital in Boston by the departments of surgery under Professor Francis Moore and medicine under Professor George Thorn. The surgical experimental lab. was headed by Joseph Murray, a plastic surgeon who had a background in very intricate surgical correction of dreadful facial deformities (Figure 1.4). He brought his skills to the laboratory and developed an improved surgical technique of kidney transplantation in dogs, in which the renal artery and vein were joined to the iliac vessels and the ureter implanted into the bladder, avoiding the discomfort of a urinary fistula with the concomitant danger of ascending infection. Professor Rene Kuss pioneered the technique of pelvic renal transplantation clinically in Paris in 1953 when a kidney graft from a mother to son, implanted using the pelvic site approach, functioned for 23 days [14]. This was an important advance in providing a surgically acceptable procedure.

Early clinical implementation

In 1954, a patient with renal failure was referred by his doctor to Dr. Merrill, a nephrologist in Dr. Thorn's department, with an accompanying note saying that 'you may be interested to know that this patient is one of identical twins and this could be relevant to your management', raising the possibility of a kidney transplant from the patient's identical twin. After careful evaluation of the ethical aspects and also a demonstration that the twins were in fact identical by accepting reciprocal skin grafts, the first identical twin transplant was performed by Dr. Murray and his colleagues at the Peter Bent Brigham Hospital and was a spectacular success [15] (Figure 1.5). It showed that as in animal experiments but also in man, if immunological rejection could be avoided, the surgery could produce an excellent long-term therapeutic result for the recipient and also the unilateral nephrectomy in the donor would not lead to long-term harm. For this and his subsequent work, Joseph Murray was awarded the Nobel Prize in Physiology or Medicine in 1990. Incidentally, the first twin donor survived for more than 50 years in good health, and served as the leading edge of follow-up regarding the safety of living donation.

Figure 1.4. Joseph Murray, shown in front of a depiction of his landmark performance of the first successful kidney transplant. Dr. Murray won the 1990 Nobel Prize for Physiology or Medicine. In certain circumstances the original autoimmune cause of renal failure in the recipient recurred in the transplanted kidney, leading to its demise despite (or perhaps because of) being derived from an

identical twin [16], and this outcome impelled the search for means of impairing host immunity. In studies on bone marrow transplantation it had been shown that the immune system of rodents could be eliminated by a lethal dose of total body X irradiation and animals could be rescued by injection of autologous bone marrow from the same strain. The bone marrow cells given intravenously homed to the bone marrow of the recipient and populated not only the blood-forming elements but also the lymphoid cells in the lymph nodes and spleen, where they could restore immunity [17]. If the bone marrow was not autologous there was danger that the transplant would fail or if partially accepted, could result in a fatal graft-against-host reaction. Later developments in bone marrow transplantation became possible using less-severe non-ablative conditioning of the recipient than the original total body irradiation and has proved to be therapeutically successful, and even the graft-against-host reaction has been harnessed as a graft against leukaemia [18,19].

The success of experimental and clinical bone marrow transplantation following total body irradiation led to hopes that similar conditioning might be effective in recipients of kidney grafts. There was one encouraging result in the dog [20] but unfortunately with the exception of two kidney grafts between non-identical twins, one at the Peter Bent Brigham Hospital and the other in Paris, all the attempts at total body irradiation failed with disastrous results, rejection not being controlled and overwhelming sepsis becoming a common terminal event [21,22]. To reduce the toxicity of total body irradiation, repeated small doses of irradiation to the spleen and lymphoid organs was developed by Slavin and Strober in Stanford [23], a technique that continues to be investigated in the pursuit of clinical tolerance (see Chapter 76).

In the late 1950s it was clear that an alternative superior method would be needed to condition the recipients of kidney grafts more safely, and an important pointer was the demonstration that the antileukaemia thiopurine drug, 6-mercaptopurine, would prevent rabbits challenged with foreign protein antigens from producing antibodies. This effect persisted after the 6-mercaptopurine treatment had been stopped and was described by the authors, Schwartz and Dameshek in 1959, as 'drug-induced immunological tolerance' [24]. 6-mercaptopurine was then investigated in London and Richmond, Virginia as an immunosuppressant in dogs with renal allografts, resulting in prolonged allograft survival but not tolerance [25,26]. However, the effect was superior to total body X irradiation. There was a high incidence of infections caused by the severe impairment of immune reactions. Hitchings and Elion, who had synthesized 6-mercaptopurine, provided a number of experimental compounds that they felt were worth investigating as possibly having better therapeutic indices than 6-mercaptopurine. One of these agents, azathioprine, was found experimentally to be slightly superior to 6-mercaptopurine and became an anchor drug for a landmark series of animal experiments and subsequently for the next phase of clinical immunosuppression, which was commenced at the Peter Bent Brigham Hospital [27]. Initial clinical results were disappointing and it was not until corticosteroids were added to the immunosuppressive regimen that some successes were obtained in allografts between unrelated individuals [28]. Azathioprine remains indicated for transplant immunosuppression and is described in more detail in Chapter 98.

Steroids had previously been investigated by Medawar and Dempster, but alone were not very effective. However, when combined with azathioprine, better results were obtained. Tom Starzl carefully documented this in Denver, in recipients of renal allografts. Goodwin had already shown that a bolus of steroids could restore function, at least temporarily, to a kidney allograft that was undergoing acute rejection [29,30].

With day-to-day monitoring of patients and adjustment of drug doses to try and find a level that would prevent rejection without severe toxicity, some 50% of renal allografts were functioning at a year, but failures were a severe burden for the patients, their relatives, and the surgeons involved. Nevertheless, during this phase techniques of experimental heart transplantation were developed by Lower and Shumway in Stanford [31]. Additionally, Starzl in Denver and Francis Moore at the Peter Bent Brigham Hospital in Boston each developed successful surgical techniques for transplanting the liver [32,33]. Experimentally head and limb transplants were performed by Demikov in Moscow, but at that time these were little more than a surgical curiosity rather than a serious move forward towards clinical application [34].

It became apparent that transplants between close blood relatives who were not twins had better results than between unrelated donors. The basis for variation was correlated with tissue groups, which were gradually becoming clarified by Dausset, Payne, Van Rood and Terasaki [35–38]. These human leukocyte antigens (HLA) were separate from blood groups, the typing of which also was required to avoid immediate graft failure due to preformed antibodies against red blood cells groups. The historical aspects of the development of HLA and its testing are covered in Chapter 3.

Starzl performed the first clinical liver transplants in 1963 [39]. However, the early failure of these grafts and the demise of the patients led to Starzl imposing a moratorium until 1967 when he recommenced a liver transplantation programme at the same time Barnard performed the first clinical heart transplant. Additional details on the first paediatric cardiac transplant can be found in Chapter 115 [40,41]. The media excitement towards the heart transplant was unprecedented in medical history and led to unfortunate consequences because all over the world cardiac surgeons attempted clinical cardiac transplantation 'to join the club'. This was extremely worrying because most of the surgeons had no background knowledge on the biology of transplantation and the difficulties of prescribing immunosuppressive therapies.

Using aziothioprine and steroids the results of cardiac and liver transplantation were poor, but a few patients did very well. Many other agents and procedures were investigated to try and improve immunosuppression. They included total drainage of lymph from the thoracic duct and ex vivo irradiation of the kidney and circulating blood. These procedures were unsuccessful, but the concept of raising antibodies against human lymphocytes proved to be more promising. This had first been investigated experimentally by Woodruff and colleagues in Edinburgh in organ grafts after a demonstration of effective antilymphocyte serum produced in rodents to prolong skin grafts [42]. The antilymphocyte antibodies were polyclonal, that is they reacted against many different epitopes that were generated when lymphocytes or thymocytes were injected into a different species, for example the horse and rabbit. These antibodies were difficult to purify and tended to vary in efficacy and toxicity from batch to batch, but some were very powerful and, as described in Chapter 98, refined rabbit antihuman thymocyte antibody is still used clinically in patients [43].

The modern era of immune management

In 1978, Borel, an immunologist working in Sandoz laboratories in Basel, Switzerland, described the immunosuppressive effects of a

fungal cyclic peptide, cyclosporine, which was being investigated as a possible antibiotic [44]. Its antibiotic properties were weak but its immunosuppressive activity, both in vitro and in vivo with skin grafts in mice was impressive. On the basis of Borel's observations we, and workers at Northwick Park, investigated cyclosporine in rats transplanted with heterotopic cardiac allografts and found cyclosporine to be extremely effective [45,46]. Our studies were extended to canine renal allografts and orthotopic cardiac allografts in pigs. In these species, and later in the rabbit, cyclosporine was shown to be a powerful immunosuppressant with few side-effects [47]. However, when it was first used in clinical renal transplants it was found to be remarkably nephrotoxic, a property that had not been suspected in the animal experiments [48]. The nephrotoxicity was particularly severe as the dosage used in the first clinical trials was based on the animal experiments and found later to be much too high. Cyclosporine proved to be a watershed in immunosuppression, with the 1-year functional survival of renal allografts increased from 50 to 80%. This early improvement changed the attitude of the medical profession towards organ transplantation, which previously had been extremely sceptical, and as a result there were only approximately 10 units worldwide seriously doing clinical organ transplants. After the introduction of cyclosporine there were, within a few years, more than 1000 centres and the anticipated shortage of organ donors suddenly became a major consideration, which has escalated ever since. The mechanism of action of cyclosporine is detailed in Chapter 17, along with descriptions of all medications specifically indicated for transplantation.

From Japan the streptomyces-derived compound, tacrolimus, was developed by the Fujisawa Company and shown by Ochiai to prolong experimental graft survival at a very low dosage [49]. After early experimental organ allografts in different species, tacrolimus was used in clinical organ transplantation and fully and exhaustively investigated by Starzl's group in Pittsburgh [50]. Tacrolimus has a similar nephrotoxic effect to cyclosporine but the hirsutism and gum-swelling, which were the common side-effects in cyclosporine-treated patients, did not occur in patients treated with tacrolimus.

The production of monoclonal antibodies by Kohler and Millstein in 1975 provided an agent with a single molecular target [51]. This was quickly exploited for use in transplantation, with the development of OKT3, a murine-origin monoclonal antibody specific for the CD3 determinant on T cells. This agent effected prompt, albeit transient, reductions in peripheral T-cell counts and was shown to reverse established acute rejection [52]. In 1986, OKT3 became the first monoclonal antibody approved for use in any human disease, and while its side-effect profile, clearance by a mouse-specific antibody response, and the emergence of other more tolerable therapies, eventually led to its withdrawal from the market, OKT3 served as a proof-of-concept for the promise of monoclonal antibody therapy in medicine in general. Similarly, the concept of humanization, that is genetic engineering of an antibody to make it largely composed of human structures to avoid a neutralizing antibody effect, was first launched in transplantation with the development of daclizumab [53]. As with OKT3, a completely new therapeutic approach first found its way into the clinic through transplantation. This drug also has been removed from modern practice, but others now find their way into our field through off-label use (see Chapter 99). Conceptually, import in this regard derives from the work of Waldmann and Winter who developed the lymphocyte-specific humanized monoclonal antibody Campath 1H or alemtuzumab, an extremely powerful antilymphocyte antibody, which eliminates lymphocytes almost completely from the circulation within a few hours [54]. It was developed for the treatment of chronic lymphatic leukaemia but was shown to be a valuable induction agent in clinical kidney transplant patients, allowing maintenance immunosuppression to be reduced to a significantly low level, which eliminates most of the toxic side-effects of maintenance drugs. This concept of powerful almost, or '*prope*', tolerance antilymphocyte induction therapy, followed by very low maintenance, does not generally result in tolerance, but is probably currently the best available treatment for recipients of organ grafts [55,56].

It has been known from the early experimental liver grafts in pigs and later in rodents that liver grafts were less severely rejected than other tissue and sometimes were accepted long-term as an 'operational' tolerance in animals not given any immunosuppression. The transplanted liver often underwent biochemical and histological rejection, which recovered spontaneously [57–59]. These observations were a background to 'experiments' performed by patients in Pittsburgh who were non-compliant in taking immunosuppression, without telling their doctors. Some of these patients with liver transplants have survived for more than 20 years without any immunosuppression and justifiably would be regarded as operationally tolerant. As discussed in Chapter 76, patients in whom immunosuppression was deliberately stopped or weaned, because of infection or as a policy to see if they were tolerant, produced variable results. Some patients accepted their grafts without deterioration indefinitely, but others developed rejection and had to return to immunosuppression. Even an extremely low dose of immunosuppression may be important in recipients of organ grafts; stopping a very low dose may lead to rapid rejection, which may be difficult to reverse [60,61].

A more biological approach to immunosuppression has been studied for some years based on successful murine experiments. Engagement of foreign tissue with the recipient immune system involves not only recognition and reaction to antigenic epitopes, but also a complicated secondary signal that binds the cells presenting the antigen to the immune reactive cells. The second signal has been studied in great detail and various methods of blocking the second, now costimulatory, signal have shown encouraging results experimentally and have now been investigated in the clinic [62]. This is described in more depth in Chapter 11.

Ethical challenges

In the past 50 years, organ transplantation has come a long way from a theoretical, fanciful concept to a fully established, practical therapy. There are still many biological obstacles to be investigated and overcome, particularly recurrent disease in the transplanted organ, the development of renal damage and diabetes associated with calcinurin-inhibiting drugs, and infection and malignancy, especially lymphoma and skin cancers. All these unsatisfactory features of organ transplants have gradually become understood and various methods of avoiding these side-effects and treating them have been developed. Indeed, an in depth understanding of these adverse conditions form the foundation of the knowledge required for the clinical practice of modern transplantation, and is approached to some degree in most chapters in this text. The success of organ grafts has raised ethical questions, which have emerged like 'a can of worms', totally unexpected by the pioneers of transplantation in the early days, but covered in numerous chapters in this textbook (e.g. Chapters 136–139). As the results of organ

transplants improve, so the demand increases, yet the donor supply does not increase *pari passu*. There are not sufficient deceased donor organ transplants in any country. Indeed, public opinion is often not in favour of deceased donation nor are some governments prepared to invest in the infrastructure necessary to educate the public or provide the medical facilities necessary for intensive care of potential donors. Spain has been the most successful nation in all areas with deceased organ donation of more than 30 cases per million but with improved treatment of head injuries and less road traffic accidents than previously, the 'donor pool' has become reduced [63,64]. This is detailed specifically in Chapter 53.

Living donors have been used extensively since the beginning of organ transplantation in identical twins. Usually the kidney transplantation can be performed ethically between related and unrelated family members and liver transplantation from parents to children. However, beyond these stipulated cases the ethics of organ donation have been strongly questioned (see Chapter 138). Recently, a child in China sold his kidney without his parents knowing to obtain cash to buy an iPod [65]. Many thousands of prisoners executed in China had their organs removed for transplantation. The transplant community in the West condemns this practice as unacceptable on a variety of grounds, including the use of organs to generate income from rich foreign 'organ tourists'. Pressure can be put on individuals to donate within a family and relations of the patient may feel forced to acquiesce or have a terrible guilt feeling if they refuse. Attitudes to donation between donor and recipient may change. A New York surgeon who had given a kidney to his wife, later divorced her and was awarded considerable damages in consideration of his previously considered altruistic gift [66]. Liver transplantation from a living adult donor to another adult has risks that are very difficult to explain to the prospective donor. Not only is there a high likelihood of prolonged morbidity, but there is a possibility that organ donation will cause the donor to lose his or her job and mortality as a result of the donor operation is high enough to be considered a significant risk. Five partial liver donors to adults have been reported to have developed liver failure themselves, four died and one was rescued by a transplant [67]. Rich patients may buy organs illegally. Seldom do the rich donate organs to poor recipients.

It is unlikely that the ethical difficulties will be easily overcome, but defining them is the first step. In the middle 1960s, attempts were made to transplant organs from animals to man. A variety of well-documented kidney transplants were reported from New Orleans, Denver, and Richmond, Virginia and there were also sporadic attempts at other organ xenografts. To date, none have been successful long-term apart from one kidney transplant from a chimpanzee to a patient in new Orleans, which functioned for 9 months, eventually succumbing to chronic rejection [68]. A great deal of effort has been put into studying xenograft reaction and defining the barriers, and this subject receives in-depth treatment in Chapter 12. However, despite intense and expensive experimentation, each barrier appears to be rather like an opaque hazard in a steeplechase where it is necessary to overcome the first barrier to see the next one and currently we do not know how many barriers there are or even if the race can be won.

Summary

In a brief period of less than 60 years, transplantation has emerged from its humble origins as a experimental curiosity to being an accepted means of life-saving therapy for most end-organ diseases. Its success has become increasingly expected, and its implementation increasingly seen as routine. In the foreseeable future, despite (or perhaps as a result of) exceptional advances in overcoming the surgical and immunological barriers to transplantation, the shortage of organ transplants will remain, and it is incumbent on the transplant community to explain honestly the situation to the public and their governments, and to face the unwelcome fact that not everybody who might benefit from a transplant will receive one; this is especially true in poor nations. As the readers makes their way through this comprehensive text, they will find vestiges of the historical landmarks outlined briefly in this introductory chapter. It is hoped that as one consumes the specifics of the expansive practice that is modern day organ transplantation, they will recognize the common thread that moves through it, from fundamental biology and discovery to similarly fundamental ethical concerns that define our humanity. In doing so, the student of transplantation will best appreciate the privilege and responsibility that this field imparts upon them.

Introduction

An understanding of one's response to a transplanted organ requires a fundamental understanding of the immune system in general, and its function in the context of physiological homeostasis. Indeed, it is important to recognize that transplant-directed allo- or xenoimmunity is mediated by processes that evolved with selective pressures completely unrelated to organ transplantation, and, thus, the components of a transplant-specific response derive from a system that has come into being to maintain one's integrity amongst numerous environmental pathogens and threats to individual integrity. Humans are exposed continually to diverse pathogens, including viruses, bacteria, fungi, and protozoa, as well as many multicellular parasites. If not prevented or counter-acted upon, infection by these pathogens results in illness and potentially death of the host. Moreover, daily physical activities can cause varied levels of trauma and associated tissue injury that must be managed satisfactory to maintain normal body function. To cope with these challenges, an intricate immune system has evolved, consisting of generalized barrier mechanisms, an array of highly responsive hematopoietic cells, and an arsenal of specialized effector molecules.

Although immunology, the study of the immune system, is generally considered a modern science [1], it has a long history, spanning ancient times to the present day, during which physicians and scientists have studied the role of immunity in health and disease. As early as 1 AD, the ancient Roman Celsus documented in *De Medicina* the heat, swelling, pain, and redness (*calor, tumor, dolor, and rubor)* that results from our body's inflammatory response to injury. In recent history, we have elucidated many of the cellular, and now molecular, processes that constitute the immune response. As our understanding of immunology has grown, so has our appreciation of the role of the immune system in the normal physiology and function of tissues and organs. Likewise, translational efforts have continued to harness an understanding of normal, pathologic, and therapeutic immune responses to improve the human condition. The study of immune responses to transplanted tissues and organs and how these can be controlled (transplant immunology) has been an area of strong academic interest and clinical success. In this chapter, we provide a brief general introductory framework of the cellular and molecular immunology necessary to comprehend subsequent, more specific and detailed chapters on the mechanisms of transplant-specific immunity (see Chapters 5, 6, and 7 for transplant-specific treatments of basic immune mechanisms). It will also establish the general vocabulary and knowledge base required to understand the references to immunology that are ubiquitous in the practice of transplantation, as will be evident throughout this text. Excellent contemporary immunology textbooks [1,2] elaborate core concepts of protective immune reactivity to foreign material and pathogens and the processes of adverse immune responses, termed immunopathology.

Generalized protective barriers and defense factors

Protective barrier tissues, such as the skin and the mucus-lined and/or ciliated epithelium of the respiratory tract serve as first lines of defense and prevent invasion by most pathogens (Figure 2.1A). Likewise, the low pH environment of the gastrointestinal system and genitourinary tract is inhospitable to most organisms. Sites susceptible to invasion, such as the conjunctiva of eye or the oral cavity, are protected by antibacterial enzymes, such as lysozyme, β-defensins, or phospholipase A. These barrier tissues also support a critical commensal bacterial flora, or microbiota, which prevents infection by "crowding out" pathogenic organisms and also play a critical role in shaping immune reactivity, especially in the gut mucosa [3].

Tissues and organs of the immune system

The lymphoid organs are categorized as primary and secondary lymphoid organs (Figure 2.1B). The primary lymphoid organs, specifically the bone marrow (BM) and thymus, are sites of lymphocyte development. The hematopoietic compartment of the human BM generates approximately 500 billion blood cells each day, and produces the diverse hematopoietic cells that support the body's innate and adaptive immune systems (Figure 2.1C). The BM and thymus constitute the primary lymphoid organs involved not only in the production but also the selection of lymphocytes, selection defined by which cells will most appropriately interact with the individual's cellular constituents both to maintain homeostasis and avoid autoimmunity. The thymus provides an inductive environment for the development of T cells from hematopoietic progenitors. Moreover, thymic stromal cells permit the selection of functional and self-tolerant T cells. Thus, the thymus is of

crucial importance in the maintenance of self-tolerance (central tolerance, see below).

Secondary lymphoid organs provide sites for collection of interstitial bodily fluid, or lymph, which is mainly blood plasma that may contain material derived from invading pathogens. Contained in this material are substances (or antigens; Ag) that elicit adaptive immune response. Likewise, secondary lymphoid organs, including the lymph nodes, spleen, and other regional lymphoid tissues, are a very important nexus for communication between innate and adaptive immune cells, and thus the site where most immune responses are initiated. The lymphatic system is connected by a series of vessels that act as part of the body's extracellular fluid recirculation system in which lymph is collected and transported to the lymph nodes, where it can be conveyed back into the blood stream.

Cells of the innate and adaptive immune system

Although the barriers and general protective substances described above are highly effective in preventing pathogens from infiltrating sites of exposure, specialized hematopoietic cells are exceptionally well equipped to counter pathogens that breach these defenses. These white blood cells, or "leukocytes," circulate in the blood, navigate the lymphoid system, and monitor/patrol/survey peripheral tissues, including the commonly transplanted organs (Figure 2.1C). Leukocytes are also critical in their support of wound healing and resolution of tissue damage.

Leukocytes are grouped in two integrated arms of the immune system: the innate and adaptive arms, based on their respective functional attributes and the uniqueness of the cell surface receptors they express. However, other important differences, described elsewhere in detail [4], exist between cells of the innate and adaptive immune systems. In brief, innate immune cells can detect pathogens and local tissue damage and respond immediately following ligation of a single activating signaling receptor. This contrasts with adaptive immune cells that require multiple permissive signals provided by other immune cells to become fully immunocompetent. Importantly, following their activation, adaptive immune cells undergo proliferation and division into clones with identical Ag recognition ability, thus amplifying the resultant immune response. Another important distinction is the ability of adaptive immune cells to persist in the body long term following their stimulation and division, and their ability to mount a "memory" response to a particular Ag (see below). Specifically, this allows a more rapid and intense response following repeated exposure to the same Ag. Innate immune cells have short life spans, and given their lack of clonal expansion, any secondary responses to an Ag will appear identical, in both time and amplitude, to a primary response. However, there is a strong inter-relationship between the cells of the innate and adaptive immune systems in regard to transplant immunity, and it is therefore difficult to describe their functions and immune responses in isolation from each other. Furthermore, evidence has accumulated that cellular "crosstalk" between innate and adaptive immune cells is important for the generation or regulation of immunity. Thus the concept of purely "innate" or "adaptive" immune responses may be more of a practical generalization than reality.

Innate immune cells

Thought to have evolved long ago as a host defense mechanism against various pathogens, cells of the innate immune system are recognized as the body's first line of defense against bacteria, fungi, yeasts, and parasites [5]. The innate immune system is comprised of inflammatory cells, often granulocytic and/or phagocytic cells, which are activated rapidly by pathogens following detection of pathogen-associated molecular patterns (PAMPS; [4,6]) and endogenous damage-associated molecular patterns (DAMPS; [7]) by pattern recognition receptors (PRR). In an important distinction from adaptive immune responses, innate cells are non-clonal, with all cells of a lineage identical in displaying the same, germline encoded receptors. Innate immune cells include leukocytes that contain granules consisting of preformed antimicrobial agents, enzymes, and other immunoregulatory material within their cytoplasm. These are classified, firstly, as granulocytes, which include neutrophils, eosinophils, basophils, and mast cells. A second group of innate immune cells, recognized for their capacity to take up and selectively process exogenous materials, includes monocytes, macrophages, and dendritic cells (DC), and are classified as "monocular phagocytes" [8,9]. A third group of innate cells with some attributes of adaptive immune cells are gamma-delta ($\gamma\delta$) T cells [10], which have ill-defined immune functions, and natural killer (NK) cells [11], which are important for their ability to kill virally infected cells or cancer cells without prior sensitization. Chapter 7 details transplant-specific mechanisms of innate immunity.

Granulocytes

In general, granulocytes respond to activation following perception of invading microbes or local inflammatory stimuli with a rapid discharge of the granulocytic and cytoplasmic immune mediators that are directly toxic to pathogens and promote local inflammation and immune responses.

Neutrophils

Neutrophils comprise a large proportion of circulating leukocytes and are of paramount importance in effective responses to microbial invasion and tissue injury [12]. Neutrophils express surface receptors and molecules that allow them to both sense and migrate to sites of infection and inflammation. Typically, the first immune cells to arrive at these sites, neutrophils phagocytose or ingest complement-opsonized (see below) microbes and damaged tissue. Neutrophils also can deploy antimicrobial reactive oxygen species (ROS) and cytotoxic substances contained within their granules, as well as augment local innate and adaptive immune responses through production of a diverse range of inflammatory mediators that influence both innate and adaptive immune cells. Neutrophils are also emerging as crucial facilitators of inflammation resolution and wound repair.

Mast cells, eosinophils, and basophils

Mast cells are rare, but long-lived cells present in peripheral tissues, especially innervated and vascularized regions [13]. Activation causes mast cells to release granules containing histamine, which increases vascular permeability and stimulates local nerves. Mast cells can also generate lipid-derived eicosanoid messengers that module the local environment and promote chemotaxis, that is the migration of other immune cells towards increasing concentrations of chemoattractant. Eosinophils and basophils are equally rare granulocytic cells that circulate in the blood and are implicated in allergic and antiparasitic responses supported by the secretion of histamine, heparin, cytokines, particularly IL-4, and chemotactic agents [14,15].

Natural killer (NK) cells

Natural killer (NK) cells are a lineage of cytotoxic innate immune cells that are especially adept at the removal of abnormal cells [16,17]. NK cells, and related NK T cells, are a heterogeneous collection of lymphocytes specialized for the elimination of pathogen-infected cells and abnormal cells. They survey the periphery with a diverse set of germ-line-encoded cell-surface receptors belonging to the immunoglobulin (Ig)-like receptor and C-type-lectin receptor families. Their ability to act as effector cells is regulated by these surface receptors, which act to inhibit or enhance NK cell cytotoxicity.

Mononuclear phagocytes

Phagocytosis, or actin-dependent, active uptake of comparatively large particles (>0.5 μm), is carried out by neutrophils and a subset of innate cells classified as mononuclear phagocytes, which includes monocytes, macrophages, and DC [8,9]. Monocytes, macrophages, and DC are, like neutrophils, considered "professional" phagocytes and perform the bulk of phagocytosis in the body [18]. Mononuclear phagocytes utilize phagocytosis not only for clearance of pathogens, but also employ this process to take up, process, and present Ag in a form recognized by adaptive immune cells [19].

Several additional, essential characteristics enable mononuclear phagocytes to move beyond a simple phagocytic effector role and to act as crucial immunological sentinels that coordinate the response of the innate and adaptive immune response. Monocytes, macrophages, and especially DC, are well equipped to sample the local environment for Ag that is captured, processed, and then presented in a form that enables T lymphocytes (T cells) of the adaptive immune system to recognize it and mount an appropriate response if necessary. As such, macrophages and DC are often described as professional Ag-presenting cells (APC). The events underlying Ag processing and presentation are described below in more detail.

Monocytes, macrophages, and DC, like other innate immune cells, express diverse, germ-line encoded environment-sampling receptors. These PRR, which enable the cells to detect PAMPs on exogenous pathogens [4] and DAMPS released by local tissue damage/cell death [20,21], include the well-studied Toll-like receptors (TLRs) [22], as well as cytokine receptors, C-type lectin receptors, NOD-like receptors, and RIG-I-like receptors [23]. Triggering of these receptors implements programs of activation and differentiation of mononuclear phagocytes that result in distinct, proinflammatory myeloid cell subsets that precisely orchestrate the subsequent adaptive immune response, especially that of T cells which recognize Ag displayed on these APC. In quiescent environments and in the absence of activating stimuli, mononuclear phagocytes are described as "immature" APC, and act in a tolerogenic fashion to suppress responses of T cells reactive to the presented Ag.

Dendritic cells (DC)

In general, DC are rare, ubiquitously distributed, migratory leukocytes, derived from $CD34^+$ hematopoietic stem cells [24–27]. They convey Ag from peripheral sites, such as skin or other non-lymphoid tissues, to T cells in secondary lymphoid organs. DC are extremely well equipped for Ag capture and for processing and presentation of Ag to rare T cells expressing specific receptors that recognize Ag peptides bound to major histocompatibility complex (MHC) molecules.

DC comprise multiple subsets (i.e. conventional migratory DC, lymphoid tissue-resident DC, inflammatory DC, and plasmacytoid DC) that differ in phenotype, location, and function [28,29]. Conventional migratory DC located in non-lymphoid organs, including epidermal Langerhans cells (LC) and DC in the intestinal mucosa, lung, or kidney, are characterized by the expression of CD11c, CD11b, or CD103 and are potent initiators of T-cell immunity [30–32]. Their common feature is an ability to migrate via afferent lymphatics from peripheral non-lymphoid tissues to draining lymph nodes (LN). In doing so, migratory DCs not only undergo maturation, but also fulfill the important role of transporting peripherally acquired Ag into the LN wherein they may pass Ag to resident DC (cross-presentation of Ag). In addition, recent studies propose that productive naïve T cell–migratory DC interactions may also occur in peripheral sites (non-lymphoid tissues), interactions that may further promote the quantity and quality of T-cell activation [33]. Lymphoid tissue-resident DC, such as $CD4^+$, $CD8^+$, or double negative DC, are found exclusively within lymphoid organs, where they differentiate from precursors that directly populate these tissues [34,35]. Plasmacytoid DC (pDC) differ substantially from conventional migratory and lymphoid resident DC, by being potent producers of key antiviral cytokines, such as type-I interferon (IFN) [36]. In addition to migratory, lymphoid-resident and pDC, inflammatory DC can develop from monocytes, both in the periphery and in secondary lymphoid organs under conditions of inflammation [37].

Critical immune regulatory functions of DC

In general, DC function primarily to convey Ag from peripheral sites, such as skin or other non-lymphoid tissues, for inspection by T cells in secondary lymphoid organs [24,38]. Importantly, DC then either promote or suppress the immune response of reactive T cells, depending on necessitating conditions in the body.

In the non-lymphoid tissues, which include the commonly transplanted organs (kidney, heart, liver, and pancreas) DC reside as "immature" APC [39–42]. When freshly isolated, they express few surface MHC molecules, which are highly polymorphic surface proteins generated from co-dominantly inherited genes. These molecules are critical to T-cell immune responses due to the strict requirement that Ag must be presented in the context of MHC for T-cell recognition and reactivity (see Chapter 5). Cells classified as APC, especially DC, take up Ag efficiently either by phagocytosis or receptor-mediated endocytosis, process the Ag in specialized intracellular compartments, and present Ag-derived peptides bound to MHC molecules on their cell surface to T lymphocytes [43] (Figure 2.2). MHC class II molecule complexes on APC interact with $CD4^+$ T cells, while MHC class I molecule complexes interact with $CD8^+$ T cells. The Ag-derived peptides presented by MHC class I molecules originate mostly from intracellular sources of pathogens and are degraded by the cytosolic proteasome, whereas peptides presented by MHC class II molecules are acquired from extracellular sources, and degraded in the lysosomal compartment [44,45]. An additional process bridging the two pathways, called cross-presentation, consists of either exogenous Ag presentation by MHC class I molecules to $CD8^+$ T cells, or by cytosolic (endogenous) proteins degraded through autophagy (a catabolic process involving degradation of a cell's own components through lysosomal machinery) and presented by MHC class II molecules to $CD4^+$ T cells [46,47]. Among APC, DC are considered the prototypic professional APC, due to their exquisite expression of T-cell costimulatory and intercellular adhesion molecules and their

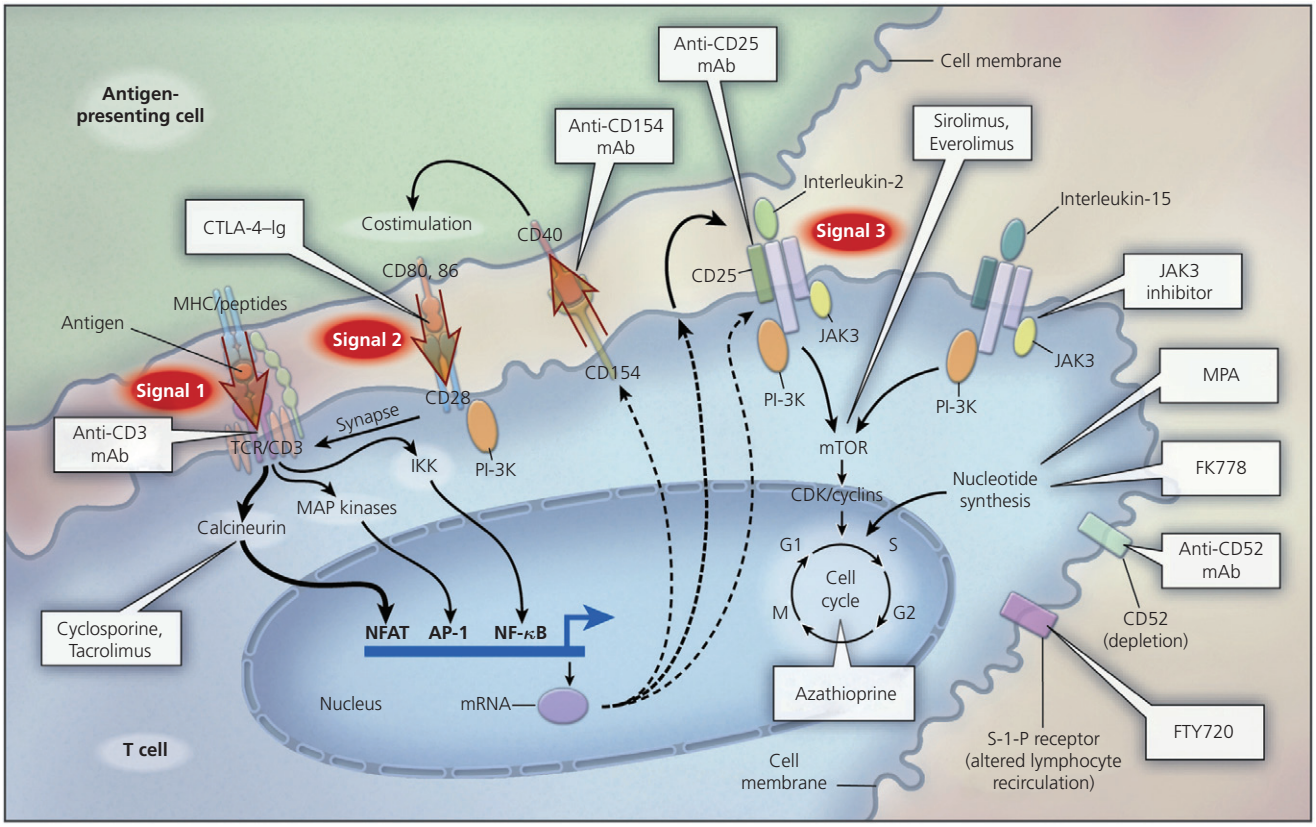

Figure 2.2. Antigen-presenting cell–T-cell interaction, depicting the three signals required for T-cell activation. From Halloran PF. Immunosuppressive Drugs for Kidney Transplantation. ability to secrete proinflammatory cytokines, critical for effective naïve T-cell priming [43]. Macrophages and activated B lymphocytes can also present Ag via their MHC class II molecules, but are less efficient APC for priming naïve T cells. Immature DC, although poorly stimulatory, are sensitive to local changes perceived by environment-sampling receptors (i.e. TLR) which detect PAMPS or DAMPS, signifying local "danger." This triggers signaling pathways that direct DC "maturation," which consists of up-regulation of costimulatory molecules and the secretion of bioactive proinflammatory cytokines that facilitate immune responses.

Macrophages

Similar to DC, macrophages are highly plastic, monocyte-derived cells that acquire different molecular and functional phenotypes following integration of environmental and cellular cues [48]. They patrol tissues by sensing the presence of infectious agents or conditions of stress/injury [49]. This role is exerted through expression of the aforementioned germ-line-encoded environment-sampling PRR. Engagement of these receptors initiates a complex sequence of intracellular and extracellular modifications referred to as activation. Activated macrophages are capable of endocytosis and Ag processing and express MHC class II and costimulatory molecules to varying degrees, according to their activation state. Thus, like DC, activated macrophages are professional APC capable of effective Ag presentation to T cells. A key difference, however, is that although both cell types can present Ag to primed T cells, only DC can present Ag effectively to naïve T cells (see below) [25]. Thus, it is likely that during the response to a pathogen (or transplanted tissue), Ag presentation by DCs is essential to initiate a robust adaptive response whereas macrophages, which exist in greater numbers within inflamed tissue, act at the interface between adaptive and innate responses by integrating signals from both primed T cells and the inflammatory environment.

In addition to their response to PAMPs and DAMPs, macrophages reach different functional states based on their interaction with fully differentiated effector T cells and exposure to specific cytokine milieu. Macrophages were described initially as either classically or alternatively activated, with these phenotypes referred to as M1 and M2, respectively [50]. M1 macrophages are instrumental in immune responses against intracellular microbes and tumors [51]. M2 macrophages are more heterogeneous, but generally play a role in killing and encapsulation of extracellular parasites, resolving type-1 inflammation, and promoting tissue repair and remodeling. M2 macrophages also play a role in immune regulation and promote tumor progression. M1 and M2 macrophages are not only distinct in function, but also express different receptors and enzymes required for their activities. M1 macrophages express high levels of inflammatory cytokines (IL-12, IL-23,TNF, IL-1β, and IL-6) and chemokines (CXCL9, CXCL10, CXCL11, CCL2, CCL3, CCL4, CCL5, and CXCL2), as well as enzymes involved in the generation of ROS and nitric oxide (NO; [51]). M2 macrophages express lower levels of inflammatory mediators, but high levels of IL-10, scavenger, mannose, and galactose receptors. Importantly, in

mice, M2 express the enzyme arginase-1 that inhibits the NO generation pathway (through inducible NO synthase (iNOS)) to generate ornithine and polyamines which are instrumental in tissue repair and fibrosis.

Although this M1/M2 dichotomy simplifies understanding of the function of macrophages as key components of the immune system, more recent investigations clearly indicate that macrophages cannot be rigidly categorized, as they can express many shades of the inflammatory spectrum determined by tissue, stimulus, and phase of inflammation. Additionally, new functions have been attributed recently to macrophages isolated at different phases of the immune response and terms such as "resolution macrophages" and "regulatory macrophages" have been proposed, further emphasizing the complexity and breadth of activity of these cells [52].

Adaptive immune cells

Adaptive immune cells, consisting of T and B cells, express unique variants of prototypic Ag receptors on their surface, described respectively as T cell and B cell receptors (TCR and BCR). The Ag specificity-determining ("variable") regions of T and B cell Ag receptors are generated via gene rearrangement by site-specific recombination machinery encoded by the recombinase activating genes 1 and 2 (*RAG1* and *RAG2*) [53]. The stochastic process generating the Ag-detecting region of the TCR and BCR instills adaptive immune cells with the potential to recognize and mount specific immune responses to any Ag. In addition to Ag from pathogens, these Ags may include self Ag, and thus immature T and B cells must undergo a selective maturation process to eliminate self-reactive and potentially autoreactive T cells. BM-derived T-cell precursors migrate to the thymus, where those expressing functional, but weakly autoreactive, TCR are selected for release to the periphery. B cells, following their generation in the BM, remain there and progress to mature B cells with the help of BM stromal cells. More details on the selective processes that T and B cells undergo are provided in the section on immunological tolerance (see below). Relationships between these cells and transplant immunity can be found in Chapters 5 and 6.

T-cell immunobiology

In addition to their identification by expression of TCR, T cells are easily identified by surface expression of CD3, a crucial signaling component of the TCR [54] (Figure 2.2). T cells are divided into two major and functionally distinct subsets, based on surface expression of CD4 or CD8. CD4 and CD8 act as co-receptors to the TCR and are critical for Ag recognition. Likewise, expression of CD4 and CD8 signifies the distinct functional roles of two critical T subsets in adaptive immune responses. In general, $CD4^+$ and $CD8^+$ T lymphocytes display largely non-overlapping functions and co-operate in generating protective immunity in the host.

T-cell recognition of Ag in MHC via the TCR

Either the CD4 or CD8 molecule on T cells, in combination with the CD3 molecule and the α/β and γ/δ chains of the TCR heterodimer, form the survey and signaling machinery of T cells. This assembly of T-cell surface proteins, CD4 or CD8/CD3/TCR is referred to as the TCR complex [55]. As alluded to above, T cells scan peripheral tissue and other cells for potential pathogens/foreign Ag through their unique TCR complexes. They receive signals in the form of information delivered by MHC molecules on the surface of other cells of the body, in particular APCs. In the case of $CD8^+$ T cells, antigenic peptide is viewed in the context of MHC class I, whereas $CD4^+$ T cells detect Ag on MHC class II. In both cases, interactions between the TCR and MHC are stabilized by the T-cell co-receptors (CD4 or CD8) which interact with the MHC molecules. The interaction of a TCR with a MHC molecule displaying its specific or cognate peptide Ag, triggers signal transduction pathways, leading to phosphorylation of key signaling molecules, including zeta-chain-associated protein kinase 70 (ZAP70)/CD3ζ, spleen tyrosine kinase (Syk), extracellular signal-regulated kinase (ERK1/2,) phosphoinositide-3-kinase/serine/threonine kinase Akt (PI3K/AKT), and nuclear factor of activated cells (NFAT) pathways, followed by downstream expression of master transcription factors, chromatin remodeling and cytoskeleton reorganization [56,57]. As a consequence of meaningful TCR-induced signaling, effector functions, such as cytokine secretion and cytolytic responses against target cells, can be executed.

$CD8^+$ T cells

Activated $CD8^+$ T cells, also referred to as cytotoxic T cells (Tc), are considered to be primary effectors in the removal of cells infected with intracellular pathogens. Tc release several cytokines, small signaling molecules that influence immune and other cells (see Cytokines Section below), and cytotoxic molecules that destroy target cells. These cytotoxic substances include granzymes, serine protease that induce target cell death by activating proapoptotic pathways, and perforin, which supports granzyme introduction into target cells leading to osmotic cell death [58]. In addition, activated $CD8^+$ T cells express FasL(CD95L), which can initiate apoptotic death of target cells expressing Fas (CD95) on their surface [59].

$CD4^+$ T cells

$CD4^+$ T cells, also known as T helper cells (Th), are of critical importance in secondary lymphoid tissues during the initial phase (priming) of the immune response. Thus they provide specific instructions to effector and memory $CD8^+$ T cells, B cells, or other immune cells (including APC), via cytokine release and expression of immunomodulatory (costimulatory) surface molecules. Moreover, in peripheral tissues, $CD4^+$ T cells may release chemokines that attract other immune cells to amplify the immune response or exert direct effector functions. Effector Th cells are crucial regulators of both adaptive T- and B-cell responses, as well as coordinators of the innate immune response. Th cell cytokine production profiles, surface molecules, and specific transcription factors are often used to categorize Th cells into distinct functional subsets (Figure 2.3) (described more completely below in Section The Cytokine Milieu and Th Cell Polarization; reviewed in [60]).

Need for APC costimulation for T-cell activation

Costimulatory molecule engagement during naïve T activation is critical for T-cell survival, proliferation, and polarization (Figure 2.2) (see Chapter 5). Upon recognition of CD28 (the costimulatory molecule expressed constitutively by naïve T cells), by its ligands CD80 and CD86 expressed on DC, naïve T cells up-regulate the high-affinity IL-2 receptor α chain (CD25) and CD40L (CD154), express antiapoptotic Bcl-xL molecules, and activate the mechanistic target of rapamycin (mTOR, previously known as the mammalian target of rapamycin) pathway, thus initiating T-cell proliferation [61]. In addition, ligation of CD40 on DC by inducible CD40L on activated T cells further licenses DC activation (up-regulation of

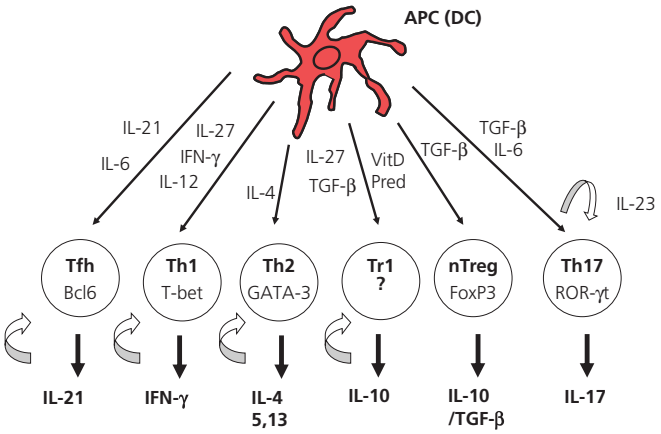

Figure 2.3. Polarization of naïve T cells into distinct helper T-cell subsets. T-cell polarization fate is determined by DC (APC) instructions conveyed to T cells which, in addition to the type of Ag (signal 1) and the nature of costimulatory factors (signal 2), provide cytokine instructions (signal 3). These signals are reinforced by cytokine release from Th cells themselves (feed-back positive loops); the cytokines instructions and master transcription factors are shown for each T helper subset.

MHC and costimulatory molecules and secretion of inflammatory cytokines) and increases the strength of cognate T-cell signal recognition [62]. Alternatively, naïve T cells that come in contact with their cognate MHC Ag on an immature APC, in the absence of costimulation, become non-responsive or anergic to cells expressing this MHC Ag [63].

The cytokine milieu and Th-cell polarization

It is well accepted that the local cytokine milieu influences T-cell polarization and lineage differentiation. The signature signal transducer and activator of transcription (STAT) molecules, which sense the extracellular cytokine environment, thus dictate the expression of master transcription factors by T cells (Figure 2.3), their cytokine signature, and the type of pathogens controlled, while silencing other T-cell lineages with inappropriate cytokine expression.

Specifically, Th1 cells express the transcription factor T-bet, secrete IL-2, IFN-γ, and TNF and serve to control intracellular pathogens [64]. STAT4 and STAT1 are important signaling molecules which receive signals from IL-12 and IFN-γ to further induce T-bet, and maintain Th1 commitment, and to repress other transcription factors, such as GATA-3, ROR-γt, and Bcl-6, and thus suppress IL-4, IL-17, and IL-21 production, respectively. Th2 cells express the transcription factor GATA3, secrete IL-4, IL-5, IL-10, and IL-13 and control extracellular infections and helminth infestations [65]. STAT3 and STAT6 further promote Th2 cell generation and commitment from naïve T cells, while antagonizing Th1 and Th17 generation. Th17 express ROR-γt and IL-17, and protect against extracellular bacteria and fungi. IL-6 and IL-23 drive Th17 responses by activating STAT3 to induce ROR-γt [66]. T follicular cells (Tfh) secrete IL-21 and are critical for providing B-cell help, Ig class switching, and Ab production [67]. They express Bcl-6, the activity of which is regulated by STAT3, IL-6, and IL-21 [68]. Th22 and Th9 are other newly described T-cell subsets whose individual significance is still under debate [69,70].

T-cell subsets that inhibit other T cells' immune responses (both CD8 and CD4 responses) in an Ag-specific manner have been identified in humans and mice [71–74]. These cells are termed regulatory T cells (Treg). Naturally occurring Treg are distinguished by display of the α chain of the IL-2 receptor (IL-2R; CD25) and by the transcription factor, forkhead box p3 (Foxp3), see below under Immunologic Tolerance. A discussion of regulatory T cells in transplantation is found generally in Chapter 5 and specifically in Chapter 8.

T-cell plasticity

The various Th subsets, with their distinct immunologic functions, as discussed above, have been regarded historically as committed "lineages" because they display elements of stability and heredity [75,76]. However, recent reports refute this dogma and provide direct evidence of T-cell subset plasticity, implicating epigenetic modifications responsible for triggering complex transcriptome signatures that allow flexibility in T-cell phenotypes [77]. Thus, GATA3/Th2 cells for example could be reprogrammed to adopt a GATA3$^+$/T-bet$^+$ and IL-4/IFN-γ phenotype in a model of lymphocytic choriomeningitis virus (LCMV) infection [78]. RORγt/IL-17 cells can be converted to RORγt$^+$/T-bet$^+$ and IL-17$^+$/IFN-γ$^+$ producers in a model of autoimmunity [79]. Likewise, IL-21 and Bcl-6 expression appears not to be restricted solely to Tfh, because these cells can also secrete Th1,Th2, and Th17 cytokines [80]. The plasticity versus stability of these T-cell subsets remains to be further elucidated given increasing knowledge of the close relationship between transcription factors and the state of cell chromatin and gene expression, as reflected by downstream cell effector function.

B-cell immunobiology

In mammals, there is no single discrete organ of B-cell development that functions as a homolog of the thymus for T cells. Instead, B cells develop at multiple sites, including the liver, BM, and spleen. Although their immunological functions are quite distinct, there are many similarities between T and B cells, including development, receptor structure, tolerogenic mechanisms, and signaling. One of the most important of these is evident from the nomenclature of the gene family to which the TCR belongs, that is the Ig supergene family. Ig genes, expressed exclusively in B cells, are the prototype of a large number of immunologically important genes, including the TCR. Secreted Ig gene products are Abs, the basis for humoral immunity. Membrane-bound Ig gene products are BCR for Ag (BCR), the B cell "equivalent" of the TCR. The processes of B-cell development, selection, and elimination or inactivation of autoreactive cells are very similar to those for T cells and will not be elaborated upon further. There are, however, two important processes that are unique to B cells: isotype switching and affinity maturation or somatic hypermutation. The transplant-specific elements of these processes are highlighted in Chapter 6.

Isotype switching

There are five primary classes (isotypes) of Ig: IgM, IgD, IgG, IgE, and IgA, determined by which constant region is used by the heavy chain, that is the ξ, δ, γ, ε, or α segments, respectively. Mature naïve B cells express both IgM and IgD on their surface, the only instance in which B cells express more than one Ig isotype. Both IgM and IgD function as BCR for Ag. After activation, B cells undergo a process of isotype switching to either IgG, which has several subclasses (IgG1, IgG2a/c, IgG2b, IgG3 in mice and IgG1, IgG2, IgG3, and IgG4 in humans), IgE, or IgA as part of further differentiation and expansion.

Somatic hypermutation and affinity maturation

Following immunization with an Ag, B cells undergo somatic point mutations in their Ig genes. The purpose of somatic mutation is to refine the Ig repertoire further. The mutation process is essentially random; therefore, some mutated Ig genes have unchanged Ag affinity, while some have higher, and others have lower Ag affinity. Since B-cell expansion, maturation, and survival are dependent upon continued Ag stimulation, those B cells whose somatic mutations have led to high-affinity Ig genes will have a selective survival advantage. The result is affinity maturation during the immune response.

B-cell activation

T-independent Ags

In general, B-cell responses to Ag require T-cell help (see below). However, a few types of Ag (i.e. those containing repetitive epitopes) are highly efficient at cross-linking membrane Ig (the B-cell receptor for Ag). These Ags, most commonly bacterial capsular polysaccharides, deliver such potent signals to the B cells that, unlike most protein Ags, T cells are not required. Therefore, these Ags are termed T-independent Ags.

Cognate interactions provide costimulatory signals

Most B cell Ags are probably unable to cross-link Ig extensively and, therefore, activate B cells by themselves. They depend on a process known as T-cell : B-cell cognate help. In this instance, the Ag binds to the B-cell surface Ig, is internalized, and is presented to $CD4^+$ T cells on B-cell MHC class II molecules. The activated T-cell : B-cell contact initiated in this way also allows the B-cell surface receptor CD40 to bind to its ligand on the T cell (CD40L, CD154). Signals through CD40 then act in concert with T-cell-derived cytokines to activate the B cell.

Ab secretion

Following appropriate activation and signaling, previously naïve B cells secrete IgM and proceed in one of two directions: development into memory cells or differentiation into Ab-secreting plasma cells. The latter fate is accompanied frequently by somatic mutation and isotype switching to IgA, IgG, or IgE, although some plasma cells do not class switch and secrete IgM. This process occurs over a period of 2 to 3 weeks, so that the initial Ab response in a naïve animal is IgM, with subsequent maturation to IgG and IgA. Abs can function in several different ways, varying by isotype. These mechanisms include fixation of complement (see below), opsonization or phagocytosis by fragment crystallizable receptor $(FcR)^+$ cells, opsonization for lysis by cells capable of Ab-mediated cellular cytotoxicity (whereby innate effector cells kill cells coated with Abs when activated through a receptor for the Ab), and induction of eosinophil degranulation.

The complement system

The complement system (Figure 2.4) is a complex system of proteolytic enzymes, regulatory proteins, and lytic proteins directed at

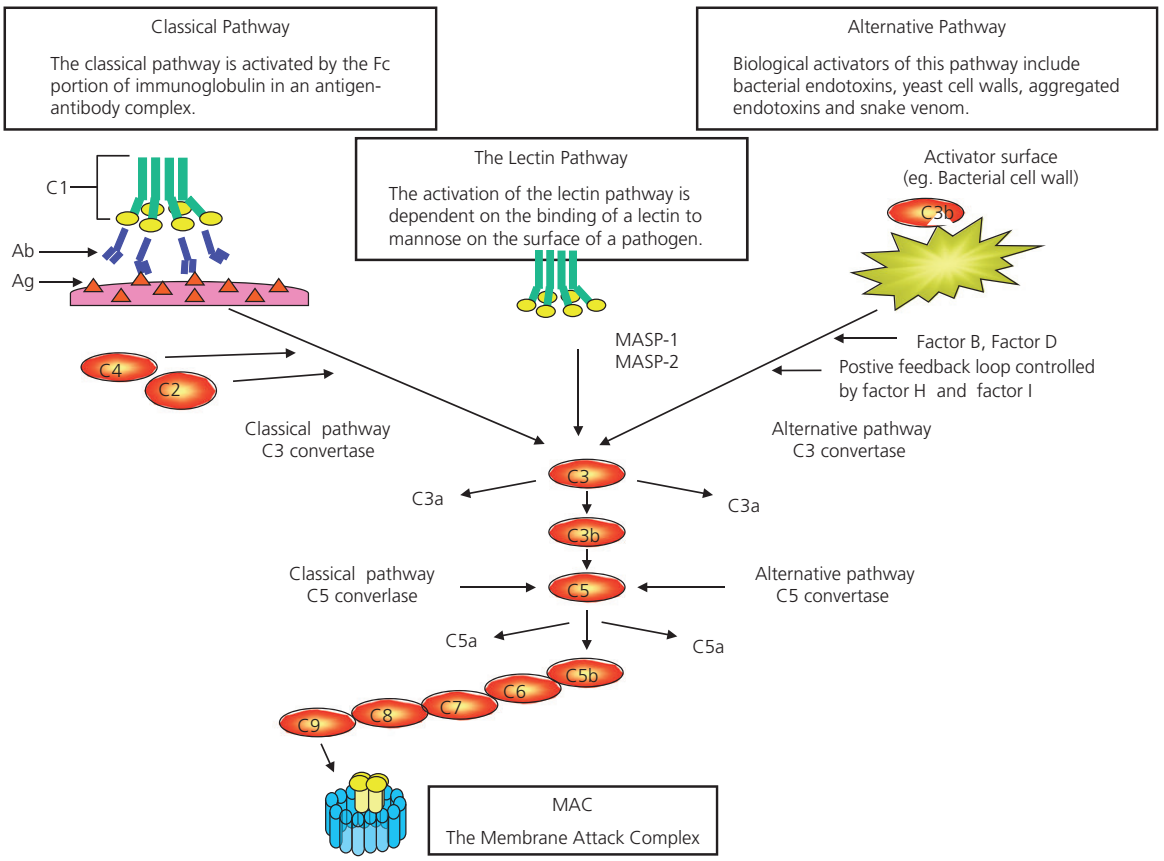

Figure 2.4. Pathways of complement activation. Complement activation is mediated by three pathways: the classic pathway, which is initiated by antigen–antibody complexes, the alternative pathway, and the lectin pathway. All pathways converge on the activation of C3 convertase, and end with the formation of membrane attach complex (MAC), which mediates cell lysis by breaking down cell membrane.

target cells [81,82]. It can be divided into three components, leading to the activation of C3, which is critical for opsonization of bacterial Ags. The split fragment C3b activates a membrane attack complex (MAC) (C5, C6, C7, C8, C9) which causes membrane damage, leading to osmotic lysis of target cells [83].

The three activation pathways are named the "classic," the "lectin binding", and the "alternative" pathways. The classic pathway of complement activation involves binding of the first component of complement (C1), to aggregated IgM or IgG Abs in the form of an Ag–Ab complex. Activated C1 is a proteolytic enzyme; the C1 esterase is capable of cleaving the next two components of the classic pathway (C4 and C2) into several fragments. The complex of C4b with C2a is a serine protease capable of cleaving C3, releasing C3a and C3b. The lectin pathway uses mannose-binding lectin (MBL)-associated serine proteases (MASP) to cleave C4b with C2a that, in turn, splits C3 into C3a and C3b. C3 can also be cleaved by a convertase that develops from the alternative pathway, which can be initiated not only by Ag–Ab complexes but also by bacteria, LPS, and many other activating surfaces. In this pathway, factor D is capable of hydrolyzing another factor, factor B, only after the latter has been bound by the C3b fragment of C3. This leads to the C3bBb complex, which is an alternative pathway C3 convertase. C3b is recognized by receptors on various cell types, including macrophages and B cells. Binding of C3b to Ab-coated bacteria is an essential step for the phagocytosis of these agents by macrophages bearing receptors for C3b. On the other hand, C3b is critical for the engagement of the terminal components of complement (C5, C9) to form the MAC, which causes cell lysis. The C5b–C9 is responsible for the complement lesion in membranes.

In addition to the role of the complement system in opsonization and as a lytic material, several of the complement fragments (C3a, C5a) formed during activation are potent mediators of inflammation. C3a binds to receptors on mast cells and basophils and induces the release of histamine and mediators of anaphylaxis. C5a is also a chemotactic attractant for neutrophils and monocytes [84]. Further information about the role of complement in transplant rejection can be found in recent reviews [85,86] (see Chapter 7).

Cytokines

Cytokines are peptides, produced by all nucleated cells, that exert pleiotropic regulatory effects on hematopoietic and other cells that participate in host defense and repair. They include lymphocyte-derived and monocyte-derived factors, hematopoietic growth factors (colony-stimulating factors; CSF), connective tissue growth factors, and chemotactic factors (chemokines). Extensive details of cytokine biology and their applications can be found in [87]. Most cytokines act locally, over short distances, as autocrine or paracrine intercellular signals, and, with few exceptions, reach the circulation and initiate systemic responses only occasionally. Cytokines generally are not produced constitutively, but are generated in response to danger signals to offset challenges to host integrity. Their functions maintain homeostasis by regulating innate host defenses and the immune system, through damage control, and by promotion of tissue repair. Cytokines are very potent and active at pM to nM concentrations. Their characteristics are summarized in Table 2.1.

Whereas many cytokines are now termed interleukins (IL) (e.g. IL-1 was formerly monocyte-derived lymphocyte-activating factor), others retain their older names (e.g. IFN-α/β, TNF, lymphotoxins (LT-α and LT-β), transforming growth factor (TGF)-β, leukocyte inhibitory factor (LIF), most CSFs and many others). The "older" names suggest only one (usually the first recognized) function of these pleiotropic agents. The "IL" terminology accommodates broader roles and, as the number of ILs has increased, now up to 35, there has been explosive interest in the molecular biology and function of these mediators of inflammation and immunity. Structural features shared by certain cytokines has allowed their grouping into "families" (Table 2.2), such as the TNF family of cytokines and the IL-1 and TGF-β families. Numerical designations have been approved for the four subfamilies of chemotactic cytokines (chemokines) and chemokine receptors (see Table 2.1) consisting of the letters CXC, C, CX3C, and CC, plus a consecutive number.

Table 2.1. Characteristic features of cytokines

- Most are simple polypeptides or glycoproteins ≲30 kDa
- Constitutive production is low or absent; production is regulated by inducing stimuli at the level of transcription or translation
- Cytokine production is transient and typical action is autocrine or paracrine, not endocrine
- Cytokines bind to specific, high-affinity cell surface receptors (Kd of 10^{-9}–10^{-12} M)
- Most cytokine actions result from an altered pattern of gene expression in target cells. Cytokine actions lead to increased (or decreased) cell proliferation, changes in differentiation state, and/or a change in function(s)
- While individual cytokine actions can be quite broad and diverse, at least some action(s) of each cytokine is (are) targeted at hematopoietic cells

Table 2.2. Shared structural features of cytokines permit their grouping into families

Family	Representative members
IL-2/IL-4	IL-2
	IL-4
	IL-5
	GM-CSF
IL-6/IL-12	IL-6
	IL-12*
Interferons-α/β	IFN-α (many subtypes)
	IFN-β
	IFN-ω
	IFN-τ
Tumor necrosis factors	TNF-α
	LT-α (TNF-β)
	LT-β
	Fas ligand
	CD40 ligand
	TRAIL
IL-10	IL-10
	IL-19
	IL-20
	IL-22
IL-17	IL-17
	IL-25
IL-1	IL-1α
	IL-1β
	IL-1R antagonist
	IL-18
TGF-β	TGF-β
	Bone morphogenetic proteins
	Inhibins
	Activins
Chemokines	CXC subfamily (CXCL1-16)
	CC subfamily (CCL1-28)
	C subfamily (CL1/lymphotactin)
	CX3C subfamily (CX3CL1/fractalkine)

*IL-12 is a heterodimer in which one subunit is structurally-related to IL-6, and the other subunit shows partial homology to the extracellular domain of the IL-6R (α chain).
TRAIL, TNFR apoptosis-inducing ligand; LT, lymphotoxin.

Structural features and categories (families) of cytokines

Some families include proteins whose primary sequences show a high degree of homology, for example all IFN-α/β family members show at least 30% homology in their amino acid sequences. In other instances, the structural relationship is more distant and based mainly on a common proposed tertiary structure and spatial organization. An example of the latter type of structural relationship is the IL-2/IL-4 family. Members of this family contain four α-helical regions in a spatially similar arrangement. Despite the identification of many structurally distinct cytokines, they can be organized into groups with functional similarities based on shared receptor (R) usage. This applies to IL-1α and IL-1β, as well as to TNF and LT, which use shared and unshared receptors. Receptor chains are shared by cytokine groups. For example, the IL-2γR chain is shared by IL-2, 4, 7, 9, 15, and 21. The gp130 chain of the IL-6R is shared by IL-6, IL-11, LIF, and other cytokines. TNF family members share receptors with homology to the TNFR. These include TNF, LTα, LTβ complex, Fas ligand, CD70, CD40L, CD30L, nerve growth factor, and more. A receptor β chain is shared by IL-3, IL-5, and granulocyte–macrophage (GM)-CSF. Homologous G-protein-coupled receptors are used by IL-8 and chemokine family members. Receptors for IFN-α, β, ω, γ, and IL-10 also exhibit homology, as do those for the TGF-β family. Because IL-12 and IL-18 have overlapping activities, their receptors may also be related.

The importance of cytokines

Cytokines are the principal orchestrators of defense processes and, as such, play key roles in host responses to exogenous and endogenous insults, repair, and restoration of homeostasis. They mediate host responses to tissue injury, invading organisms, tumors, and to cell and tissue transplants. Importantly, microbial pathogens can produce molecular variants of cytokines (e.g. viral IL-10), their receptors, and chemokine antagonists which subvert host inflammatory and immune defenses. Deletion of these products reduces the pathogenicity of these viruses. The development of highly sensitive methods of detection has revealed the presence of detectable, but low levels of cytokines associated with a variety of binding proteins in the serum. This probably reflects the production of cytokines in response to the many non-pathogenic stimulants present in the normal environment. Detection and measurement of cytokines in disease states may provide useful diagnostic tools. Moreover, the therapeutic administration of pharmacological doses of cytokines is employed in a wide variety of infectious diseases, autoimmune disorders, and malignancies. This has also prompted the evaluation of cytokine antagonists for their anti-inflammatory properties (e.g. TNFR).

Synergistic and antagonistic interactions

Actions of cytokines are contextual and can be influenced profoundly by the milieu in which they function and, in particular, by the presence or absence of other biologically active factors (i.e. other cytokines, hormones, growth factors, prostaglandins, microbial products, etc.). Under normal conditions a cell rarely, if ever, encounters only one cytokine at a time. Thus, a cell is more likely to be exposed to multiple cytokines and other biologically active factors, resulting in biological actions that reflect various synergistic and antagonistic interactions of various factors present. Table 2.3 summarizes typical features of cytokine actions.

Table 2.3. Characteristic cytokine actions

Action	Features
Pleiotropy	Multiple target cells and actions
Redundancy	Distinct cytokines have similar actions
Synergism/ antagonism	Exposure of cells concurrently to >1 cytokine may lead to qualitatively different responses (e.g. synergy between IFN-γ and TNF-α)
Cytokine cascade	A cytokine may increase (or decrease) production of another cytokine
Receptor transmodulation	A cytokine may increase (or decrease) the expression of receptors for another cytokine or growth factor
Receptor trans-signaling	A cytokine may increase (or decrease) signaling by receptors for other cytokines or growth factors

Stimulatory and inhibitory properties of cytokines

An important characteristic of cytokines is their ability to stimulate or inhibit the production of other cytokines. Consequently, many cytokine actions are indirect, that is they are due to an increase or decrease in production of other cytokines, resulting in an altered biological response. An example of such an indirect action is that the mitogenic action of IL-1 in mouse thymocytes involves stimulation of IL-2 production, and that IL-2 is the actual effector molecule responsible for stimulation of thymocyte proliferation. The stimulatory effect of IL-1 on IL-2 production and the role of this cytokine interaction in T-cell proliferation typify the actions of many other cytokines. Another example is the stimulation of IFN-γ production by IL-12. IL-12 that is produced by activated APC induces IFN-γ production in T cells and NK cells and is a major regulator of IFN-γ production. IL-25 stimulates IL-4, IL-5, and IL-13 production in T cells.

Although less numerous than reports of their stimulatory interactions, cytokines can also inhibit cytokine production. Thus IL-10 inhibits cytokine production by Th1 cells and by monocytes/macrophages/DC. Many of the anti-inflammatory and immunosuppressive actions of TGF-β are also due to its ability to suppress cytokine production in T cells and APC. A good example of stimulatory and inhibitory interactions involving multiple sets of cytokines is the development of polarized Th1 and Th2 responses. Thus Th1 cells secrete IL-2 and IFN-γ and are efficient in activating cellular immune responses that enhance the elimination of intracellular pathogens. By contrast, Th2 cells secrete IL-4, IL-5, IL-10, and IL-13, which promote Ab responses, especially IgE production, leading to allergy. A major player in these processes is IL-12, which promotes IFN-γ production and Th1 development.

Redundancy and pleiotropy

Extensive redundancy and pleiotropy in cytokine actions can make it difficult to predict the uniqueness and necessity for individual cytokine actions in vivo. Determining how cytokines function in the intact host has been aided greatly by the development of the technique of targeted gene disruption. However, a great deal still remains to be learned about the complex interactions that eventually determine the outcome of cytokine actions in the complex in vivo environment.

Immunological tolerance

T and B cells are highly effective in defending the host from invasion and colonization by pathogens; however, they can also attack the host. This risk arises during ontogeny, from the mechanism

used to generate T- and B-cell Ag receptors (TCR, BCR). As described above, these receptors are generated by joining V, D, and J segments at the TCR and Ig loci. The emerging repertoires contain unpredictably diverse V segments and include receptors capable of binding to Ags from self-proteins. Multiple checkpoints are needed to prevent either the generation or functional activity of autoreactive lymphocytes [88]. Furthermore, as lymphocytes are generated continuously throughout life, there is a life-long need for these controls.

Although tolerance-promoting mechanisms are tightly integrated and often act at the same time, they can be categorized in two major groups: (1) checkpoints that control the development of lymphocytes—commonly referred to as "central tolerance," and (2) checkpoints that influence the activity of fully developed lymphocytes, or "peripheral tolerance." Understanding the mechanisms of tolerance is key to understanding how to treat and monitor transplant recipients, and a thorough discussion of these mechanisms as they relate to transplantation tolerance is found in Chapter 11. This is particularly important when considering that some immunosuppressive drugs, while blocking lymphocyte activation, also inhibit intrinsic programs of tolerance induction. Thus, careful consideration must be afforded to their optimal application.

T-cell central tolerance

During intrathymic T-cell development, the spontaneous rearrangement of TCR chain segments is halted only when the newly formed TCR binds to an intrathymic ligand [89]. Stronger and/or longer positively selecting signals generated as a result of co-ligation of the TCR and the CD4 co-receptor results in instruction of CD4 helper lineage fate, while weaker and/or shorter signals initiated by the TCR and the CD8 co-receptor result in CD8 cytotoxic lineage fate determination. Very strong signaling, however, results in apoptosis of the engaged thymocytes—commonly referred to as "negative selection." Deletion of thymocytes is based on the Ags present in the thymic medulla, raising the issue of how tolerance to tissue-specific Ags occurs. Presentation of peripheral tissue-specific Ags within the thymus is made possible either by immigration of peripheral APC (DC and B cells), in addition to promiscuous Ag expression by thymic epithelial cells facilitated by the recently discovered transcription factor Aire (autoimmune regulatory) expressed in the thymic medulla.

Not all thymocytes that recognize self-Ag with high avidity are deleted. Engagement of TCR ligands with high affinity can induce the generation of Treg that play an essential role in maintenance of self-tolerance at the level of lymphocyte activation (see below). This is one point where the distinction between central and peripheral tolerance becomes indistinct, complicating our understanding of the contribution of each individual mechanism.

T-cell peripheral tolerance

Autoreactive T cells can escape negative selection when their TCR is of sufficiently low avidity for self-proteins, or when they bear TCR with high avidity for tissue-restricted Ags that are not expressed in sufficient amounts in the thymus. For these T cells, immune tolerance must rely on peripheral mechanisms [90].

Ignorance

One barrier to self MHC complex recognition is the physical separation of potentially autoreactive T cells from the parenchymal cells that express the target Ag. Naïve T cells circulate from blood to secondary lymphoid organs, to efferent lymph, and then back again to the blood. Thus, naïve T cells are excluded from non-lymphoid peripheral tissues, where the likelihood of coming in contact with a tissue-resident cell expressing a high density of a tissue restricted Ag is higher. These specific trafficking patterns of naïve T cells promote a state of "ignorance" (unawareness) to tissue-specific Ag.

Deletion and anergy

As indicated earlier, activation of T cells requires the integration of signals generated through the TCR and costimulatory molecules engaged in the interaction with mature APC. This requirement enacts an important checkpoint for the maintenance of tolerance [91,92]. When a T cell recognizes a target Ag in the absence of costimulation, the engaged T cell initiates an abortive activation process that results in the deletion of most of the daughter cells. This takes place through activation of a suicide program incorporated in the T-cell differentiation mechanism, which is commonly referred to as apoptosis. Interestingly, not all reactive cells that encounter their Ag in the absence of costimulation are eliminated. During abortive T-cell activation, the remaining cells enter a state of functional inactivity defined as "anergy." Similarly to apoptosis, anergy is a program enforced through a delicate balance between activation and inhibition of specific genes. The main characteristic of anergic cells is their inability to respond to subsequent engagement of the TCR with the same Ag, even when this new encounter occurs in the presence of costimulation. Although the advantage of the apoptotic program is evident, the benefit of maintaining circulating anergic cells is still under investigation. It is believed to provide two main advantages; first, it guarantees the existence of cells able to recognize a different Ag (pathogenic) with sufficient affinity to allow reversal of the anergic state, thus contributing to the maintenance of a wide repertoire of patrolling cells. At the same time, the anergic cells could join the pool of regulatory cells that control the activation of other autoreactive lymphocytes, as indicated below.

Regulatory T cells

As mentioned briefly in the previous sections, T lymphocyte development is characterized not only by the selection of potential effector cells that will attack their target, but also by T cells with the ability to regulate the activation of the immune system, so-called Treg (also see Chapter 8) [93]. First recognized as $CD25^{+}CD4^{+}$ T cells, and later shown to specifically express the transcription factor Foxp3, these cells are naturally present as a functionally distinct T-cell subpopulation, and their deficiency produces autoimmune disease. Evidence is now accumulating that Treg buffer almost every adaptive immune response, both physiological or pathological. The thymus of an adult animal produces natural Treg continually. Their selection appears to be induced on high-affinity, self-reactive TCRs, although more understanding is needed. Once in the circulation, these cells are programmed to control immune reactivity in every circumstance where self-Ags are involved. This is achieved through multiple mechanisms [94]. These range from the ability of Treg to interact with APC and reduce their presenting and T-cell stimulatory function, to active inhibition of the activation and proliferation of naïve T cells, as well as control of the damaging function of fully differentiated T effector cells. Several mechanisms of suppression may operate synergistically, and in a complementary manner.

The involvement of Treg in almost every immune response is more easily understood when it is considered that low-level

autoimmunity may occur frequently as a result of tissue damage due to microbial infection and consequent activation of DC that present self-Ag to self-reactive T cells. Treg are automatically recruited to sites of inflammation, activated, and able to suppress autoreactive T cells and thus prevent the progression of autoimmunity to chronic autoimmune disease.

In addition to thymic production of natural Treg, naïve T cells in the periphery can be induced to upregulate Foxp3 expression and consequently acquire Treg functions. There is accumulating evidence that such induced Treg are present at least in the intestine. Although it remains uncertain to what extent such induced Foxp3$^+$ Treg contribute to systemic self tolerance, it is reasonable to speculate that they play complementary roles and that deficiency of both natural and induced Foxp3$^+$ Treg is responsible for severe autoimmune diseases.

Another mechanism contributing to the decision between tolerance and immunity is the capacity of B cells to act as regulators rather than effectors [95,96]. Although the first description of regulatory B cells (Bregs) dates back many years, they have recently re-emerged in the form of a population of IL-10-secreting B cells in mice, with a comparable population in humans that exhibit the capacity to control both T-cell- and B-cell-mediated responses.

B-cell central tolerance

B cells belong to three distinct lineages: B1a, B1b, and B2 cells. B1 cells respond in a T-cell-independent manner, and seem essential for the production of Abs against some pathogenic bacteria and parasites that require an innate-like response. Conversely, B2 cells are activated through T-cell licensing in germinal centers and are required for adaptive immunity. These complementary activities underscore the need for multiple mechanisms acting at different stages of B-cell development and activation to control the possible production of self-reactive Abs [89,97].

It is estimated that more than half of all newly generated BCRs are capable of binding self-Ags. However, not all self-Ag-binding BCR are necessarily detrimental to the organism. For example, a certain proportion of BCR may bind self Ags with too low an affinity to trigger an autoimmune response, while they may bind strongly enough to Ags derived from invading pathogens to exert a protective host defense effect. This further underscores the complexity of the process of purging or controlling specifically those autoreactive B cells that are harmful.

Mature B1 and B2 cells emerge only after passing through checkpoints, several of which enforce self-tolerance through assessment of Ag avidity (affinity and density) and the signaling threshold of the BCR. During the formation of a pre-B cell in the BM (or fetal liver), a significant number of cells are blocked in their development. It is still unclear how much of this negative selection of pre-BCRs is mediated by binding of self Ag and how much is due to lack of formation of a functional receptor. Unfortunately, almost nothing is known about the self-Ag-presenting modes that establish central B-cell tolerance. In human B-cell development, some, but not all, autoreactive cells are lost during the transition from pre-B to immature B cells, defining an additional checkpoint for self-reactivity that needs to be better elucidated. Less controversy exists for immature B cells (confirmed in both rodent and human systems). At this stage, autoreactive BCRs can be purged by "receptor editing," a process through which Ag binding induces continued rearrangement of Ig gene segments. This process results in a change in the specificity of the autoreactive population, as it is also paired with the clonal deletion of B cells that retain their self-reactivity.

B-cell peripheral tolerance

The existence of checkpoints during B-cell development in the BM allows approximately 10% of all newly generated immature B cells to emerge from the BM as transitional (T1 then T2) cells. Although fairly efficient, these mechanisms do not remove all potentially autoreactive B cells, as these transitional cells migrate to the spleen, where they may encounter peripheral self-Ags absent in the BM. High-avidity interactions with these Ags lead to rapid deletion of B cells at the T1 stage. By contrast, low or very low avidity interactions result in the induction of anergy. This state is characterized by desensitization of BCR signaling, resulting in decreased responsiveness, failure of Ag-presenting function and Ab-producing capabilities, and an inability to compete for limiting amounts of B-cell survival factors. Furthermore, the remaining transitional B cells that interact with moderate intensity to either self or foreign Ags relocate, similarly to mature naïve B cells, to the T-cell zone in search of help. In the absence of T-cell help (or alternative costimulatory signals), these stimulated transitional B cells die within 2–3 days, irrespective of their specificity.

Differently from T cells, B cells, once mature, can further expand their BCR repertoire of specificity through somatic hypermutation of Ig variable region genes within germinal centers following Ag stimulation. This leads inevitably to the appearance of cells expressing antiself receptors and requires additional control mechanisms. The environment of germinal centers plays a pivotal role in preventing the development of a self-reacting repertoire among mature naïve B cells. This represents a microenvironment in which hypermutating B cells are positively selected on the basis of affinity, but negatively selected against self-reactivity due to local competition for Ag presented on follicular DC and access to help provided at this site by Tfh cells. Similarly to transitional B cells, germinal center B cells are deleted following Ag exposure if they do not receive survival signals from Tfh cells.

Immunological memory

When the immune system is challenged a second or subsequent time by the same foreign material, the response is generally characterized by faster kinetics of lymphocyte activation (both of T and B cells) and elimination of the foreign material, a phenomenon referred to as immunological memory [98].

T-cell memory

As described earlier, a productive interaction between a T cell and an APC triggers the former to divide and become an effector cell. Under physiological conditions where these effectors (a blend of CD4 T subsets and CD8 cytotoxic T cells) execute a rapid clearance of the triggering Ags, the number of effector cells peaks about a week into the response. About 90% of these effector cells then die during a 1- to 2-week-long contraction phase, which leaves a residual population of long-lived memory T cells. These memory cells are phenotypically and functionally distinct from naïve T cells, the main characteristic being a lower activation threshold that allows them to respond rapidly upon restimulation [99]. There is recent recognition that the distinction between naïve and memory status has marked implications with regard to a cells capacity for alloreactivity, and this is covered in depth in Chapter 9. Memory cells are heterogenous however, and are thought to exist in at least two classes [100]: effector memory T cells (Tem cells) and central memory T cells (Tcm cells). Tem cells express homing receptors that facilitate migration to non-lymphoid sites of inflammation and

produce a variety of microbicidal cytokines within several hours of TCR stimulation. Conversely, Tcm cells do not produce prototypic "effector" cytokines immediately after stimulation through the TCR, although they do secrete IL-2 and proliferate extensively and acquire effector cytokine production later. Additionally, these cells express receptors (e.g. CD62L and CCR7) that promote migration to lymph nodes and mucosal lymphoid organs. It has therefore been postulated that Tcm cells circulate to these locations and probably therein undergo secondary responses representing a source for new Tem cells.

These characteristics indicate that the generation of Tem and Tcm cells confers a qualitatively and quantitatively distinct immune response upon successive (but interrupted) exposures to Ag. This leads to an improved secondary immune response compared to the primary response, one that is greater in magnitude, faster, more sensitive to low doses of Ag, and more effective in the diversity or complexity of secondary effectors.

B-cell memory

As discussed above, B-cell activation comprises a process of selection in the germinal centers (influenced by interactions with APC and by the environment defined by activated T cells) that results in "affinity maturation" of the responding cells. After this process, some B cells differentiate into Ab-secreting plasma cells, while others become memory B cells (Bmem) [101,102]. These Bmem stop dividing and enter a quiescent state that allows them to persist for a long time, the entire life of an individual in some instances. Similarly to the memory response of T cells, the existence of Bmem confers different characteristics on a secondary humoral response. This response develops in a shorter time (approx 3–5 versus 7–10 days in a primary response), is typified by a greater amount of Ab production and lasts for a longer period. Additionally, the secondary response is characterized by secretion of Ab with higher affinity for the Ag (due to the initial affinity maturation process) and by the presence of isotypes other than IgM (mainly IgG, IgA, and IgE) that are better suited to respond rapidly to the multitude of Ags associated with a pathogen previously encountered and to serve different anatomical sites.

Summary

Immunology in general forms the basis for understanding how one exists as an individual within a sea of pathogens and threats to one's homeostatic integrity. While this is fundamental to the maintenance of health, it runs counter to the practice of organ sharing, and, as such, is integral to the requirements for immune modulation that result in the successes and challenges of modern transplantation. Throughout this text, the reader should recognize that the numerous interconnected elements of physiologic immunity that require constraint to allow for allograft survival, evolved first as important means of self-preservation. As such, the transplant researcher and clinician should be cognizant of the consequences of excessive suppression of immune function, and strive to work within the confines and elegance of the immune system.

CHAPTER 3

Transplant Antigens: A Brief History of HLA

Paul I. Terasaki
University of California and Terasaki Foundation, Los Angeles, CA, USA

Introduction

One of the most significant discoveries relevant to the practice of organ transplantation was the elucidation of the major histocompatibility complex (MHC), known in humans as HLA and mapped to chromosome 6. Histocompatibility typing, essentially defining the content of the MHC for a donor and recipient pair, has been an established practice in transplantation since its methodology was established, and alloimmune responses are now accepted to be largely responsive to polymorphisms mapped to this region. Indeed, the development of alloantibodies toward HLA polymorphisms is a fundamental metric used to establish organ allocation, and is increasingly recognized as an indicator of ongoing alloimmune destruction of a transplanted organ. This chapter describes the major events culminating in the modern understanding of HLA, and will be useful to the reader in orienting to the concepts of transplant biology in general. It specifically serves as a companion to the broader history of clinical transplantation found in Chapter 1, and to the specific chapters on modern histocompatibility lab and alloantibody testing in Chapters 36 and 89, respectively.

Early investigations

The advent of clinical kidney transplantation in the late 1950s drove the development of knowledge of HLA. When Joseph Murray and David Hume boldly transplanted kidneys in humans [1,2], relatively little scientific support existed for such human experimentation. Skin grafts with animals [3] and kidney transplants in dogs [4] had survived only a matter of weeks. Studies in mice by Peter Gorer and George Snell [5] had shown that a histocompatibility system existed, and that it controlled whether tissues could be grafted from one animal to another. It was called the "H-2 system," and there was general agreement that a similar system probably existed in humans. The challenge then was to identify this human histocompatibility system.

After discovery of the ABO system [6], how antigens of the red cell could be detected was well known. Researchers then turned to white cells as the best avenue for isolating the factors of histocompatibility in humans. Because transfusion reactions in patients who had been multiply transfused suggested that antibodies were involved, Peter Miesher [7] and others used techniques borrowed from work with red cells—mainly agglutination—to begin studies on leukocyte antigens. Jean Dausset, working at a blood bank in France, found antibodies in three patients that reacted similarly. The discovery led him to postulate the first leukocyte antigen group, which he called MAC [8]. Johannes van Rood, also working at a blood bank, but in Holland, studied leukoagglutinating antibodies in pregnant women, searching for specificities [9]. From the outset, the problem was the unreliability of the agglutination test because of difficulties in handling granulocytes. To resolve the variability problem, Van Rood came up with the idea of using computers to sort out complex reactions, resulting in the identification of the 4a and 4b specificities [10]. At about the same time, Rose Payne at Stanford—also working on leukoagglutinating antibodies in pregnant women [11]—collaborated with Walter and Julia Bodmer to find two antigenic groups, which they called LA1 and LA2 [12].

Recognizing that we researchers needed to agree on methods used for tissue typing, the first histocompatibility workshop was organized at Duke University by Bernard Amos in 1964 to compare methods [13]. Five labs used the leukoagglutination test, and one or two labs demonstrated tests by mixed agglutination, complement fixation, indirect antiglobulin consumption, mixed lymphocyte culture, and the microlymphocyte cytotoxicity test [14]. In the second workshop (1965), hosted by Van Rood in Holland, ten labs used leukoagglutination, and only Ruggero Ceppellini and our lab used the microcytotoxicity test (Figure 3.1) [15]. Most important, we were now able to cross-compare results of tissue types identified in the different labs because we all typed the same panel of blood donors. We began to see that we had, among us, identified ten types [15]. Work continued furiously in the various labs, and 2 years later, in 1967, the third histocompatibility workshop was organized in Torino by Ceppellini, with 16 labs participating [16]. We all typed 11 families, making it possible to see for the first time that a *single* system or genetic locus was producing all these reactions.

After the workshop, a WHO conference was held to decide on nomenclature [17]. Amos summarized the wrangles in the committee [18] over whether to call the system "Hu," as Dausset had called his, or "LA," as Payne and the Bodmers had called theirs; and as noted by Amos [18], I suggested "HLA" as a compromise, though at the same time, as part of the compromise, the first antigen of Dausset came to be called HLA 2 and Payne and Bodmer's LA 1 became HLA 1. The association of this nomenclature with the term "human leukocyte antigens" was eventually applied post hoc, but not part of the actual naming convention as it originated.

With 13 antigens identified and now placed in one locus, the principal basis of the HLA system was established in 1967, a bare 3 years after the first workshop. Flemming Kissmeyer-Nielsen provided evidence that there were at least two parts to the system: the A and B loci [19]. At the fourth workshop, at UCLA in 1970,

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

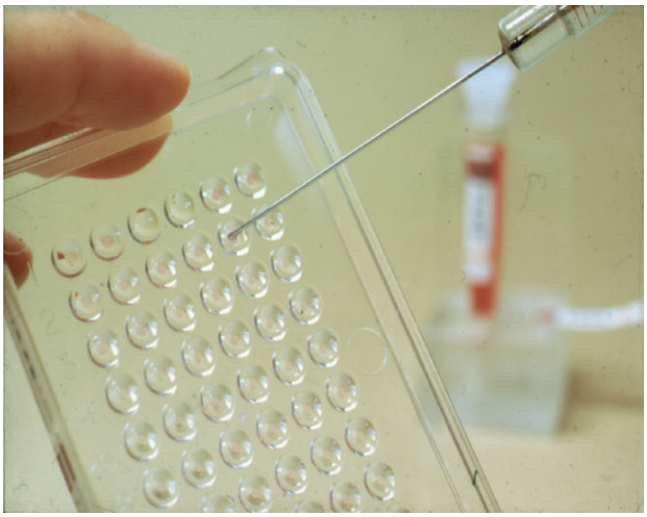

Figure 3.1. The microlymphocyte cytotoxicity test was introduced in 1964. It utilizes 0.0001 mL of antisera, 0.001 mL of lymphocytes, and 0.005 mL of rabbit complement. The drop of oil in each well prevents evaporation and allows the addition of successive reagents into the well without the necessity of removing and adding a cap, because the oil always goes to the top. (From the author's personal collection.)

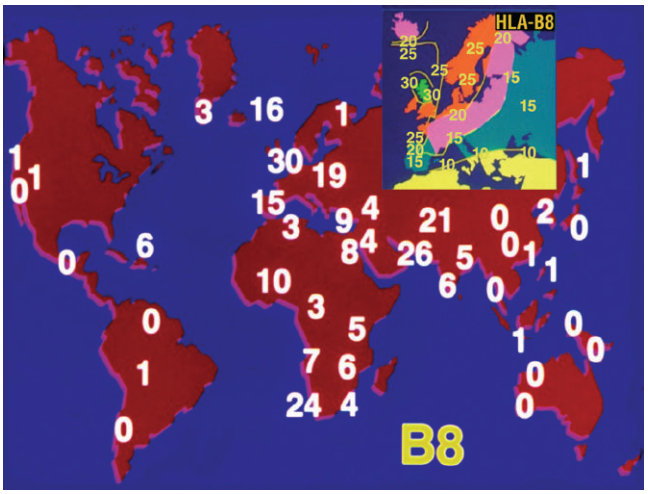

Figure 3.2. The worldwide distribution of HLA B8 antigen. The numbers indicate the frequency within each population. B8 can be seen to be a Caucasian antigen, rarely present in Asia and in American Indians. Even among Caucasians, as shown in the insert, the frequency of B8 shows a gradient in Europe from north to south. (From the author's personal collection.)

the microcytotoxicity test [20] was adopted as the international standard. This method was used at all subsequent workshops. In 1970, 116 sera were exchanged between 15 labs, and, thanks to the microcytotoxicity test, as many as 298 families could be tested. We ended up with 27 specificities [21].

It should be noted that during this time, Baruj Benacerraf was conducting experiments involving the immune response of outbred animals immunized with antigens with restricted heterogeneity, such as hapten conjugates of poly-L-lysine. His observation that the immune response varied and could be mapped to a genetic locus of what he called immune response genes were consistent with the concepts of the MHC.

A major application of HLA for anthropological studies was inaugurated by Dausset at the fifth workshop, in Evian (1975). Typers were assigned various geographic areas, and a world map charting the frequencies of HLA specificities was compiled [22]. Major racial groups could be identified, and racially associated specificities tracked in various national groups. For example, B8, which appears in Caucasians, was shown to vary from 30% in Scots, to 20% in French, 10% in Italians, and 5% in the Caucasians of Middle Eastern countries (Figure 3.2).

This great diversity in human populations led to the use of HLA in paternity testing: the father could almost certainly be identified because the inherited paternal chromosome would be unique [23]. A small tissue-typing triumph occurred when it demonstrated that two non-identical twins had different fathers [24].

HLA C locus antigens were identified at the sixth workshop, in Aarhus [25], and DR locus antigens at the seventh, in Oxford [26]. By the time the eighth workshop, in Los Angeles, was over, 78 specificities had been defined [27]. Since that time, seven more international workshops have been held—one every 2 to 3 years—to further define HLA specificities. The major change during that time was the introduction of DNA technology, which has led to the identification of more than 5000 HLA specificities.

When, at the UCLA tissue-typing lab., we discovered how to keep lymphocytes alive for as long as 2 weeks, we started the International Cell Exchange (1974) [28]. Four cells were sent every month to international laboratories to test blind and report their typing. This aided in worldwide standardization of HLA typing. The monthly cell exchange continues to this day, 38 years later.

In 1980, the Nobel Prize in Physiology or Medicine was awarded to Jean Dausset, George Snell, and Baruj Benacerraf "for their discoveries concerning genetically determined structures on the cell surface that regulate immunological reactions" (Figure 3.3). Ten recollections of the pioneers of HLA appear in *History of HLA*, edited by Terasaki, and published by the UCLA in 1990.

HLA and disease

Patients with almost every known disease have been HLA typed to see if particular specificities are associated with the disease. There was a frenzy of activity in the 1970s, and, by the time we wrote a summary book in 1985, there had been more than 4000 papers published on more than 540 diseases [29]. From this large body of work, little remains of clinical value: only testing for B27 to diagnose ankylosing spondylitis [30,31] is widely used. Narcolepsy and DR 52, DQ1 are as highly associated [32], or perhaps more so, but this association does not seem to be used as much clinically. Autoimmune disease is clearly associated with DR3 and DQ2 [29] but the association is not high enough to be clinically useful. Proof of the idea that HLA is linked to an immune-response gene—and therefore linked to many diseases—has not materialized. It had been proposed that the HLA molecule and the molecule of various infectious diseases contain similar amino acid sequences, but such mimicry of HLA with pathogens has not been clearly shown for any disease. HLA was associated with adverse reactions to abacavir [33], a finding that suggests a different area of HLA application. But, overall, the initial high hopes that HLA

might be strongly associated with many diseases have been disappointed.

HLA and transplantation

One area of medicine in which HLA was shown to be of great importance was in transplantation. Again at UCLA, we realized that a meaningful compilation of transplant outcomes—to gauge the effect of matching donor–recipient tissue types—could only be accomplished by testing patients from distant transplant centers because only a few transplants were then being performed at each center. Accordingly, from 1964 on, we started a system of mailing blood samples [34] so that transplants as far away as Paris could be analyzed [35]. This was possible because of our use of lymphocytes as targets—lymphocytes being able to survive for several days. This program let us document the effectiveness of tissue typing before other labs. We tested blood from donors and recipients from eight different centers, and, in 1968, first showed that kidney transplants from HLA-identical sibling donors have the highest graft survival [36].

Then we discovered a great anomaly. As we accumulated more and more cases, it became evident that mismatched transplants were doing well, contrary to everyone's expectation. I saw no alternative but to announce this finding at The Hague International Transplant conference in September 1970 [37]. This brought down a firestorm on our heads because, on "scientific" grounds, this could not be correct. Patients doing well *must* have been well matched. The NIH, which was funding our work at that point, put together a large committee to make a site visit within 3 months of the Hague meeting. An account of this is given in Thomas Starzl's book *The Puzzle People* [38]. Our NIH contract was cancelled in 1971, 6 months after the Hague meeting. In addition, Dausset called an urgent meeting of all tissue typers for January, in Paris, to gainsay our Hague statement. Results for the labs were pooled in hope that, collectively, they would show that we were wrong. The analysis was never published—presumably because the data did not support the sought-after refutation. Instead, chapters by the more prominent tissue typers were published in *Transplant Proceedings* volume 3, 1971, with each author suggesting that *something* was wrong with our analysis as emphasized by the lead editorial by Dausset and Rapaport [39]. On the left hand side of Figure 3.4 is the slide I showed at The Hague that caused so much trouble. On the x-axis is the clinical rank of the patients, with A being the best; F = failure and N = non-immunological failure. On the y-axis is the degree of HLA matching, with D being the worst match. As can be noted, many mismatched patients had a good clinical result. The right hand slide in Figure 3.4 shows the results of transplants performed between 1987 and 1995 from the United Network for Organ Sharing (UNOS) Kidney Transplant Registry. The same type of trend is shown, with mismatched patients doing well, and matched patients doing well, but with relatively small numbers.

The tissue-typing community's upset and turmoil seem understandable. It was "obvious" to everyone with a scientific background that HLA mismatching should result in early failures. Just as, earlier, immunologists who could not obtain more than a few weeks survival of animal skin grafts were shocked that Hume and Murray transplanted kidneys in humans, the same basic scientists concluded that it should be impossible to have mismatched transplants doing well. As noted, the HLA system's extreme polymorphism meant that almost all patients were different from their unrelated deceased donors. But Starzl had no inhibitions about flouting basic "scientific" theory. When he saw that mismatched patients were having good results, he decided that HLA matching should not hold him back from doing transplants. Indeed, he has stated that his major effort in liver transplants was made possible only when he decided to ignore HLA typing. He was the first surgeon to take this path; but others soon followed, and HLA typing started to get a bad name.

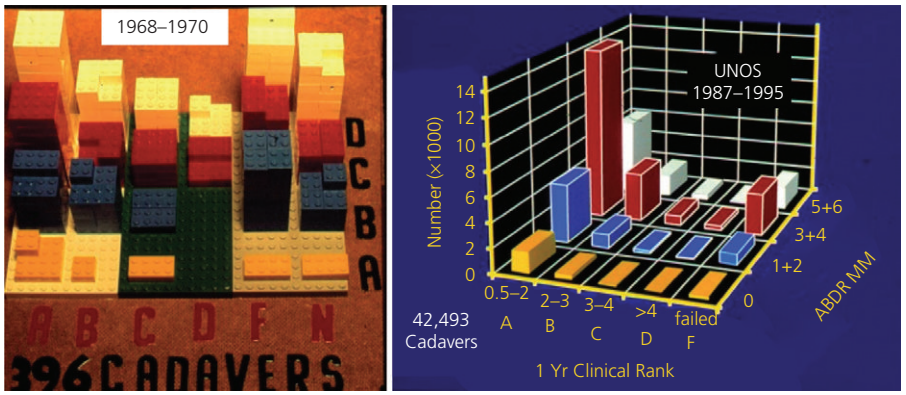

Figure 3.4. The correlation between clinical rank in the x-axis with the match grade in the y-axis is shown here for two periods. The left-hand figure was presented at The Hague International Transplant meeting in 1970. It shows the results for kidneys transplanted between 1968 and 1970. Note that although many badly mismatched transplants (shown in white) did poorly, many mismatched grafts had good results as shown by a clinical rank of A. This same tendency of mismatched transplants doing well is noted in transplants performed 17 years later as shown in the right hand graph. There were very few well-matched grafts in both eras, and they tended to do well. (From the author's personal collection.)

In the meantime, bone marrow transplants began, with the first successful operations relying on HLA typing to confirm the tissue match between the patients and their HLA-identical donors [40]. Donnall Thomas started his program that would encompass large numbers of bone marrow transplants, all based on HLA typing, which, for bone marrow transplants, was essential. But finding donors, other than siblings, was a major problem because the odds were against any given unrelated donor being a close enough match to the patient. The marrow donor program, started in 1987 with help from the Navy, was made into a national program to type the HLA of unrelated volunteer donors and create a registry to find HLA-matched donors for patients. The task becomes herculean as we increased the known number of HLA alleles, currently over 5000 types. Today, there are more than 9.5 million volunteer donors in the National Marrow Donor Program and 16 million donors registered worldwide.

The role of HLA typing for solid organs has been a completely different story. Despite the incipient "bad name" of HLA matching, when mismatches were made to work—thanks to advances in immunosuppression—clinicians recognized that perfect matches worked best [36]. When we found that mismatched patients were doing well, we started a kidney registry in 1971 to see if factors that influence outcomes could be identified. As a concomitant of that purpose, the UCLA registry became one of the most important resources for tracking the effect of HLA matching [41]. To overcome the obvious difficulty in obtaining good matches, we devised a simple cold storage method to send kidneys long distances to matched recipients [42]. This zero-mismatch program was supported by UNOS, and in 1988 the first series of 88 patients who received zero-mismatched kidneys was reported and further extended [43]. Since then, more than 21 000 kidneys have been shipped nationally to zero-mismatched patients using the UNOS system, and in all analyses of the effect of HLA matching, patients with well-matched kidneys have always survived at the highest rate, [44] while those with the largest number of mismatched antigens have generally fared the worst. Nevertheless, as a class, mismatched kidneys have done almost as well as the zero mismatched. Similarly, numerous analyses done of US data show that the difference between the grades of mismatch has not exceeded a few percentage points. This has impelled UNOS to discontinue allocating priority points for A locus matches in 1995, and B locus matches in 2003. The policy changes have not affected the overall outcome of transplants [45].

Currently, then, HLA matching is essential for bone marrow transplants, but not practical for organ transplants. Only by having a national registry and shipping kidneys to distant places has it been possible to obtain well-matched kidney transplants in about 14% of deceased-donor grafts in the USA.

HLA antibodies

HLA antibodies took a trajectory different from that of HLA matching. As noted earlier, only with antibodies was it possible to define the HLA system. However, aside from being used as reagents, antibodies have increased in importance in assessing the result of transplants. Antibodies in the recipient directed against the donor's antigens were found to cause hyperacute rejection of kidneys [46]. Moreover, antibodies present in patients before transplantation could be used to define a state of presensitization, with a higher risk of early failure [47]. It was important to determine the specificity of the antibodies so that donors having those specificities could be avoided. The method used for over 30 years was to test the serum with a panel of pretyped cells. From the reactions, it was possible, with the aid of computers, to determine the specificity of the antibodies. The problem was that because each cell has A, B, C, and DR antigens, it was difficult to determine which of the antigens had reacted to the antibody—resulting in inaccurate assignments. Only with the advent of recombinant cells has it been possible to coat beads with a single antigen so that each specificity can be detected accurately [48]. These techniques are detailed in Chapter 89.

In the past decade, HLA antibodies have zoomed in importance to transplantation because they are postulated as the *cause* of graft rejection [49]. Some of the evidence amassed leading to this conclusion is: almost all patients with a rejected kidney were shown to have antibodies [50]; antibodies could be eluted from kidneys that were rejected [51]; patients who developed antibodies after transplantation were shown to have a higher rate of failure than those without antibodies [52]—and this was true for transplants of kidneys (Figure 3.5) [53–56], hearts [57–59], lungs [60,61], livers

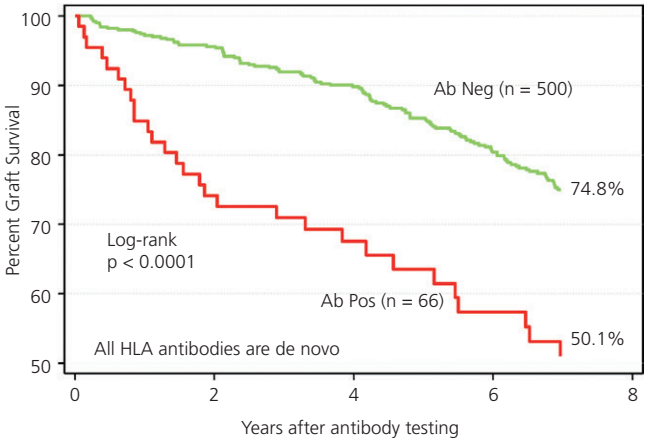

Figure 3.5. In 2002, as part of the International Histocompatibility Workshop, kidney transplant patients (n = 566) with well-functioning kidneys were tested once, and classified as negative or positive for HLA antibodies. After 8 years' observation, it can be seen that those who were positive on a single test have continued to lose their grafts compared with patients who were negative. (Adapted from the author's personal collection.)

[62], and pancreas [63,64]. Most important, patients with rejected kidneys could be shown to have antibodies detectable *before* rejection of the kidney. All these factors fit the nine criteria, developed by Bradford Hill and Richard Doll, that allowed a logical progression from association to causality [65]. We therefore concluded that HLA antibodies are causally related to rejection of grafts [66]. Recently accumulated evidence shows that following acute antibody-mediated rejection, antibody reduction led to superior survival compared with that of patients in whom antibody intensity was not reduced [67–69]. This finding was in acute rejection patients who all had histologic reversal of their rejection. Additionally, removing antibodies in kidney and lung transplant patients prior to evidence of allograft dysfunction was also shown to enhance allograft function and improve survival [70]. Improving function by removal of antibodies constitutes final proof that HLA antibodies cause graft rejection, and likely account for the majority of allograft loss.

Summary

HLA, the major histocompatibility locus in man, has had an intriguing history from the time it was first given its name in 1967. In the ensuing 44 years, HLA has emerged as the most polymorphic system known to man, with over 5000 types identified so far. This variety has made bone marrow transplants from unrelated donors extremely difficult. With most organs—such as hearts, livers, and lungs—it was impossible to obtain matches from unrelated deceased donors for transplant recipients. So transplant surgeons were forced to ignore HLA matching, relying instead on ever improving immunosuppression. Even in kidney transplants, use of healthy living unrelated donors has shown that the HLA system can largely be disregarded. However, it is becoming increasingly clear that, although mismatches can be initially ignored, antibodies are eventually formed against the mismatches in a number of patients. The donor-specific antibodies then react against the organs and cause graft loss. Recent findings show that removal of these antibodies results in longer graft survival, the final and persuasive indication that the antibodies had been causing graft loss. The HLA system is thus critical for transplantation, though in ways not initially envisioned.

CHAPTER 4

Transplant Antigen Biology

Raja Rajalingam, Qiuheng Zhang, J. Michael Cecka, and Elaine F. Reed

Department of Pathology and Laboratory Medicine and UCLA Immunogenetics Center, David Geffen School of Medicine, University of California Los Angeles, Los Angeles, CA, USA

Introduction

Transplantation of organs or tissues from one individual to another is complicated by the presence of antigens that differ between the donor and recipient and provoke, or are targeted by, a destructive immune response. These transplantation or histocompatibility antigens are of varying types, complexity, and influence on the transplant process. The major blood group antigens, A and B, for example, which react with natural antibodies found in individuals negative for these antigens and cause immediate reactions, are limited in scope and therefore easily avoided through donor and recipient matching. The major histocompatibility complex antigens, however, are more challenging barriers to transplantation. Incompatibilities at the human leukocyte antigens (HLA) cannot be avoided, except between siblings that inherit the same set of HLA antigens from the parents. The extremely polymorphic HLA antigens themselves play key roles in normal immune responses and both their similarities and differences between individuals allow for alloimmune responses generated as a result of both direct and indirect antigen presentation. As a result, the immune response to allogeneic exposure may be many times more vigorous than the immune response to nominal antigens and transplantation requires lifelong manipulation of the recipient's immune system to prevent graft destruction. In this chapter, we describe the biology, genetics, structure, and function of the major human transplant antigens, HLA. We will also describe those non-HLA antigens thought to play a role in alloimmunity. This chapter complements Chapters 36 and 89, which detail the methods for detecting HLA differences and HLA-specific antibodies, respectively. As an understanding of HLA is paramount to an understanding of alloimmunity in general, the history of our understanding of HLA recounts much of the history of transplantation, and is presented in Chapter 3.

Genetics of the major histocompatibility complex (MHC)

The MHC in humans is an ~5 megabase region on the short arm of chromosome 6 [1,2]. The human MHC comprises 224 gene loci and is distinguished from other regions of the human genome by its high gene density. Nearly 57% of the MHC genes (128 genes) are predicted to be expressed and 40% of the expressed genes have known immune function. Figure 4.1 shows a schematic map of the major genes of the human MHC. These are traditionally grouped into three distinct non-overlapping regions, designated from the centromere to the telomere as the class II, III, and I regions, respectively.

MHC class I

This cluster comprises three sets of genes that encode proteins with similar structure but different properties. The **classical class I genes** (or class Ia) include three highly polymorphic genes (*HLA-A*, *HLA-B*, and *HLA-C*), which encode the membrane-spanning α chains (heavy chains) of HLA class I molecules. The α chains are expressed as heterodimers along with a non-covalently bound light chain, β_2-microglobulin (β_2m) which is produced by a non-polymorphic, non-MHC gene located on chromosome 15. All three class Ia molecules are normally expressed on the surface of all nucleated cells.

The **non-classical class I genes** (or class Ib) include three genes that encode a functional molecule (*HLA-E*, *HLA-F*, and *HLA-G*) and 12 pseudogenes that do not express a protein belonging to this category. The class Ib molecules display a high degree of similarity with class Ia products in sequence and structural association with β2m, but differ in two attributes: first, the expression of the class Ib molecules is restricted to certain cells types; and second, the class Ib molecules show limited polymorphism.

The **class I-like genes** (or class Ic) include seven MHC class I-related chain (MIC) genes, of which only two (*MICA* and *MICB*) encode functional molecules and the remainder are pseudogenes. The MIC proteins are structurally related to the HLA class I molecules, but fail to form trimolecular complexes because they do not associate with β2m and also do not bind peptides for presentation to T cells. The MIC gene expression is restricted mainly to fibroblasts and epithelial cells, and induced by stress in other cell types. In contrast to class Ib genes, both *MICA* and *MICB* genes are highly polymorphic.

The HLA class I genes comprise eight exons, each encoding a distinct domain: exon-1 (leader peptide), exon-2 (α1 domain), exon-3 (α2 domain), exon-4 (α3 domain), exon-5 (transmembrane region), and exons 6–8 (short cytoplasmic tail).

MHC class II

The class II cluster comprises genes that encode for the classical (HLA-DR, HLA-DQ, and HLA-DP) and non-classical (HLA-DM and HLA-DO) class II molecules. The class II molecules are heterodimers of α and β chains and each chain is encoded by a different gene in the MHC region (α-chain by gene-A and β-chain by gene-B) (Figures 4.1 and 4.2). The HLA class II genes comprise

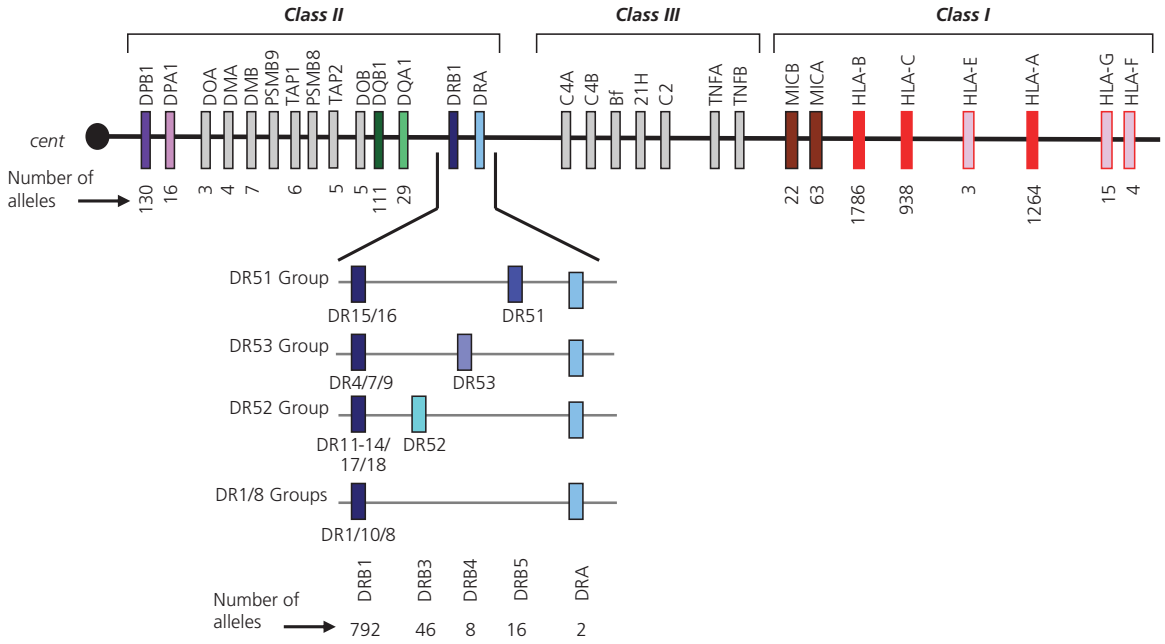

Figure 4.1. Genomic map of the human major histocompatibility complex (MHC). Schematic map of the human MHC on chromosome 6 comprising three non-overlapping regions: class I, class II, and class II. The centromere (circle) and major MHC genes (boxes) are indicated in order, but not drawn to scale. The haplotypic differences in DRB gene content in the class II DR region are indicated. The serological specificities encoded by each functional DRB gene are provided beneath the appropriate locus. The number of distinct alleles are indicated under each locus (source: IMGT/HLA database, Release 3.6, October 2011; http://www.ebi.ac.uk/imgt/hla/stats.html). The non-functional HLA gene fragments (pseudogenes) dispersed across the class I (*HLA-H*, *-J*, *-K*, *-L*, *-N*, *-P*, *-S*, *-T*, *-U*, *-V*, *-W*, *-X*, *-Y*, *MICC*, *MICD*, and *MICE*) and class II (*HLA-Z*, *DRB2*, *DRB6*, *DRB7*, *DRB8*, *DRB9*, *DQA2*, *DQB2*, *DQB3*, *DPA2*, *DPA3*, and *DPB2*) regions are not indicated.

seven exons, each encoding a distinct domain: exon-1 (leader peptide), exon-2 (α1 or β1 domain), exon-3 (α2 or β2 domain), exon-4 (transmembrane region), and exons 5–7 (short cytoplasmic tail). Unlike the classical class II genes, the non-classical class II gene products are not expressed on the cell surface, but are involved in peptide loading onto classical class II molecules.

The HLA-DR region contains a single monomorphic DRA gene and multiple polymorphic DRB genes. Nine distinct DRB genes have been identified, of which four (*DRB1*, *DRB3*, *DRB4*, and *DRB5*) are functional and polymorphic and encode the β chain of a specific class II molecule, and five are non-functional pseudogenes (*DRB2*, *DRB6*, *DRB7*, *DRB8*, and *DRB9*). The number and type of DRB genes are variable by haplotype, with five distinct gene-content haplotypes: the DR1-group, the DR8-group, the DR51 group, the DR52 group, and the DR53 group (Figure 4.1). All five haplotypes carry a *DRB1* gene, but the DR51, DR52, and DR53 group haplotypes contain an additional functional DRB gene (*DRB5*, *DRB3*, or *DRB4*, respectively), and therefore the DR51, DR52, and DR53 group haplotypes express two DR molecules—one from the *DRB1* gene (β-chain) and the DRA gene (α-chain) and another from the *DRB5*, *DRB3*, or *DRB4* gene (β-chain) and DRA gene (α-chain) (Figure 4.2).

The DQ region contains five genes (*DQA1*, *DQA2*, *DQB1*, *DQB2*, and *DQB3*) of which only *DQA1* and *DQB1* encode functional proteins, α and β chains, respectively, which together form the DQ heterodimer at the cell surface (Figure 4.2). In contrast to the DR genes, both *DQA1* and *DQB1* genes are polymorphic and consequently additional polymorphism is generated by different "cis" and "trans" chain combinations, creating four different DQ heterodimers. The DP region contains two DPA genes (*DPA1* and *DPA2*) and two DPB genes (*DPB1* and *DPB2*) of which only *DPA1* and *DPB1* are functional. As with the DQ genes, both *DPA1* and *DPB1* genes are polymorphic and thus may produce four different DP heterodimers by different "cis" and "trans" combinations.

The MHC class II regions include several non-HLA genes whose products are involved in antigen processing and transportation, such as genes of proteasome-related sequences (*PSMB8* and *PSMB9*) and transporter antigen proteins (*TAP1* and *TAP2*). The *PSMB8* and *PSMB9* are the IFN-γ induced subunits of the class I associated proteasomes that produce the antigenic peptides required by class I proteins for presentation to CTLs. The *TAP1* and *TAP2* are members of the ATP binding cassette gene superfamily involved in peptide transport from the cytoplasm to the endoplasmic reticulum.

MHC class III

The class III cluster comprises genes that have no structural or functional correlation with HLA genes. A large number of class III region genes encode molecules participating in antigen processing and presentation, the complement system, and in the inflammatory process. The class III region also includes several genes with no identified immune function.

Nature of HLA polymorphism

Most polymorphisms in HLA gene coding regions correspond to amino acid positions that interact with antigenic peptides or the T-cell receptor [3]. HLA class I polymorphisms are predominant in the first 180 amino acids of the heavy chain and the class II polymorphisms are found in the first 90–95 amino acids of the α

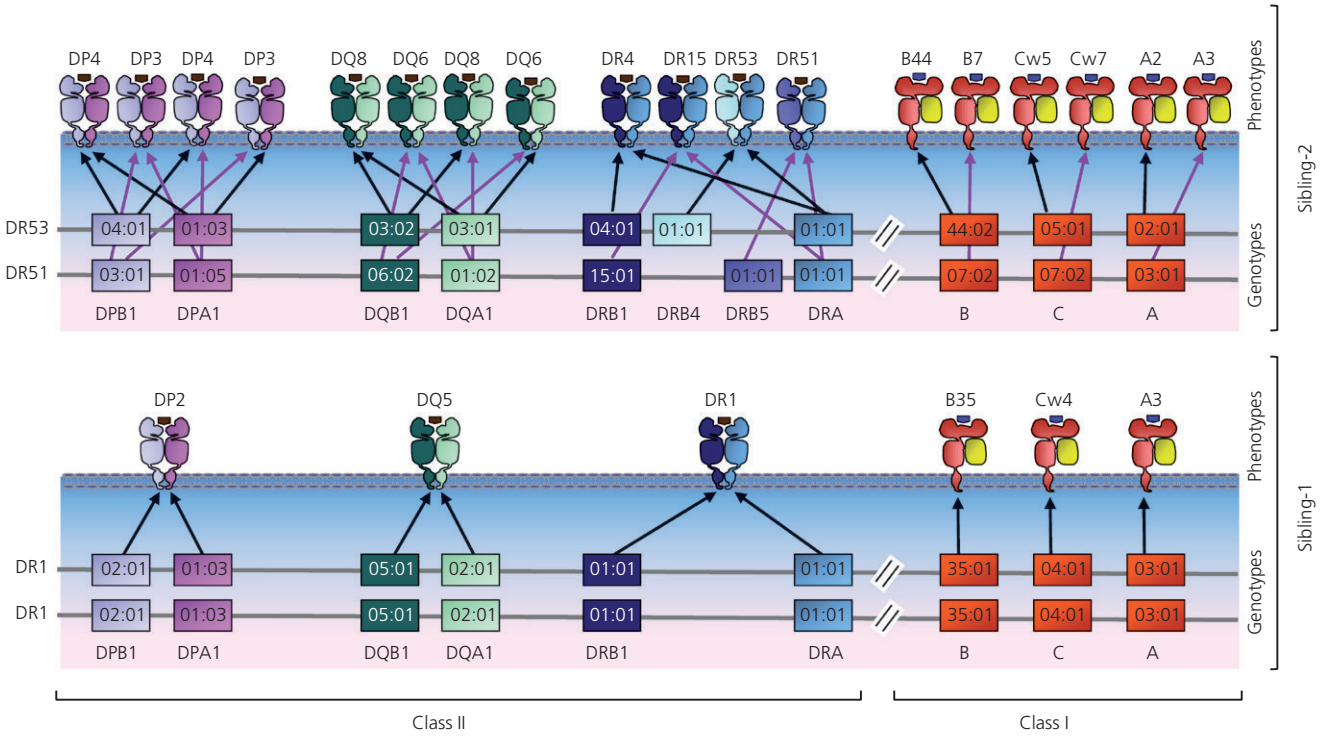

Figure 4.2. The number and type of HLA molecules can differ substantially even between two siblings. Distinct HLA genotype and phenotype constellations of two siblings within a same family are shown. Sibling-1 carries two copies of DR1-group haplotypes (one from the mother and another from the father) that are identical in all classical HLA genes (HLA-A*03:01, B*35:01, C*04:01, DRB1*01:01, DRA*01:01, DQB1*05:01, DQA1*02:01, DPB1*02:01, and DPA1*01:03), and therefore express a single HLA type at each locus (A1, B27, Cw7, DR1, DQ5, and DP4) for a total of six distinct HLA molecules. In contrast, sibling-2 carries the DR53 and DR51 haplotypes that display different alleles at each locus (A2, A3, B7, B44, Cw5, Cw7, DR4, DR15, DR51, DR53, DQ6, DQ8, DP3, and DP4) for a total of 18 different HLA molecules.

and/or β chains [4]. The exons or segments of the gene that encode these polymorphic residues are exons 2 and 3 for class I, and exon 2 for class II genes. DNA-based HLA typing methods target these highly polymorphic regions [5]. Comparison of HLA alleles reveals a characteristic pattern of sequence differences that are the result of recombination events between alleles of the same locus, which is presumably driven by positive Darwinian selection to promote diversity in the repertoire of HLA-binding antigenic peptides [6].

Every allele is a pastiche of sequence motifs shared with other alleles and thus most substitutions are shared by two or more HLA alleles of the same locus (Figure 4.3). The patchwork pattern of sequence polymorphism is probably generated by segmental exchanges through recombination and gene conversion [7]. The shared patchwork pattern of polymorphism complicates HLA typing as well as HLA antibody identification. Because of the extensive sharing of two distinguishing sequences of a given locus with other alleles of the same locus, it is often impossible to assign the actual allele pair unambiguously using current technologies. Additional tiered tests are performed to exclude some allele combinations. A current list of all allele combinations that provide ambiguous results is found at the IMGT/HLA database (<http://www.ebi.ac.uk/imgt/hla/ambig.html>), which provides a database for officially recognized HLA sequences.

Human diversity in HLA repertoire

Being diploid, humans have two copies of the MHC gene complex, one of paternal origin and the other of maternal origin. Because HLA genes are highly polymorphic, alleles of each HLA gene within an individual are almost always different (heterozygous) [8]. Because both HLA alleles are expressed at comparable levels on the cell surface (co-dominant expression), humans can differ in the number and type of HLA molecules expressed on their cell surface. For instance, an individual carrying two copies of DR1-group haplotypes (one from mother and another from father) that are identical in all classical HLA genes (*HLA-A*, *B*, *C*, *DRB1*, *DRA*, *DQB1*, *DQA1*, *DPB1*, and *DPA1*) can express a single HLA type from each of these loci (e.g. A1, B27, Cw7, DR1, DQ5, and DP4—in total six distinct HLA molecules) (Figure 4.2, sibling-1). In contrast, a sibling carrying the DR53 and DR51 haplotypes who displays different alleles at all HLA loci can express two HLA-A molecules, two HLA-B molecules, two HLA-Cw molecules, four HLA-DR molecules, four HLA-DQ molecules, and four HLA-DP molecules (18 different HLA molecules) (Figure 4.2, sibling-2). As a consequence of simple Mendelian inheritance, such an extreme diversity described in these two siblings can occur at the rate of 25% if their parents carry the following haplotypic constellations: mother with DR51 and DR1; father with DR53 and DR1.

Some HLA genes have well over 1000 alleles and their haplotype combinations produce extensive diversity in populations (Figure 4.1) [9]. The polymorphism is so high that in a mixed population (non-endogamic), no two individuals have exactly the same set of MHC genes and molecules. Such a high degree of polymorphism is important both within an individual and between individuals. Within an individual, inheritance of duplicate (homozygous HLA alleles) may result in a disadvantage against chronic viral infection

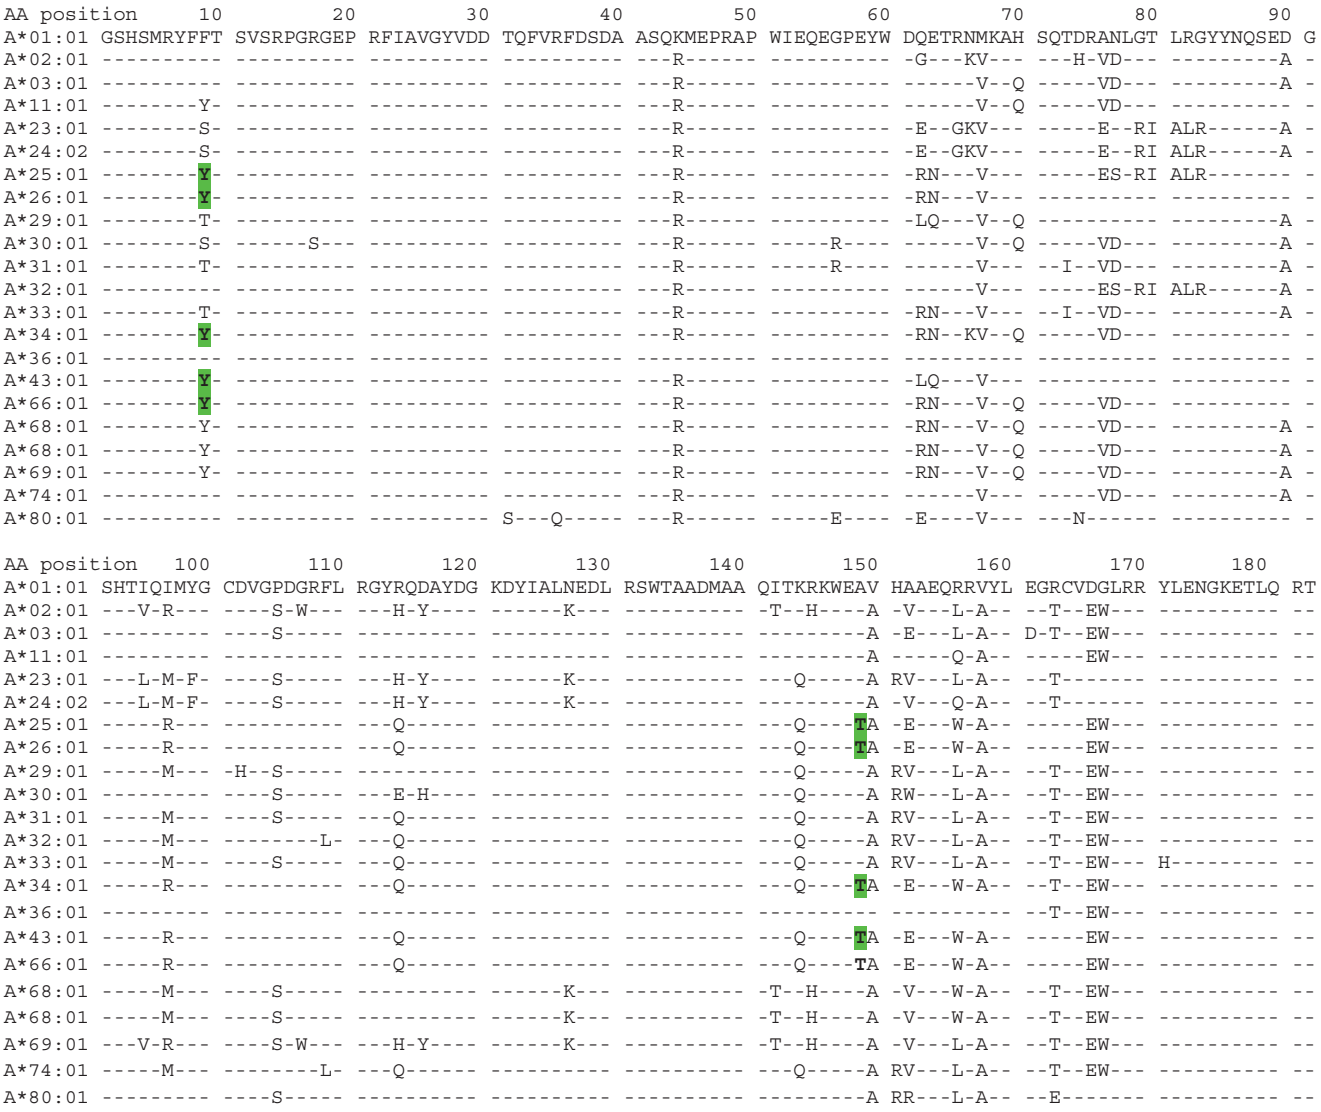

Figure 4.3. Nature of HLA sequence polymorphism. Amino acid sequences of α1 (top panel) and α2 (bottom panel) domains of common HLA-A allotypes representing major antigen groups. HLA-A*01:01 is the reference sequence listed at the top, and amino acid positions of other alleles identical to the reference are displayed as hyphens (-). Amino acid differences from the reference sequence are indicated by standard single letter codes. The majority of the substitutions are shared by more than one sequence. The green shadows identify amino acids that constitute epitope(s) shared by multiple allotypes HLA-A25, A26, A34, A43, and A66.

due to a diminished repertoire of viral peptides available for presentation to T cells. The hypothesis of heterozygote advantage (over-dominant selection) proposes that individuals heterozygous at HLA loci are able to present a wider range of antigenic peptides from a pathogen to the immune system than homozygotes, enhancing immune surveillance [10]. Maximum HLA heterozygosity of class I loci (A, B, and C) delayed acquired immunodeficiency syndrome (AIDS) onset among patients infected with human immunodeficiency virus-type 1 (HIV-1), whereas individuals who were homozygous for one or more loci progressed rapidly to AIDS and death [11]. Over-dominant selection would therefore be expected to favor individuals with the most divergent range of peptide binding specificities.

At the population level, HLA polymorphism provides a mechanism to limit the spread of epidemic pathogens, which might otherwise propagate unchecked throughout a host population. The presence of many different alleles in a population ensures there will always be at least a few individuals with a specific HLA molecule (rare or new alleles) able to load appropriate peptides to develop an adequate immune response to overcome the pathogen, so that the population survives the pandemic. The principle of rare allele advantage (frequency-dependent selection) is that an individual with a rare (e.g. new) MHC allele might respond better to a new pathogen variant, thereby conferring an advantage on that individual in a population in which the pathogen is prevalent [12]. Such frequency-dependent selection may have caused the increased frequency of HLA-B*53 in the Gambian population exposed to malaria. Similarly, HLA-B54 is found almost exclusively in Japanese and nearby Asian countries, and HLA-A74 is common among Blacks, but is very rare in other populations. Therefore, different

subsets of HLA alleles appear to have been selected over time in a given population and the total number of alleles maintained varies across human populations [13,14]. Furthermore, populations such as Native Americans may have experienced bottlenecks or founding events resulting in a more limited diversity of HLA alleles [15]. Linkage disequilibrium is a phenomenon where alleles at adjacent HLA loci are inherited together more often than would be expected by chance. For example, if HLA-A1 and HLA-B8 occur at gene frequencies of 16% and 10%, respectively, in a population, the probability of finding them together should be 1.6%. However, the actual occurrence of HLA-A1–B8 combination is significantly above the predicted incidence (about 8%). Positive selection is thought to be operating on the haplotype and that the linked loci confer a selective advantage for the host [16].

HLA nomenclature

The HLA nomenclature can be daunting as the change from serological typing (which defined antigens) to DNA typing (which defines alleles) resulted in some conflicts [9]. The HLA antigens were named sequentially as they were identified by antisera. Often specificities could be refined as antibodies "split" antigen specificities into two or more new specificities, often identifying alleles or allele groups within a family of related antigens. The more common HLA antigens have lower numbers, A2 or B7, and those that came later or were less common had higher numbers. HLA-B40, for example, was subsequently split into two groups renamed B60 and B61. The standard DNA nomenclature built on this basis and includes four fields (for example, HLA-A*02:01:01:01) delineated by a colon separating antigen, allele group, and designations for silent substitutions (those which don't result in a change in the protein) and differences in non-coding regions [9]. In the clinical setting, HLA typing for hematopoietic stem cell transplants is reported at the allele level (HLA-A*02:01) and HLA typing for solid organ transplants is reported at the antigen level (HLA-A2). The latter usually is the first two digits after the asterisk, but because the DNA nomenclature uses allele groups that are related by nucleotide sequence similarities, there are a few exceptions [17]: B*15:01 corresponds to the B62 antigen, B*15:02 to B75, B*40:01 to B60, and B*40:02 to B61. Similarly for HLA class II alleles, DRB1*03:01 corresponds to the DR17 antigen, DRB1*03:02 to DR18, DQB1*03:01 to DQ7, DQB1*03:02 to DQ8, and DQB1*03:03 to DQ9). In each case, the alleles correspond to splits of the parent antigen.

HLA epitopes and the structural basis of cross-reactivity

The localized and sometimes overlapping nature of HLA polymorphisms (shown in Figure 4.3) results in molecules with an array of alloantigenic structures, which range from those uniquely associated with a single allele to those shared by related HLA molecules. Immunization to a single HLA alloantigen (by pregnancy, transfusions, or allografts) can result in antibody production against a series of HLA antigens that share sequence motifs (termed epitopes) with the immunizing antigen. Antibodies adsorbed and eluted from purified HLA antigens attached to microspheres show reactivity patterns with HLA molecules that correlate with specific shared amino acids that map to regions of the HLA molecular structures and likely affect the antibody-binding site [18]. These antigens belong to cross-reactive groups (CREGs) as defined by specific antibodies. For instance, immunization to the HLA-A25 antigen can result in antibodies against HLA-A25, A26, A34, A43, and A66 that share amino acids at position 9 (tyrosine) and 149 (threonine), which are not present at these positions in other HLA antigens.

Structure and function of HLA molecules

The HLA class I and class II molecules differ in their structure, the cells on which they are expressed, the source of antigens they process, and the functionally distinct subsets of T cells with which they interact.

HLA class I molecular structure

The HLA class I molecules (A, B, and C) are heterodimeric transmembrane proteins that consist of a 32 kD α chain that is non-covalently associated with a 12 kD β_2-microglobulin (β_2m) light chain (Figure 4.4). The α chain is comprised of three segments α_1, α_2, and α_3, each of about 90 amino acids in length. X-ray crystallography studies revealed that the α_1 and α_2 domains fold together into a single structure consisting of two segmented α_1 helices lying on an eight-stranded β pleated sheet [19]. The folding of the α_1 and α_2 domains forms a cleft that binds self and non-self peptides. The peptide binding cleft of the HLA class I molecule is about 25 Å

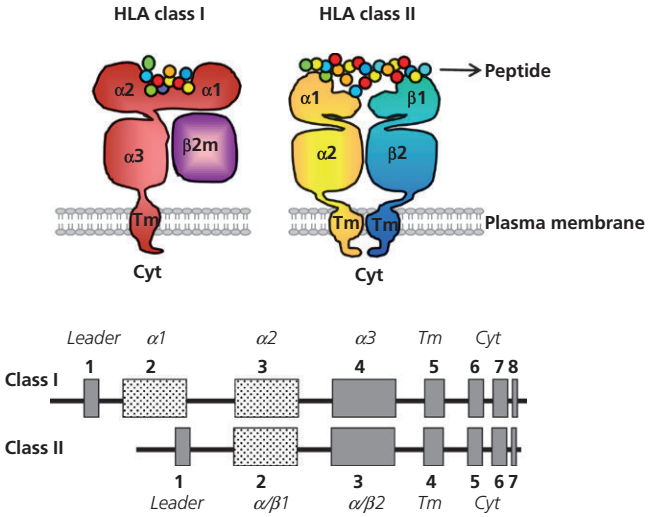

Figure 4.4. Structural organization of HLA proteins (top panel) and genes (bottom panel). The HLA class I molecule is a heterodimer of a membrane-spanning heavy α chain (encoded by *HLA-A*, *-B*, or *-C* gene) bound non-covalently to a non-MHC gene (located in chromosome 15) encoded light β2-microglobulin (β2m) chain, which does not span the membrane. The α chain folds into three domains: α1, α2, and α3. The α1 and α2 domains form an antigen-binding groove. The HLA class II molecule is composed of two transmembrane glycoprotein chains, α (encoded by *DRA*, *DQA1*, or *DPA1*) and β (encoded by *DRB1*, *DQB1,* or *DPB1*). Each chain has two domains, and the two chains together form a compact four-domain structure similar to that of HLA class I molecule. The α1 and β1 domains of class II molecules form a peptide-binding cleft. The class I genes comprise eight exons (shown in boxes) while the class II genes comprise seven exons. The protein domain encoded by each exon is shown in italics. Exons 2 and 3 of class I and exon 2 of class II genes (speckled boxes) encode the polymorphic antigen binding domains. (Angstroms) long and accommodates small peptides of 8–11 amino acids in length.

The α_3 domain of class I binds non-covalently to β_2m, which is necessary for the correct folding of the molecule on the surface of the cell. The α_3 domain also contains a highly conserved α3 immunoglobulin-like domain that binds to the CD8 molecule on T cells [20]. The carboxyl terminal end of the molecule contains a hydrophobic transmembrane region consisting of 41 amino acid residues and a short cytoplasmic tail comprised of 27 residues. The stable expression of the class I molecule requires the assembly of a trimolecular complex formed by the class I α chain, β_2m and bound self or non-self peptide.

HLA class II molecular structure

The HLA class II molecules DR, DQ, and DP are heterodimers composed of two transmembrane glycoprotein chains comprising an α chain of 32–34 kD and a 29–32 kD β chain (Figure 4.4). The α_2 and β_2 domains fold to form a peptide binding cleft [21]. The polymorphic residues are primarily located in the α_1 and β_1 domains and participate in peptide binding and interactions with T-cell receptors. The ends of the class II peptide-binding groove are open and therefore can accommodate larger peptides of 30 residues or more in length [22,23]. One loop in the α_2 domain of class II serves as the docking site for the CD4 molecule. The carboxyl terminal ends of the α_2 and β_2 domains consist of a short hydrophobic transmembrane region, which anchors the molecule into the plasma membrane, followed by a short hydrophilic cytoplasmic tail.

Structural basis of peptide binding to HLA class I and class II molecules

Peptide binding to HLA class I and II molecules is guided by interactions between specific amino acid residues in the peptides and complementary amino acid residues that form the β-strands of the bottom of the cleft and the α-helices on the sides of the cleft. The polymorphisms that are found primarily in the α_1 and α_2 domains of the class I molecule and the α_1 and β_1 domains of class II molecules form the peptide-binding pockets. The polymorphic amino acid side chains alter the electrostatic surface charge, hydrophobicity, size, and shape of the HLA antigen pockets and govern whether a particular peptide will bind to the cleft [24,25]. The residues of the peptide that fit into these pockets are called anchor residues. The extensive polymorphisms alter the peptide binding characteristics of each HLA class I and class II allele so that each allele binds a unique set of peptides. The length of the peptides bound to class I molecules are generally eight to ten amino acids in length. The amino- and carboxyl-ends of the peptide are buried into the cleft and bind to conserved heavy chain residues via a series of hydrogen bonds. The peptides bound to class II molecules are longer (10–30 amino acids) and attach in an extended conformation with the ends of the peptide hanging over the edges of the cleft [21]. Whether a peptide will bind or not to a given class I allele is governed by the amino acid side chains that form the anchor residues of the antigen binding cleft. Therefore, the set of peptides that can be bound by a specific HLA class I allele often share a common "sequence motif." There are several websites that contain useful information on the peptide binding motifs and algorithms, which enable the prediction of specific peptides to bind HLA molecules including: http://www.ashi-hla.org/, http://www.ebi.ac.uk/imgt/hla/, http://www-bimas.cit.nih.gov/molbio/hla_bind/index.shtml and http://www.syfpeithi.de/.

Antigen processing and presentation

Antigen processing and presentation is the manner by which antigen-presenting cells express antigen on their cell surface in a form recognizable by lymphocytes. The cellular processes and surface molecules facilitating antigen presentation in general are discussed in more depth in Chapter 2. Antigen processing includes protein fragmentation (proteolysis), association of the fragments with HLA antigens, and expression of the peptide-HLA complex at the cell surface where they can be recognized by the T-cell receptor (TCR) on a T cell. HLA class I and class II molecules process and present antigen in a fundamentally distinct manner. HLA class I molecules present foreign and self-peptides that are generated in the cytosol of the cell (Figure 4.5) [26] whereas HLA class II molecules present protein antigens primarily, but not exclusively, from extracellular sources (Figure 4.6) [27–29].

The major source of peptides for HLA class I presentation are derived from processing of endogenous proteins into peptides by the proteasome [30] (Figure 4.5). The proteasome is a large multiprotein enzyme complex found in the cytoplasm of cells [31]. The proteasome is comprised of 14 subunits with broad proteolytic activity and functions to degrade cytoplasmic proteins into peptides. Protein targeting to the proteasome for degradation requires that the protein is first covalently linked to a small protein called ubiquitin [32]. The protein is then unfolded, the ubiquitin is removed, and the protein is degraded in the proteasome to a wide range of peptides. Interestingly, two of the proteasome subunits, PSMB9 and PSMB8, are encoded within the class II region and their activity is specifically turned on by proinflammatory cytokines such as INF-γ [33]. Thus, immune cells activated by INF-γ express variant proteasomes called "immunoproteasomes" which are characterized by unique catalytic subunits. The immunoproteasome has an enhanced catalytic activity compared to standard proteasomes and recent studies suggest that this enhanced activity of the immunoproteasome prevents the accumulation of degradation substrates that would otherwise accumulate during inflammation [34].

The loading of peptides on HLA class I molecules is a highly coordinated process involving several chaperone proteins that are present in the endoplasmic reticulum (ER) [35,36] (Figure 4.5). Following the synthesis of the heavy chain of HLA class I, it is targeted to the ER where it binds to the membrane-associated ER chaperones calnexin and Grp78. These chaperones are involved in the insertion of the class I polypeptide into the lumenal compartment of the ER and initiate heavy chain folding and intrachain disulfide bond formation. Upon dissociation from calnexin, the class I heavy chain associates with β_2m and binds to the ortholog chaperone calreticulin and is incorporated into the peptide-loading complex. The peptide-loading complex orchestrates the loading of an optimal peptide onto MHC class I molecules. The peptide-loading complex contains the two subunits of the transporter associated with antigen processing (TAP1 and TAP2), transmembrane glycoprotein tapasin, the soluble ER chaperone calreticulin and the soluble thiol oxidoreductase ERp57 [35]. The peptides are translocated into the endoplasmic reticulum via TAP1 and TAP2 molecules. The TAP genes are encoded within the class II region of the MHC, linked to the *PSMB9* and *PSMB8* genes [37]. TAP associates with peptides on the cytoplasmic side of the ER membrane and with class I molecules on the lumenal surface and delivers peptides directly to the class I molecules. In the ER, the peptides can be trimmed (if required) to the required length of 8-10 amino acids for binding to class I molecules by ERAAP (or ERAP1), a specialized ER-associated aminopepsidase that recognizes the peptide

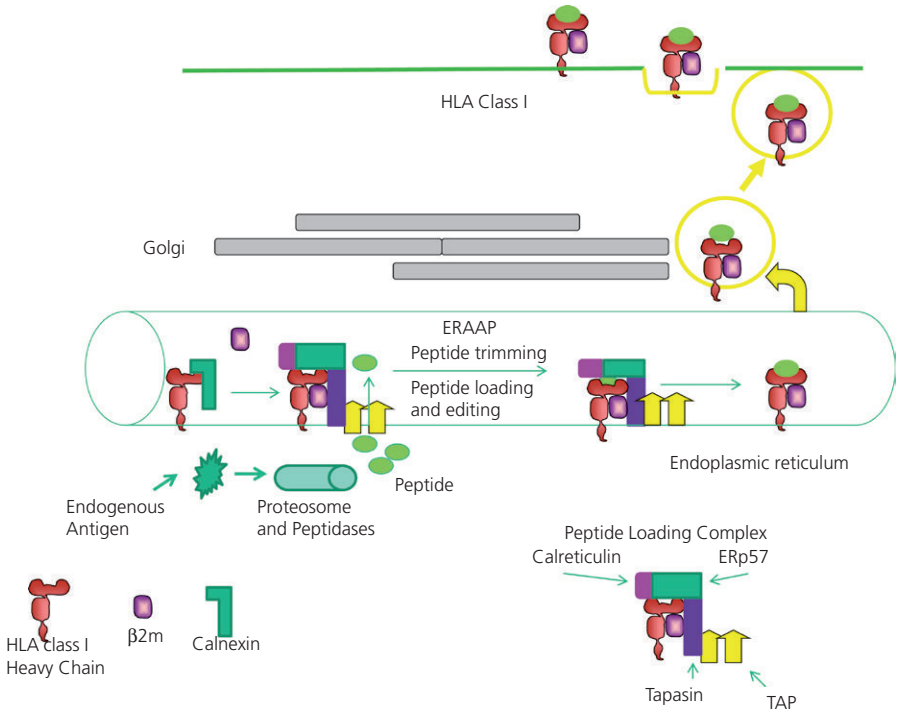

Figure 4.5. Schematic representation of MHC class I molecule peptide processing and presentation. MHC class I heavy chains assemble with β2m and are recruited to the peptide-loading complex in the endoplasmic reticulum. MHC class I molecules initially associate with the chaperone calnexin, which triggers folding and disulfide bond formation. Upon dissociation from calnexin, the class I heavy chain associates with β_2m and binds to the chaperone calreticulin and is incorporated into the peptide-loading complex. The peptide-loading complex contains the two subunits of the transporter associated with antigen processing (TAP1 and TAP2), transmembrane glycoprotein tapasin, calreticulin, and ERp57. The peptides are translocated into the endoplasmic reticulum via TAP1 and TAP2 molecules. Tapasin facilitates peptide loading and ERAAP functions to trim peptides at their amino-terminal ends before and after binding to the MHC class I molecules. The peptide-MHC class I molecules are then exported to the cell surface.

carboxyl terminus and trims the amino terminus to generate peptides of 8-10 residues in length [38]. The TAP-associated glycoprotein called tapasin is also encoded in the MHC and functions to facilitate peptide loading of class I molecules in the ER [39]. Tapasin bridges HLA class I molecules to the TAP molecules in association with the chaperone calreticulum and the thiol oxidoreductase ERp57, which together form the peptide-loading complex [39,40]. Tapasin stabilizes the empty class I dimer, retaining it in the ER until peptide loading by the peptide-loading complex. HLA class I molecules can be tapasin-dependent or tapasin-independent for peptide loading [40].

The primary repertoire of peptides bound to class I includes a variety of proteins derived from proteasomal degradation of intracellular products of the cytosol, including HLA molecules themselves. However, there are specialized cells, particularly macrophages and dendritic cells (DC) that can capture extracellular antigens and process and present these antigens to CD8 T cells through a process called cross-presentation [41]. During cross-presentation, it is thought that elements of the ER are incorporated into phagosomes and endosomes. Cross-presentation is important in presenting peptides from viruses that do not infect the DC [42]. Cross-presentation is also involved in tolerance to self-proteins that are not synthesized in the DC.

HLA class II molecules present peptides that are generated in the endocytic compartment of the cell (Figure 4.6). Many of the peptides presented by class II molecules are derived from exogenous antigens, but they can also be derived from the cytoplasm of the cell through the process of autophagy [43–45]. Exogenous antigens are internalized and then transported to lysosomes and endosomes containing proteolytic enzymes including legumain, cathepsin L, and cathepsin S [35]. Class II molecules are assembled in the ER with a protein called invariant chain (Ii) or CD74. The invariant chain blocks peptides from being loaded on class II molecules in the ER and chaperones the newly synthesized class II molecules to MCII, a specialized endosomal compartment where peptide loading occurs [46]. In the acidified MCII compartment the invariant chain is degraded by cathepsin-mediated proteolysis [47] to generate the class II-associated invariant chain peptide or CLIP [48]. CLIP binds to the cleft of the class II molecule and inside the cleft is protected from degradation. CLIP needs to be removed in order to make the cleft accessible to peptides produced from extracellular proteins. HLA-DMA and HLA-DMB are encoded within the class II region and function to catalyze the dissociation of CLIP and promote peptide loading in the endocytic compartment [49,50]. DM functions to ensure efficient association of peptides and edits complexes such that the stable peptide binders to HLA class II are favored [51]. The activity of DM can be further modified by another HLA class II encoded protein called HLA-DO, which can act as a peptide editor by altering the pH optimum of DM-mediated peptide loading of MHC class II to more acidic conditions [52]. The peptides that bind to class II molecules are generated by proteases called cathepsins, which are present in the endosomal compartments. Interestingly, there are differences in the repertoire of cathepsins used by different APC, which can influence the nature of the

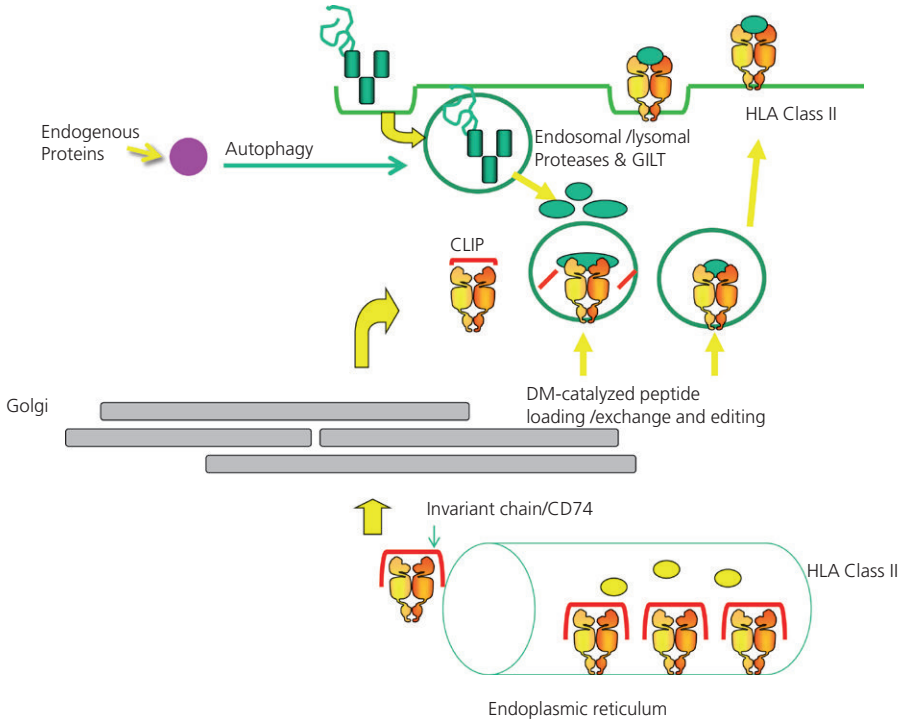

Figure 4.6. Schematic representation of MHC class II molecule peptide processing and presentation. MHC class II molecules assemble in the endoplasmic reticulum with invariant chain (Ii), which contains the endosomal targeting signal. In the endosomal compartments, Ii is cleaved leaving only the smaller fragment CLIP occupying the peptide binding cleft. Exogenous proteins are internalized into the endosomal pathway and their unfolding and fragmentation is catalyzed by the disulfide reductase GILT and lysosomal proteases. HLA-DM catalyzes the release of CLIP followed by the binding of peptide fragments and peptide exchange. HLA-DM edits the repertoire of peptide-MHC class II complexes that are transported to the cell surface.

peptides generated [53]. An additional lysosomal processing enzyme called gamma-interferon induced lysosomal thiol reductase or GILT has been identified for the presentation of some antigens with disulfide bonds [54]. Studies by the Cresswell lab. showed that GILT can also be important for the cross-presentation of a subset of viral antigens on MHC class I molecules [55].

Cytoplasmic and membrane cellular proteins may also enter the class II pathway of antigen presentation as a result of normal turnover of cellular proteins, a process referred to as autophagy. In this pathway, cytoplasmic proteins are trapped in ER-derived vesicles called autophagosomes, and these vesicles fuse with lysosomes and the cytoplasmic proteins are degraded and can be delivered to class II molecules as are peptides derived from exogenous antigens [56] (Figure 4.6). The processing and presentation of self-proteins is thought to be important in the process of central tolerance induction [57]. In addition to tolerance induction, studies show that some viral antigens can be intracellularly processed for cross-presentation by class II molecules [45], a mechanism which is likely to be important for protection against viral pathogens.

Differential expression of HLA class I and class II molecules

HLA class I and class II molecules have distinct distributions among cells, which reflect the different effector functions of the T cells that recognize them. HLA class I molecules present peptides from intracellular pathogens, commonly viruses, to $CD8^+$ cytotoxic T cells, which are specialized to kill any cell that they specifically recognize [58]. Class I molecules are constitutively expressed on all nucleated cells. The broad expression of class I molecule expression is linked to the function of class I molecules in presenting intracellular pathogens such as viruses. In contrast, HLA class II molecules present peptides from extracellular antigens to CD4 T cells, which in turn regulate the activation other effector cells of the immune system. Thus, HLA class II molecules are normally found on professional antigen-presenting cells, including B lymphocytes, dendritic cells, and macrophages. Cytokines, including INF-α, INF-β, and INF-γ and tumor necrosis factor a (TNF-α), increase the expression level of class I molecules. Class II molecule expression is augmented by INF-γ. Cytokines increase HLA class I and class II expression by increasing the rate of gene transcription. This effect is mediated by the binding of cytokine-activated transcription factors to regulatory DNA sequences in the promoter regions of the HLA class I and class II genes. The expression of HLA class II molecules is inducible on many cell types, including T cells, in response to cytokines. Transcription of class II genes is controlled by a master regulatory factor, which is known as the MHC-II transactivator, CIITA [59]. Differential activation of the three independent promoters that drive expression of the gene encoding the class II transactivator ultimately determines the exquisitely regulated pattern of MHC class II gene expression. In addition to increasing the transcription of the class I and class II genes and β2m, INF-γ also increases transcription of the proteasome and subunits of TAP.

HLA Class Ib molecules

HLA-E, F, G, and Hfe (HLA-H) molecules are non-classical class I molecules encoded within the MHC region [60]. These molecules

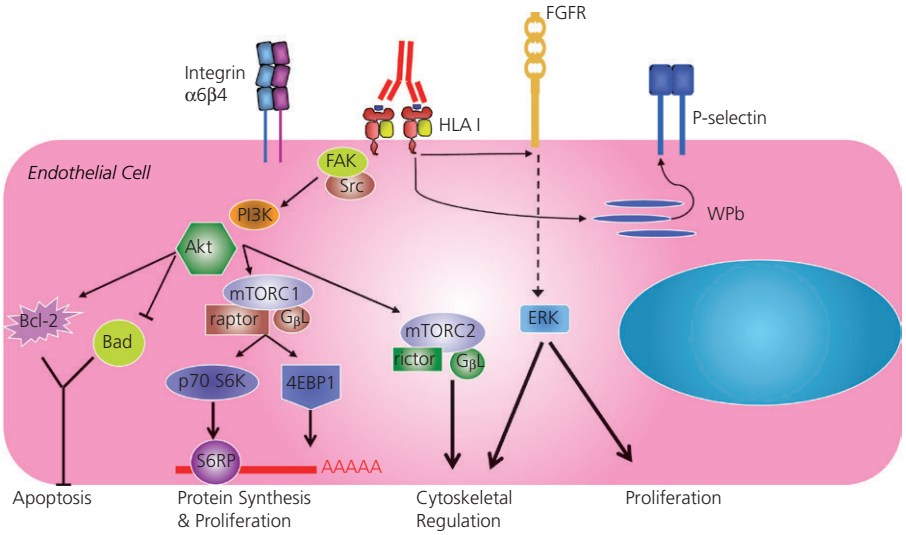

Figure 4.7. Cross-linking of HLA I by antibodies induces cell signaling pathways leading to cell growth, cytoskeletal modulation, and resistance to cell death. After ligation of HLA I on endothelium, cell surface expression of fibroblast growth factor receptor (FGFR) is rapidly increased, supporting increased cell sensitivity to growth factors and increased activation of ERK. Src and FAK are activated, resulting in activation of the PI3k/Akt axis. FAK is also an important regulator of the cytoskeleton, supporting focal adhesions. PI3K-dependent activation of Akt results in antiapoptotic and progrowth signals. Akt influences the apoptotic regulators, inhibiting the proapoptotic factor Bad and increasing levels of the antiapoptotic factors Bcl-2 and Bcl-xL. These actions result in cellular resistance to death from signals such as complement activation. Akt also targets the mammalian target of rapamycin (mTOR), which exists in two distinct complexes; mTOR complex 1 (mTORC1) and mTOR complex 2 (mTORC2). mTOR complex 1 triggers S6 kinase and S6RP activation, proteins that are essential during protein synthesis. In addition, mTORC1 regulates 4EBP-1 to increase translation of mRNA. In contrast, mTOR complex 2 acts on downstream cytoskeletal regulators to control the organization of the actin cytoskeleton. After HLA I cross-linking by antibodies, endothelial cells display dramatic stress fibers and focal adhesions, events that are dependent upon mTORC2. mTORC2 provides positive feedback to Akt. Finally, HLA I antibodies trigger rapid mobilization of endothelial cell vesicles containing von Willebrand Factor and P-selectin. This exocytosis leads to increased cell surface P-selectin, which initiates the leukocyte recruitment cascade.

associate with β2m and have a restricted polymorphism and bind a limited set of peptides. HLA-E is transcribed in most tissues. HLA-E has a limited polymorphism with only nine alleles (three protein variants). It has a binding cleft that holds a restricted set of peptides derived from the signal sequence of HLA-A, B, C, and G molecules. HLA-E binds to the CD94-NKG2A/C receptors on natural killer (NK) cells and modulate NK cell function [61].

HLA-G has a limited tissue expression and is primarily expressed in immune privileged sites including the trophoblast, thymus, and cornea [62]. In its soluble form, HLA-G is thought to inhibit maternal immunoreactivity to the fetus. HLA-G peptide presentation is limited to presentation of a nanomer peptide derived from some intracellular proteins. HLA-G interacts with leukocyte Ig-like inhibitory receptors (LIR-1 and LIR-2) and KIR2DL4 receptor. HLA-F is an intracellular protein rather than a membrane protein and its function is not well established.

HFE gene is a class I-like gene that associates with β2m for expression. HFE does not bind peptides but instead acts as a receptor binding site for the transferrin receptor to transport iron across the cell membrane. Individuals with mutations in the *HFE* gene (tyrosine 282) lack expression of *HFE* and cannot provide a negative feedback for iron absorption, which results in a disease called hemochromatosis. Hemochromatosis is a disease of iron overload and is associated with increased levels of iron in the serum and deposition in organs such as the liver.

HLA-mediated signal transduction

Cross-linking of HLA molecules induces signaling in lymphocytes, endothelial cells (EC), and smooth muscle cells (SMC). Cross-linking of HLA I or II with antibodies in B cells, T cells, or antigen-presenting cells results either in programmed cell death or activation and proliferation [63]. The pathways leading to death or proliferation in immune cells have common second messengers, including intracellular calcium, PLC, PKC, and Src family kinases [64–67]. Anti-MHC I antibodies also induce proliferation of human aortic EC [68–71] and airway epithelial cells [72,73], suggesting a process by which alloantibody may contribute to chronic allograft rejection and development of transplant vasculopathy (TV) [74].

Cross-linking of HLA class I molecules with antibody causes a molecular association between HLA I and the integrin subunit β4 and subsequent activation of intracellular signals leading to cell survival, proliferation, and migration (Figure 4.7) [75,76]. Upon antibody ligation of class I molecules, the tyrosine kinase Src is phosphorylated [77]. Src is a critical signal transducer, which regulates such cell functions as cytoskeletal changes, migration, mitogenesis, cell cycle progression, and cell survival. Next, focal adhesion kinase (FAK) phosphorylation permits complex formation with Src family kinases [71,77,78], allowing for maximal kinase activity. FAK then facilitates phosphorylation of paxillin, an adaptor protein involved in focal adhesion formation, which recruits other signaling molecules to specific compartments in the cell. One major functional consequence of FAK and paxillin activation is cytoskeletal rearrangement and formation or stabilization of focal adhesions [77,78], which are important in regulation of endothelial permeability as well as signal transduction [79]. HLA I ligation activates phosphatidylinositol 3 kinase (PI3K) and recruits 3-phosphoinositide dependent protein kinase (PDK1) and Akt, to the membrane. Akt contributes to cell proliferation by activating the mTOR pathway.

mTOR is present in two complexes in the cell. mTOR complex 1 (mTORC1) regulates ribosomal biogenesis and protein synthesis, and comprises mTOR, raptor, and GbetaL. mTOR complex 2 (mTORC2) includes mTOR, Sin1, GbetaL, and rictor, and participates in cytoskeletal regulation and feedback to Akt [80]. After HLA I ligation, mTOR is phosphorylated and forms signaling complexes that activate downstream targets, including S6Kinase, S6 ribosomal protein, and 4E-BP1. Additionally, RhoA is rapidly translocated to the cell membrane following HLA class I ligation in a manner that is associated with stress fiber formation and cytoskeleton reorganization [69]. These signaling cascades, which alter the cytoskeleton following HLA class I ligation, are linked to cell proliferation pathways, which involve mTOR activation [71,80]. In particular, mTORC2, which is composed of Rictor, Sin1, and GβL, has been shown to modulate the cytoskeleton through its stimulation of F-actin stress fibers, paxillin, RhoA, Rac1, Cdc42, and PKCα.

Stimulation of EC with a low dose of HLA I antibodies promotes cell survival and resistance to death [81–84]. HLA I cross-linking causes phosphorylation of the proapoptotic protein Bad, which results in its sequestration from the mitochondria by the 14-3-3 proteins (Figure 4.7) [85]. These Bcl family members suppress programmed cell death by regulating mitochondrial membrane permeability to prevent activation of caspases. Transplanted heart and renal allografts from patients with circulating DSA and mouse cardiac allografts undergoing AMR also had increased Bcl-2 expression, confirming these findings in vivo [84,86]. Other antiapoptotic genes, which protect from cell death, are up-regulated after HLA I ligation, including heme oxygenase 1 [83,87].

Further exploration of EC proliferation pathways revealed that following class I ligation, fibroblast growth factor receptor (FGFR) cell surface expression is up-regulated (Figure 4.7) [70,88]. Increased FGFR expression was associated with increased bFGF ligand binding and increased cell proliferation via the MAPK pathway. These data indicate that the up-regulation of FGFR and the resulting cell proliferation is an alternative pathway to the class I induced-FAK/actin-dependent cell proliferation pathway.

In addition to cell survival and proliferation signals, anti-HLA I antibodies also cause leukocyte recruitment through induction of adhesion molecules in the endothelium (Figure 4.7). Ligation of HLA with antibodies causes release of endothelial vesicles known as Weibel–Palade bodies and rapid presentation of P-selectin, which facilitates leukocytic cell adherence [89]. Study of chronic rejection in rat cardiac allografts showed a correlation between increased P-selectin expression in the intima and intimal thickening [90,91].

Killer cell immunoglobulin-like receptors (KIR)

In addition to the antigen presentation to cytotoxic T cells, the HLA class I molecules serve as ligands for NK receptors. The NK cells represent 5–25% of the mononuclear cell fraction of normal human peripheral blood. Historically, NK cells were considered to be components of innate immunity (see Chapter 7 of additional discussions of innate immunity) because their intrinsic spontaneous killing does not require any restriction by the target cell's HLA and the bound peptides. It is now clear that NK cells use a highly specific and complex target cell recognition receptor system arbitrated by the integration of signals triggered through a multitude of inhibitory and activating receptors of a wide array of conventional germline-encoded gene families [92].

KIRs are considered to be the key receptors involved in human NK cell development and function. Fourteen distinct KIR receptors have been identified, of which seven are inhibitory types and remainders are activating receptors. Upon engaging with distinct HLA class I ligands (HLA-A, B, and C), the inhibitory KIR receptors dampen NK cell reactivity. The activating KIR receptors are believed to stimulate NK cell reactivity when they sense unknown ligands expressed on the target cells, such as "induced-self" that are structurally related to HLA class I molecules (e.g. MICA and MICB), "altered-self" (HLA class I molecule loaded with foreign peptide), or pathogen encoded "non-self" (molecules associated with infection, tumor transformation, and allograft antigens). KIR loci are highly polymorphic and map to chromosome 19. KIR and HLA gene families segregate independently, yielding many individuals who express KIR receptors for which they lack HLA class I ligands, and vice versa, creating human diversity in the number and type of KIR-HLA gene combinations, some of which have been correlated with the susceptibility to certain diseases [93].

Because NK cells can spontaneously deliver effector function, it is critical that they do not attack surrounding healthy cells. To prevent such detrimental autoimmune responses, NK cells express at least one inhibitory receptor to the self-HLA class I molecule [94]. Interaction of inhibitory KIR receptors with cognate HLA class I ligands further sets the threshold of NK cell functional competence [95]. Abundant expression of HLA class I molecules on normal healthy cells provide ligands for a variety of inhibitory receptors of NK cells, and consequently healthy cells become tolerant to NK cell attack. Down-regulation of HLA class I expression due to certain viral infections, neoplastic transformations, or other forms of stress, relieves the inhibitory influence on NK cells, permitting NK cells to eliminate these unhealthy target cells, a phenomenon originally described as the "missing-self" hypothesis [96].

In an allogeneic transplantation setting, even within HLA compatible transplants (but not HLA-A,B,C identical transplants), the recipient NK cells expressing an inhibitory receptor can be activated when confronted with allograft cells lacking relevant HLA class I ligand for that inhibitory receptor [97]. A study by van Bergen and colleagues revealed that the absence of donor HLA class I ligands for the recipient inhibitory KIR receptors is associated with reduced long-term graft survival in HLA-A,B,DR compatible kidney transplantations [98,99]. Kunert et al. [100] found an association between a higher number of inhibitory receptors in the recipient's genotype and patients with stable renal function. Vampa et al. [101] found recipients carrying more activating KIR genes triggered more NK cytotoxicity against their donors than recipients carrying fewer activating KIR genes. These studies provide evidence that suppressing NK cell activity may be important to improve renal allograft survival.

Non-HLA transplant antigens

Although the immune response to HLA antigens plays the central role in allograft rejection, evidence shows that non-HLA antigens also contribute to the pathogenesis of acute and chronic rejection and decrease long-term graft survival of solid organ transplants [102]. While many of these non-HLA antigens remain poorly defined, the majority are autoantigens except for the MICA antigens [103,104] and are generally implicated by the presence of antibodies associated with graft dysfunction. The principal antigenic targets are expressed on cells of the allograft, including endothelium and epithelium. Antiendothelial cell antibodies (AECAs) represent a heterogeneous group of antibodies comprising both IgM and IgG subclasses and are directed against a variety

of antigenic determinants [105]. Other autoantigens, including vimentin and cardiac myosin (CM) in heart [106,107], collagen V (Col V) and K-α1 tubulin in lung [108,109], and agrin and angiotensin II receptor type I (AT1) in kidney transplantation [110,111], have been identified as immune targets with poor transplant outcomes. Pathogenesis of these autoantibodies in transplant recipients have been demonstrated in several ways: (1) they induce cellular damage in vitro; (2) they cause graft rejection when passively transferred in an animal model; and (3) their removal by plasmapheresis or immunosuppressants results in an improvement of clinical signs of disease.

It is easier to understand the pathogenesis of antibodies against extracellular antigens than antibodies directed against inaccessible intracellular antigens. However, during transplantation, tissue damage caused by cold ischemia reperfusion injury and inflammation caused by transplant surgery may activate antidonor alloimmunity via the direct and indirect allorecognition pathways, leading to the release of intracellular antigens from the injured cells. These alloantigens can be presented via the indirect recognition pathway to host T cells to generate autoreactive cellular and humoral immune responses. The indirect alloimmune response, once initiated, can spread to additional determinants within the primary target antigen, called intramolecular epitope spreading. It is likely that repeated stimulation of $CD4^+$ T cells with self-antigens surpasses the threshold of self-tolerance and leads to the development of autoantibody-inducing $CD4^+$ T cells. This post-transplant autoimmunity can contribute to graft failure. It has been demonstrated that administration of anti-MHC class I antibodies into the native lungs of mice triggered $CD4^+$ T-cell driven autoreactivity, production of IL-1β and TNF-α, and the development of antibodies to the self-antigens K-α1 tubulin and collagen V [112].

Anti-MICA antibodies

MICA is encoded by a highly polymorphic gene with at least 63 alleles located in the MHC class I region [113]. MICA antigens have a restricted tissue distribution and are expressed on epithelium, endothelium, keratinocytes, and fibroblasts. *MICA* genes contain a heat shock response element (HRE) promoter and their expression levels can be induced in response to cellular stress mediated by ischemia reperfusion injury, and cytokines such as IL-2, IL-4, and IL-15. MICA acts as a ligand for the activating NKG2D receptor of NK cells and subset of T cells. MICA neither binds β2m nor peptides.

Alloantibodies against MICA have been associated with acute and chronic vascular rejection of renal and heart transplants. In a large multicenter study, presensitization to MICA was associated with increased graft loss in renal recipients transplanted with donors who were well matched for HLA. MICA antibodies have been shown to mediate complement-dependent cytotoxicity against endothelial cells, suggesting these antibodies can cause complement-mediated damage of the allograft [114]. However, most studies reporting a role for MICA in transplantation have been indirect and circumstantial because the donor specificity of the antibodies was not ascertained.

Summary

The major histocompatibility complex (MHC) is a tightly linked group of genes present in all vertebrate species. The MHC encodes a variety of proteins associated with the immune system involved in antigen presentation, peptide transporter molecules TAP1 and 2, molecules that catalyze and regulate peptide exchange, complement components C2, C4, and factor B, cytokines TNF-α and TNF-β, heat shock proteins 70-1 and 2, 21-hydroxylase (involved in steroid metabolism), and other less well-defined products and regulatory elements. The HLA class I and class II cell surface antigens in humans that are the major transplantation antigens are encoded by the human MHC.

Some MHC genes are remarkably polymorphic. Humans have more than 10 000 HLA-A, -B, -C, -DR, -DQ, and DP alleles that have been identified, which encode at least 100 antigens that can be detected serologically. Diversity is generated by a number of interesting and novel genetic mechanisms and is likely selected by adaptations to pathogens and disease.

Each individual inherits a distinct constellation of MHC class I and class II molecules in a strict Mendelian fashion with a crossover frequency of about $<1\%$ between A and DQB1. The probability of siblings matched at the HLA-A, -B, -C, -DR, and -DQ loci is 25%.

The MHC molecules play a key role in immune responses by presenting peptides derived from protein antigens to T cells with specific receptors. Affinities for CD8 and CD4 cell surface molecules preferentially direct presentation of peptides from intracellular proteins to $CD8^+$ T cells and intracellular proteins to $CD4^+$ T cells by class I and class II MHC molecules, respectively. Intracellular protein peptides are loaded into the cleft of MHC class I molecules in the endoplasmic reticulum, whereas the cleft of MHC class II molecules is protected in the ER but is subsequently loaded with peptides from extracellular proteins in endocytoplasmic vesicles.

Allogeneic HLA molecules provoke both T- and B-cell immune responses. Antibodies may recognize a range of structural features (epitopes) that are unique, or shared by a few or many HLA antigens resulting in cross-reactivity.

Other non-HLA antigens may act as transplantation antigens as well, including cryptic antigens not normally expressed extracellularly and autoantigens, most of which probably stimulate the recipient immune system via direct or indirect presentation on HLA molecules. HLA molecules are also ligands for natural killer cells, which represent an emerging area of study for their role in clinical transplantation.

CHAPTER 5

Cellular Mechanisms of Adaptive Immunity

Maria-Luisa Alegre
Department of Medicine, Section of Rheumatology, University of Chicago, Chicago, IL, USA

Introduction

Organs transplanted between genetically distinct individuals are rejected in a T-cell-dependent manner. The ability of host T cells to recognize antigens from transplanted organs within the same species is known as allorecognition and, in the absence of some degree of immune modification, results in recipient T-cell activation, proliferation, differentiation, acquisition of effector functions, migration to the allograft, and eventual destruction of the transplant. Innate immune cells are essential for initial presentation of alloantigen to naïve T cells in secondary lymphoid organs and, in the graft, can also be activated by effector T cells and be deleterious to the transplant via secretion of inflammatory factors. Additionally, activated T cells can help B cells produce alloantibodies, driving humoral immune mechanisms that can also damage the graft. In this chapter, we will review key features of allorecognition and T-cell-dependent allograft rejection. Details of humoral alloimmunity can be found in Chapter 6. This chapter will focus on mechanisms involved directly in T-cell-mediated graft destruction; more general discussions of physiologic cellular immunity can be found in Chapter 2. Specifics of the histological and clinical presentations of cell-mediated rejection are found in organ specific chapters on the histopathological syndromes (Section Histopathological Syndromes of Graft Rejection and Recurrent Disease) and clinical diagnosis and management (Section Clinical Allograft Rejection Syndromes: Diagnosis and Management) of graft rejection, respectively.

T-cell recognition of alloantigens: Direct, semidirect, and indirect presentation

T cells express a T-cell receptor (TCR) that can bind complexes formed by peptides positioned in the groove of MHC molecules, themselves expressed on the surface of antigen-presenting cells (APCs). T cells are educated in the thymus such that their TCRs recognize self-MHC complexes presenting peptides derived from endogenous self-proteins, with $CD8^+$ T cells recognizing MHC class I (HLA-A, B, and C in the human) and $CD4^+$ T cells engaging MHC class II (HLA-DR, DP, DQ). Detailed descriptions of MHC antigens can be found in Chapter 4. Thymocytes with TCRs that recognize self-peptide/MHC (pMHC) with high affinity are eliminated in a process called negative selection, which reduces the frequency of T cells capable of mediating autoimmunity, while thymocytes with sufficient affinity for self-pMHC to trigger survival pathways, but not enough to result in full activation, are positively selected. In contrast, thymocytes that cannot bind self-pMHC die by neglect. Thus, mature T cells that populate the body are "restricted" to recognition of self-MHC molecules. When these molecules present the normal array of endogenous self-peptides outside of the thymus, engaged T cells receive survival signals without being activated or proliferating [1]. Each of these T cells has the ability to be fully activated by a given "foreign" cognate peptide that may replace basal-state endogenous peptides on self-MHC molecules and may originate from an infectious organism, a somatically mutated protein, or an allogeneic cell. Presentation of an allogeneic peptide (derived from allogeneic MHC molecules or from polymorphic variations between donor and recipient non-MHC proteins termed **minor antigens**) in this context of self-MHC molecules is called **indirect presentation** and requires host APCs to pick up antigens from dying donor cells by phagocytosis, pinocytosis, or endocytosis (Figure 5.1).

Surprisingly, despite thymic selection producing T cells with TCRs restricted by self-MHC molecules, many T cells can also bind to allogeneic MHC molecules, presumably because there is no process by which alloreactive T cells would be eliminated in the thymus as allogeneic MHC molecules are not expressed in the thymus. In fact, whereas only approximately 1 in 10^6 T cells may recognize a "foreign" antigen on a given self-MHC allele, it is estimated that 1–10% of T cells can engage allogeneic MHC molecules directly [2]. This high precursor frequency had initially led scientists to hypothesize that T cells may bind allogeneic MHC molecules in a different manner from self-MHC molecules, perhaps contacting only MHC residues and thus being permissive to multiple peptides presented on each MHC allele. However, analysis of the few TCR/p/alloMHC crystal structures that have been solved (see below), suggests that the interactions are peptide-dependent [3]. The spectrum of receptor ligand interactions that make up one's alloimmune repertoire are considered further in Chapter 9. MHC molecules are highly polymorphic with hundreds of MHC alleles within the population, and each person being able to express up to six MHC class I and six MHC class II alleles (three of each on each chromosome 6; also see Chapter 4). Because each MHC allele can present a multitude of endogenous peptides, the

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

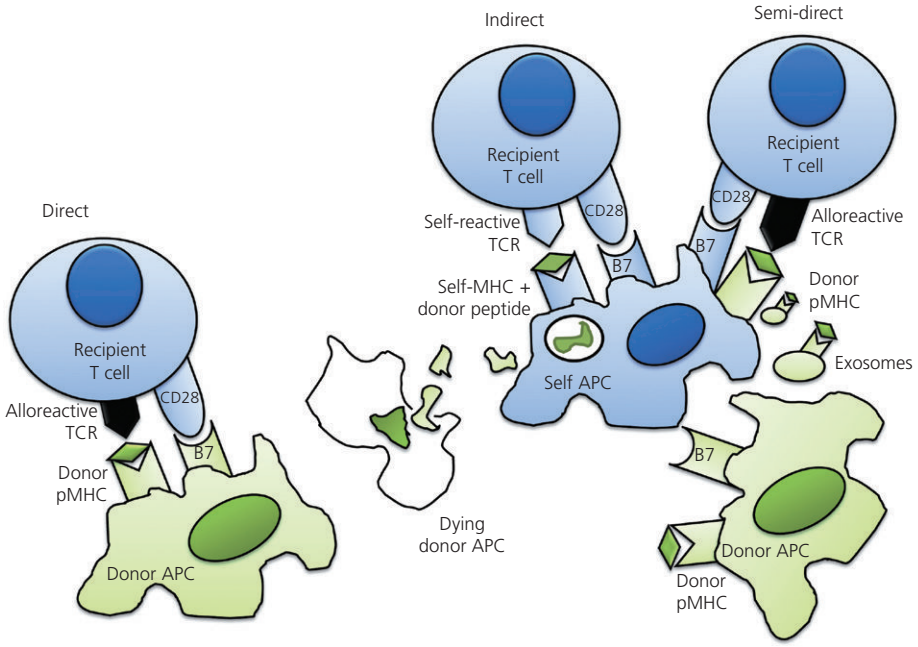

Figure 5.1. Types of allorecognition. T cells are selected in the thymus based on the restriction of their TCR to recognition of self-MHC molecules. However, a proportion of T cells can also recognize allogeneic MHC molecules/donor peptides either via cross-reactivity between allo- and self-MHC/peptide complexes or via distinct TCR/MHC docking sites. After transplantation, these T cells can recognize allogeneic MHC directly on the surface of donor APCs or parenchymal cells (direct recognition). In addition fragments of intact membranes containing donor MHC may fuse with membranes of recipient APCs either following cell–cell contact or cell–endosome contact, such that T cells can recognize intact donor MHC on recipient APCs (semidirect presentation). Finally, fragments of dying transplant cells can be picked up by recipient APCs and allogeneic peptides derived from polymorphic proteins distinct between donor and recipient can be presented by self-MHC molecules (indirect presentation). These mechanisms can all apply either to $CD4^+$ T cells recognizing donor or recipient MHC class II and $CD8^+$ T cells recognizing donor or recipient MHC class I.

combination of T cells that can each recognize a specific peptide with a given allogeneic MHC allele can add up to a very high number, possibly explaining the high frequency of T cells with direct alloreactivity.

Direct allorecognition by host T cells of donor peptide/donor MHC molecules can occur either on donor APCs contained in the transplanted organ (**direct presentation**), or following transfer of fragments of intact membranes from donor cells onto recipient APCs (**semidirect presentation**) [4] (Figure 5.1) (see Chapter 2). The latter may occur as a result of cell–cell contact between host and donor cells or via the transfer of donor exosomes that fuse with the plasma membrane of host APCs. Traditionally, MHC class I is described as predominantly presenting peptides derived from cytosolic proteins translocated to the endoplasmic reticulum by the transporter associated with antigen processing (TAP), and MHC class II presenting peptides from extracellular proteins delivered to endolysosomes by phagocytosis, pinocytosis, or endocytosis. However, it is now clear that extracellular proteins can be presented by MHC class I and cytosolic proteins by MHC class II. Delivery of intracellular cytoplasmic antigens to the endolysosomal pathway for class II presentation can occur from endosomes generated during autophagy [5,6] whereas extracellular phagosome cargo may seep out of the organelle into the cytoplasm by an incompletely understood mechanism and become available to the proteasome for processing, TAP translocation, and class I presentation [7]. These pathways further widen the possible peptide repertoires for both direct and indirect T-cell allorecognition.

Structural recognition of alloantigens by the TCR

The TCR comprises an α and a β chain that form three hypervariable complementarity-determining regions (CDRs) responsible for contacting amino acid residues on the peptide and the MHC molecule. Active investigation has been devoted to understanding how T cells raised to be restricted by self-MHC can recognize allogeneic MHC directly. A major obstacle to this research has been that the endogenous peptides naturally presented on MHC molecules are most often not known and could be derived from anywhere within the donor proteome. Only a handful of TCRs with both self-pMHC and allo-pMHC known ligands have been co-crystallized and directly compared [8]. Some structures have revealed molecular mimicry whereby allogeneic peptide/allo-MHC complexes mimic the conformation of foreign peptide/self-MHC although taking advantage of some TCR and pMHC plasticity (induced fit) to optimize interactions. Other structures have evidenced a distinct strategy of engagement by the TCR on self-MHC versus allo-MHC complexes, but in both instances including contacts on both the peptide and the MHC molecule itself. A report further demonstrates that alloreactivity is limited by the endogenous peptide repertoire, suggesting that allorecognition, like conventional recognition of foreign peptide on self-MHC, is critically peptide dependent and peptide specific [9]. It has also been suggested that T cells that express two TCRs of distinct specificities because of failed allelic exclusion of the α chain (1–8% of the T-cell repertoire) have a greater alloreactivity [10] (also see Chapter 9). As the rules

of allorecognition become better defined, it may become possible to predict cross-reactivity of host T cells on donor pMHC to help choose optimal donors with lower potential to activate recipient T cells.

T-cell costimulation and differentiation

In addition to requiring TCR engagement, full initial activation of naïve T cells (**T-cell priming**) can only occur when additional surface molecules termed costimulatory receptors are ligated simultaneously to the TCR [11]. Few costimulatory receptors are expressed on naïve T cells and CD28 is thought to be the principal one. CD28 is the receptor for CD80 (B7-1) and CD86 (B7-2) ligands expressed on APCs and further up-regulated during inflammatory conditions on APCs and some parenchymal cells. Blockade of CD28 during TCR binding has been shown to result in apoptosis or subsequent unresponsiveness of T cells to restimulation, a state termed **T-cell anergy**. These findings have led to the development of the reagents abatacept and belatacept that can bind CD80 and CD86 and prevent these ligands from engaging and activating CD28, therefore markedly reducing T-cell priming. Belatacept was approved in 2011 as an immunosuppressive drug for kidney transplantation. These agents prevent activation of alloreactive T cells after transplantation, hopefully leading to their apoptosis or anergy, without affecting T cells of other specificities whose TCR is not being engaged at the time of Belatacept treatment.

Following T-cell activation, T cells up-regulate many additional costimulatory receptors, including members of the immunoglobulin superfamily such as ICOS, from the TNF receptor family such as 4-1BB and OX40, and from the T-cell immunoglobulin mucin (TIM) family [12]. Activated T cells also up-regulate CD40L (CD154), a TNF family member that engages the TNFR family member CD40 on APCs and drives APCs to express higher levels of MHC, CD80, and CD86 and to produce cytokines. Many of the costimulatory molecules remain expressed after naïve T cells differentiate into effector cells and memory cells, such that it is more difficult to suppress previously activated than naïve T cells, as these receptors can lower the threshold of T-cell activation. Ligands for these costimulatory receptors are expressed on APCs and some of them can be up-regulated on parenchymal cells such as epithelial and endothelial cells.

In addition to expression of costimulatory receptors that can promote T-cell activation, stimulated T cells up-regulate members of the costimulatory family that inhibit or terminate T-cell activation and are sometimes called co-inhibitory receptors. These include CTLA-4 (binds to CD80 and CD86 with higher affinity than CD28), PD-1 (binds PDL1 and PDL2), BTLA (binds HVEM), LAG3 (binds MHC class II), and as yet unidentified receptors on T cells of newly described ligands on APCs that include B7-H4, B7S3, BTNL2, and VISTA. All these inhibitory receptors are members of the immunoglobulin superfamily, and their induction is necessary to restrain T-cell responses as animals deficient in these molecules have various degrees of lymphoproliferation and autoimmunity, which is lethal in the case of CTLA-4 deficiency. The ligands to these receptors are expressed on APCs, as well as on some parenchymal cells.

Upon stimulation, naïve T cells produce IL-2 and use it as an autocrine growth factor to proliferate. In addition, depending on the cytokines they encounter during their multiplication, they can differentiate into various types of effector T cells distinguished by the profile of cytokine production they acquire (Figure 5.2). $CD4^+$ T cells are often referred to as T helper cells (Th), whereas $CD8^+$ T cells are frequently called cytotoxic T cells (Tc) (see Chapter 2). Activated T cells exposed to IL-12 will differentiate into effector T cells that predominantly produce IFN-γ and are termed Th1/Tc1, whereas encounter with IL-4 will drive differentiation of Th2/Tc2

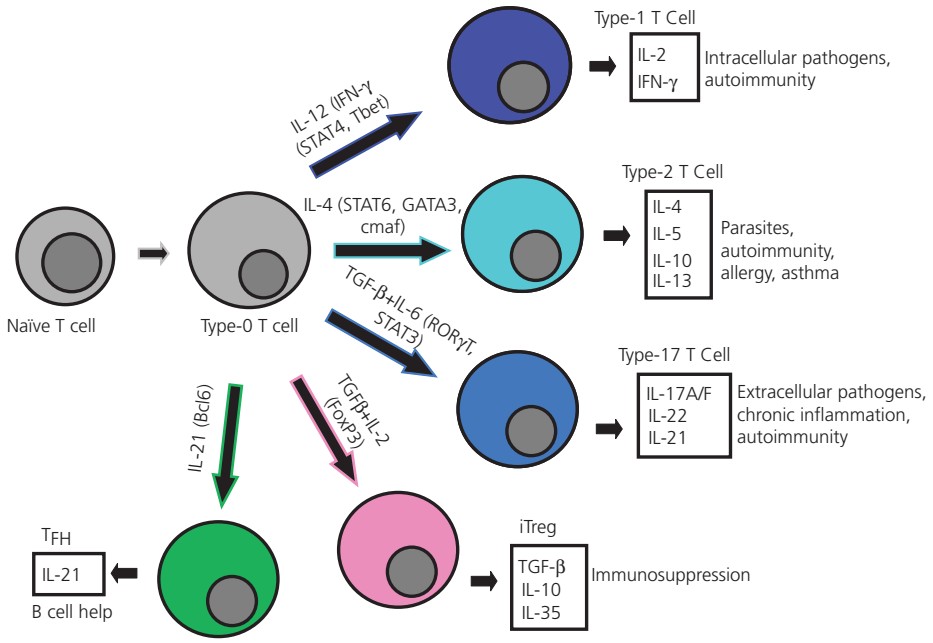

Figure 5.2. Pathways of T-cell differentiation. Upon activation, T cells can be driven toward different functional phenotypes, shown in this figure and based on varying exposures to cytokines and the actions of different transcription factors. In general, these take on prototypical patterns leading to the development of five major types of T cells: Th-1, Th-2, Th-17, induced T regulatory cells (iTreg), and T follicular helper cells (Tfh).

cells that produce IL-4, IL-5, IL-10, and IL-13, and exposure to TGF-β and IL-6 will result in differentiation of Th17/Tc17 cells that produce IL-17A (IL-17), IL-17F, and IL-22 [13,14]. These discrete cytokine profiles of effector T cells are each uniquely qualified to respond to specific pathogens, with Th1 cells playing a major role in the elimination of intracellular pathogens, Th2 cells fighting parasites, and Th17 cells being important against extracellular micro-organisms. Under some circumstances these cells can also become pathogenic, with Th1 and Th17 cells associated with autoimmunity and Th2 cells with asthma and allergies. In transplantation, acute allograft rejection has mostly been correlated with the presence of IFN-γ-producing Th1/Tc1 cells, although presence of IL-17 is becoming increasingly recognized in rejecting allografts and Th2 cells and Th2 cytokines also having been shown capable of driving rejection.

After proliferation and differentiation, T cells go through a contraction phase in which the majority undergo apoptosis or cell-cycle arrest as a means to terminate the immune response, with the remaining T cells acquiring memory characteristics. In transplantation, T cell-deficient mice transferred with memory T cells can reject allogeneic grafts with faster kinetics than those receiving naïve T cells [15]. Importantly, prior immune responses to microbes results in generation of pathogen-specific memory T cells some of which, like naïve T cells, can also be alloreactive [16]. These memory cells are less susceptible to conventional immunosuppressive therapies and can constitute an important barrier to allograft acceptance (see Chapter 9).

In addition to conventional $CD4^+$ and $CD8^+$ T cells, a subset of $CD4^+$ T cells has been shown to express the transcription factor Foxp3 and lack the ability to produce IL-2. Instead, these cells suppress the function of conventional T cells in vitro and in vivo and are now referred to as regulatory T cells (Tregs) (see Chapter 8)[17]. Tregs are essential to maintain T-cell homeostasis and prevent autoimmunity, as mice deficient in Tregs or mice in which Tregs are permanently eliminated after adulthood die rapidly of lymphoproliferation and autoimmunity. A congenital disease of loss of function mutations in the *Foxp3* gene is known in humans as IPEX syndrome and similarly leads to autoimmunity. Two types of $Foxp3^+$ Tregs have been described. The first one develops in the thymus, like conventional T cells, and is often called natural Tregs (nTregs). The second type develops from mature naïve T cells activated in the presence of TGF-β and IL-2 or retinoic acid in vitro or in vivo, and is referred to as induced or adaptive Tregs (iTregs). Tregs form about 5–10% of $CD4^+$ T cells in mice and humans. Both nTregs and iTregs can suppress immune responses and it has been shown that both are necessary, at least in mice, to maintain T-cell homeostasis [18]. In transplantation, it has been shown that iTregs can be induced following costimulation blockade protocols of tolerance induction [19], and both nTregs and iTregs can be visualized in accepted islet allografts [20]. However, the relative importance of each subset in controlling acute or chronic rejection remains to be established. Because nTregs and iTregs both express CD4, Foxp3, high CD25, and low levels of CD127, it remains challenging to distinguish them. It has been reported that nTregs express higher levels of the transcription factor Helios than iTregs [21], although this remains controversial, and that iTregs have specific sites within the *Foxp3* gene that remain partially methylated when compared to nTregs [22,23].

Because iTregs can be generated in vitro from PBMCs and expanded to very high numbers, clinical trials are exploring the safety and efficacy of transferring iTregs adoptively into transplant recipients. Initial trials in bone marrow transplantation have shown reduction of graft-versus-host disease (GVHD) and trials in solid organ transplantation are starting both in Europe and in the USA [24].

Innate immune signals that influence T-cell responses

Upon activation, APCs can secrete cytokines that help shape T-cell differentiation. Because the immune system evolved to fight infections, receptors that recognize molecular patterns present in microbes are critical in driving APC activation and bridging innate and adaptive immunity (see Chapter 2). Pathogen-associated molecular patterns (PAMPs) include endotoxin, flagellin, proteoglycans, unmethylated CpG motifs, double-stranded RNA, and many others [25]. These PAMPs can bind Toll-like receptors (TLRs) expressed on the plasma membrane and endosomal membranes of APCs, but also of T cells and some parenchymal cells [26]. Engagement of TLRs in APCs results in up-regulation of costimulatory ligands, thus facilitating their presentation of antigen to T cells, as well as production of cytokines such as type I IFN, IL-1, TNF, IL-6, and IL-12. These cytokines define the type of differentiation that the activated T cells will undergo, based on the appropriate response to the infecting organism, with, as mentioned above, IL-12 facilitating Th1 and IL-6 promoting Th17 differentiation. Importantly, molecular pattern-containing factors generated during sterile inflammation, such as that experienced by allografts during ischemia and reperfusion, can also activate some TLRs, mostly TLR2 and TLR4, either by ligating them directly or by sensitizing these TLRs to minimal concentrations of microbial ligands [27]. In the context of transplantation, several of these damage-associated molecular patterns (DAMPs) have been described that serve as adjuvants to augment alloresponses. HMGB1, heat shock protein (HSP), and hyaluronan have all been shown to potentiate alloreactivity [25]. In addition, haptoglobin, an acute phase protein, was reported to be up-regulated in transplanted tissues and haptoglobin-deficient skin displayed prolonged survival after transplantation in mice with more than half the animals retaining their grafts long term [28]. These data suggest that localized therapies to reduce TLR signaling by donor organs may be beneficial in transplantation.

Importantly, some TLRs are expressed in T cells themselves, including conventional T cells and Tregs. Engagement of TLRs in conventional T cells has been shown to promote T-cell activation and T-cell survival [29], while their engagement in Tregs can, depending on the circumstances, either enhance or prevent their suppression function perhaps by affecting epigenetic regulation of the *Foxp3* gene [30–36]. In transplantation, TLR engagement at the time of transplantation has been shown to prevent the induction of transplantation tolerance by costimulation-blockade therapies in mice and drive the differentiation of alloreactive T cells into Th1 and Th17 phenotypes, while inhibition of both IL-6 and IL-17 restored graft survival [37–39]. These data indicate that sensing of damage or infections by these innate receptors can shape the type of T-cell alloresponse to an allograft and promote T cell-dependent rejection by different effector mechanisms [40,41]. Therapeutic targeting of these inflammatory pathways is being considered to facilitate transplantation tolerance.

TLRs are not the only receptors that can sense damage and pathogens. Another type of membrane-bound receptor, C-type lectin receptors (CLRs), can engage fungal and bacterial PAMPs and trigger the production of inflammatory cytokines such as TNF and

IL-6. The other receptors described to date are all cytosolic and include NOD-like receptors (NLRs) that sense a variety of PAMPs, particulate matter, crystals, and other sterile inflammatory factors, to induce either IL-1 production downstream of the inflammasome or inflammatory cytokines, as well as RIG-I-like receptors (RLRs) that sense RNA, and receptors that sense DNA, both of which trigger type I IFN production (and IL-1 for some DNA-sensing receptors). The impact of these receptors on alloimmunity remains to be determined, but it is likely that dying donor cells will trigger several of these pathways thus enhancing alloreactivity.

Where are T cells primed after transplantation?

Donor parenchymal cells in a transplanted graft all express MHC class I and can therefore be recognized by host $CD8^+$ T cells with direct alloreactivity. Endothelial and some epithelial cells exposed to the stress of ischemia and reperfusion can up-regulate MHC class II and therefore be recognized by host $CD4^+$ T cells with direct alloreactivity. However, unlike professional APCs that also express MHC class II, such as activated dendritic cells, macrophages, and B cells, most parenchymal cells do not express costimulatory ligands and therefore cannot activate T cells, as T cells, especially in their naïve state, require engagement of costimulatory receptors such as CD28 at the time of TCR ligation to be able to mount a productive immune response. Therefore, most of the activation of T cells with direct alloreactivity is thought to be triggered initially by donor APCs carried by the graft and often termed passenger leukocytes. Studies performed by Lafferty and colleagues in the 1970s showed that elimination of passenger leukocytes from donor tissue by in vitro culture markedly reduced their immunogenicity [42]. Donor APCs are known to migrate into draining secondary lymphoid organs, spleen, and lymph nodes, patrolled by T cells in search of their cognate antigen. In addition, recipient APCs that pick up dying donor cells or membranes also migrate to secondary lymphoid organs to present alloantigen indirectly or semidirectly. However, as discussed previously, the precursor frequency of T cells recognizing alloantigen directly is higher than that of T cells with indirect allorecognition, such that direct activation of alloreactive T cells by donor APCs is believed to be the predominant pathway of T-cell activation initially after transplantation. As the half-life of donor APCs is short, the indirect pathway of allorecognition becomes predominant over time and may therefore play a role in later episodes of acute rejection and in chronic rejection. Evidence that secondary lymphoid organs are essential for alloreactive T-cell priming and graft rejection was demonstrated by using mice with genetic mutations resulting in lymph node agenesis (Aly/Aly mice) in which a surgical splenectomy was performed (see Chapter 14). Aly/Aly mice failed to reject allogeneic skin grafts whereas mice lacking both lymph nodes and spleen could not reject vascularized heart transplants [43,44]. Interestingly, lymph nodes also appear to be required for the induction of transplantation tolerance by costimulation blocking therapies [45], suggesting that T-cell activation can be aborted at the site of priming with long-lasting consequences.

Importantly, requirement for secondary lymphoid organs was only absolute for naïve T cells, as transfer of memory T cells into splenectomized Aly/Aly mice resulted in recall responses, propagation of alloreactive T cells, and transplant rejection independently of lymph nodes and spleen [46]. This property of memory cells enhances the challenge for their immunosuppression as they may be more difficult to inhibit before they can do damage if they can go directly to the graft.

Effector phase of the alloimmune response: T cells go to the graft

Once primed, naïve T cells proliferate, differentiate, and acquire effector functions. Their egress from lymph nodes is regulated by the sphingosine-1 phosphate (S1P) receptor and agonistic activity of S1P1 by the drug FTY720 has been shown experimentally to result in trapping of lymphocytes in thymus, lymph nodes, and Peyer's patches [47], although clinical trials with FTY720 at the doses tested have not revealed immunosuppressive efficacy. Once in circulation, effector T cells are thought to enter inflamed tissues in response to chemokine gradients, though graft infiltration and acute rejection can still occur when chemokine signaling is blocked, and the exact chemokines that recruit T cells to specific transplanted organs or the cells that produce them have not been fully uncovered [48]. Neutrophils that infiltrate allografts following ischemia reperfusion have been shown to promote recruitment of $CD8^+$ T cells into allografts and depletion of polymorphonuclear cells can synergize with costimulation blockade therapy to prevent rejection of cardiac allografts in mice [49], suggesting an avenue to reduce acute graft infiltration.

In considering how effector T cells can recognize alloantigen at the graft site and trigger transplant damage (Figure 5.3), one needs to consider separately $CD4^+$ and $CD8^+$ T cells with direct versus indirect allorecognition. $CD8^+$ T cells with direct allorecognition should be able to engage alloantigen on all nucleated transplant cells as they all express MHC class I. It has been shown that $CD8^+$ T cells can be activated by allogeneic endothelial cells and that cardiac allografts can be rejected when donor MHC class I is present only on non-hematopoietic cells in mice [50]. These results suggest that recognition of alloantigen in the vasculature is essential either for entry of direct $CD8^+$ T cells into the graft for subsequent killing of parenchymal cells, or that $CD8^+$ T cells can injure vascular endothelial cells resulting in downstream graft damage by nutrient deprivation or thromboembolic events.

Expression of MHC class II is more restricted than that of MHC class I, with only dendritic cells, macrophages, B cells, activated endothelial cells, and some epithelial cells expressing it. Therefore, $CD4^+$ T cells with direct allorecognition should have more limited access to alloantigen in the graft. Expression of donor MHC class II in cardiac allografts has been shown to be sufficient for CD4-mediated rejection in the absence of host MHC class II in mice [51]. Moreover, donor class II on hematopoietic cells was shown to be more important than on endothelial cells [52]. It is not exactly clear how engagement of donor hematopoietic cells in the graft can result in graft rejection by $CD4^+$ T cells, but it is thought that T cells may activate donor APCs to produce inflammatory factors that are toxic to parenchymal cells in the transplant. Once donor APCs have left the graft, interaction of direct $CD4^+$ T cells with class II-expressing parenchymal cells may result in their inactivation or death because of insufficient costimulation, or in a switch to a Th2 phenotype. Indeed, the frequency of direct pathway-reactive T cells is known to decrease over time after transplantation [4].

T cells with indirect allorecognition can also play a role in allograft rejection. For $CD8^+$ T cells with indirect allospecificity to be activated, they need to encounter host cells presenting peptides derived from donor MHC or other polymorphic proteins presumably acquired via phagocytosis of dying donor cells, with donor

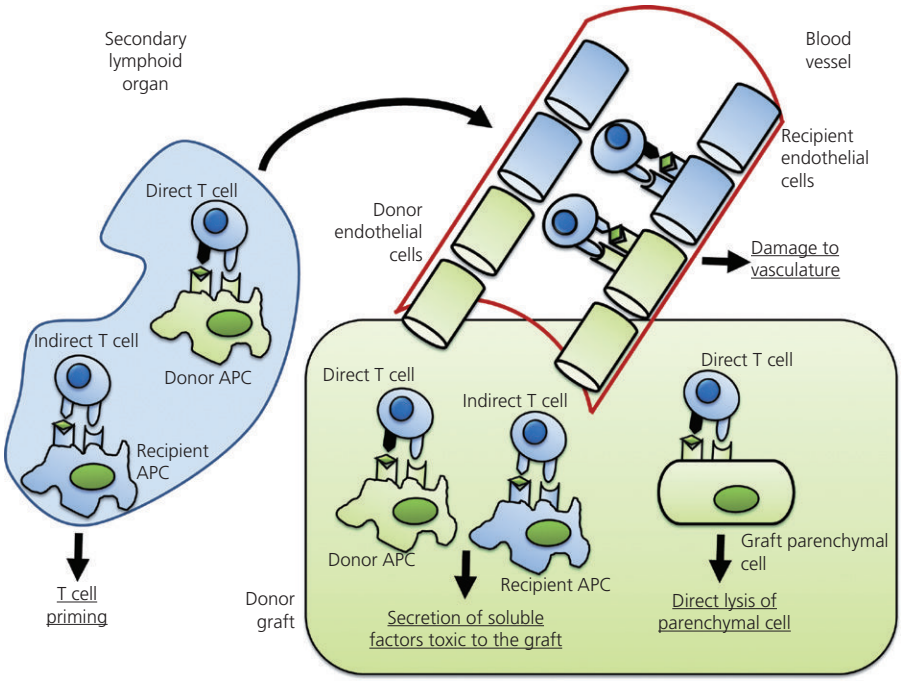

Figure 5.3. Mechanisms of T cell-mediated allograft rejection. T cells with direct and indirect alloreactivity can be primed in secondary lymphoid organs by donor and recipient APCs, respectively. Once activated these T cells proliferate, differentiate, acquire effector functions, and migrate via efferent lymphatics to the bloodstream. Upon reaching the transplant, alloreactive T cells may recognize recipient endothelial cells presenting allopeptides or donor endothelial cells in the graft and may mediate damage to the vasculature, therefore compromising the organ. Recognition of alloantigen on endothelial cells may also facilitate their recruitment/entry into the allograft. T cells that infiltrate the graft may recognize donor or recipient APCs presenting peptides. This may result in activation of both the T cell and the APC to secrete inflammatory factors that may damage the graft. Alternatively, T cells with direct alloreactivity may also recognize parenchymal cells and cause their death via Fas signaling or perforin and granzyme cytotoxicity. In some instances, $CD4^+$ T cells or $CD8^+$ T cells may be independently sufficient to reject a transplant; in other cases, activated $CD4^+$ T cells may help activated $CD8^+$ T cells develop their effector functions. In stable allografts, endothelial and parenchymal cells may not express costimulatory ligands anymore and their encounter may result in T-cell death or inactivation to perpetuate tolerance, rather than in T-cell activation and rejection episodes. Tregs with direct and indirect specificity may also be at play to inhibit alloresponses, both at the priming stage in secondary lymphoid organs and at the effector stage in the graft.

proteins escaping the endosome to enter the cytosolic TAP/endoplasmic reticulum/self-MHC class I pathway. Endothelial cells are capable of cross-presenting donor antigens in this manner [53]. Evidence for a pathogenic role of indirect $CD8^+$ cells in alloresponses has been revealed using TCR transgenic $CD8^+$ T cells specific for a male antigen presented by host MHC class I ($H\text{-}2^b$) and unable to recognize donor MHC ($H\text{-}2^k$). These T cells were shown to reject donor skin grafts with which they cannot interact, in an IFN-γ-dependent manner, and only if the vasculature expressed self-MHC molecules [54]. However, indirect $CD8^+$ T cells had no effect in a fully mismatched cardiac allograft model [55], thus questioning the impact of this pathway when direct recognition pathways are also operating.

The role of $CD4^+$ T cells with indirect recognition has been addressed similarly by using TCR transgenic T cells specific for a male antigen presented by host MHC class II. By using heart allografts from male mice with a disparate MHC alleles that cannot present the antigen to the transgenic $CD4^+$ T cells, it was found that host endothelial cells that progressively replace donor endothelial cells in the graft could activate the indirect $CD4^+$ T cells to induce graft vasculopathy and chronic rejection [56]. Overall, all these studies emphasize the important immunological function of endothelial cells, as APCs or as targets of effector T cells. Endothelial cells can also serve as targets for alloantibodies and innate immune cells, making them central players in acute and chronic rejection and deserving of special attention in future research [57]. B cells are also important for the priming of indirect $CD4^+$ T cells, as lack of MHC class II confined to the B cell compartment can result in reduced activation of alloreactive $CD4^+$ T cells and in turn diminished alloantibody production and prolonged cardiac allograft survival in mice [58].

The TCRs of Tregs can also have direct and indirect reactivity with alloantigen, but it has been shown that Tregs with indirect specificity have greater capacity to suppress alloresponses in vivo [59]. Interestingly, the inhibitory function of Tregs in alloresponses has been shown to depend on IFN-γ production by Tregs [60], an observation consistent with earlier reports demonstrating the resistance of mice deficient in IFN-γ-dependent signaling to transplantation tolerance [61]. Thus, IFN-γ may be a double-edged cytokine, important in the pathogenesis by Th1/Tc1 cells but also in the immunosuppressive function of Tregs. The predominant suppression of indirect alloresponses by Tregs has been confirmed in stable kidney transplant patients as depletion of Tregs in PBMCs resulted in enhanced IFN-γ production to HLA-DR-specific peptides [62]. The ability of Tregs to suppress indirect alloresponses positions them well to control chronic rejection, which may be more dependent on indirect presentation of alloantigen after passenger leukocytes have died. Indeed, the presence of a higher

number of Tregs in renal transplant patient biopsies containing inflamed fibrosis has been reported to correlate with better allograft survival [63]. Furthermore, Tregs with indirect specificity have been shown in rats to suppress in vivo production of alloantibodies [64] that are known to contribute to chronic rejection.

Another important consideration in the biology of Tregs following transplantation is whether they can suppress both T-cell priming in secondary lymphoid organs and effector T-cell responses in the allograft. Tregs have been shown to migrate from blood to inflamed islet allografts and back to draining lymph nodes, and to prevent migration of dendritic cells to secondary lymphoid organs [65]. Therefore, Tregs can reduce initial alloreactivity, T-cell priming and help the induction of tolerance. In addition, Tregs have been shown to accumulate in accepted allografts after costimulation blockade, and their sustained suppression at the graft site has recently been shown to be essential for infectious transplantation tolerance, a process by which new effector T cells become iTregs if their cognate antigen is expressed by APCs that can also present to existing Tregs [66,67]. These data indicate that Tregs also participate in the maintenance of tolerance.

Effector T cells: Th1, Th2, Th17, and cytotoxic T cells

Rejection of different organs has been shown to depend differently on T-cell subsets, at least in murine models (see Chapter 14). It is interesting to note that although the majority of the T-cell infiltrate in rejecting hearts is formed by $CD8^+$ T cells, cardiac allograft rejection can occur in the absence of $CD8^+$ but not of $CD4^+$ T cells, indicating that class II expression in the graft is sufficient for $CD4^+$ T cells to mediate rejection and suggesting alternative rejection mechanisms to cytolysis, as many $CD4^+$ T cells do not contain cytotoxic granules. Nevertheless, when the strength of the $CD4^+$ T-cell alloresponse is decreased such as in CD28-deficient mice, acute rejection becomes dependent on both $CD4^+$ and $CD8^+$ T cells, underscoring the participation of the latter T-cell subset, especially under conditions of immunosuppression [68].

Rejection of pancreatic islets has been reported to be dependent on either $CD4^+$ or $CD8^+$ T cells, depending on the strain combinations employed. Similarly, either $CD4^+$ or $CD8^+$ T cells are sufficient to drive skin and intestine allograft rejection. It may be that strong activation of $CD8^+$ T cells, as with Langerhans cells, obviates their requirement for $CD4^+$ T-cell help for their activation. However, $CD4^+$ T-cell help may be necessary for generation of alloreactive memory $CD8^+$ T cells [69].

The relative importance of distinct effector phenotypes, such as Th1, Th2, and Th17, in allograft rejection remains a subject of debate. IFN-γ production is most often associated with allograft rejection and T-bet, the signature transcription factor of Th1/Tc1 cells, can be detected in biopsies from kidney transplant recipients undergoing acute rejection [70]. However, mice deficient in IFN-γ are not impaired in allograft rejection but rather in allograft tolerance [61,71,72] and mice lacking STAT4, a transcription factor downstream of IL-12 without which Th1 differentiation is defective, do not display impaired allograft rejection [73,74]. Similarly, high serum concentrations of IFN-γ have been reported in patients without episodes of rejection [75]. It is important to note that IFN-γ and T-bet can be expressed by many cell types in addition to Th1/Tc1 cells, including NK cells, Tregs, and even dendritic cells, such that detection of this cytokine in mixed lymphocyte reactions does not equate Th1 alloreactivity.

Given their more recent discovery, Th17 cells have been under scrutiny in many pathological processes, with transplant rejection being no exception. IL-17 expression has been identified in many allografts undergoing acute or chronic rejection and IL-17 mRNA has been found in urinary sediments of kidney recipients [63,76–79]. Blockade of IL-17 was initially shown to prolong survival of rat cardiac allografts [80]. In mouse models, the pathogenic role of Th17/Tc17 cells has been evidenced principally in animals deficient in T-bet that become resistant to costimulation blockade-mediated induction of transplantation tolerance in a Tc17-dependent manner in one model or develop Th17-dependent accelerated vasculopathy in another [81,82]. In wild-type mice, signaling by TLR agonists at the time of transplantation was also shown to result in IL-6 production and promotion of IL-6/IL-17-dependent allograft rejection [38]. This is consistent with the demonstration that phagocytosis of infected apoptotic cells, which will trigger both TGF-β production from ingestion of apoptotic material and IL-6 production through stimulation of endogenous TLRs is a clinical situation in which Th17 cells may differentiate in vivo [83]. Additionally, exposure of self-antigens, such as collagen V or tubulin, following transplant injury has been reported to give rise to autoimmune Th17 cells with pathological consequences on allografts, both in animals and humans [84–88]. Importantly, some T cells can co-produce IFN-γ and IL-17 and may constitute a particularly pathogenic T-cell subset. It is important to note that differentiation into effector Th and Tc phenotypes may not be as terminal as initially thought and cells may retain pluripotency and plasticity to convert into other phenotypes depending on the environment [89], suggesting that it may be important to monitor T-cell function over time in transplant recipients to adjust immunosuppressive strategies to changing alloresponses.

Memory $CD8^+$ T cells are one of the first cells to enter allografts and initiate graft rejection [90], making this pathway important to suppress. The pathogenic role of effector and memory $CD8^+$ T cells in allograft rejection has been most often ascribed to their ability to produce IFN-γ and to lyse target cells via their perforin and granzyme-containing granules or via up-regulation of FasL (CD95L), which can kill by engaging the proapoptotic molecule Fas (CD95) on target cells [91,92]. In mice, FasL and perforin have been shown to play redundant, but obligatory, roles for acute rejection of pancreatic islets [93] with IFN-γ produced by the $CD8^+$ T cells themselves being also critical [94]. Perforin and granzyme are also important in chronic rejection, with knockout mice showing reduced apoptosis of endothelial cells and diminished subsequent allograft vasculopathy [95,96]. Importantly, granzyme B is also expressed in Tregs and plays a role in their suppressive function by allowing them to lyse $CD4^+$ T cells [97]. Consistent with this observation, expression of granzyme B in $Foxp3^+$ cells was necessary for the induction of skin allograft tolerance in mice [98], a reminder that effector pathways can have opposite consequences depending on the cells in which they are expressed.

Therapeutic implications

Because allograft rejection is absolutely T cell-dependent, immunosuppressive strategies have concentrated on preventing T-cell responses. The pathways targeted are covered in depth in Chapter 17. Most existing immunosuppressive agents such as calcineurin inhibitors or DNA synthesis inhibitors attempt to decrease T-cell activation and proliferation and do not induce transplantation tolerance. Experimental approaches to induce tolerance have aimed

either at deleting alloreactive T cells (using depleting antibodies, irradiation, or pruning strategies [99]), or at inducing their inactivation either intrinsically (through costimulation blockade or immunotherapy with tolerogenic APCs), or extrinsically (harnessing the suppressive power of Tregs, myeloid-derived suppressor cells, mesenchymal stem cells, or other cells) [99,100]. Interestingly, mTOR inhibition can promote iTreg differentiation while preventing differentiation of Th1, Th2, and Th17 cells [101], making rapamycin an attractive drug in transplantation, although it has also been shown to promote memory $CD8^+$ T-cell responses when used at lower doses [102,103]. Because deletion of T cells can paradoxically result in the proliferation of residual T cells to fill the space and their acquisition of memory characteristics with their inherent resistance to tolerance induction [104], a combination of partial deletion with induction of anergy and/or suppression of residual T cells may seem the more rational approach to the induction of tolerance.

Summary

The T cell and its biology remain at the core of transplant biology, and an understanding of the mechanisms involved in T-cell-mediated allorecognition remains fundamental to the practice of clinical transplantation. T-cell function precipitates essentially all of the clinical syndromes of acute cellular allograft rejection, and are central to most of the antibody-mediated forms of rejection, as well. Given the critical role of T cells in protective immunity, this biology also is relevant to an understanding of the infectious and malignant complications that continue to confound the long-term management of transplant recipients.

CHAPTER 6

Humoral Mechanisms of Adaptive Immunity

William M. Baldwin III and Robert L. Fairchild
Department of Immunology, Cleveland Clinic, Cleveland, OH, USA

Introduction

Humoral mechanisms of immunology comprise fluid phase reactants, including antibodies, complement, coagulation factors, and cytokines. As part of the adaptive immune response, antibody has antigen-specific receptors; whereas complement and cytokines are antigen non-specific mediators of the innate immune system. All of these mediators can also engage cells of the innate immune system, notably platelets, granulocytes, monocyte/macrophages, and NK cells. These innate cellular and humoral mediators can greatly amplify and modify antibody-mediated injury. As a result, humoral mediators can cause a spectrum of allograft destruction, ranging from hyperacute through acute to chronic rejection. In this chapter we will first consider humoral mediators separately. Then we will discuss the interactions of antibody and mediators with recipient and donor cells that contribute to tissue injury in allografts. The chapter will focus on mechanisms involved directly in graft destruction; more general discussions of physiologic humoral immunity can be found in Chapter 2. Specifics of the histological and clinical presentations of antibody mediated rejection are found in organ specific chapters on the histopathological syndromes (Section Histopathological Syndromes of Graft Rejection and Recurrent Disease) and clinical diagnosis and management (Section Clinical Allograft Rejection Syndromes: Diagnosis and Management) of graft rejection, respectively.

Antibodies

The structure and function of antibodies is determined by multiple factors, all of which change as the immune response progresses. De novo antibody responses to allografts begin with low levels of IgM antibodies followed by IgG antibodies that increase in quantity and quality. Although IgM and IgG share fundamental elements of immunoglobulins, namely two antigen binding fragments (Fabs) joined to a constant fragment (crystallizable fragment or Fc), key structural differences generate distinct functions (Figure 6.1) (see Chapter 2). For example, the individual Fabs of IgM antibodies bind antigen with low affinity, but the combined binding avidity that results from ten identical Fabs in the pentameric structure of IgM is as much as 10^7 times higher. The pentameric structure of IgM also facilitates activation of complement by linking five Fcs together.

As the immune response progresses, antibodies switch from IgM to IgG, which undergo affinity maturation through a process of mutation and selection. This results in IgG antibodies with increasingly higher affinity Fabs. With time, the avidity of monomeric IgG alloantibodies exceeds avidity achieved by pentameric IgM. The switch to IgG brings several new dimensions to the immune response. The smaller (about 150 kD) monomeric IgG traverses capillary and venous barriers much more readily than the very large (900 kD) pentameric IgM, such that almost half of the IgG exists in the interstitial and lymphatic compartments. The evolution of subclasses of IgG has added functional diversity. Humans have four subclasses of IgG with different Fc structures that diversify function. IgG1 and 3 activate complement more effectively than IgG2, and IgG4 does not activate complement. Similarly, each subclass has different binding affinities for Fc receptors (FcRs) on leukocytes. The range of functions is further increased by multiple types of receptors for IgG Fc (FcγR) which are expressed by most populations of leukocytes [1]. In contrast, only one IgM-specific FcμR has been defined, which is expressed by T and B lymphocytes [2]. Leukocytes of both mice and humans express a family of FcγRs that have different affinities and that deliver stimulatory or inhibitory signals. Mice and humans both have one high-affinity FcγR (FcγRI) and multiple low to medium-affinity FcγRs that initiate activating signals, as well as one low to medium-affinity FcγR (FcγRIIB) which contains a negative regulatory immunoreceptor tyrosine based inhibitory motif (ITIM) in the cytoplasmic domain.

It is important to remember that antibodies are glycoproteins, and both the protein and carbohydrate portions of the molecule contribute to function. The protein structure determines the number and location of carbohydrate side chains. All IgG and IgM antibodies have glycosylation sites on the Fc, and the carbohydrate side chains can modify the interaction of Fc with complement and FcRs [3]. Moreover, a minority of antibodies has glycosylation sites in the Fab regions which can alter antigen binding significantly.

Understanding of immunoglobulin glycosylation has several important ramifications. First, variations in glycosylation that are known to occur in patients with differences in drug therapies, age, sex, or pregnancy [4–7] may alter the consequences of antibody responses to transplants. Second, Ravetch and colleagues [8] have modified the glycosylation of immunoglobulins to produce more immunomodulatory preparations of intravenous immunoglobulin (IVIg).

Numerous mechanisms have been developed to detect graft-specific alloantibodies. These are covered in Chapter 89.

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

	IgM	IgG
Subtypes	None	1,2,3,4
C activation	+++	0 to +++
FcR	Limited	Multiple
Half-life	5 days	7 (G3) – 23 days
Function	Natural, early	Affinity Mature

Figure 6.1. Diagram of basic IgG antibody structure showing heavy chains (pink) and light chains (green), with constant regions (pale) and variable regions (dark). Papain cleaves IgG in the hinge region (checked) into three fragments: one Fc (fragment crystallizable) and two Fab (fragment antigen binding). The glycosylation site on the Fc is indicated by the yellow hexagon. The table compares important functions of IgM and IgG antibodies.

Antigens

Antigens are a critical part of the equation determining the results of antibody-mediated immunity. Antigenic variables that influence antibody function include structure and distribution. The high concentration of MHC class I antigens on all vascular endothelial cells provides an optimal target for antibodies to bind closely enough to activate complement and engage low as well as high-affinity FcRs on leukocytes. The expression of MHC class II antigens on endothelial cells is less uniform. In humans, for example, MHC class II antigens are constitutively expressed on all vascular endothelium in the heart, but confined to capillaries and veins in kidneys. However, the expression of MHC antigens is increased during ischemia–reperfusion and at sites of inflammation. An in depth discussion of MHC can be found in Chapter 4.

Like MHC antigens, the major blood group antigens A and B are expressed in high concentrations on endothelial cells. However, there are distinctions between MHC and blood group antigens [9]. The A and B antigens are terminal carbohydrate epitopes that can be linked to four different core saccharide chains attached to either lipids or proteins to form glycolipids or glycoproteins. The A and B epitopes have been shown to be covalently linked to various membrane glycoproteins as well as to soluble proteins such as von Willebrand factor (vWf) released by endothelial cells [10,11].

Other antigens that are still under investigation as potentially important targets for antibody-mediated rejection include MICA (major histocompatibility complex class I–related chain A), minor alloantigens, and autoantigens [12]. Unlike MHC antigens, these antigens are either expressed in low concentration, in intracellular locations, or as cryptic epitopes that are not exposed under normal conditions. Therefore, in quiescent conditions these antigens may not be optimal targets for antibodies. However, inflammation associated with transplantation (brain death of the donor, ischemia–reperfusion injury, and surgical trauma) or with subsequent rejection or infection can up-regulate the expression of these antigens to increase their susceptibility to antibody-mediated rejection. As an example of this interaction, it has been shown that antibody production to MICA is frequently a consequence of antibody responses to HLA [13].

Complement

When high concentrations of antibodies bind to allogeneic cells, the complete complement cascade can be activated by either the classical or lectin pathway depending upon the structure of the carbohydrate side chains on the Fc, which have variable terminal sugars (see Chapters 2 and 7). In contrast to most serum glycoproteins, only a minority of human IgG carbohydrates has a terminal sialic acid. Instead, the branches of these side chains frequently terminate with galactose residues that increase binding of C1q [14], the initiator of the classical pathway. Variation in antibody glycosylation is a well-known aspect of autoimmune diseases [15]. Antibodies that lack the terminal sialic acid and galactose (referred to as G0 antibodies) have exposed terminal *N*-acetyl glucosamine (GlcNAc) residues. Mannose binding lectin (MBL), the initiator of the lectin pathway, binds avidly to GlcNAc on G0 antibodies. G0 autoantibodies have been confirmed to activate complement through the lectin pathway in both humans and mice [14]. In mice, G0 IgG levels are higher in autoimmune-prone mice and increase with age and non-specific inflammatory stimuli [16]. In humans, the heterogeneity in terminal sugar residues is dependent on certain diseases, drug therapies, age, and sex [4–7].

Both C1 and MBL require two or more adjacent Fc regions of IgM or IgG for effective binding and activation. This permits the enzymatic subunits of bound C1 (namely C1r and C1s) or MBL (MBL-associated serine proteases; MASP) to start a series of enzymatic steps that can significantly amplify and diversify the immune response by producing increasing amounts of biologically active "split products" [17] (Figure 6.2). The details of the complement cascade are reviewed in Chapter 2. Briefly, C4 is first cleaved into two fragments—C4a and C4b. The small C4a fragment is a soluble mediator and the larger C4b contains a thioester group. This thioester can form a covalent bond with a hydroxyl or amino group on the closest protein or carbohydrate. This first enzymatic step can result in a significant amplification with about 25 molecules of C4b bound on or near the activating antibody [18]. More downstream, C4b serves as an attachment site for C2, which is then cleaved by C1s to generate C2a, which remains associated with C4b. The C4bC2a complex is the classical pathway C3 convertase that cleaves the central complement component, C3, into two fragments, C3a and C3b. The small C3a fragment is a fluid-phase vasoactive mediator that can bind to C3a receptors (C3aR) on nearby endothelial cells or mast cells. The larger fragment, C3b, is structurally homologous to C4b and contains a thioester group that can bind covalently. C3b has similar but more extensive functions compared to C4b. Like C4b, it serves as a ligand for cells with complement receptor 1 (CR1; CD35). Additionally. C3b can bind factor B of the alternative pathway of complement and engage the alternative pathway, which serves as an amplification loop that results in more C3 split products (Figure 6.3). As the result of the classical and amplification pathways, around 250 C3b fragments can be deposited on target cells for each C1 or MBL.

In combination with adjacent complement split products, C3b forms the classical and alternative C5 convertases (C4bC2aC3b and C3bBbC3b, respectively), which cleave C5 into C5a and C5b. It is at this point that the complement cascade intensifies its proinflammatory effects [19]. The small fragment, C5a, is quantitatively much

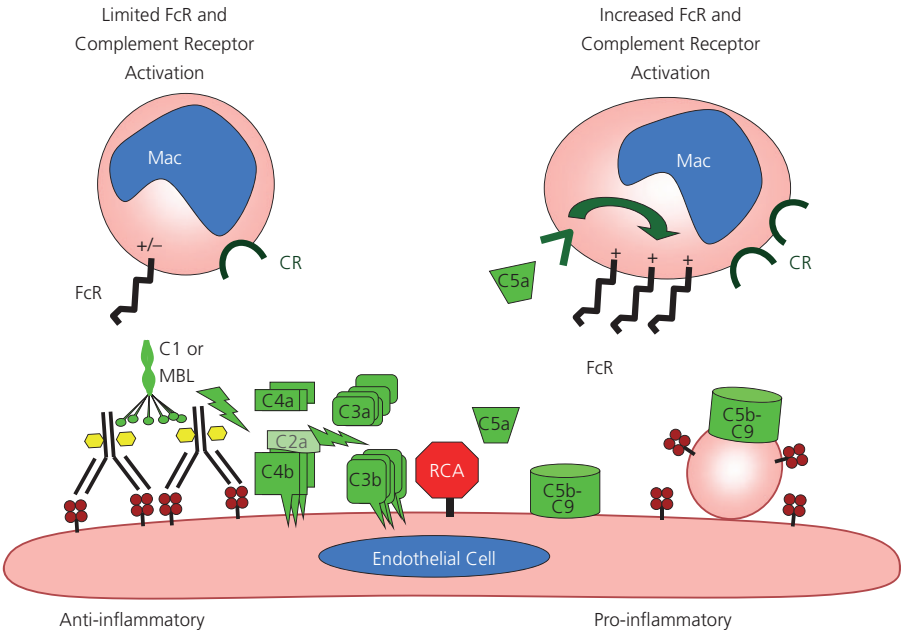

Figure 6.2. Diagram of increasingly proinflammatory effects of complement activation by antibody. Leukocytes with Fc receptors (e.g. neutrophils and macrophages) can be stimulated by antibodies bound to antigen. The strength of Fc receptor interactions with IgG is dependent on the carbohydrate side chains (yellow hexagons) on the antibodies. The carbohydrate side chains on IgG also interact with the first components of the classical and lectin complement pathways. At least two closely spaced IgG antibodies are required to initiate binding of one C1 or MBL molecule. C1 or MBL can enzymatically cleave many molecules of C4, which produce C4b that can bind covalently to cell membranes. C4b anchors the classical convertase (a complex of C4b and C2a) that cleaves large numbers of C3 producing C3b, which can bind covalently to tissues, and C3a, which is chemoattractant for neutrophils and macrophages. C3b joins C4bC2a in the formation of classical C5 convertase, which cleaves C5 into C5a and C5b. C5b initiates the formation of the membrane attack complex (MAC; C5b-C9). Both the C3 and C5 convertases are the target of several regulators of complement activation (RCA). As a result, endothelial lysis is not widespread in AMR, but sublytic amounts of MAC can stimulate endothelial cells to produce cytokines, express adhesion molecules, and shed microparticles containing the offending MAC. C5a is pivotal inflammatory mediator because it is an extremely potent chemoattractant for neutrophils and macrophages, and it also causes macrophages to up-regulate the stimulatory Fc RIII and down-regulate the inhibitory Fc RIIB for IgG. These receptors make macrophages more responsive to antibodies and complement split products. (Reproduced with permission from reference [17].)

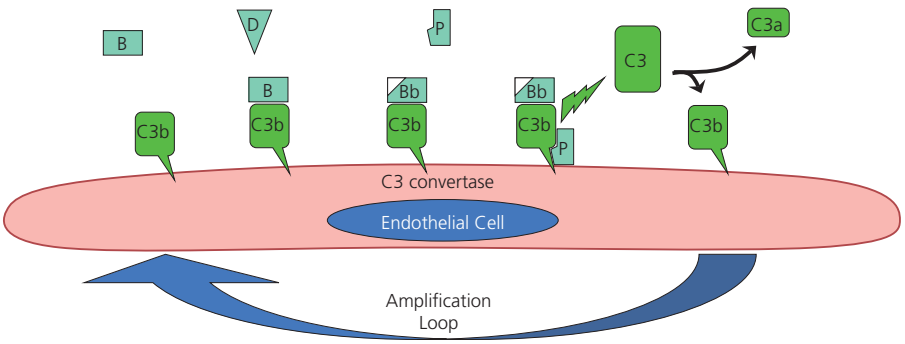

Figure 6.3. Once C3b is attached to a cell membrane, it can serve as the nidus for an amplification loop in which the alternative pathway generates more C3b. In this process, C3b acts as an anchor for factor B (B), which is then cleaved by factor D (D) to form the C3 convertase, C3bBb. Properdin (P) binds to this complex and stabilizes this enzyme. This stabilized enzyme complex has an increased half-life to cleave more C3 into C3b and creates a long-lived feedback loop.

more potent as a chemotactic agent than C3a and polarizes macrophages towards proinflammatory functions as described later. As shown in Figure 6.2, the larger fragment, C5b, initiates assembly of the terminal components of complement (C5b–C9) into a pore-forming structure, the membrane attack complex (MAC). As will be discussed below, MAC, even at sublytic concentrations, alters endothelial cell function.

Complement is a key component of the innate immune response to injury. Additional details regarding its role in this context are found in Chapter 7.

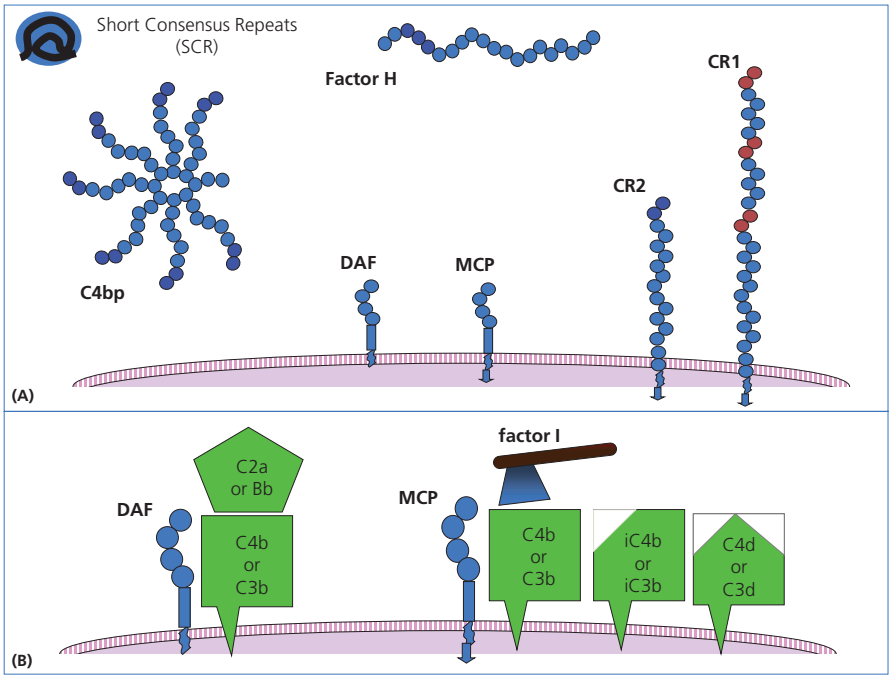

Figure 6.4. Diagram of the regulators of complement activation. (A) Structure of regulators that are composed of various numbers of highly conserved short consensus repeats. (B) Illustration of dissociation of convertases by decay accelerating factor (DAF) and co-factor function of membrane co-factor protein (MCP). DAF accelerates the dissociation of both the classical and alternative C3 convertases (C4bC2a and C3bBb). MCP serves as a co-factor for the enzymatic factor I to cleave C4b or C3b first to iC4b or iC3b, which are then further cleaved to C4d or C3d.

Complement regulation

Not surprisingly, this progression of potent effector molecules is highly regulated at almost every step. However, different regulatory molecules can modify the immune response in divergent directions. Regulation of complement is of increasing importance to transplantation both in understanding antibody-mediated rejection and as potential therapeutic interventions that modulate the complement system.

Regulation begins at the initial step of complement activation with C1 inhibitor, a serine protease inhibitor of the serpin superfamily. It provides a substrate to capture serine proteases, including C1r, C1s, and MASPs. This leaves the non-enzymatic C1q or MBL bound to antibody. In the setting of tissue injury, both C1q and MBL are critical for the clearance of apoptotic bodies by scavenger macrophages and the avoidance of autoimmunity [20,21]. It is possible that engagement of macrophages through C1q receptors also has beneficial effects in allografts. In fact, Bishop and colleagues have reported that allografts are rejected more rapidly by C1q-deficient mice [22].

As a serine protease inhibitor, C1 inhibitor has additional effects that are potentially salutary for transplants. These include inhibition of the kallikrein and coagulation systems [23]. More recent studies indicate that C1 inhibitor can bind to selectins on endothelial cells and interfere with leukocyte rolling [24].

The majority of complement regulators are focused on C4b and C3b. Many of these regulators are composed of various numbers of highly conserved short consensus repeats and are members of the regulators of complement activation (RCA) gene cluster, which is located on chromosome 1 (Figure 6.4A). In general, these regulators work through two mechanisms: dissociation of convertases and co-factor functions (Figure 6.4B). C4 binding protein (C4bp) and decay accelerating factor (DAF; CD55) accelerate the dissociation of C2a from C4b and decrease the half-life of this C3 convertase. In contrast, membrane co-factor protein (MCP; CD46) serves as a co-factor for the enzymatic factor I to cleave C4b or C3b first to iC4b or iC3b, which are then further cleaved to C4d or C3d. C4bp, factor H and complement receptor 1 (CR1; CD35) also function as co-factors for factor I (Figure 6.4A). The terminal complement components are regulated by protectin (CD59), which prevents the association of C9 with C5b-C8.

The balance among complement mediators and regulators is responsive to inflammation. IL-1, IL-6, IL-8, and TNF stimulate the liver to produce acute-phase proteins, among which are complement components and regulators. Hepatic production of MBL, C3, factor B, C5, C1 inhibitor, and C4bp are increased in response to inflammatory cytokines. At local sites of inflammation, both macrophages and certain parenchymal cells, notably epithelial cells, can produce complement components [25–27]. This is counterbalanced by the up-regulation of complement regulators on the surface of endothelial cells. In particular, DAF has been demonstrated to be up-regulated during antibody-mediated rejection in some renal and cardiac transplants [28,29].

The expression of regulators is sufficient to prevent lysis of most cells in allografts when moderate levels of complement are activated. However, high levels of antibodies can overwhelm the regulatory molecules and cause lysis of endothelial cells, which manifests as hyperacute rejection. Short of lysis, a range of outcomes is possible depending on the balance of split products that are produced.

Therapeutic intervention can moderate activation of complement at different steps. C5 has been recognized as a tipping point to intense inflammation. As a result, monoclonal antibodies that

block C5 cleavage, soluble C5a receptors, and antagonists of C5a receptors have been developed and are at various stages of clinical application [19]. The humanized anti-C5 antibody, eculizumab, has been demonstrated to inhibit antibody-mediated rejection in patients [30].

Human C1 inhibitor is now in clinical trials with renal transplant recipients. This approach is attractive because it inhibits the enzymatic components of both C1 and MBL but does not interfere with the apoptotic clearance mechanisms of C1q and MBL. The additional effects of C1 inhibitor on the kallikrein and coagulation systems [23] may also benefit transplant recipients.

Incompatibilities between humans and distant phylogenic species such as the pig significantly confound xenotransplantation. In depth discussions of complement regulation and preformed antibodies as they relate to xenotransplantation can be found in Chapter 12.

Cells

In addition to deposits of complement split products, the pathological changes observed in acute humoral rejection include endothelial cell activation and granulocyte or monocyte margination [31,32]. These responses are predictable from direct and indirect effects of antibodies on each of the cell types. Endothelial cells lining blood vessels of organ transplants are the first available target for antibodies. When antibodies cross-link MHC antigens on endothelial cells, von Willebrand factor and P-selectin are exocytosed within minutes from Weibel–Palade storage granules [33]. This results in platelet adhesion and activation, which extends the inflammation quantitatively and qualitatively because of the large numbers of platelets and the wide variety of mediators released by platelets [34,35]. Of particular relevance to transplants are the chemokines and ligands that engage neutrophils, macrophages, and T cells. These include IL-8, PF4 (CXCL4), RANTES (CCL5), P-selectin, and CD40L (CD154) that are stored in alpha granules of platelets. Activation of endothelial cells by antibodies is augmented by complement activation products beginning with the successively more potent anaphylatoxins (C4a, C3a, and C5a) and progressing to MAC. The anaphylatoxins increase vascular permeability by binding specific receptors on endothelial cells and mast cells [19]. Finally, MAC in sublytic amounts, and even incompletely assembled MAC (C5b-C8), cause calcium fluxes that activate endothelial cells [36–38]. This results in an immediate response of cell contraction and exocytosis of preformed adhesion molecules. In the presence of inflammatory cytokines such as IL-1α and TNF, endothelial cells activated by MAC synthesize chemokines for neutrophils and monocytes (IL-8 and MCP-1; CCL2), and up-regulate adhesion molecules (P-selectin, E-selectin, and ICAM-1) for leukocyte infiltration. Antibodies and MAC independently and together also induce endothelial cells to produce growth factors (PDGF and FGF) and to proliferate, responses that are of particular relevance to chronic rejection [39–41]. Unlike erythrocytes, nucleated cells react by rapidly shedding or invaginating membrane containing MAC [42,43], but this releases potentially antigenic microvesicles that can be acquired and presented to initiate or amplify adaptive immune responses.

Neutrophils and macrophages, which are characteristic participants in antibody-mediated rejection, both express multiple Fc and complement receptors. These receptors have interactive effects that are best illustrated by C5aR and FcR. In addition to being an extremely potent chemoattractant for neutrophils and macrophages, C5a also causes macrophages to up-regulate the stimulatory FcγRIII and down-regulate the inhibitory FcγRIIB for IgG [44], making macrophages more responsive to antibodies. Similarly, stimulation through FcR causes macrophages to produce more complement [45].

Although monocytes and macrophages are associated with rejection, they have a wide range of functions from proinflammatory to profibrotic to anti-inflammatory [46–48]. These subpopulations of macrophages have been most fully defined relative to T cells. In this context, proinflammatory (or M1) macrophages are stimulated by IFNγ and TNF from Th1 or NK cells to produce IL-12, IL-1, and IL-6 (also see Chapter 2). In contrast, profibrotic (or M2) macrophages arise in response to IL-4 from Th2 cells and characteristically produce TGFβ and connective tissue growth factor (CTGF). Finally, anti-inflammatory (or regulatory) macrophages respond to and produce IL-10.

Ischemic injury has been found to elicit a first wave of inflammatory macrophages followed by wound healing macrophages [48,49]. The macrophages that infiltrate allografts in response to different sets of humoral immune mediators have not been characterized. However, the most congruent analogy is that activation through C5aR and stimulatory FcR would polarize macrophages towards inflammation. At the other end of the spectrum would be macrophages stimulated by early complement components in the absence of terminal complement activation. As discussed in the complement section, C1q or MBL are known to mediate the removal of apoptotic blebs by macrophages without causing inflammation or fibrosis [50–54].

Types of humoral rejection

Concepts about the manifestations of humoral rejection were dominated by the original catastrophic experiences with hyperactue rejection. With increasingly sophisticated methods for detecting antibodies and probing biopsies, new concepts about more subtle effects of humoral immunity have evolved.

Hyperacute rejection

In hyperacute rejection, high levels of antibodies activate enough complement to exceed all of the regulatory barriers and significant lysis of vascular endothelial cells occurs. This disruption of vascular integrity results in hemorrhage and thrombosis. Copious amounts of complement split products also attract and activate numerous neutrophils that typify hyperacute rejection. A landmark publication in 1969 by Patel and Terasaki [55] described and validated a serological test for preformed antibodies. The history leading to this revolutionary realization is detailed in Chapter 3. This test demonstrated antibodies in about 30% of patients. Over a third of the patients with antibodies were cross-match positive for donor-specific antibodies (DSA). Hyperacute rejection occurred in 80% of the patients with DSA versus about 15% of the patients with antibodies to antigens not expressed on the transplant. Hyperacute rejection was very frequent (almost 41%) in patients who received second transplants. By 1974, Mel Williams reported, in a memorial symposium for David Hume, that implementation of the cross-match test had eliminated hyperacute rejection in a series of 24 patients with second transplants [56].

Acute rejection

The amount of complement activation depends on the titer and class of antibodies, and on the density of the target antigen.

Alloantibodies produced after transplantation by naïve or memory B cells do not immediately attain high titers. Low levels of antibodies result in less complement activation, which is better controlled by the many regulatory mechanisms.

When sufficient complement is activated that regulation of C3 convertase is overridden and significant amounts of C5 convertase are formed, then a complete picture of humoral rejection is found. This includes edema as the result of increased vascular permeability, deposition of C4 and C3 split products (C4d and C3d), and margination and infiltration of neutrophils and macrophages. Expert panels of pathologists have agreed upon these basic findings for antibody-mediated rejection in renal, cardiac, and pancreatic transplants [57–59]. A universal marker for monocytes and macrophages is usually employed to define the mononuclear infiltrates. This of course does not distinguish subtypes of macrophages.

When little complement is activated due to lower titers of antibodies, varying mixtures of non-complement activating antibodies, or antibodies to less densely expressed antigens, then the pathological findings are less obvious. Acute graft dysfunction has been described in the absence of C4d [60]. These cases have sometimes been attributed to complement-independent effects of antibody. It is also possible that these cases represent patients with low amounts of certain complement regulators. Low levels of circulating factor H, for example, allow the alternative C3 convertase to have a longer half-life, which would permit even small amounts of C4 activation to cause significant C3 and C5 production through the inadequately regulated amplification loop. The importance of normal factor H function in preventing excessive C3 activation has been demonstrated in animals treated with blocking antibodies to factor H and in humans with mutations that alter the functioning factor H [61]. The expression of membrane bound complement regulators could also be critical [62]. DAF, which is up-regulated in response to inflammatory cytokines, is expressed at lower levels in some cases of antibody-mediated rejection of both renal and cardiac transplants [28,29]. Again this would be expected to prolong the function of C3 convertase and result in more C3 activation.

Conversely, C4d has been found in some biopsies that do not show any other evidence of humoral rejection. It has been suggested that antibodies to donor-specific HLA in association with C4d deposits in the absence of inflammation and graft dysfunction represents subclinical rejection [63]. In non-human primate models, these findings can predate evidence of chronic rejection by months [64].

Chronic rejection

Clinically, humoral immune responses have been linked to chronic rejection in renal transplants [65]. Circulating DSA and C4d deposits in biopsies of renal transplants have been associated with eventual development of glomerulopathy. However, chronic glomerulopathy is much more prevalent than C4d deposition. Sis and colleagues have noted a high incidence of endothelial disturbance on a molecular level in the absence of demonstrable C4d deposits and this molecular signature of endothelial injury is correlated with chronic graft failure [66,67]. In part, this may reflect a selective process because high titers of antibodies that activate readily detectable amounts of complement would produce acute graft dysfunction. Lower titers of antibodies can cause complement-independent responses of endothelial cells and smooth muscle cells that can contribute to chronic vascular changes. These include up-regulation of fibroblast growth factor (FGF) receptors and increased proliferation [68]. Low levels of antibody and complement activation can also stimulate endothelial cells to endocytose or exocytose adulterated segments of their plasma membrane [42,43]. Experimental animal models have demonstrated that even large amounts of covalently bound complement split products (C4d and C3d) can be diminished to undetectable levels within 3 to 5 days after donor-specific antibodies are eliminated [69].

Accommodation and tolerance

Renal transplants incompatible for the major blood group antigens A and B have provided insights into two non-inflammatory outcomes of humoral immune responses: accommodation and tolerance. Antibodies to A and B antigens differ from antibodies to HLA in that "natural" hemagglutinin antibodies develop in the first year of life, presumably in response to cross-reactive carbohydrate antigens on bacteria that colonize the gut. Hyperacute or acute rejection can be avoided by depleting the natural antibodies in the recipient before and for the first weeks after transplantation. After this critical period, renewed production of antibodies does result in deposition of C4d in the peritubular capillaries, but often in the absence of margination of leukocytes or graft dysfunction [70,71]. The apparent resilience of grafts to antibodies and complement is termed accommodation. Several aspects of accommodation are instructive relative to humoral immune responses. The first relates to antibody titer. Antibodies to A and B blood group antigens can cause hyperacute rejection when the antibody titer is high and antibodies are not depleted before transplantation [72]. Recurrent antibody responses associated with accommodation usually develop gradually and attain only low titer. The development of hemagglutinins with titers >64 is associated with episodes of rejection [73]. Secondly, to allow grafts to accommodate, antibody depletion is maintained during the postoperative period when transplants experience non-specific inflammation due to ischemia–reperfusion and surgical trauma. Finally, the biochemical properties of the carbohydrate blood group antigens may be critical. The fact that the A and B antigens can be linked to soluble proteins released by endothelial cells such as vWf, as well as various membrane proteins in kidneys [10,11], may modify critical aspects of antibody distribution and complement activation. The typical markers of complement activation that are observed in accommodation, namely C4d and C3d, are end products of regulation by factor I. These split products do not necessarily indicate that the very proinflammatory C5 and MAC have been activated. Many activation products of the early complement components, notably C1q and iC3b, have anti-inflammatory functions. As noted in the section on complement, C1q is critical for the removal of apoptotic bodies without stimulating inflammation or antigen presentation. Similarly, when iC3b interacts with CR3 (CD11b/CD18) on antigen-presenting cells, production and secretion of the proinflammatory cytokines IL-1β, IL-6, IL-12, and TNF are decreased [74–76]. CR3 can also be up-regulated on T cells, and cross-linking this complement receptor inhibits T-cell proliferation and IL-2 release [77].

It is not clear whether tolerance to blood group antigens or HLA can be achieved through the activities of C1q or iC3b. Certainly, apparent cases of accommodation in the presence of antibodies to HLA are less stable than those for blood group-incompatible transplants. However, long-term tolerance to ABO-incompatible allografts can be achieved when ABO-incompatible hearts are successfully transplanted into infants within 6 months of birth. These transplants induce tolerance to the donor blood group as evidenced by the lack of B cells capable of producing antibodies to

donor blood group antigen [78]. The donor antigens remain expressed on the graft endothelium, but recipient B cells do not produce antibodies to donor blood group antigens, while antibodies do develop normally to non-donor blood group antigens. Over the long term, a minority of these patients have been reported to develop antibodies to donor blood group antigens [79], but these antibodies may recognize A and B epitopes attached to carbohydrate backbones expressed by erythrocytes used in hemagglutination assays and not the graft endothelium [80].

Summary

Humoral immunity encompasses a wide array of interdependent mediators, regulators, receptors, and cells that can create devastating pathological changes ranging from hyperacute to acute rejection. At the other end of the spectrum, humoral immunity may be associated with chronic changes or even down-modulate tissue injury. The appreciation of humoral mechanisms of graft destruction has improved markedly in recent years. Its future challenge will be to find means of controlling these processes so as to avoid their effects in a graft-specific manner.

Introduction

Innate immunity is a key component of immunity in general, and, together with the adaptive immune system, it forms an intricate system that protects us from countless invading pathogens. The innate immune system also contributes to tissue homeostasis by eliminating cancerous and stressed cells. The innate response is carried out by innate immune cells, which include dendritic cells (DC), macrophages, monocytes, natural killer (NK) cells, neutrophils, mast cells, and eosinophils. In contrast to the cells of the adaptive immune system, namely T and B cells, innate immune cells do not possess somatically rearranged cell surface receptors that directly recognize foreign antigens. Instead, they express a plethora of pattern recognition receptors that engage conserved pathogen moieties, danger signals, and damaged cell products; they also express receptors for complement products, antibodies, and additional non-polymorphic activating and inhibitory receptors that constantly sense "self" or "missing self" to control cellular responses. These features allow innate immune cells to form the first line of defense and also influence the commencement, duration, and the character of adaptive immune responses.

Historically, transplant research primarily has focused on cells of the adaptive immune system, particularly the involvement of T cells in graft injury. This is rooted in the experimental observation that tissue and organ transplants often survive long term in the absence of T cells in allograft recipients. Recently, the contribution of innate immune cells to transplant outcomes (rejection or acceptance) is increasingly appreciated [1–3]. Innate immune cells can be activated by microbial products or by endogenous ligands (alarmins) from damaged grafts; some innate cells can respond directly to allografts. Such cells influence transplant outcomes through a variety of mechanisms, including the modification of the T-cell activation programs. In various settings, innate immune cells are closely involved in rejecting or protecting allotransplants, depending on the context and tolerizing protocols; they also contribute to a wide spectrum of graft injury. Therefore, innate immune cells are important contributors to alloimmunity in general, and, because of that, successful induction of transplant tolerance requires a better understanding and rational targeting of such cells following transplantation. In this chapter we review key cells and molecular pathways in the innate immune system, detail how the innate system responds to allotransplants, and summarize the challenges and opportunities in therapeutic targeting of the innate immune system in transplant settings. This chapter will complement Chapters 5 and 6, which deal with the cellular and humoral elements of the acquired immune response, respectively.

The innate immune system

The innate immune system consists of a variety of cell types, molecular sensors, cell surface activating and inhibitory receptors, and soluble mediators. The key elements in the system are discussed below in detail.

Dendritic cells

Dendritic cells (DC) are a rare cell type in the immune system, representing ~1% of total lymphoid cells; they are widely distributed in the body and are identified morphologically by having long dendrites projecting from the body of the cells (see Chapter 2). Dendritic cells are developed from bone-marrow precursors, and, based on anatomic locations, surface markers, and maturation status, they can be divided into various subsets [4,5]. DCs in the lymphoid tissues are called lymphoid tissue resident DCs and those in other sites are often termed interstitial DCs. Phenotypically, DCs express the β integrin CD11c, and, in combination with other surface markers, they can be further divided into **myeloid DCs** ($CD11c^+CD11b^+CD205^-$), **lymphoid DCs** ($CD11c^+CD11b^-CD205^+$), and **plasmacytoid DCs** ($CD11c^+B220^+PDCA^+$). Thus, DCs, though highly specialized, are extremely heterogeneous, and different DC subsets perform different functions in vivo. Earlier studies indicate that various DC subsets reside in different locations in the lymphoid tissues and exhibit striking difference in their expression of chemokines, chemokine receptors, and homing receptors. They also secrete different cytokines upon activation, which subsequently create different cytokine milieu for the differentiation of adaptive T cells. For example, plasmacytoid DCs produce copious amount of type I interferons whereas myeloid DCs secret high levels of IL-12 upon activation.

The primary function of DCs is to engulf, process, and present foreign antigens to cells of the adaptive immune system. However, DCs are very dynamic; their phenotypes and functions can be profoundly modulated by a variety of mechanisms. They express an incredibly complex array of toll-like receptors (see below) that allow them to respond to microbial products or endogenous tissue products collectively called "danger signals"; they are capable of

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

producing and also responding to a plethora of inflammatory cytokines. These responses often result in further proliferation and maturation of DCs, as reflected by the heightened expression of MHC molecules and T-cell costimulatory molecules on the cell surface (e.g. CD80, CD86, CD40, and OX40 ligand etc.). During this process, DCs are often transformed into potent antigen-presenting cells (APCs) that are highly efficient in the activation of adaptive immune cells (see Chapter 6) Thus, depending on the presence or absence of "danger signals," DCs can remain in a state of resting cells or become fully activated, and there is evidence that resting and activated DCs may perform different functions in vivo. While activated DCs are potent triggers of immune activation, resting DCs are likely required for immune tolerance by engaging and supporting regulatory cells [6]. The demonstration that genetic ablation of DCs in naïve mice results in widespread autoimmune diseases suggests that DCs are essential not only for robust immunity but also for tolerance and immune homeostasis [7]. Thus, DCs provide an essential link between the innate and adaptive immune systems; they are also well positioned at the interface between immunity and immune tolerance.

Monocytes and macrophages

Monocytes and macrophages are mononuclear phagocytes with many special characteristics. Monocytes are developed from bone marrow myeloid precursor cells, reside in the blood, and, upon inflammatory triggering, they rapidly infiltrate inflammatory sites where they mature into macrophages [8]. In some organs, macrophages acquire additional tissue-specific features and become integral cellular component of the organ, such as Kupffer's cells in the liver and glia cells in the brain. In humans, monocytes constitute 5–10% of the peripheral circulating leukocytes in the blood. Although monocytes and macrophages are closely related, they can be distinguished by different surface markers. For example, monocytes are $CD11b^{high}$ and $F4/80^{-}$, and they express low levels of MHC class II and CD80, CD86, CD40 costimulatory molecules. In contrast, macrophages are $CD11b^{high}$ and $F4/80^{+}$, and also have high levels of surface MHC class II, CD80, CD86, and CD40 molecules. Besides differentiating to macrophages at inflammatory sites, monocytes also differentiate into myeloid DCs in situ in selected models. Additionally, $CD14^{+}CD16^{-}$ monocytes are highly efficient at phagocytosis and can produce high levels of inflammatory cytokines, whereas $CD14^{low}CD16^{+}$ monocytes express MHC class II molecules and are highly efficient at antigen presentation [8]. Furthermore, studies using intravital microscopy to directly examine blood monocytes in vivo revealed additional complexity. For instance, $Ly6C^{-}GR1^{-}$ monocytes patrol the vessel walls, and after extravasation differentiate into type II (M2) macrophages (see below), whereas $Ly6C^{+}GR1^{+}$ monocytes differentiate into dendritic cell-like cells or generate an type I macrophages (M1) [9].

Macrophages are a major cellular infiltrate at inflammatory sites; they primarily function as APCs and inflammatory cells [10]. Macrophages efficiently phagocytose foreign entities and then present the antigenic epitopes to T cells to initiate the adaptive immunity; they also produce, as well as respond to, a wide array of inflammatory cytokines, which further amplify their phagocytosis and APC functions. Similar to DCs, macrophages also consist of multiple phenotypic and functionally different subsets. The cytokine milieu in which macrophages are stimulated plays a decisive role in the polarization of macrophages. For instance, in an environment rich in IFN-γ, TNF-α, or IL-12, macrophages are polarized toward **type I macrophages** or M1 macrophages. M1 macrophages are highly inflammatory cells, facilitate Th1 induction, and exhibit cell-cidal activities, primarily through the production of reactive oxygen species and TNF [11]. On the other hand, **type II macrophages** or M2 macrophages are generated in an IL-4 rich milieu, and M2 macrophages exhibit immune modulatory function and promote wound healing [12,13]. Mechanistically, IL-4 stimulates arginase activity in macrophages, which converts arginine into ornithine, leading to enhanced collagen production and wound healing. M2 macrophages also produce the suppressive cytokines IL-10, TGF-β, and prostaglandin E2 which suppress T-cell activation. M1 and M2 macrophages may represent extreme ends of a rather wide spectrum of macrophage function, but they do highlight the plasticity of macrophages and the importance of environmental cues in determining macrophage functions [14].

Additionally, under certain conditions some macrophages can become potent inducers of $Foxp3^{+}$ Tregs, most likely via the expression of PD-L1, which indirectly contribute to immune regulation (covered in Chapter 8) [15,16], while others contribute to immune regulation and tolerance by differentiating into **myeloid-derived suppressor cells** (MDSC), a cell type with potent immunosuppressive properties [17]. Finally, there is emerging evidence that macrophages can be alloreactive and respond directly to allo [18] or xenoantigens [19], although the exact molecular basis for such alloreactivity remains to be defined.

Natural killer cells

Natural killer (NK) cells are a major cell type in the innate immune system and represent the third largest lymphocyte population in the blood (besides T cells and B cells). NK cells are well represented in the blood, spleen, lymph nodes, and other lymphoid tissues; they also reside in non-lymphoid sites in large numbers, especially in the liver and the lungs [20]. NK cells are present in cellular infiltrates at inflammatory sites where they closely interact with other innate and adaptive immune cells.

Mature NK cells exhibit remarkable cytolytic activities; they readily kill target cells without prior antigen priming, which contrasts sharply to adaptive T cells. Target cell killing is mediated primarily by the release of perforin and granzymes, which are tightly packed inside NK cells as large preformed granules, and target cell recognition by NK cells triggers rapid degranulation and target cell apoptosis. NK cells also produce copious amounts cytokines upon stimulation, and such cytokines include both proinflammatory (e.g. IFN-γ, TNF) and anti-inflammatory cytokines (e.g. IL-10, TGF-β), thus exerting diverse impacts on the nature of the immune response.

A key feature of NK cells is the multiplicity of cell surface receptors they express, and these receptors collectively control development, education, and effector functions of NK cells (Figure 7.1). Functionally, the NK receptors are divided into **activating receptors** and **inhibitory receptors** [21,22]. The activating receptors include natural cytotoxicity receptors or NCR (NKp46, NKp44, NKp30), c-type lectin-like Ly49 receptors in the mouse (e.g. Ly49H, Ly49D), and killer immunoglobulin-like receptors (KIR) and NKG2 family receptors (NKG2C, NKG2D) in humans. Certain NK subsets also express CD16 and CD27 which function as activating receptors. In mice, the inhibitory NK receptors belong to the Ly49 family (e.g. Ly49C, Ly49G, Ly49I), whereas human NK cells express inhibitory receptors of the KIR family, which include KIR2DL1, KIR2DL2, KIR2DL3, KIR3DL1, and KIR3DL2. In both humans and mice, NK cells also express the heterodimeric inhibitory receptor NKG2A-CD94. With few exceptions, most NK activating

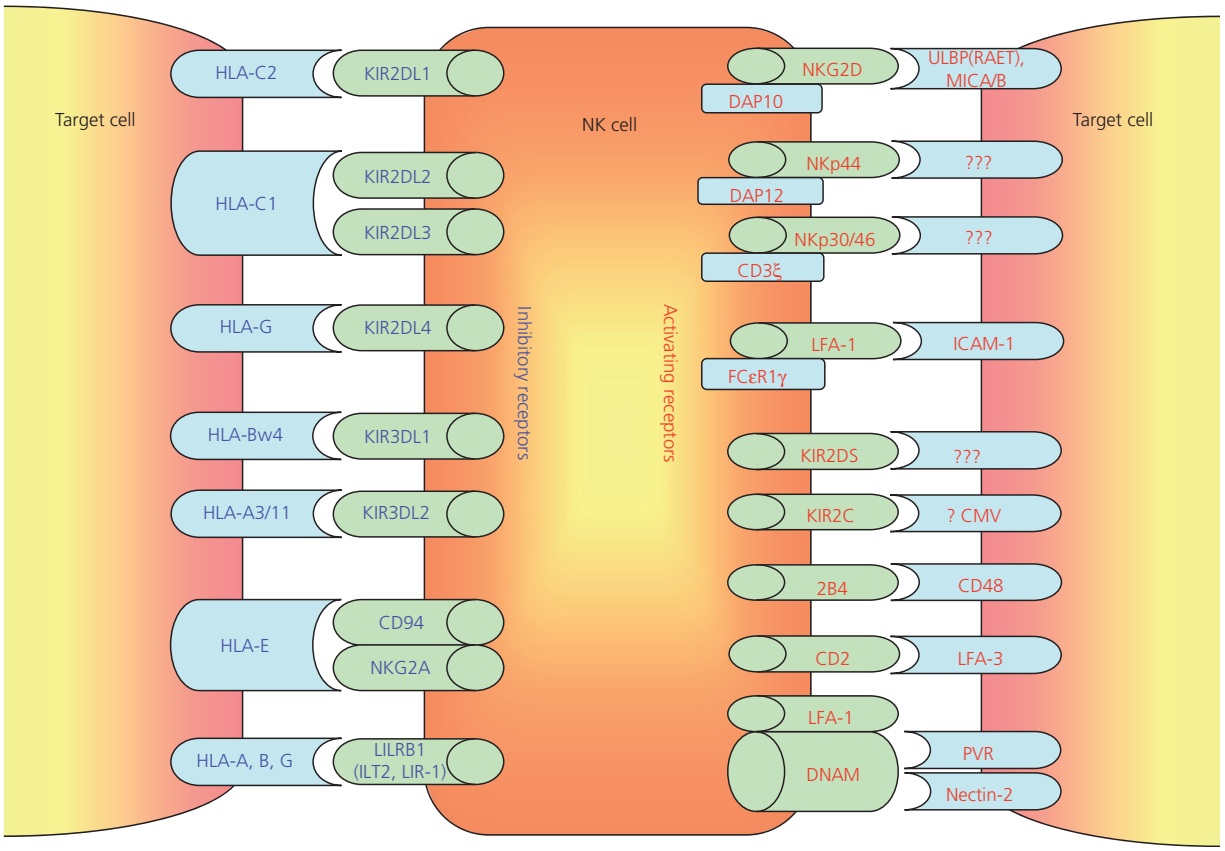

Figure 7.1. Human NK cells express multiple activating and inhibitory receptors. The NK receptors on human NK cells can be divided into activating receptors and inhibitory receptors. The ligands for the inhibitory receptors are self-MHC class I molecules, and those for the activating receptors include pathogens, some MHC molecules, and induced surface molecules on stressed or damaged cells. Signals from both activating and inhibitory receptors collectively control the function of NK cells.

receptors lack signaling motifs in their cytoplasmic domains. Instead, they recruit adaptor molecules DAP10, DAP12, CD3ς, or FcεRIγ to transduce activating signals. In contrast, the inhibitory NK receptors directly signal through the immunoreceptor-based tyrosine inhibitory motifs (ITIM) in their cytoplasmic tails. As can be envisioned, the ligands for such NK receptors are extremely diverse, which include pathogens, polymorphic MHC class I molecules or class I-related molecules, de novo induced molecules on damaged or stressed cells.

Much of the NK biology revolves around inhibitory receptors. As mentioned above, the ligands for inhibitory receptors are self-MHC class I molecules, and engagement of self-MHC class I by NK inhibitory receptors prevents self-destruction and ensures self-tolerance; such NK cells are also selected to undergo further maturation and become functionally competent killers against non-self-targets. This feature is developmentally acquired and often called "**NK education**" or "**NK licensing**" [23]. Most mature NK cells in the periphery express at least one inhibitory receptor, and therefore are fully licensed; the more inhibitory receptors individual NK cells express, the greater their killing potential toward target cells. Those that fail to express inhibitory receptors are rendered anergic or incompetent (**unlicensed NK cells**). Hence, upon encountering target cells that are missing or have down-regulated self-MHC class I molecules, NK cells will unleash their potent killing activities. This also applies in certain cases to MHC class I mismatched target cells in transplantation (both bone marrow and solid organ transplants) [24,25], and NK-mediated killing in this setting is called "**missing self-recognition**" [26]. However, in most cases, NK cells constantly survey the surroundings, integrate signals from both activating and inhibitory receptors, and then determine their actions. Thus, if multiple activating receptors are engaged, such activating receptors can override the inhibitory signals to initiate NK mediated killing of target cells. For instance, damaged and stressed cells often express multiple ligands for NK activating receptors in addition to self-MHC class I, and therefore are often killed by NK cells, a process also called "**induced self-recognition.**"

In essence, NK cells are controlled by the balance of inhibitory and activating signals, with the ultimate outcome determined by a hierarchy of signals. There is a predominance of inhibitory signals under physiological conditions. Under conditions of viral infection, NK cells that do not express inhibitory receptors (unlicensed NK cells) respond much better than those that express the inhibitory receptors. Also, NK licensing is a dynamic and continuous process in such a way that mature NK cells can be re-educated [27]. Additionally, different regulatory mechanisms may operate in the control of cytokine production by NK cells. The diversity and plasticity of NK cells suggest that their roles in immune responses are complex.

Evidence suggests that NK cells may have some features of adaptive immunity, specifically the acquisition of immunologic memory. Seminal studies in murine models showed that following activation, NK cells showed a similar pattern of expansion and contraction

as do $CD8^+$ T cells, and these NK cells persisted at increased frequencies and responded with increased magnitude and kinetics upon secondary rechallenge [28]. The implications of NK cell memory in transplantation are poorly understood.

Innate sensors

Innate immune cells respond vigorously to pathogens and tissue injuries, and this is mediated by a complex array of molecular sensors initially called **pattern recognition receptors or PRRs**. These sensor molecules recognize conserved pathogen-associated molecular patterns (PAMPs) derived from bacteria, mycobacteria, DNA and RNA viruses, fungi, and protozoans; they also recognize structures from damaged or stressed autologous cells known as damage-associated molecular patterns (DAMPs) or alarmins, and examples of these structures include heat shock proteins, peptidoglycan, high-mobility group box chromosomal protein 1 (HMGB1), heparin sulfate, glucose regulated protein, fibrinogen, hyaluronic acid, and nucleotide fragments (see Chapter 2). Engagement of these innate sensors by corresponding ligands elicits the activation of immune and inflammatory genes, and the products of which drive immune responses to eliminate invading pathogens or promote tissue repair [29].

There are three families of innate sensors indentified thus far and each family includes numerous members (Figure 7.2). **Toll-like receptors** or TLRs are by far the best-studied family [30]. Other two families include **NOD-like receptors** (NLRs) [31] and **RIG-like receptors** (RLRs) [32]. The TLR family consists of at least 13 members and, apart from TLR3, TLR7, TLR8, TLR9, which are intracellular receptors associated with endosomal membrane, the rest are transmembrane receptors consisting of an extracellular domain, a transmembrane domain, and an intracellular domain. The extracellular domain contains multiple leucine-rich repeat motifs (LRRs) that are involved in ligand binding; the intracellular domain signals through either the MyD88-dependent pathway, which activates the NF-κB transcription factor or the TRIF-dependent pathway, which stimulates type I interferons [33]. In contrast to the membrane-anchored TLRs, NLRs are free cytoplasmic proteins consisting of multiple functional domains involved in ligand binding, oligomerization, and signal transduction. There are 23 members in the NLR family, but NOD1, NOD2, NALP1-3, and Ipaf are the best studied ones. NOD1 and NOD2 activate NF-κB, with subsequent expression of potent inflammatory cytokines, including pro-IL-1β and pro-IL-18. NALP1-3, Ipaf form inflammasomes and activate caspase 1 and caspase 5, resulting in processing and production of active IL-1β and IL-18 [30]. RLRs are an interesting family of innate sensors; they are cytoplasmic proteins akin to NLRs. Similar to intracellular TLRs (TLR3, TLR7, TLR8, TLR9), RLRs stimulate NF-κB activation and type I interferon

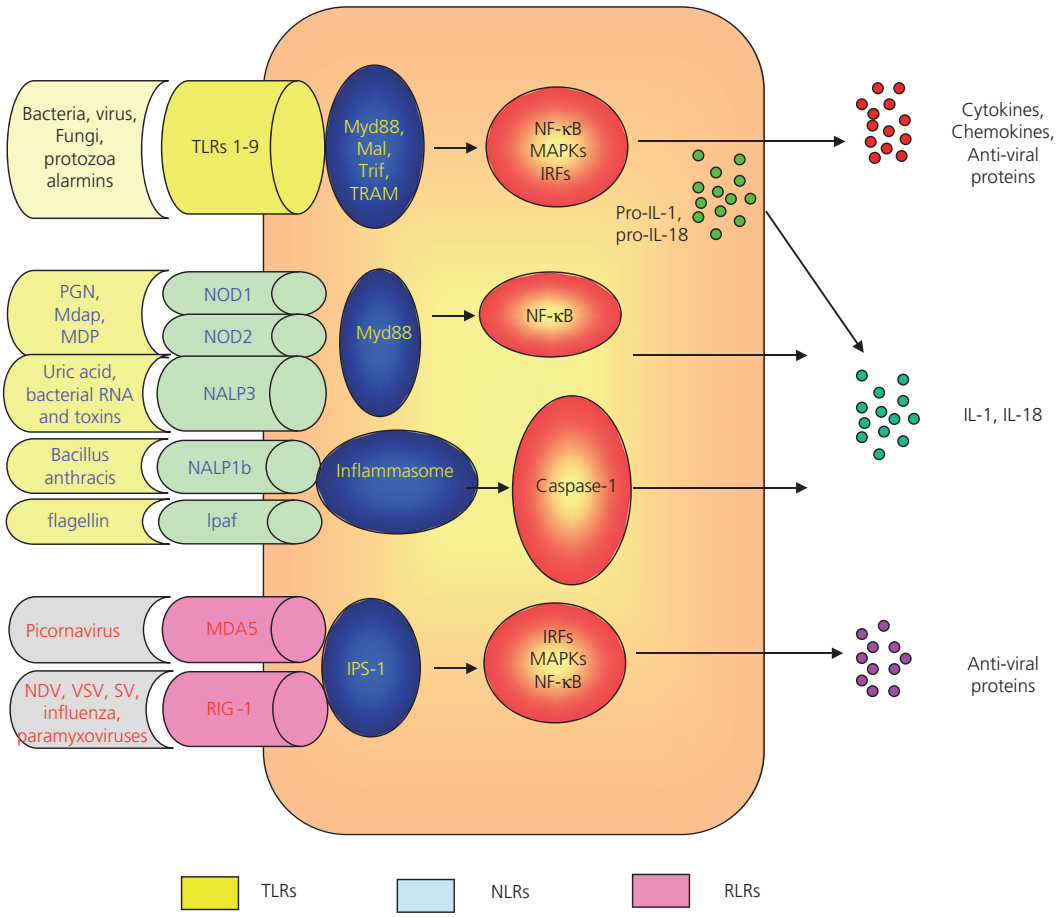

Figure 7.2. Molecular sensors expressed by innate immune cells. The innate sensors are broadly divided into three families, which include transmembrane receptors and intracellular ones. They respond to pathogen products and endogenous ligands from damaged cells, with certain degrees of specificities. Together, they provide an extraordinary early warning system to detect and respond to "danger signals."

production. However, RLRs sense viral nucleic acids in the cytoplasm whereas intracellular TLRs recognize viral products in the endosomal compartments [32]. In addition, RLRs are widely expressed in innate immune cells and rapidly up-regulated in response to type I interferons. Together, these families of sensor molecules provide an extraordinary early warning system against pathogens and tissue injuries.

TLRs, NLRs, and RLRs respond to pathogens with a certain degree of specificity. TLRs recognize extracellular and intracellular pathogens, and individual TLRs respond to different entities. NLRs sense intracellular bacteria-derived products while RLRs detect intracellular viral nucleic acids. These receptors also interact with one another to trigger optimal responses, as exemplified by the interplay of NOD1-2 and NALP1-3 in the generation of active IL-1 and IL-18. Stimulation of these receptors results in the activation of innate immune cells, production of potent proinflammatory cytokines, maturation of DCs, and initiation of adaptive immunity. Thus, the innate sensors play a critical role linking the innate and adaptive responses (see Chapter 5).

Complement

Complement is an integral part of the innate immune system and consists of numerous serum proteins (C1 to C9) (Figure 7.3). Serum complement is produced primarily in the liver and studies indicate that other tissues and cells also produce complement locally. Complement activation is tightly controlled by both positive and negative regulators [34]. Details of the three different pathways of complement activation are reviewed in Chapter 2.

The classical pathway of complement activation is a primary effector mechanism in antibody-mediated vascular injury. However, in other inflammatory responses including ischemia reperfusion injury, complement products can additionally function as a "danger signal" and aid in T-cell priming by acting as chemoattractants. Complement activation can be inhibited by multiple regulatory proteins. **Decay accelerating factor** (DAF, CD55) is a cell surface molecule that accelerates the decay of C3 convertases, thus preventing the amplification of complement cascade and formation of the downstream membrane attack complex [35]. Other inhibitory proteins include CD46 and CD59. Because of their regulatory properties, such inhibitory proteins have been targeted in preventing complement-mediated graft injury, including ischemia reperfusion injury, which is discussed below.

Aside from mediating cell lysis, chemoattraction, and innate cell activation, the role of complement has been markedly expanded recently to include costimulation of T-cell activation [36,37] and maturation of DCs [38]. T cells and DCs can produce complement components and also express receptors for C3a and C5a. Both cell types employ the complement pathway to optimally function. In this setting, complement produced in situ, rather than systemic complement, is critically involved [39]. Similarly, graft-derived complement has been shown to contribute graft injury following transplantation [40].

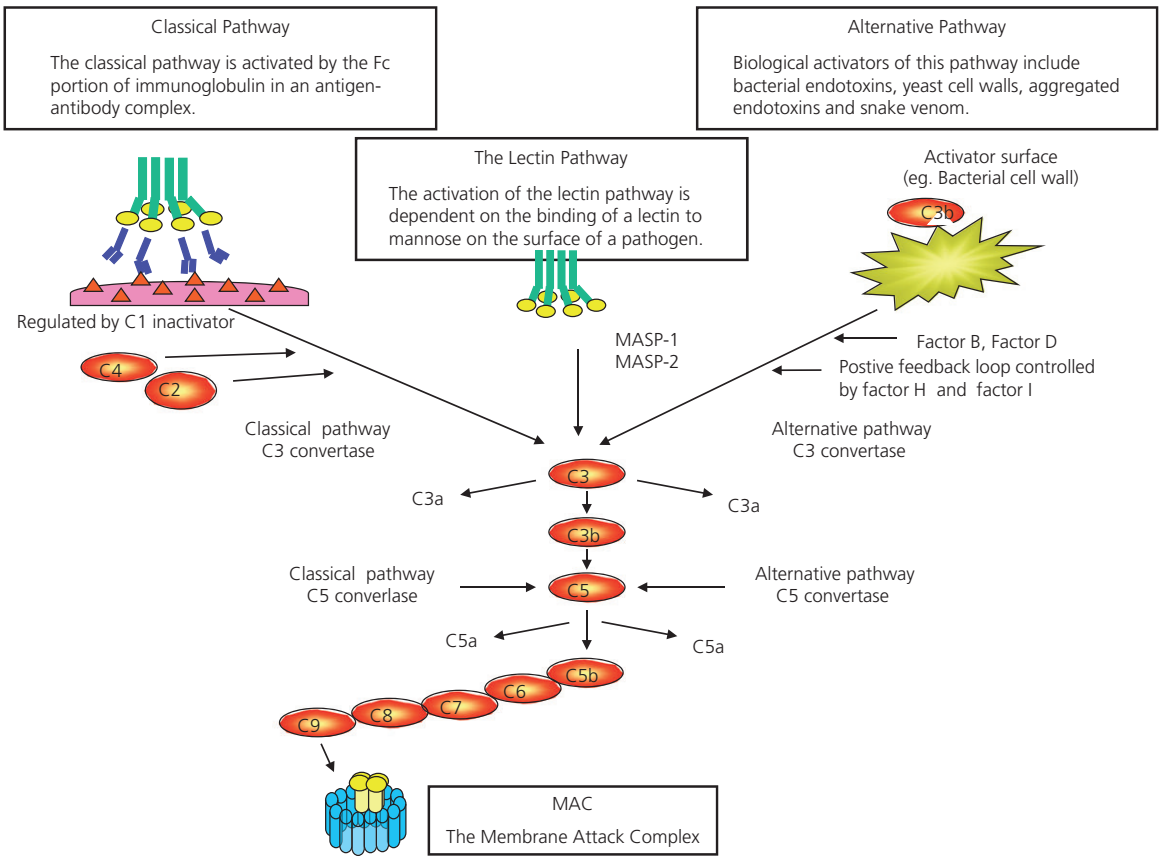

Figure 7.3. Pathways of complement activation. Complement activation is mediated by three pathways: the classical pathway, which is initiated by antigen–antibody complexes, the alternative pathway, and the lectin pathway. All pathways converge on the activation of C3 convertase, and end with the formation of membrane attack complex (MAC), which mediates cell lysis by breaking down cell membranes.

Innate responses to transplants

The immune system responds to allotransplants in strikingly different ways, ranging from ischemia reperfusion injury to rejection, and eventually to tolerance induction, and the innate arm is intimately involved in all processes, thus critically affecting the fate of the transplant.

Ischemia reperfusion injury (IRI)

In solid organ transplantation, surgical trauma, graft ischemia, preservation, and reperfusion are integral parts of the procedure, which inevitably results in tissue injury. The imbalance of metabolic supply and demand during ischemia also creates an intense intragraft hypoxia and vascular dysfunction, leading to further graft damage. Damaged or stressed graft constituents first mobilize the innate immune cells via a variety of pathways that lead to tissue inflammation, production of reactive oxygen species (ROS), and proinflammatory cytokines, APC activation, and ultimately, greater risk of graft loss. This process involves virtually all innate immune cells, molecular sensors, and pathways.

Graft ischemia reperfusion injury (IRI) triggers rapid influx of monocytes, macrophages, neutrophils, and NK cells, as well as certain memory T cells, into the grafts; IRI also mobilizes graft interstitial DCs and migration of host DCs. This massive cellular infiltration, probably in response to potent inflammatory cytokines, chemokines, and complement products, creates an ideal ground for collaboration, activation, and amplification of cellular responses. In this context, key processes include (1) stimulation of TLRs by DAMPs from damaged cells; (2) production of additional inflammatory, cytotoxic cytokines and ROS by activated innate cells; (3) maturation of APCs capable of inducing adaptive responses; and (4) induction of stress markers on otherwise healthy cells, which are recognized by NK cells and trigger NK-mediated killing. All of these responses have been extensively studied in preclinical models, and certain pathways are becoming attractive therapeutic targets for further clinical development. For example, damaged cells release a large amount of the nuclear protein HMGB1, which engages TLR2, TLR4, or RAGE to activate innate immune cells. Thus, mice lacking TLR4, MyD88, and/or TRIF were protected from IRI [41]. Similarly, in liver IRI and myocardial infarction models, the degree of tissue damage was markedly reduced in TLR4-deficient mice [42,43]. At a cellular level, depletion of macrophages with liposomal clodronate or inhibiting their trafficking to the graft ameliorates tissue damage. Furthermore, in models of renal IRI, depletion of kidney DCs in CD11c-DTR reporter mice with diphtheria toxin protected against tubular cell necrosis, leading to less renal dysfunction [44]. Additionally, NK cells readily kill renal tubular epithelial cells through recognition of an induced molecule Rae-1 after ischemia reperfusion, and NK deficiency or antibody-mediated NK depletion protected against kidney IR injury [45]. These findings provide solid evidence to support the importance of the innate immune system in graft IRI.

Complement also contributes to ischemia reperfusion injury, and seminal studies using cobra venom factor to inhibit complement demonstrated mitigation of IRI [46]. Other studies have since shown the importance of various complement components in IRI [47]. For instance, complement receptor 1, complement receptor-related gene Y, C1 esterase, C3 [48], C5 [49], factor B, and decay-accelerating factor (DAF) [35,50] have all been implicated in IRI in various animal models. Indeed, treatment of mice with DAF, which inhibits C3 convertase, prior to reperfusion protects them from IR injury [51]. This protective effect was due to the decrease in complement activation and proinflammatory cytokine release. While serum complement derived from the liver is responsible for antibody-initiated mediated injury, it appears that the graft-derived complement also contributes to IRI [40,52]. It has been shown in murine models that recipients with normal serum complement levels show prolonged graft survival when transplanted with C3-deficient kidneys. Additionally, transplant of these grafts into syngeneic recipients prevented IR injury [53]. Further proof of the importance of local complement to tissue injury came from studies where over-expression of a complement regulatory protein DAF on graft endothelium reduced the extent of IRI following transplantation [54].

Acute rejection

In most cases, innate immune cells, though possessing various effector mechanisms, do not directly mediate acute and complete allograft rejection themselves. However, innate immune cells are fundamentally involved in the control of adaptive T-cell programs, thus indirectly affecting the nature of the rejection response. This aspect of the innate immune system plays important roles in transplant outcomes and is being increasingly appreciated.

The transplanted grafts provide an ideal environment for the innate immune system to act. The "danger signals" generated by IRI stimulate the production of potent proinflammatory cytokines, such as IL-1, IL-6, TNF, and chemokines (e.g. MIP-1α, MIP-1β, MCP-1, IP-10, RANTES, etc.), which mobilize graft interstitial DCs and also mediate rapid influx of host monocytes, macrophages, neutrophils, and host DCs, as well as adaptive T cells and B cells (see Chapter 2). The innate cells infiltrating the grafts produce additional inflammatory cytokines and chemokines upon activation, further amplifying the inflammatory milieu in the graft. This rich inflammatory milieu drives proliferation and maturation of APCs, which includes up-regulation of MHC class I and class II molecules on the cell surface and induction of costimulatory molecules (CD80, CD86, CD40, OX40L, etc.). Matured APCs effectively engage T cells and B cells to initiate the rejection response [55]. Thus, innate immune cells partner with adaptive T cells and B cells to mediate acute rejection. In other words, adaptive immune cells require activated and mature APCs to present alloantigens to trigger their activation. This interdependence in graft rejection was shown in some preclinical animal models. In a minor alloantigen mismatched mouse model (male to female skin transplantation), genetic deficiency for the adaptor molecule MyD88, which prevents TLR signaling and therefore maturation of APCs, led to indefinite skin graft survival [56]. In a more stringent setting, deficiency of both MyD88 and TRIF prolonged the survival of MHC mismatched allografts [57]. These findings also highlight the importance of innate sensors in APC maturation and allograft rejection.

During acute rejection, there is reciprocal migration of APCs, especially DCs. Host DCs can infiltrate the transplanted graft and graft DCs can home to the host's draining lymph nodes. The relative importance of these pathways in transplantation is a matter of continuing debate, but either pathway can trigger acute rejection. Although donor DCs and host DCs present alloantigens differently to T cells, the same mechanisms (i.e. innate sensors, proinflammatory cytokines) are involved in driving their activation and maturation, which allow them to optimally engage T cells. Some innate immune cells, such as macrophages and NK cells, once acquiring effector functions, contribute significantly to the destruction phase of an acute rejection response. Macrophages have long been identified in allograft biopsies of human kidney transplants and in animal

models; they may account for 40–60% of infiltrating leukocytes [58] as detected by immunohistochemical staining for CD68, an intracellular lysozyme-associated glycoprotein used most commonly to detect human macrophages. There are also observations that macrophage infiltration is also seen with acute vascular rejection with endothelilitis or intimal arteritis [59]. As viewed from animal models of acute rejection where macrophage depletion or antagonism [60–62] was explored, it is clear that these cells are critical components of the acute response against the allograft. This conclusion is also supported by clinical studies. In renal allograft recipients in whom T cells have been depleted with alemtuzumab, acute graft rejection occurs despite exceptionally low peripheral T-cell counts, and is often associated with massive infiltration of monocytes [63]. Similarly, eosinophil-driven acute rejection has been observed in intestinal transplantation using alemtuzumab or thymoglobulin [64]. Along the same line, NK cells also contribute to acute rejection. For example, in CD28KO mice, antibody-mediated blockade of NKG2D, an NK-cell-activating receptor, significantly prolongs cardiac graft survival [65], suggesting that NK cells facilitate rejection [66]. Additionally, if NK cells are activated by IL-15, they themselves are capable of mediating acute rejection in the absence of T or B lymphocytes [67].

Among the innate molecules, complement has a unique role in allograft rejection. In transplant models where complement activation is induced, graft destruction is incredibly fast (it can be within hours) and is always irreversible. Graft rejection in this setting often involves vascular endothelial damage, blood coagulation, and activation innate cells without the participation of adaptive T cells. The best example is humoral rejection or acute antibody-mediated rejection (AMR) triggered by antidonor alloantibodies (see Chapter 6) [68]. The antidonor antibodies (mostly against donor HLA molecules, ABO antigens, and endothelial antigens) form immune complexes with donor antigens in the grafts, activate complement cascade via the classical pathway. This process is robust, initiated by the activation of C1 and resulted in formation of MAC (C5b-C9 complex), generation of chemoattractants C3a and C5a, and consequently massive cell death, intragraft inflammation, and extensive blood coagulation in the grafts. In addition, recent studies indicate that T cells and APCs themselves produce complement components, and also express receptors for selected complement elements (e.g. receptors for C3a and C5a). Thus, they can employ the locally produced complement to optimally function, through effects on maturation of APCs and costimulation of T-cell activation upon alloantigen stimulation [52,69]. Furthermore, the engagement of C3aR and C5aR on APCs induces the release of innate cytokines (IL-12, IL-23) and up-regulates costimulatory molecules, again amplifying the T effector response [37,39]. This provides another example of how innate molecules enhance adaptive immune response in the transplant settings. The role of complement in alloreactive T-cell immunity and IR injury explains, at least in part, the fact that murine kidney allografts deficient in C3 exhibit long-term survival [40], whereas those deficient in DAF have worse outcomes [70].

Chronic rejection

Chronic allograft rejection involves mainly the graft vasculature [71,72]. Morphologically, chronic rejection is characterized by concentric neointimal proliferation and eventual occlusion of blood vessels, and this lesion affects vessels of all sizes in the graft. Also, extensive graft interstitial fibrosis is frequently accompanied by vasculature changes. These features are unique to transplants, and therefore also called transplant vasculopathy. In contrast to acute rejection, chronic rejection takes much longer to develop and often requires years following transplantation in patients. This has become a major cause of graft loss impeding long-term transplant success in the clinic. The exact mechanisms of chronic rejection remain elusive, but the current belief is that chronic rejection is perhaps a manifestation of graft injury and remodeling over a long period of time in which both immune and non-immune pathways are critically involved. Importantly, current studies suggest the importance of innate immune mechanisms in the pathogenesis of chronic transplant rejection.

There are distinct features in chronic rejection. In contrast to acute rejection, innate immune cells, mostly monocytes and macrophages, dominate the cellular infiltrates in the lesions, and alloantibodies and complement depositions are also frequently detected. Furthermore, molecular profiling studies often demonstrate ongoing tissue inflammation in chronic lesions, as shown by the heightened expression of multiple inflammatory cytokines. Thus, it is conceivable that tissue damages driven by innate cells, pathways, and innate molecular sensors may contribute significantly to the development of transplant vasculopathy.

It has been shown that TLR signals are strongly associated with the development of atherosclerosis, which is a hallmark of chronic allograft vasculopathy [73,74]. Recently, TLR2, TLR4 and the adaptor proteins MyD88 and TRIF have all been found to be key mediators of chronic rejection in a fully mismatched mouse kidney transplant model [75]. Additionally, in heart transplant patients with evidence of allograft endothelial dysfunction, TLR4 expression and secretion of IL-12 and TNF, which are downstream targets of TLR signaling, were found to be at higher levels than in heart recipients without endothelial dysfunction [76], suggesting the involvement of innate sensors in cellular activation. At a cellular level, macrophages infiltrate heart allografts and contribute to transplant vasculopathy in an animal model of chronic rejection [77]. In this model, partial depletion of macrophages using carrageenan reduced the severity of chronic vasculopathy. This was independent of phagocytosis, as treatment with gadolinium, which inhibits phagocytosis, had no effect on the severity of the disease. In another study, targeting macrophage function using an adenoviral strategy ameliorated the histological features of allograft dysfunction in a rat model of interstitial fibrosis and tubular atrophy (IF/TA) [78]. Mechanistically, monocytes/macrophages, by infiltrating the damaged allograft parenchyma under the influence of chemoattractants, secret growth factors and profibrotic cytokines such TGF-β and IL-13 [12]. They can also directly differentiate into fibrocytes [79], thus promoting synthesis of extracellular matrix proteins and stimulating transition of tubular epithelial cells into fibroblasts [12]. In human transplant recipients, presence of macrophages in early biopsy specimens is predictive of IF/TA development [80,81].

The presence of circulating alloantibodies against HLA, MHC class I polypeptide-related sequence A (MICA), autoantigens, and endothelial antigens increases the risk of long-term graft loss [82,83]. The effector response initiated by alloantibodies in graft damage involves primarily innate pathways. Of central importance is the activation of complement. Indeed, in kidney transplantation in humans, the glomerulopathy and arteriopathy seen in chronic rejection are closely associated with C4d deposition in the graft, supporting a role of complement activation in chronic graft injury [68]. In animal models, C6 deficiency, which affects the formation of the terminal membrane attack complex of the complement

cascade, reduces the severity and onset of graft arteriosclerosis [84]. Studies also demonstrate the importance of locally derived complement (rather than systemic complement) in chronic kidney graft injury. For example, C3-deficient kidney transplants are resistant to adriamycin-induced tubular damage when transplanted into wild-type recipients [85]. In C3a-receptor-deficient mice, adriamycin induced less kidney injury with lower expression of interstitial type 1 collagen and α-smooth muscle actin. Injury by graft-derived complement is also thought to impact long-term graft outcome in humans.

There are circumstances where alloantibody-induced chronic allograft rejection can still arise independent of complement, and a study identified NK cells as key effector cells in driving chronic graft damage [86]. In a mouse model of heart transplantation in which graft recipients are deficient for T cells and B cells (i.e. recombinase-activating gene (RAG)-deficient mice), infusion of donor alloantibodies into transplant recipients induced prominent allograft vasculopathy. Similar findings were observed using either non-complement fixing alloantibodies or recipient mice deficient in complement activation. This suggests that antibody-mediated transplant vasculopathy can still occur via a **complement-independent pathway**. In fact, there are observations in the clinic that some kidney transplant patients develop arteriopathy or glomerulopathy in the absence of C4d deposition is the grafts [87], again supporting a complement independent mechanism of chronic rejection. Interestingly, NK cells are identified as key mediators in transplant vasculopathy independent of complement, as depletion of NK cells or deficiency of NK cells in transplant recipients completely prevented the incidence of chronic rejection induced by donor alloantibodies [86]. Another observation is that in a cohort of MHC compatible kidney transplant patients, KIR mismatches between donors and recipients, which generates alloreactive NK cells, are associated with the worst graft outcomes, thus indirectly suggesting a role for NK cells in clinical chronic graft loss [88]. Together, these findings call attention to innate immune cells and mechanisms in chronic allograft rejection.

Graft acceptance or tolerance

Transplant tolerance is an actively acquired state in which cytopathic responses to allotransplants are absent while those to pathogens are well preserved. Importantly this tolerant state can be stably maintained without prolonged immunosuppression. This is covered in depth in Chapter 11. Traditionally, cells of the innate immune system are thought as initiators of immune responses and, therefore, associated with rejection. However, emerging data have revealed that such cells can also be required for induction and maintenance of transplant tolerance.

A key principle in transplant tolerance is the promotion of death of effector T cells and stimulation of regulatory cells (see Chapter 8) [89]. Innate immune cells and pathways can have significant impacts on both arms of the tolerant induction process (Figure 7.4). For example, DCs are required not only for robust immunity but also for tolerance, as in vivo deletion of $CD11c^+$ DCs in naïve mice breaks down tolerance and induces widespread autoimmunity [7]. This revelation led to the characterization and application of "tolerogenic DCs" in tolerance induction. In fact, DCs contribute to

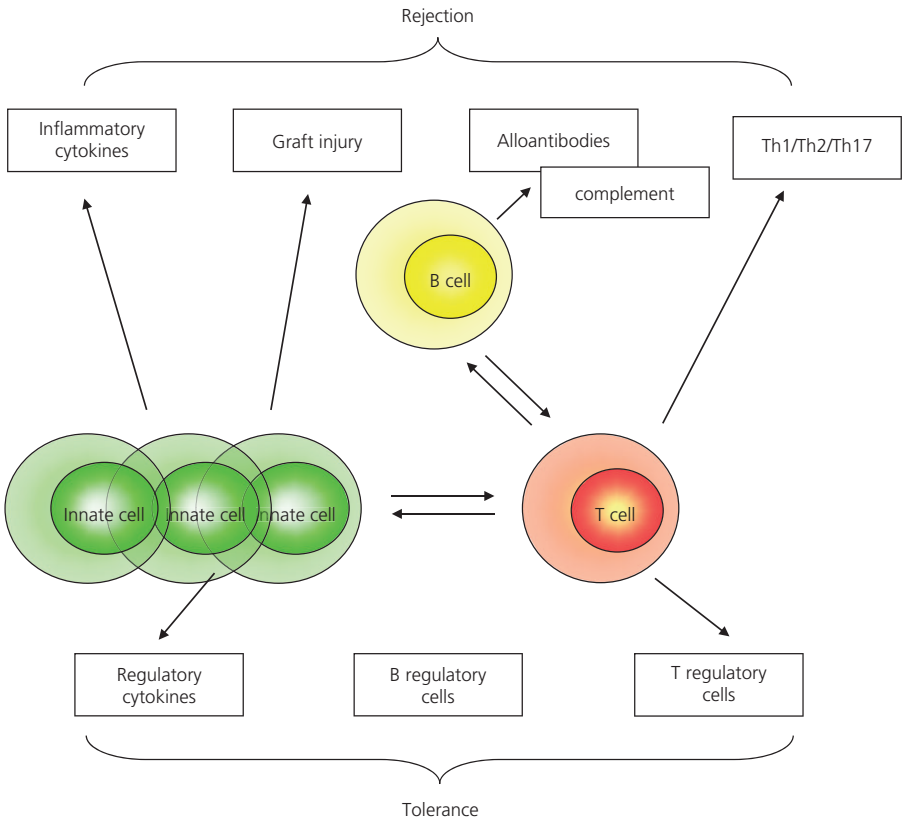

Figure 7.4. Interaction of innate and adaptive immune cells in transplantation. The innate immune cells, similar to their adaptive counterparts, regulate both graft rejection and tolerance induction via a variety of mechanisms, depending on context, models, and tolerizing therapies.

tolerance in several different ways. Mature DCs can drive apoptotic deletion of cytopathic effector T cells following a proliferation burst; subsets of DCs also mediate the induction of Foxp3$^+$ Tregs or homeostasis of natural Tregs. Additionally, DCs, particularly CD8$^+$ DCs, are very efficient at phagocytosis of apoptotic cells, owing to their expression of DEC205, Clec9A, CD36, Tim-1, and Tim-4 [90–92], and clearance of apoptotic cells is a critical process for maintaining tolerance [93]. Also, phagocytosis of allogeneic apoptotic cells inhibits DC maturation, which down-modulates their allostimulatory function, whilst promoting Treg cells [94]. Thus, "tolerogenic DCs" as a cell therapy approach continues to hold promise in transplant tolerance.

Other innate cell types exhibit similar features in tolerance induction. In certain settings, monocyte/macrophages can exert potent anti-inflammatory and immunosuppressive effects that help maintain peripheral tolerance. For example, alternatively activated M2 macrophages or regulatory macrophages (Mregs, see Chapter 2) are capable of secreting anti-inflammatory cytokines, such as IL-10 and TGF-β that are involved in tapering immune responses and resolution of graft inflammation [12]. In fact, some studies demonstrate that adoptive transfer of Mregs can ameliorate the induction of experimental autoimmune encephalitis (a mouse model of multiple sclerosis), and prevent autoimmune colitis by inducing and expanding Foxp3$^+$ Tregs [16]. Additionally, adoptive transfer of donor-derived Mregs in a cohort of human kidney transplant recipients allowed for significant reduction in the use of immunosuppressive drugs [95]. Similarly, NK cells also employ different mechanisms to promote transplant tolerance. NK cells, guided by "missing self-recognition," can eliminate graft-derived allogeneic DCs, thus reducing T-cell priming by the direct pathway of antigen presentation [25]. Killing of donor cells by NK cells favors the indirect antigen presentation, which is implicated in tolerance induction. Also, some NK cells exhibit regulatory function through IL-10-dependent mechanisms and contribute to tolerance by tipping the balance towards regulation [96].

The striking dichotomy of innate immune cells in transplant settings (rejection versus tolerance) is most likely context dependent, in that different cell subsets can exert divergent effects depending on their maturation status and interactions with other cell types. For example, in many instances NK cells can be tolerogenic; however, further NK maturation by IL-15 signaling promotes rejection; M1 macrophages are proinflammatory and M2 macrophages are immunosuppressive. Additionally, TLR signaling mediates maturation of DCs and monocytes in rejection. However, Tregs also express certain TLRs, and TLR stimulation can increase the suppressive properties of Tregs and thus facilitate tolerance. This context-dependent function of innate pathways and context-dependent regulation of innate immune cells constitute a major challenge in manipulating the immune responses to allotransplants.

Summary

In summary, cells of the innate immune arm become activated early following ischemia reperfusion injury and are implicated in the pathogenesis of acute and chronic rejection in both animal models and humans. A significant challenge is that the complex interactions amongst diverse subsets of innate immune cells in vivo in transplant settings are poorly understood. In addition, the dynamic cross-talk between innate and adaptive immunity necessitates a further understanding of both arms for the purpose of tolerance induction.

CHAPTER 8

Mechanisms of Immune Regulation

Kathryn J. Wood, Andrew Bushell, and Joanna Hester
Transplantation Research Immunology Group, Nuffield Department of Surgical Sciences, John Radcliffe Hospital, Oxford, UK

Introduction

The majority of the leukocyte subsets that can contribute to the destruction of a transplant through rejection can also play a role in regulating or controlling immune responsiveness [1]. In some cases, the regulatory cells comprise specialized populations that are selected or differentiate to have functional regulatory or suppressive properties. In other situations, the microenvironment present within the allograft or the lymphoid tissue will enable the immune response at that site to be controlled. In transplantation, T cells have often taken centre stage, both in immune responses that lead to rejection and the destruction of transplanted cells, organs, or tissues, as well as in controlling these unwanted aggressive immune responses. However, other populations of leukocytes can also have this dual functionality, including, for example, B cells where antibody-secreting as well as regulatory B cells have been identified and dendritic cells that can both stimulate immune responses as well as induce immunological tolerance [2]. In this chapter, we will review both the mechanisms of regulation that can be used by the immune system to prevent unwanted immune responses, as well as some of the different cell populations that have been shown to play a role in the regulation of alloimmune responses in vivo. While specific manipulation of these mechanisms remains a future potential, it is likely that regulation plays a substantial role in determining the ultimate effect of conventional immunosuppressants and influences the balance of graft acceptance and rejection both in experimental and clinical practice. Discussions in this chapter complement those on the mechanisms of tolerance found in Chapter 11.

Cell death

The death or deletion of lymphocytes that can recognize and respond to self-antigens or, after transplantation, donor alloantigens is a very effective mechanism for eliminating lymphocytes from the immune repertoire that have the potential to damage the graft, thereby creating unresponsiveness or tolerance to donor alloantigens. Both T cells and B cells can be deleted from the repertoire in this manner.

Central deletion of alloantigen reactive T cells

The ability of the immune system to shape the T-cell repertoire by eliminating or deleting T cells that express a T-cell receptor that will either be of no use or could be dangerous to the host in the future is a critical part of the process of T-cell development in the thymus. T-cell precursors differentiate in the bone marrow from haematopoietic stem cells and then migrate to the thymus. Upon entry into the thymus, these progenitor cells begin to rearrange their T-cell receptor (TCR) genes and undergo a programme of thymic selection. This involves a complex sequence of events whereby $CD4^+CD8^+$ thymocytes expressing a complete $\alpha\beta$TCR undergo positive and negative selection before thymocytes leave the thymus, emigrating to the periphery as mature single-positive (i.e. expressing either CD4 or CD8) T cells. The process of positive selection identifies or selects T cells that express a TCR of sufficiently high affinity to self peptide major histocompatibility complex (pMHC) complexes such that the cell receives survival signals. T cells that express a TCR with no affinity for self pMHC complexes are not selected and die by apoptosis. Cells with TCRs that have too high an affinity for self pMHC complexes, and therefore could react with self-antigens expressed by tissues in the periphery, are deleted in a process known as negative selection. Through these mechanisms, T cells capable of recognizing self MHC molecules bound to foreign peptides that are potentially useful to the host immune system are maintained and populate the periphery, while ensuring that the majority of dangerous self or autoreactive T cells are eliminated.

To ensure that negative selection of T cells is as complete as possible and thereby reduce the potential of autoimmune disease, a wide a range of self pMHC complexes must be present or expressed in the thymus. As some proteins are expressed exclusively in the periphery, this process requires a special mechanism and is controlled by the autoimmune regulator, AIRE. AIRE is a transcriptional regulator that promotes expression of a large repertoire of mRNA transcripts encoding different proteins in the thymus that would normally only be expressed in tissues in the periphery. In this way, T cells undergoing selection in the thymus will encounter a wide range of self pMHC complexes. Importantly, mutations in AIRE can impair its function and as a consequence the deletion of self-reactive T cells in the thymus is affected. Defects in AIRE function result in the emergence of self-reactive T cells into the periphery where they can attack specific organs, leading to autoimmune disease [3]. This system is very sensitive and the absence of just one AIRE-induced peptide in the thymus can lead to autoimmunity [4].

While AIRE is very effective at ensuring a wide range of pMHC complexes are expressed in the thymus, the process of negative selection remains incomplete and therefore some T cells that are potentially harmful to the host may escape negative selection and

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

be present in the peripheral immune repertoire. To guard against harm coming to the host, the immune system has developed a fail-safe mechanism to control the activity of these unwanted T cells by also selecting in the thymus a population of so-called thymus-derived or naturally occurring regulatory T cells (nTreg) [5]. This process of selection allows T cells with an intermediate, rather than a high, affinity for self-pMHC complexes to express the transcription factor Foxp3 [6]. Following selection, Treg migrate to the periphery alongside other T cells, where they can control any potentially harmful self-reactive T cells.

The phenomenon of central tolerance (i.e. deletion of unwanted T cells) has been exploited to facilitate the induction of transplantation tolerance. Central deletion of alloreactive T cells has been achieved via direct delivery of alloantigen into the thymus via intrathymic injection [7,8] and by the establishment of allogeneic mixed bone marrow chimeras in experimental models [9]. These studies provide evidence that mechanisms of deletion of antigen reactive cells in the thymus may be harnessed to facilitate operational transplantation tolerance.

Peripheral deletion of alloantigen reactive T cells—activation-induced cell death or immune exhaustion

Apoptosis of antigen-reactive T cells via activation-induced cell death (AICD) is another mechanism for controlling immune reactivity. AICD is a process through which T cells undergo cell death in the periphery [10]. Following restimulation through TCR, a number of different molecules, including CD95 (FAS), tumour necrosis factor receptor 1 (TNFR1), and tumour necrosis factor related apoptosis inducing ligand receptor (TRAILR), can play a role in AICD depending on the circumstances, triggering a complex series of signalling events, which ultimately lead to caspase activation, DNA fragmentation, cytoskeletal degradation, and cell death.

Deletion of alloantigen reactive B cells

The elimination of B cells from the repertoire is also a mechanism that has evolved to ensure that B cells that are polyreactive and capable of binding self-antigens are eliminated in the bone marrow before they enter the periphery. As rearrangement of immunoglobulin genes occurs at random to enable as many foreign protein and carbohydrate antigens to be recognized as possible, it inevitably leads to the generation of B cells that express B cell-receptors (BCR) that can recognize self-antigens. Estimates vary, but suggest that up to 70% of the immature B cells produced are self-reactive. Of the order of one-third of these immature B cells are eliminated by receptor editing, whereby new gene rearrangements result in the production of an alternate light chain that can pair with the existing heavy chain, altering the antigen recognition properties of the expressed BCR. When an immature B cell recognizes self-antigen with high avidity it rapidly internalizes the antigen and undergoes a period of developmental arrest. Lymph node homing receptors, such as CD62 ligand (CD62L) are not expressed, and the receptors for B-cell activating factor (BAFF), a cytokine required for B-cell survival, are not induced. In addition, recombinase-activating genes remain switched on, which allow the B-cell receptor (BCR) to be replaced by editing the light chain. Any B cell undergoing this process will die after 1–2 days if it fails to express a non-autoreactive receptor. Death through this pathway does not require FAS and is, in part, due to antigen-induced expression of the Bcl-2 interacting mediator of cell death (Bim), which inhibits B-cell survival proteins from the Bcl-2 family.

Receptor editing is a mechanism that could be used to delete immature B cells capable of recognizing donor alloantigens from the repertoire, particularly in situations where the repertoire is reshaped following leukocyte depletion or the induction of mixed chimerism, as well as when organs are transplanted into young infants.

If receptor editing fails to eliminate all of the self-reactive B cells generated, residual immature B cells expressing highly self-reactive receptors are triggered to die by interaction with self antigen. This mechanism of control or regulation has been studied using immunoglobulin transgenic mice and the data obtained suggest that B cells are deleted efficiently when the antigen they recognize is membrane bound. The efficiency of this process was found to be dependent on the probability that the immature B cells encountered the relevant self-antigen and therefore its efficiency is clearly related to antigen density or frequency.

Deletion of B cells capable of recognizing donor alloantigens from the repertoire of a transplant recipient is a mechanism that can be harnessed in transplantation. This mechanism of regulation is most efficient when the antigens recognized are present at high doses. Infant recipients of ABO-incompatible heart allografts have been shown to delete B cells capable of making antibodies to blood group antigens presented on the heart transplant [11]. Mixed chimerism strategies that result in the co-existence of donor and recipient bone marrow should also enable donor reactive B cells to be deleted if the level of chimerism achieved is sufficient to ensure that B cells encounter donor cells [12].

Anergy

Anergy is a term used to describe the functional inactivation of lymphocytes resulting in the cells becoming refractory or unresponsiveness to further stimulation. Anergy is characterized by biochemical changes that lead to some degree of developmental arrest in the responding cells and an increased threshold for activation when they re-encounter their cognate antigen. This mechanism of controlling immune responsiveness is applicable to T cells and B cells and may contribute in some settings to the mechanisms that can be brought into play to control immune reactivity to alloantigens after transplantation. However, it is important to note that anergy is a reversible state of unresponsiveness.

T-cell anergy

T cells in the periphery are activated as a consequence of signals delivered from the TCR following recognition and binding of a relevant pMHC complex (signal 1) and from ligand–receptor interactions between molecules on the T cell and antigen-presenting cell (APC), which are collectively known as costimulatory pathways (signal 2). In vitro, antigen recognition (i.e. TCR ligation by the relevant pMHC complex) in the absence of costimulation has been shown to induce T-cell anergy [13]. The absence of costimulation, through CD28, at the time of antigen recognition was demonstrated to be critical for the induction of T-cell anergy in these in vitro systems. In vivo, induction of T-cell anergy has also been shown to be dependent on ligation of CTLA-4 (CD152).

As knowledge of costimulatory pathways has evolved, it has become clear that other ligand–receptor interactions may also contribute to the development and/or maintenance of T-cell anergy. The costimulatory molecule programmed death 1 (PD-1) is highly expressed on anergic T cells and in some tissues and its interaction with its ligand, PDL-1, has also been shown to be involved in the

induction and possibly maintenance of T-cell anergy. Hence, in vitro and in vivo, T-cell anergy can result from ligation of TCRs in the absence of the correct additional costimulatory signals, resulting in the attenuation of the T-cell activation process thereby limiting the ability of T cells to respond.

B-cell anergy

As highlighted above for T cells, the mechanisms of central B-cell tolerance are also incomplete. Thus, self-reactive B cells can escape central tolerance in the bone marrow and emerge into the periphery. Peripheral self-reactive B cells that bind their cognate antigen through the BCR with lower affinity become anergic. This is due to altered intracellular signalling when the B cells are chronically exposed to low levels of antigen [14]. In experimental models, B-cell anergy has been demonstrated in B cells that bind soluble antigens with low avidity.

In a normal heterogeneous B-cell repertoire, both anergic B cells that bind self-antigen as well as recirculating naïve follicular B cells that bind foreign antigen localize to the T-cell zones of the secondary lymphoid organs. In the absence of T-cell help and the activation of additional signalling pathways in the anergic B cells, these cells die within 1–5 days. In contrast, when the naïve B cells engage antigen in the presence of T cell help they collaborate with CD4 cells and differentiate into antibody-secreting plasma cells.

Costimulation by toll-like receptor (TLR) ligands has been found to be blocked in anergic B cells. In the early phase after transplantation this may be helpful, as it is clear that TLRs are activated by damaged cells present in the transplanted organ or tissues and contribute to the rejection process. After transplantation, it would clearly also be advantageous to maintain low avidity, alloreactive B cells in an anergic state to prevent them from secreting donor-specific antibodies (DSA) later in the post-transplant course. Strategies for achieving this are still being sought. It is interesting to note that immunosuppressive agents, such as cyclosporine A (CsA), have not been particularly effective at preventing antibody-mediated chronic allograft rejection [15] where clusters of B cells have been identified in allografts undergoing chronic rejection [16]. This lack of effectiveness may be due to the inability of CsA to mimic the signalling events that occur in anergic B cells.

Immunoregulation

As strategies of inducing and maintaining immunological unresponsiveness or tolerance to self-antigens, deletion and anergy are either incomplete or unstable. The immune system has therefore developed a number of fail-safe mechanisms to ensure that tolerance is maintained despite the presence of self-reactive T cells and B cells in the periphery. These same fail-safe mechanisms, which include populations of regulatory or suppressor cells capable of controlling any potentially autoreactive lymphocytes, can be used to control immune responsiveness to alloantigens after transplantation.

Regulatory T cells

Many different types of T cells with regulatory activity have been described including: $CD4^+$ T cells [17,18]; $CD8^+$ T cells [19–21]; $CD4^-CD8^-$ double-negative T cells [22]; NKT cells [23]; and γδT cells [24]. As $CD4^+$ T cells with regulatory functions have been studied in greater depth to date, this section of the chapter will focus on this population of regulatory cells.

$CD25^+FOXP3^+$ T regulatory cells (Treg) can arise via two distinct developmental pathways. First, as mentioned above, thymus-derived or naturally occurring (nTreg) differentiate in the thymus and are thought to function primarily to suppress responses to self-antigen and hence prevent autoimmune disease. Evidence for this comes from studies in patients with rare genetic defects and in mice with either naturally occurring or genetically engineered defects. For example, profound immune dysregulation leading to autoimmunity is observed in patients with the immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome. IPEX patients have been found to have a point mutation in the gene encoding factor forkhead box P3 (*FOXP3*) [25,26], the master gene for T-cell regulation, resulting in functional impairment of Treg activity in vitro [27]. Scurfy mice also have mutations in *foxp3* and a related immune profile [28]. Second, when $CD4^+$ T cells encounter antigen in a tolerogenic microenvironment in the periphery, such as when antigen is presented by immature dendritic cells (DCs) or in the presence of immunosuppressive cytokines, the $CD4^+$ T cells differentiate into 'adaptive' antigen induced Treg (iTreg) [6]. In the context of transplantation, it can be argued that this pathway may be the more important route to generating donor alloantigen reactive Treg after transplantation [29]. Interestingly, despite their distinct developmental origins, both nTreg and iTreg rely on sustained expression of high levels of the transcription of *FOXP3* for their suppressive function (Figure 8.1).

Importantly, transplantation provided some of the earliest evidence for suppression or immune regulation by T cells in vivo. Data from neonatal tolerance studies suggested that additional mechanisms beyond deletion of donor-reactive cells were involved [30,31]. Later, a clear indication that long-term allograft survival in the absence of long-term immunosuppression, a status referred to as operational transplantation tolerance, involved the presence of T cells with the ability to regulate the function of naïve alloreactive T cells, thereby preventing the rejection of a fresh graft, was reported [32,33]. Subsequently, this form of cellular regulation was found to be associated with $CD4^+$ T cells and Hall and colleagues were the first to suggest that CD25 might be a useful marker for identifying

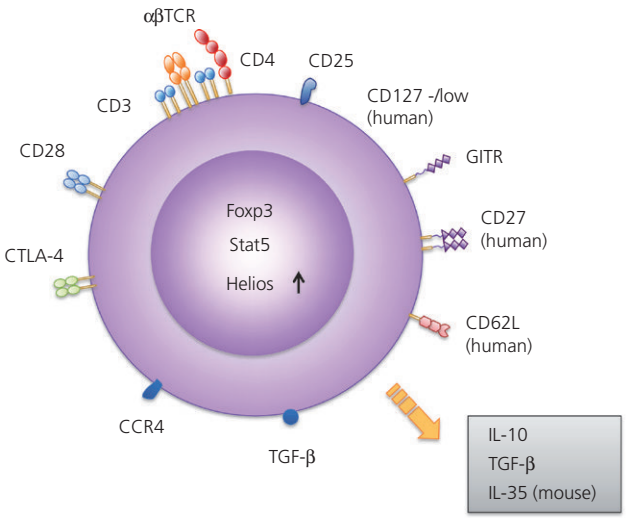

Figure 8.1. Regulatory T-cell characteristics. Shown are the intracellular transcriptional characteristics, surface molecules and defining cytokines of T cells with specialized regulatory potential.

$CD4^+$ T cells with regulatory activity [34]. Similar data were obtained in a rat renal allograft model where operational tolerance was induced by donor-specific blood transfusion [35,36]. As a direct demonstration that $CD4^+$ T cells expressing high levels of CD25 could regulate rejection, Hara and colleagues showed that co-transfer of $CD4^+CD25^+$ T cells from tolerant animals led to indefinite skin graft survival in 80% of immunodeficient mice reconstituted with naïve CBA effector T cells [37].

In the absence of any previous exposure to alloantigen, there are usually insufficient numbers of nTreg to prevent rejection of a fully allogeneic (MHC + minor histocompatibility antigen mismatched) graft as the frequency of T cells present in the repertoire capable of making a destructive response to the graft far out numbers the relatively small number of nTreg present and rejection occurs [37]. The fact that nTreg cannot prevent destruction of an allograft in the absence of immunosuppression does not mean that the cells do not function. However, under these circumstances, the balance between rejection and regulation is against regulation, as the suppressive activity of any Treg present is overwhelmed by the destructive response mediated by effector T cells. The presence of pre-existing donor alloantigen reactive memory T cells in the recipient can also overwhelm immune regulation as the kinetics of activation of the memory cells is very rapid and unless very high numbers of Treg are present at the outset of the response, the balance between rejection and regulation is pushed markedly in favour of rejection [38]. Importantly, this critical balance between graft destruction and acceptance can be shifted in a number of ways, notably by employing strategies that increase the relative frequency and/or the activation status and consequently the functional activity of aTreg that can then respond to donor alloantigens before or in the early period after transplantation [39,40], or by inhibiting or reducing the activity of the effector cells.

Whilst the observation that mice with long-term surviving allografts contain populations of alloantigen-reactive $CD25^+$ Treg was important, these experiments were unable to distinguish between Treg that were generated by the induction strategy itself and those that arose simply by the presence of the accepted allograft. In terms of developing potential clinical approaches, it is important to clarify whether induction strategies that ultimately lead to long-term operational tolerance can drive Treg development independently of the graft itself. Data demonstrating that exposure to alloantigen in the absence of a transplant can lead to the induction of $CD4^+CD25^+$ Treg were obtained in a number of studies. For example, when $CD4^+CD25^+$ were isolated from mice 28 days after pretreatment with donor alloantigen in combination with non-depleting anti-CD4 therapy, these cells prevented rejection of a test skin graft in a sensitive adoptive transfer model [41]. Critically, protection of the test graft was not observed with similar populations isolated from naïve mice, or mice treated with anti-CD4-only or DST-only demonstrating that tolerance mediated by $CD25^+$ Treg can indeed be induced in vivo before transplantation if recipients are exposed to donor alloantigen under permissive conditions. Moreover, data demonstrating that the presence of the allograft alone can lead to the development of T cells with regulatory properties that can protect a challenged graft from rejection [42], even when the allograft itself has been rejected [43], have been reported. Both of these examples demonstrate that T cells with regulatory activity can be induced in the presence of alloantigen in the form of the allograft or an infusion of alloantigen or indeed both, and that these cells can contribute to controlling subsequent responses to alloantigen in vivo.

Another important issue that has been under investigation is where Treg that can control allograft rejection function most effectively and where they can be found or detected in vivo. There is evidence that the location in which Treg function may change with time after transplantation. Early in the response after transplantation, Treg have been shown to be present and functionally active in the draining lymph nodes, while later in the post-transplant course Treg have been shown to function within the allograft itself [44]. Indeed there is increasing evidence that an important site of immune regulation is within the allograft itself where Treg function to create an environment that is permissive of control [45,46]. Moreover, re-exposing Treg to antigen in a tissue may enable them to become more potent suppressors and, therefore, more effective at controlling rejection [47].

Although a significant body of work has demonstrated that Treg can control responses to alloantigen, most studies have used either in vitro assays or experimental models whereby cells are adoptively transferred into immunodeficient recipients where allograft rejection is driven by relatively small numbers of effector T cells compared to the number that would be found in a full immune repertoire in vivo. Arguably, a much more relevant question for clinical application of this approach is what role do Treg play in an intact immune system? In transplantation, Treg-specific inactivation was used to show that in the anti-CD4/DST tolerance induction model described above, the survival of primary heart allografts in normal, lymphoreplete recipients is also unequivocally dependent on iTreg driven by the tolerance induction protocol [48]. These data suggest that it should indeed be possible to boost the function of Tregs in non-lymphopenic transplant patients.

Regulatory B cells

B cells with the capacity to suppress the development of autoimmune diseases in mice were first described in the 1980s. Regulatory B cells (Breg) express high levels of CD1d, CD21, CD24 and IgM and moderate levels of CD19, although some heterogeneity has been described, suggesting that different subsets of Breg may exist [49] (Figure 8.2). One of the characteristics of B cells with regulatory activity is their ability to secrete IL-10. CD40 stimulation appears to be required to stimulate IL-10 production and has been reported to be necessary for activation of Breg, enabling them to manifest their functional activity and suppress Th1 differentiation.

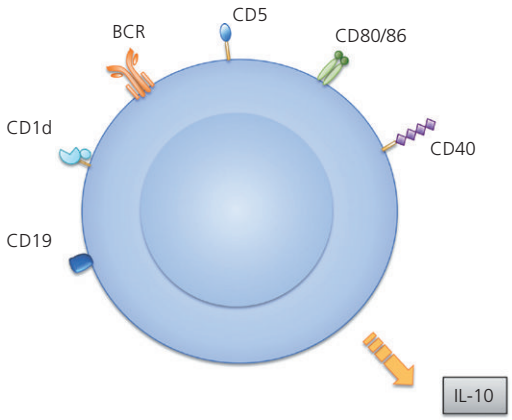

Figure 8.2. Regulatory B-cell characteristics. Shown are the surface molecules and defining cytokines expressed by B cells with specialized regulatory potential.

It has been suggested that there is a link between regulatory B cells and T cells, with Breg acting as potent generators of Treg. Breg have been described in both mouse and human. Mouse Breg express T cell Ig domain and mucin domain protein 1 (Tim 1) [50]. While human regulatory B cells share some properties with their mouse counterparts, including an immature phenotype, and comprise a small subset of the total B cell pool.

In transplantation, there is only indirect evidence that Breg may play a role in controlling immune responses to alloantigens. Interestingly, in renal transplant recipients who have a functioning graft in the absence of immunosuppression, a B-cell signature was found to be associated with this state of operational tolerance to donor alloantigens [51,52]. A distinct, but also B-cell dominated signature of tolerance was identified in a separate cohort of long-term immunosuppression free renal transplant recipients [53].

Experimental studies on the role of Breg in transplantation are limited at present. In a rat model of long-term kidney transplantation tolerance, a shift in both peripheral and intragraft gene expression from IgG to IgM was observed, as well as IgM^+, but not IgG^+ B-cell clusters within the graft [54]. In mice, Tim-1 ligation on B cells induced Tim-1^+ B cells with regulatory activity [50], suggesting a potential therapeutic strategy for increasing the number of Breg *in vivo*. More work is required to determine and characterize the contribution of Breg in the regulation of alloimmune responses and the relationship with the production of DSA [55].

Dendritic cells

DC are central to the activation/priming of an immune response, but paradoxically they can also promote the development of tolerance [1,56,57]. Initially, immature myeloid DC that express low levels of MHC class II and costimulatory molecules at the cell surface were identified as the dominant form of DC that had the capacity to induce T-cell tolerance. In contrast, mature myeloid DC that express much higher levels of both MHC and costimulatory molecules were found to prime T-cell responses most efficiently. However, subsequently, mature DC have also been shown to have the capacity to induce tolerance and, therefore, the relationship between the state of maturity of a DC and its tolerogenic potential is now not thought to be a significant factor in determining whether a DC stimulates or inhibits the development of an alloimmune responses.

There are many studies demonstrating that DC can promote tolerance to solid organ allografts and bone marrow grafts [56]. For example, a single injection of donor-derived DC 7 days before transplantation of a MHC-mismatched heart allograft extends [58] or prolongs survival indefinitely [59] in a donor-specific manner. The potential tolerogenic effects of DC can be potentiated by the co-administration of immune-modulating agents such as costimulation blockade [60]. 'Alternatively activated' or 'regulatory' DC, which have low costimulatory ability, can also, when administered 7 days before transplantation, protect MHC-mismatched skin grafts from rejection [61] and mice from lethal acute graft-versus-host disease when administered 7 days before transplantation [62].

Plasmacytoid DC (pDC) are arguably the best characterized of the DC subsets that can influence the course of an immune response towards regulation. pDC were originally defined by their capacity to secrete large amounts of type I interferons in response to viruses and to play an essential role in protecting individuals against inflammatory responses to harmless antigens, but they have now also been shown to be able to induce human regulatory T cells in vitro. These regulatory cells produce significant amounts of interleukin IL10, low IFN-γ, but no IL4, IL5, or transforming growth factor (TGF)-β [63]. Non-lymphoid tissue pDC, such as those residing in the airways, gut, and liver, play a significant role in regulating mucosal immunity and are critical for the development of tolerance to inhaled or ingested antigens.

The molecular mechanisms used by pDC to promote tolerance are complex [64], including evidence that they can promote the differentiation of $Foxp3^+$ Treg. In transplantation models, tolerizing pDCs can acquire alloantigen in the allograft and then migrate through the blood to home to peripheral lymph nodes, where they induce the generation of $CCR4^+CD4^+CD25^+Foxp3^+$ Treg [65]. Significantly, infusion of donor-derived pDC 7 days before transplant were found to be capable of prolonging subsequent heart allograft survival (from 9 to 22 days) in the absence of immunosuppressive therapy [66], but this effect was markedly enhanced by anti-CD154 mAb administration [67]. In mice, pre-pDC appear to be the principal cell type that facilitates haematopoietic stem cell engraftment and induction of donor-specific skin graft tolerance in allogeneic recipients [63]. The combination of DC, administered with costimulatory blockade, may be the most promising approach identified thus far.

Myeloid-derived suppressor cells

Myeloid-derived suppressor cells (MDSC) have been associated with many suppressive functions, both antigen specific and non-specific. These include regulation of innate immunity, T-cell activation and tumour immunity. MDSC are a heterogeneous population of progenitor cells that can accumulate in tissues during an inflammatory immune response. The expansion and activation of MDSC is regulated by factors produced by other cells that are present in the same microenvironment; the other cell types involved include stromal cells, activated T cells and in tumours, the tumour cells themselves.

A number of MDSC subsets have been described in both mice and humans [68] (Figure 8.3; adapted from data summarized in [69]). Despite the heterogeneity, common phenotypic markers are expressed including Gr1 and CD11b in mice and CD33, CD11b, CD34 and low levels of MHC class II in humans. Activated MDSC suppress proliferation and cytokine production by T, B and NK cells in vitro through mechanisms that include the enzyme inducible nitric oxide synthase 1, which induces nitric oxide production, and arginase 1, which depletes arginine. Both of these pathways can induce several mechanisms that inhibit cell function. MDSC also appear to be able to be modify T-cell differentiation pathways and it has been reported that they promote Treg differentiation.

In experimental models, MDSC can play a role in the induction of tolerance to alloantigens. For example, transplantation tolerance could not be induced in mice that did not express MHC class II on circulating leukocytes; a finding consistent with a requirement for recipient MHC class II^+ cells for the induction of tolerance to alloantigens [70]. Moreover, data suggesting direct evidence of a tolerogenic role for $CD11b^+CD115^+Gr1^+$ monocytes for heart allografts in mice [71] and, in the rat, evidence for iNOS-expressing MDSCs in kidney have been reported [72].

Regulatory macrophages

Macrophages are inherently plastic in terms of the functional outcome of activation. Classically activated macrophages are highly proinflammatory and are generated in response to ligation of TLRs, resulting in the activation of inflammatory signalling cascades and the production of inflammatory cytokines including tumour

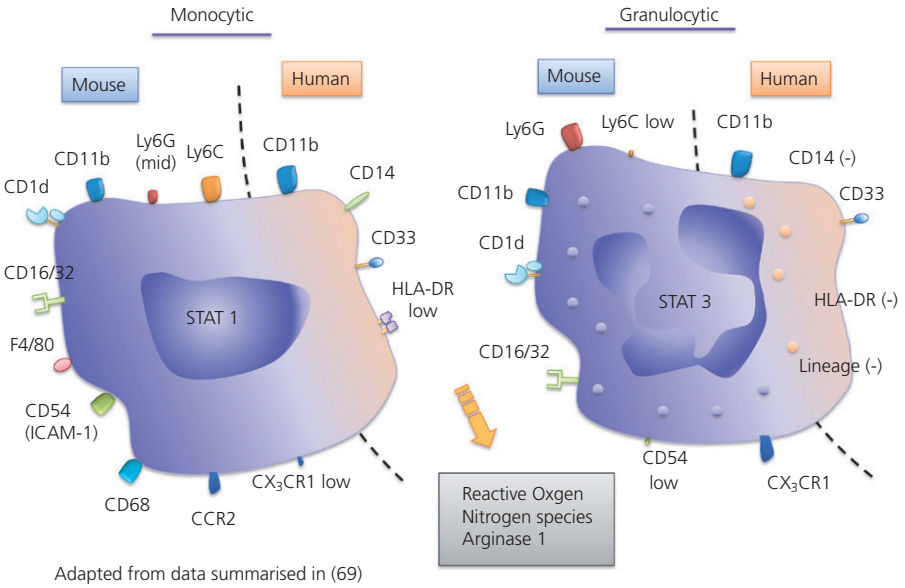

Figure 8.3. Myeloid-derived suppressor cell characteristics. Shown are the intracellular transcriptional characteristics, surface molecules and defining cytokines of myeloid-derived cells (left, monocytic; right, granulocytic) with specialized regulatory potential.

necrosis factor-α and IL-1β. Alternatively activated macrophages, induced by exposure to the cytokine IL-4, are less proinflammatory and in some settings can create a microenvironment that modulates immune responses that would otherwise be deleterious to the tissues in which they reside [73]. Regulatory macrophages may represent an additional population, which is distinct from the other two forms whose main physiological role is to dampen inflammatory immune responses and prevent the immunopathology associated with prolonged classical macrophage activation [74].

Regulatory macrophages produce high amounts of IL-10 usually following costimulation with two ligands, for example TLR and immune complexes. They do not express arginase and are not dependent on STAT6 signalling, as are alternatively activated macrophages. At present, there are no well-established stable or convenient surface markers specific for regulatory macrophages (Figure 8.4 [75];). In tissues, regulatory macrophages are anatomically positioned to interact with lymphocytes, and therefore there is evidence that these cells can influence the activity of each other. In vitro, regulatory macrophages are efficient APCs that induce highly polarized antigen-specific T-cell responses dominated by the production of Th2 cytokines.

Human regulatory macrophages isolated from the peripheral blood have the capacity to regulate immune responses to alloantigens, and in a pilot study have been administered intravenously to living donor kidney transplant recipients [76].

Ignorance

Arguably, the simplest mechanism that facilitates the maintenance of peripheral tolerance is T-cell ignorance of self-antigen. In this setting, autoreactive T cells escape negative selection within the thymus and enter the periphery, but such T cells are either prevented from accessing sites that express their cognate peptide or they never see enough peptide to enable them to overcome activation thresholds [77]. In transplantation it is hard to envisage how this mechanism could operate to regulate the alloimmune response effectively in a sustained manner.

Summary

Immunoregulation is a complex process involving multiple mechanisms and often more than one cell type that work together to contain and control immune responses. These processes are necessary to avoid unwanted immune responses and limit peripheral effects of wanted immune responses. While there are not methods to manipulate these mechanisms precisely, they no doubt play a role in determining the ultimate fate of an allograft and will be increasingly important in finely managing alloimmune responses in the future.

Acknowledgments

The work from the authors' own laboratory described in this review was supported by grants from The Wellcome Trust, Medical Research Council, British Heart Foundation, Roche Organ Transplant Research Fund and European Union through RISET, The ONE Study, OPTISTEM, TRIAD and BioDRIM projects. The authors would like to thank all members of TRIG past and present for their valuable contributions to the data reviewed in this chapter.

CHAPTER 9

The Spectrum of Alloimmunity, Heterologous Immunity, and Relevant Autoimmunity

Mandy L. Ford, Andrew B. Adams, and Christian P. Larsen
Emory Transplant Center, Department of Surgery, Emory University, Atlanta, GA, USA

Introduction

Immune alloreactivity is the sum of the actions of multiple effector cell types and their secreted products responding to foreign human antigens within the context of the trauma, cellular damage, and ischemia reperfusion injury that accompanies surgical transplantation. Although the fundamental underpinnings of alloreactivity are similar between individuals, the magnitude and character of an alloimmune response varies considerably from one person to another, with changes in the alloantigen disparity involved, and over time as the responder changes their immune history. Indeed, these changes are increasingly recognized as being critical to our understanding of the variability seen in outbred animals and in clinical transplantation. In this chapter we will review the factors underlying the variability inherent in alloreactivity, and highlight mechanisms by which the immune history of a given recipient can fundamentally shape their alloreactive potential.

The spectrum of alloreactivity

At the core of ones alloreactive potential rest three primary cell types that recognize alloantigen and initiate the alloimmune response; they are natural killer (NK) cells and T and B lymphocytes. These cells are activated following recognition of donor-derived foreign antigen, in the case of B and T cells, or the absence of self-MHC, in the case of NK cells. While the details regarding the mechanisms of activation and mediation of graft rejection will be covered specifically in Chapters 5 and 6, it is important to note that the alloreactive potential, or strength and intensity of alloreactive immune response, varies widely between individuals and between different donor and recipient pairs. Indeed, it varies over time within a single individual against a defined donor. Many factors underlie this differential degree of alloreactivity, the most conspicuous of which is the degree of MHC matching between the donor and recipient. However, the character and functionality of the recipient's immune system likely plays an important role in determining the magnitude and character of the alloreactive response to a given donor tissue. Given the central involvement of the above-mentioned cells, a review of their contributions is appropriate.

Lymphocytes as effectors of alloimmunity following transplantation

As discussed above, three main subclasses of lymphocytes can participate in the alloimmune response following transplantation. While the role of NK-cell-mediated rejection in solid organ transplantation remains controversial [1–5], and will be covered in depth in Chapter 7, recent evidence suggests that the infectious history of a given individual can impact the nature of the NK-cell compartment [6,7]. Specifically, it is now known that although NK cells do not undergo rearrangement in the genes encoding their activating receptors, they do undergo a clonal expansion-like process during viral infection which results in the generation of long-lived progeny that meet the criteria of immunologic memory [6,7]. Importantly, these memory NK cells have been shown to mediate more efficacious secondary responses against previously encountered pathogens [6,7], raising the possibility that prior immune events resulting in NK-cell activation might increase the NK-mediated barrier to transplantation. Further work to assess the impact of virally induced NK-cell memory on alloimmunity is required.

The spectrum of pre-existing humoral alloimmunity in patients awaiting transplantation is better elucidated, and covered in Chapter 6. The degree of humoral sensitization is defined using panel reactive antibody (PRA, described in depth in Chapter 36). PRA assess the frequency of HLA molecules in a defined panel to which serum antibodies from a given patient will react, and is generally regarded as a given patient's overall risk of experiencing humoral rejection. For example, a PRA of 20% would suggest that patient would be incompatible with 1 out of every 5 donors. In practice, PRA values span a wide range across individuals, but it is estimated that approximately 30% of dialysis patients exhibit a PRA of greater than 20%, which is defined as highly sensitized [8], and half of those possess PRAs of >80% [9]. Furthermore, it is general assumed that high pretransplant PRA portends post-transplant risk for antibody-mediated graft injury; although this is most relevant for PRA that includes donor-specific alloantibody [9]. Interestingly, a study comparing PRA and panel-reactive T-cell responses in potential renal transplant recipients revealed that the level of pretransplant alloantibodies did not always correlate with the frequency of pretransplant donor-reactive T cells, suggesting that the presence of T-cell

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

alloreactivity did not routinely imply B-cell sensitization and vice versa [8]. In general alloantibody is considered to be T-dependent, but T cells can respond to processed antigen, whereas alloantibody is by its nature directed toward the quaternary structure of an antigen. Thus, it is understandable that the spectrum of these two processes is non-identical. The origin of alloantibodies in patients that have never before been transplanted is most commonly explained by occult exposure to alloantigen through transfusion or pregnancy and it is well established that prior pregnancy may influence the generation of alloantibody [8]. In addition, however, it also is known that systemic viral infection can result in polyclonal activation and subsequent secretion of antibody with broad specificity unrelated to the inciting organism [10]. While this polyclonal antibody is T-independent and not the result of a germinal center reaction (also see Chapter 2), it has the potential to contain antibodies of alloreactive specificity [10]. Again, the contribution of this mechanism to the observed spectrum of humoral alloimmunity across individuals warrants further investigation. In contrast, given the predominant role of cell-mediated immunity in transplant rejection and more in-depth research regarding the nature of alloreactive T cells, much more is known about the spectrum of alloimmunity among T cells, and the mechanisms by which external influences such as exposure to environmental antigens, pathogens, and aging can impact the alloimmune response. For this reason, the remainder of the chapter will focus primarily on T-cell alloimmunity.

The T-cell repertoire and its recognition of pathogens and alloantigens

To defend against an ever-changing panoply of pathogens, the mammalian immune system has evolved the capacity to generate an extraordinarily diverse repertoire of T cells bearing receptors, which are capable of discriminating foreign peptides presented in the context of self-MHC. While the theoretical upper limit of diversity may exceed 1×10^{13}, it is estimated that the actual number of different clonotypes expressed is closer to 2×10^6 in mice and 2.5×10^7 in humans (reviewed in [11]). Theoretical and experimental evidence suggest that the size of the clonal population of T cells bearing identical receptors is approximately 100–200 in mice and between 1000 and 4000 in humans. Studies of the response to lymphocytic choriomeningitis virus (LCMV), a small RNA virus, indicate that the T-cell precursor frequency (defined as the number of naïve T cells specific for a given peptide–MHC combination in mice before antigenic challenge) responding to immunodominant class I and class II restricted epitopes have similar precursor frequencies in the range of 1–2 per 10^5 $CD8^+$ or $CD4^+$ T cells [12,13].

While the immune system did not evolve to reject transplanted tissues, it is nonetheless apparent that immune responses against tissues from non-genetically identical individuals within a species are particularly potent. This is due, at least in part, to the high frequency of T cells that respond to this allogeneic stimulus [14–16]. In fact, in experimental systems, it has been found that 0.1–10% of a naïve individual's T-cell repertoire is capable of reacting with alloantigens expressed by a given fully MHC-disparate donor [14], a figure that is 2–3 logs greater than the estimated precursor frequency of virus-specific responses [12,13]. By combining the estimates of the number of distinct clones in the repertoire noted above with an intermediate estimate of frequency of alloreactivity (~1%), mice and humans would bear approximately 20 000 and 250 000 distinct alloreactive clones, respectively. Thus, the response to pathogens and transplants are initiated from fundamentally different ranges of initial precursor frequencies, a fact that is likely to have major implications on the outcome of the T-cell response.

Impact of T-cell precursor frequency on T-cell behavior

High T-cell precursor frequency is one of the hallmarks of alloreactivity. It is known that this high T-cell precursor frequency fundamentally alters the quality, in addition to the quantity, of responding T-cell populations. Specifically, a study by Marzo et al. revealed that naïve T-cell precursor frequency strongly influenced the outcome of $CD8^+$ T-cell differentiation, with higher precursor frequencies resulting in a net increase in central memory $CD8^+$ T cells [17]. High T-cell precursor frequency also accelerated the kinetics of T-cell expansion [18], but paradoxically shortened the life-span of both naïve and memory T-cell populations [19]. Furthermore, other investigators have made the intriguing observation that a high frequency of $CD8^+$ precursors can convert a helper-dependent response into a helper-independent and CD154-independent response [20], and studies have demonstrated an important role for naïve $CD4^+$ and $CD8^+$ T-cell precursor frequency in determining the degree donor-reactive T-cell proliferation and differentiation following transplantation, and in mediating costimulation blockade-resistant rejection [21,22]. Specifically, naïve T cells present at very high frequencies pretransplant appear to obviate the requirement for CD28 and CD154-mediated costimulation. This critical role for high precursor frequency in determining the potency of alloreactive T-cell responses has been demonstrated for both naïve and memory T cells [23–26]. Alloreactive T cells responding from an initial high precursor frequency exhibit increased expression of CD25, the high-affinity IL-2 receptor [27], decreased expression of the inhibitory receptor programmed death-1 (PD-1) [25], a reduced requirement for $CD4^+$ T-cell help [22], and must undergo fewer rounds of cell division in order to reach a critical threshold number of effectors in order to mediate graft rejection (Figure 9.1) [24]. The major role of high-frequency T-cell responses in mediating allograft rejection is further exemplified by observations that increased MHC matching, which reduces the number of allogeneic epitopes present and thus the number of alloreactive T-cell clones recruited into the response, results in increased 5-year graft survival (Figure 9.2). Taken together, these studies demonstrate that high-frequency T-cell responses, present either as naïve or memory alloreactive T-cell populations, play an important role in mediating allograft rejection [28].

The molecular basis of alloreactivity

During the study of allorecognition over the last half-century, this high precursor frequency has led to speculation that allorecognition is fundamentally different from TCR recognition of a nominal antigen. What is the molecular basis of this high precursor frequency? Early studies raised the possibility that due to the evolutionarily selected propensity of the germline-encoded TCR gene segments to bind to MHC molecules, perhaps in the absence of negative selection TCRs were ligating MHC in a peptide-independent manner. If all alloreactive TCRs could bind allogeneic MHC regardless of the particular peptide presented, this might lead to a very high precursor frequency. However, the peptide independence of allorecognition failed to be supported by crystal structures of allospecific TCR contacting its ligand; these studies revealed the same orthogonal orientation in which the TCR CDR3 regions contact the MHC peptide-binding groove [29]. Subsequent studies

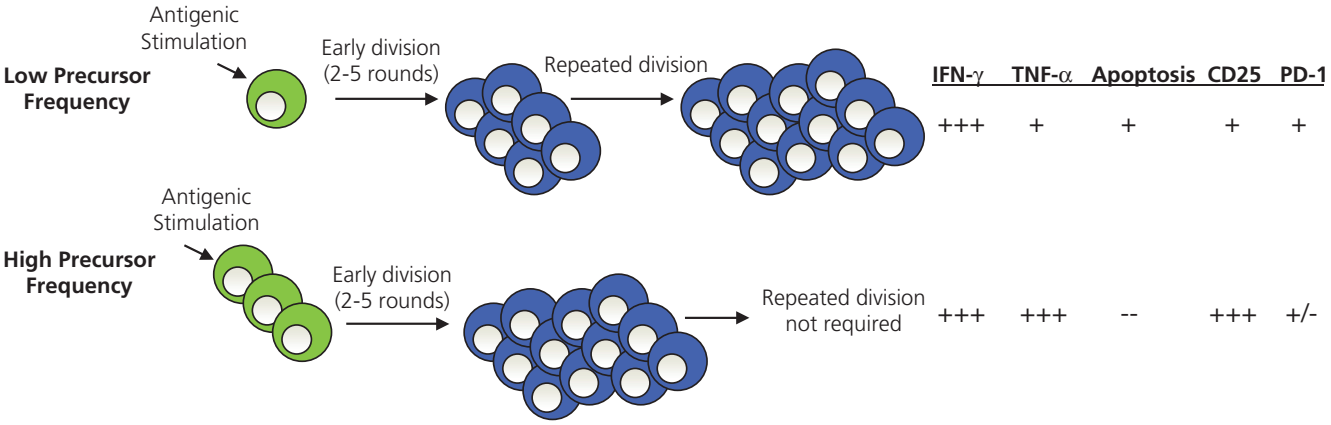

Figure 9.1. Impact of high T-cell precursor frequency on the quality of the alloreactive T-cell response. T cells responding from an initial low precursor frequency must undergo many more rounds of division in order to reach a critical threshold number of alloreactive effectors and mediate rejection of the graft, while T cells responding from an initial high precursor frequency require many fewer rounds of division in order to achieve this threshold. T cells stimulated at higher precursor frequencies also have a greater proportion of high-quality dual cytokine producing cells, decreased frequencies of apoptotic cells, increased expression of CD25, and decreased expression of IL-2.

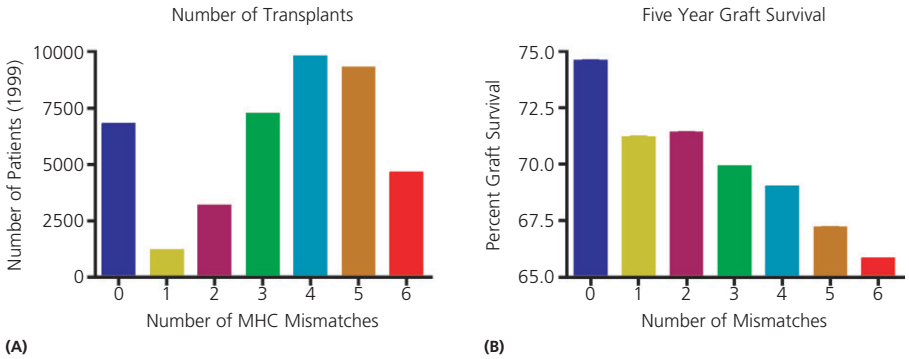

Figure 9.2. Impact of MHC matching on 5-year renal allograft survival. (A) The percentage of surviving grafts at 5 years post transplant is shown for recipients that received a deceased donor, non-extended criteria donor (ECD) renal allograft that were mismatched at 0, 1, 2, 3, 4, 5, or 6 MHC loci. (B) The number of transplant recipients from the data set in (A) that received transplants mismatched at 0–6 MHC loci. Data are derived from the 2006 OPTN/SRTR annual report [118].

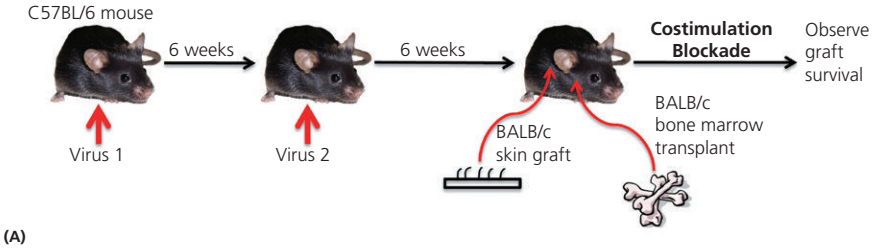
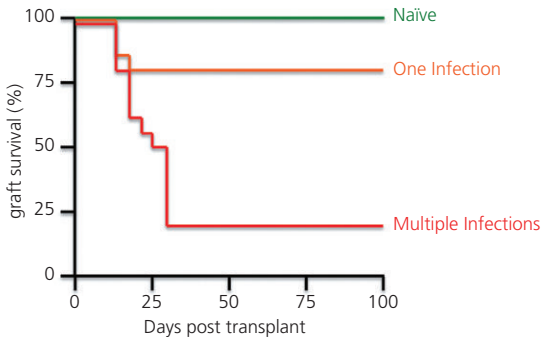
have gone on to definitively demonstrate the peptide dependence of alloreactivity [30,31]. While it is likely that the high alloreactive precursor frequency stems in part from the large number of alloepitopes that can be presented by a given donor-derived APC, there is also another factor that likely contributes to high alloreactive precursor frequency; namely, the polyspecificity of alloreactive T-cell clones. This was demonstrated in a seminal study interrogating the specificity of alloreactive $CD4^+$ T cells for peptide:MHC complexes, where the authors found that alloreactive T cells have the inherent propensity to respond to multiple, distinct peptide epitopes that do not share sequence homology [32]. A similar observation was made in $CD8^+$ human T-cell clones, in that when human T cells were primed with a single tumor antigen presented on self-MHC, the responding T-cell clones were highly specific for that particular antigen, as would be expected [33]. Strikingly, however, when T-cell populations were primed with the tumor antigen presented on allogeneic MHC, the responding T-cell clones recognized not only the immunizing antigen, but also a wide range of distinct peptide epitopes [33]. Taken together, these data demonstrate the polyspecificity of alloreactive T cells relative to conventional T cells, a property that allows them to respond to many unrelated peptide sequences, thereby increasing the frequency of T-cell clones recruited into a given antidonor response [30].

Heterologous immunity: Interactions of pathogen exposure and alloreactivity

Many studies conducted over several decades have documented the ability of pre-existing immunity to pathogens to impact alloreactivity, a phenomenon termed heterologous immunity. In the vast majority of cases, pathogen exposure functions to enhance the cellular alloimmune response and in some cases can precipitate graft rejection (Figure 9.3). In broad strokes, there are two potential mechanisms by which pathogen exposure can augment alloimmunity: (1) antigen-dependent activation of alloreactive T cells, and (2) antigen-independent augmentation of alloimmunity in the setting of a concurrent transplant. Thus, while early studies documented the phenomenon of pathogen-mediated augmentation of alloimmunity [34], they failed to differentiate between these two hypotheses as an explanation for the observed results. More



(A)



(B)

Figure 9.3. Experimental evidence for pathogen-induced heterologous immunity [23]. (A) The experimental design used to demonstrate the influence of viral pathogen exposure on allograft survival. Mice are serially exposed to various viral pathogens and allowed to fend off the infectious. Transplants (e.g. skin and or bone marrow) are then performed using a costimulation blockade-based immunosuppression regimen and graft survival is observed. (B) Animals receiving transplants after multiple infections have worse allograft survival than those that are viral naïve or relatively less virally experienced.

recently, however, new experimental evidence has emerged identifying true molecular mimicry as a potential explanation for the observed alloreactivity within heterologous immune responses [35,36]. We will consider each of these mechanisms of heterologous immunity separately below.

Evidence for alloreactivity among memory

The immune repertoire of a given individual is fundamentally altered over the lifetime of that individual as a result of the particular set of immune challenges that person is faced with. Responses to environmental antigens, viruses, and bacteria fundamentally alter both the composition and character of the T- and B-cell repertoires. It is known that while laboratory mice contain only 2–10% antigen-experienced memory T cells [37], approximately 50% of the peripheral T-cell compartments of adult humans are $CD45RO^+$ $CD45RA^-$ memory T cells [38], as a result of infection with, and response to, multiple agents over the life of the host. These memory T cells possess a great deal of heterogeneity within their phenotypes, functionalities, trafficking patterns, and requirements for optimal recall responses [39]. But does alloreactivity exist within these memory T compartments in normal healthy unsensitized individuals? For many years, there was considerable debate concerning the relative representation of alloreactive clones among memory T-cell populations [38,40]. This important question was first asked using an approach that involved cord blood-derived T-cell preparations, which could be shown to contain very few memory T cells [38], and later using ELISPOT-based experiments to identify those cells that were capable of rapidly producing interferon (IFN)-γ in response to brief stimulation with alloantigen, which is a hallmark of T-cell memory [41]. More recently, polychromatic flow cytometric techniques have been used to both identify and sort subsets of naïve ($CD45RO^-CD62L^+$), central memory ($CD45RO^+$ $CD62L^+$), effector memory ($CD45RO^+$ $CD62L^-$), and terminal effector memory ($CD45RO^-$ $CD62L^-$) T cells within both the $CD4^+$ and $CD8^+$ T-cell compartments, and to assess the precursor frequencies of alloreactive T cells within these subsets [42]. These data have revealed that alloreactivity may manifest differently in different T-cell subsets. For example, a higher precursor frequency of alloreactive T cells is detected among naïve as compared to memory $CD8^+$ T cells when proliferation is used as a measure of alloreactivity, but $CD8^+$ Tem appear to contain a higher precursor frequency of alloreactive T cells as compared to naïve $CD8^+$ T cells when perforin or granzyme expression is used as a read out [42]. It is therefore important to consider that notion that despite the fact that frequencies of alloreactive T-cell clones might be comparable between naïve and memory T-cell compartments, the immunological manifestation of recognition of alloantigen might be very different, with potential profound impacts on graft acceptance versus rejection. In this regard, determining the precise effector functions of alloreactive T cells that are most critical for graft destruction remains an important goal.

Heterologous immunity and the generation of alloreactive T-cell memory

Donor-reactive memory T cells can arise through multiple independent mechanisms (Figure 9.4), many if not all of which are likely at play in an individual transplant recipient. The origin of allospecific memory T cells can generally be categorized into three main subdivisions: (1) "traditional" donor-reactive memory T cells generated following sensitization with alloantigen (i.e. a prior transplant, transfusion, or pregnancy, (2) memory T cells that arose through antigen-independent mechanisms, and (3) allocross-reactive memory T cells that were elicited following exposure to non-alloantigens. First, it is clear that donor-reactive memory T cells are generated in the setting of a failed prior allograft (Figure 9.4). Evidence from both experimental models [43,44] and clinical patients [41] consistently demonstrates poorer outcomes in recipients of a failed prior graft, consistent with "second set" rejection. Alloreactive memory T cells can also arise during pregnancy, during which time (despite the presence of multiple immunologic mechanisms functioning at the fetal/maternal interface to promote tolerance of the fetus) a female can become primed against paternal

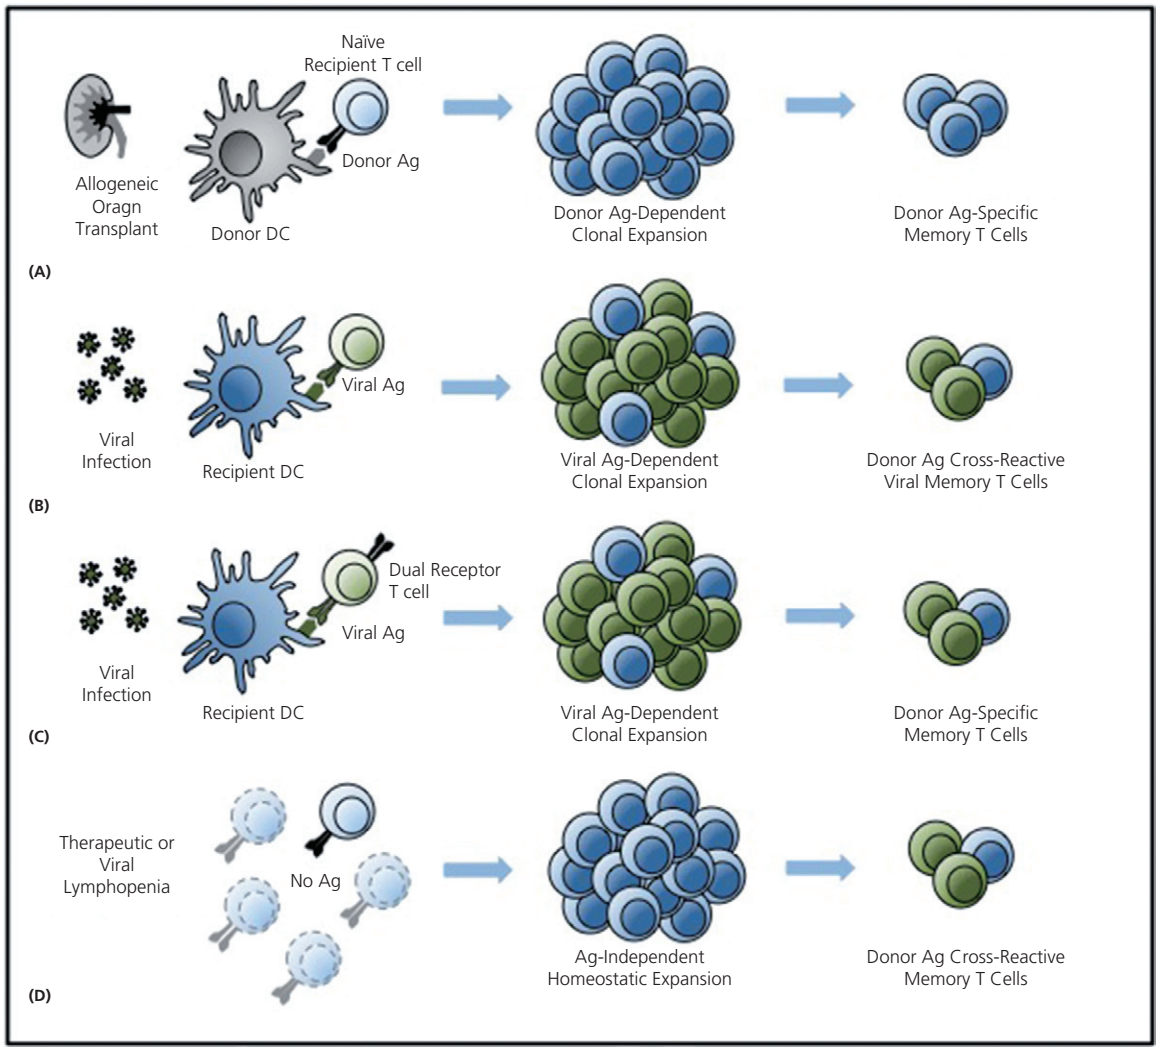


Figure 9.4. Mechanisms by which donor-reactive memory T cells may arise. Alloreactive memory T cells can be generated through at least four independent mechanisms. (A) "Traditional" donor-reactive memory may arise via sensitization with alloantigen in the form of prior transplant, blood transfusion, or pregnancy. (B) Alloreactive memory T cells may arise following sensitization with pathogen-derived antigens that elicit memory T cells, which, by virtue of the degenerate nature of their TCR, cross-react with alloantigen. (C) Alloreactive memory T cells may also arise following activation of dual-receptor T cells. These cells possess one receptor specific for a non-alloantigen, and, when activated by non-alloantigen, result in memory T cells. If these cells bear a second receptor that is alloreactive, they may respond to alloantigen as a memory T cell. (D) Alloreactive memory T cells may also be generated via homeostatic reconstitution following virally or pharmacologically induced lymphopenia. Light blue and green T cells represent naïve T cells. Clonally expanding and memory T-cell populations contain combinations of pathogen-reactive (green) and alloreactive (blue) cells. Ag, antigen; DC, dendritic cell. Reproduced from Krummey SM and Ford ML. Heterogeneity within T Cell Memory: Implications for Transplant Tolerance, 2012. Frontiers in Immunology. 3:36. Epub 2012 Mar 1. PMCID: PMC3342058 [119]. antigens carried by the fetus [45]. With regard to allosensitization following blood transfusion, it has been shown that immunity generated by platelet transfusion is sufficient to induce rejection following subsequent bone marrow transplantation in murine recipients [46]. Because of the high rate of prior platelet transfusion in liver transplant recipients in particular, these data indicate that highly transfused transplant recipients may be at an increased risk for memory T-cell-mediated graft rejection.

A second mechanism by which alloreactive memory T cells might be elicited is the scenario in which a lymphopenic environment exists in the host (Figure 9.4). Under these conditions, naïve $CD4^+$ and $CD8^+$ alloreactive precursors can be induced to undergo antigen-independent, but IL-7-dependent, homeostatic proliferation and subsequent differentiation into memory T cells [47,48]. This phenomenon was demonstrated by seminal studies from Turka and colleagues, which showed that transfer of naïve lymphocyte populations into T- and B-cell deficient severe combined immunodeficiency (SCID) recipients, as well as antibody-induced depletion of lymphocytes in murine transplant recipients, resulted in rapid reconstitution of the peripheral T-cell compartment with memory T cells [49]. The clinical relevance of these findings lies in the fact that lymphopenia occurs following infection with viral pathogens such as HIV, following interferon therapy for the treatment of HCV, and following therapeutic depletion of T cells for the

treatment of autoimmunity or transplantation [50]. Studies from the basic immunology literature have shown that "pseudomemory" T cells arising from lymphopenia followed by homeostatic reconstitution have both phenotypic and functional characteristics of memory T cells, and behave as memory T cells during secondary rechallenge [47,48]. Thus, lymphopenia-induced immunologic memory is essentially indistinguishable from true memory that arose via antigen-dependent mechanisms. Memory cells generated following homeostatic expansion have also been shown to constitute a barrier to transplantation tolerance induction, discussed further below [49].

Next, alloreactive memory T cells can theoretically arise following prior activation of dual-receptor T cells (Figure 9.4), a mechanism that is often overlooked. Alloreactive dual receptor memory T cells can arise through a situation in which two distinct TCRs, one specific for an alloantigen and one specific for a pathogen or other non-alloantigen, co-exist on the same T cell. If that T cell encounters the non-alloantigen for which it is specific, it would become activated and differentiate into a memory T cell. If at some future time that same T cell were to encounter its cognate alloantigen via the second receptor, it would respond as with the kinetics and activation threshold of a memory T cell despite never having previously encountered alloantigen. What is the evidence that dual receptor T cells exist in mice or man? While the vast majority of peripheral T cells express a single alpha and single beta chain owing to the principle of TCR gene alleleic exclusion, it has been shown that up to 30% of mature peripheral human T cells express a second alpha chain at the mRNA level, and up to 8% express one at the protein level [51]. Given the existence of these dual receptor T cells, what is the evidence that these cells possess alloreactivity and can therefore contribute to allograft rejection? Studies in a murine model of graft-versus-host disease (GVHD) revealed that a higher frequency of dual-receptor $CD4^+$ T cells were observed in the alloreactive T-cell compartment as compared to the non-alloreactive T-cell compartment [52]. However, the precise role these cells may play in either GVHD or rejection of solid organ transplants, both in mice and in humans, remains to be fully elucidated.

Existence of alloreactive memory as a result of TCR cross-reactivity

In addition to the mechanisms discussed above, evidence exists in both mouse and human systems indicating that in a process termed heterologous immunity, alloreactive memory T cells are generated following previous exposure to non-alloantigens [23,53,54]. For example, in certain instances, it is known that microbial pathogens activate antigen-specific T cells that then cross-react with allogeneic tissue and result in graft rejection [36,53,55–57]. This phenomenon occurs when TCRs present on virus-specific memory T cells cross-react with alloantigen, due to the inherent ability of TCR to recognize a bind to a range of related peptide:MHC ligands [58–60]. Indeed, it has been estimated that a single TCR may be capable of recognizing up to 10^6 distinct ligands, and computational analysis of the T-cell repertoire suggested that this high degree of TCR cross-reactivity is in fact required for complete coverage of the multitude of potential peptide epitopes that could be generated by pathogens or other foreign antigens [11]. Experimental evidence to suggest that such cross-reactivity between pathogen-derived and graft-derived epitopes exists is derived from data showing that $CD8^+$ T cells specific for EBV-EBNA3A restricted by HLA-B8 are cross-reactive against HLA-B44 complexed to an unrelated self-peptide [55–57,61]. Cross-reactivity between viral and alloepitopes has been demonstrated in several other examples as well, including the fact that $CD4^+$ T cells specific for a tetanus toxoid epitope presented by HLA-DR3 are cross-reactive with the allogeneic MHC molecule HLA-DR4 [62], and a T cell specific for herpes simplex virus (HSV)-VP13/14 presented by HLA- A2 cross-react with the allo-MHC molecule HLA-B44 [63]. As mentioned above, alloreactive T cells have also been shown to be more promiscuous, or have increased "polyspecificity" as compared to cells specific for a nominal antigen [30,31]. This finding of "polyspecificity" of alloreactive T cells was further confirmed by crystallographic studies that interrogated the molecular mechanisms underlying the observed cross-reactivity of EBV-EBNA3A/HLA-B08 restricted TCR with HLA-B44 molecules [35], and found that the binding orientation of a single monoclonal TCR to two discrete, unrelated cognate and allogeneic peptide:MHC complexes were virtually identical. Furthermore, the authors of this study proposed an induced-fit model to explain TCR recognition of alloepitopes, because TCR ligation was required for the viral and allopeptides to acquire the same conformation [35,64]. These insights into the biochemical mechanisms by which pathogen-elicited memory T cells cross-react with alloantigens have therefore definitively demonstrated that heterologous immunity can function at the level of molecular mimicry, facilitated in part by the intrinsic promiscuous nature of alloreactive T-cell clones.

These very specific examples therefore confirm the existence of molecular mimicry as a potential mechanism underlying heterologous immunity, but exactly how common do pathogen-elicited allocross-reactive memory T cells actually occur in humans? A 2010 study revealed that cross-reactive pathogen-specific T-cell clones specific for alloantigens is actually quite common. Using MHC tetramers for FACS-purification of T-cell lines and clones specific for the latent viral pathogens EBV and CMV, the authors tested the reactivity of the resulting cells against a large panel of HLA-typed antigen presenting cells. Interestingly, 80% of $CD8^+$ T-cell lines and 45% of pathogen-derived antigen-specific $CD8^+$ T-cell clones were allocross-reactive against at least one MHC allele [65]. In this study, both the pathogen- and alloreactivity could be conferred by a single TCR, thus demonstrating TCR cross-reactivity at the level of molecular mimicry and excluding a role dual receptor T cells [65]. Furthermore, the potential for pathogen infection or immunization to augment alloimmunity has been demonstrated in case reports, including one in which varicella zoster virus vaccination precipitated the generation of an alloreactive T-cell response [66]. These studies reveal that pathogen-elicited allocross-reactive T-cell memory is not uncommon and therefore may have profound effects on outcomes in clinical transplantation [67]. Specifically, if a large proportion of memory T-cell clones within an individual T-cell repertoire possess intrinsic alloreactivity, and a single individual possesses tens of millions of memory T-cell clones, it is therefore important to ask not simply if donor-reactive memory T cells exist in any given individual, but rather the extent to which they exist, and to determine the extent to which their frequency, phenotype, and functionality poses a threat to long-term graft survival. In this way, the prior immune and infectious histories of individual patients fundamentally shape the spectrum of alloimmunity within the population of transplant recipients.

Specific donor/recipient combination impacts degree of alloreactive T-cell memory

Given the existence of alloreactivity among memory T cells, it had previously been hypothesized that due to the lower activation

threshold of memory T cells, many different alloantigens might be capable of stimulating memory T cells, and that recipients possessing high frequencies of alloreactive memory T cells may exhibit sensitization to a wider range of potential donors. However, while it is true that alloreactive TCRs possess intrinsic cross reactivity, the above-mentioned studies using virus-specific human memory T-cell clones demonstrated that this cross-reactivity was usually confined to a single HLA allele [65]. Thus, while several studies have now shown that that alloreactivity exists among memory, the extent to which donor-reactive memory T cells are present appears to be highly dependent on the donor tissue tested. For example, in a 2007 study, $CD8^+$ memory T cells from 11 different non-human primates were stimulated with a panel of cells expressing 14 different HLA molecules, and results indicated that donor-reactive $CD8^+$ memory T-cell precursor frequencies within an individual memory T-cell compartment spanned an over 40-fold range, depending on the HLA type of the allostimulator [68]. Quite striking was the finding that the precursor frequencies spanned a range far greater than those observed for naïve alloreactive T cells, a finding which may imply that the wide range in donor-reactive memory T-cell precursor frequencies was not due to intrinsic differences in the alloreactive T-cell repertoires of these animals, but instead was a result of differential expansion of alloreactive T-cell clones due to differences in their immunologic histories [68].

Impact of bystander activation on allospecific immunity and graft rejection

The studies discussed in the previous section conclusively demonstrate that the generation of alloreactive memory T cells via TCR cross-reactivity is an important mechanism through which prior pathogen infection can result in increased alloimmunity. However, pathogen infections can also impact alloimmunity via so-called "bystander activation," an antigen-independent process. The effect of bystander activation is variable based on the type and timing of the infection relative to the time of transplantation. Specifically, concurrent infection of a murine transplant recipient with an acute viral (LCMV Armstrong) or bacterial (*Listeria monocytogenes)* infection can result in augmented alloimmunity, resulting in more highly differentiated alloreactive effectors, accelerated allograft rejection, and a loss of tolerance induction [69,70]. However, LCMV Armstrong infection after tolerance is already established has no effect on the maintenance of graft survival [69], while *Listeria* infection induces a loss of tolerance and precipitates graft rejection in 100% of recipients in an IFN-β and IL-6 dependent manner [71]. Interestingly, another bacterial infection, *Staphylococcus aureus*, fails to break established tolerance [71]. Furthermore, prior infection with *Listeria* has no effect on subsequent tolerance induction, whereas prior infection with LCMV Armstrong abrogates tolerance induction in approximately 7% of recipients [72]. In contrast, prior infection of transplant recipients with LCMV clone 13 or murine homolog of human Epstein–Barr virus (EBV), which both persist for the life of the host and presumably induce some low level of inflammation either at baseline or during episodes of viral reactivation, completely inhibited tolerance induction in 100% of the recipients [72,73]. Another example in which pathogen-associated inflammation functions to enhance an alloimmune response is seen in the case of experimental infection with murine polyoma virus, a relative of human BK virus that infects the kidney, resulting in an experimental model of polyoma virus-associated nephropathy (PVAN) [74], which affects some transplant recipients. In mouse models, polyoma virus infection resulted in loss of allogeneic but not syngeneic transplanted kidneys [74], along with a concomitant increase in alloantigen-specific $CD8^+$ T cells [74]. In this system TCR cross-reactivity of viral-specific T cells with alloepitopes has failed to be detected, suggesting instead that the increased inflammatory milieu generated by the polyomavirus infection increased the activation and differentiation of the alloreactive T-cell clones in an antigen-independent manner. This hypothesis was confirmed in a subsequent study in which immunodeficient animals with very high viral loads failed to undergo graft loss, suggesting a non-infectious etiology for graft failure [75]. Indeed, adoptive transfer of alloreactive, but not polyoma virus-specific, T cells resulted in graft loss [75]. In summary, the inflammatory milieu established following a particular viral or bacterial infection can profoundly impact the intensity and outcome of alloimmune responses in an antigen-independent manner [76]. The mechanisms underlying this phenomenon likely involve the ability of a particular infectious agent to activate the innate immune response (see Chapter 7), by inducing the adjuvant effects of cytokines such as IL-6 and type I interferons [71,77], and engaging toll-like receptor (TLR) [78] or other pathogen-associated molecular pattern (PAMP) receptors in order to license alloepitope-presenting dendritic cells [79,80].

Aging and alloreactive immune competence

Alloimmunity can also be impacted by age [81]. The aging immune system is populated by an increasing frequency of memory T cells, in particular Tem cells [82,83], and numerous studies have shown that allograft rejection proceeds with slower kinetics in aged mice [84,85]. This delayed rejection is attributable to altered T-cell responses, in that adoptive transfer of aged alloreactive T cells into young T-cell-deficient hosts still results in delayed rejection kinetics, whereas adoptive transfer of young alloreactive T cells into aged T-cell-deficient hosts does not [85]. However, aging does not seem to impair the ability of donor-derived DCs to initiate alloimmune responses in experimental models [85]. These findings in experimental models are supported by clinical observations that recipient age is associated with decreased incidence of acute rejection [86–90], but that donor age is associated with increased incidence of acute rejection [86]. Furthermore, latent viral infections, particularly CMV, induce inflationary T-cell responses that can achieve frequencies of 50–80% of the peripheral $CD8^+$ T-cell compartment in aged individuals [91–95], a phenomenon that may have the effect of "squeezing out" alloreactive T cells. Thus, in these ways, aging and the associated impact of latent viral infections can have a profound impact on alloreactive immune competence.

Impact of pre-existing autoimmunity on alloreactivity

Alloreactivity may also be impacted by the presence of pre-existing organ-specific or systemic autoimmunity, which very often was the underlying disease that necessitated transplantation in the first place. Recurrent autoimmunity can manifest in the setting of renal, liver, and islet/pancreas transplantation. Patients undergoing renal transplantation may have concurrent autoimmune conditions such as lupus, Goodpasture's disease, IgA nephropathy, etc., which result in pretransplant glomerulonephritis [96,97]. In terms of liver transplantation, there are three main autoimmune conditions for which transplantation is a potential eventual therapeutic option: primary biliary cirrhosis, primary sclerosing cholangitis, and autoimmune

hepatitis. Recurrent disease occurs in up to 20–40% of liver transplant recipients undergoing orthotopic liver transplantation for these indications, most commonly during the second or third year post transplantation [98]. Unmasking of underlying autoimmunity is thought to occur following reduction in maintenance immunosuppression, and is characterized by abnormal liver function tests and a lymphocytic infiltrate upon liver biopsy [98]. Finally, patients with type 1 diabetes mellitus may undergo renal, combined renal/pancreas, or islet transplantation for their disease. Overall, recipients transplanted for autoimmune indications are likely at increased risk of acute rejection [99], and control of recurrent autoimmune disease usually requires an increase in immunosuppression in order to attenuate the survival and/or function of autoreactive lymphocytes.

Increased alloreactivity as a result of cross-reactive autoreactive T cells or autoantibody

Underlying autoimmunity may impact alloreactivity through three distinct mechanisms. First, patients with pre-existing autoimmunity often possess effector/memory T cells and/or antibodies specific for autoantigens, which can recognize these antigens in the context of donor tissue and thus mediate destruction of the graft. For example, the presence of circulating autoantibodies specific for glomerular antigens can directly result in kidney transplant damage in patients with IgA nephropathy and Goodpasture's disease [96,97]. Furthermore, it is well known that type I diabetic recipients of islet allografts possess memory, and perhaps even activated effector, T cells directed against β cell antigens that persist after the autoimmune response that resulted in destruction of the β cells has subsided. Given the existence of very well-characterized murine models of type 1 diabetes, extensive work has been done to explore the effect of pre-existent β cell-specific T-cell responses on islet allograft survival in diabetic recipients and responsiveness to various immunosuppressive regimens. For example, in NOD mice that spontaneously develop type 1 diabetes through the peripheral activation of β cell antigen-specific T cells, early treatment with either CTLA-4 Ig [100], anti-CD154 [101], or anti-LFA-1 [102] prevents the onset of insulitis and overt diabetes. However, delaying treatment until after disease has been established (>9–10 weeks of age in most studies), does not inhibit the disease process [100,101]. Therefore, these results suggest that therapies that have efficacy in inhibiting the generation of de novo antigen-specific T-cell responses may prolong islet allo- or xenograft survival in non-autoimmune recipients, but may do little to attenuate pre-existing β-cell-specific T-cell responses in type 1 diabetic recipients.

In this regard, patients with pre-existing autoimmunity may behave as presensitized patients in that these effector/memory T cells and organ-specific antibody that cross-react with alloantigen may make them more refractory to immunosuppression. This point raises interesting questions about the importance of MHC matching in transplant recipients with pre-existing autoimmunity, in that close MHC matching may raise the likelihood of recurrent autoimmunity due to the increased probability of pre-existing autoreactive T-cell populations recognizing autoantigens in the context of well-matched allogeneic MHC. In contrast, MHC discordant grafts, and to a greater extent xenografts, may be far less susceptible to recurrent autoimmunity due to the decreased likelihood of autoreactive TCR recognition of autoantigens in discordant MHC molecules.

Second, the presence of an inflammatory state initiated by the underlying autoimmunity can potentiate the generation of a more aggressive alloimmune response following transplantation. For example, the presence of TLR ligation and DC activation from antinuclear antibodies in patients with lupus nephritis and IgA nephropathy can potentiate the de novo alloimmune response in these recipients [96,97]. Furthermore, perivascular complement deposition resulting from these pre-existing autoimmune conditions can also facilitate the development of antibody-mediated rejection following renal transplantation [96,97].

Third, genetic factors resulting in the propensity to develop autoimmunity may also render a given transplant recipient more likely to develop aggressive alloimmunity. This is best appreciated in studies of mouse models, where strains of mice that are genetically predisposed to develop autoimmunity, including SJL and C57BL/6 (which develop experimental autoimmune encephalomyelitis), and NOD (which develop type I diabetes) also exhibit more aggressive alloimmune responses and are less susceptible to many therapeutic interventions [103]. In sum, the mechanisms underlying the observed increased incidence of allograft rejection in autoimmune recipients are likely multifactorial. Dissecting the contributions of each of the above mechanisms to the observed increase in clinical rejection in this patient population remains an important goal.

Therapeutic interventions targeting alloreactive and autoreactive T-cell memory

No matter which of the above mechanisms graft-specific memory T cells arise through, these cells are likely to negatively impact long-term allograft survival due to their reduced threshold for activation. For example, studies using either standard calcineurin inhibitor-based immunosuppression [41] or an experimental tolerance induction regimen [104] have observed direct correlation between donor-reactive memory T-cell precursor frequency (measured by IFN-γ production following short ex vivo restimulation) and increased risk of acute rejection. However, in vitro analysis of alloreactive memory T-cell responses revealed a strong inhibitory effect of tacrolimus on alloreactive memory T-cell proliferation [105]. Given the known toxicities associated with the use of calcineurin inhibition [106], identification and therapeutic targeting of alternate pathways to inhibit alloreactive memory T-cell recall responses is an important area of investigation. In addition, it is now well-appreciated that memory $CD8^+$ T cells largely resistant to the effects of CD28 costimulation blockade, a fact that may in part underlie the increased incidence and severity of acute rejection episodes observed in patients treated with the CD28 blocker belatacept [107] versus cyclosporine in Phase II and Phase III clinical trials [108–110].

Several additional pathways have been identified in experimental systems as being important for alloreactive memory T-cell responses (Figure 9.5) (see Chapter 18). For example, Vu et al. demonstrated in a murine transplant system that blockade of OX40, but not ICOS, CD70, or 41BB synergized with CD28/CD40 blockade to memory T-cell-mediated graft rejection [111]. However, other studies have found that anti-CD70 could inhibit rejection mediated by memory cells in mice lacking lymph nodes [112]. In addition, blockade of the inducible costimulatory molecule (ICOS, CD278) has been shown to effectively inhibit the effector functions of graft-infiltrating memory T cells [113].

Another potential strategy to limit the pathogenicity of memory T cells might be to block their ability traffic into transplanted tissue. Studies have shown that antagonism of LFA-1 and VLA-4, both of which are integrins that facilitate leukocyte entry into inflamed

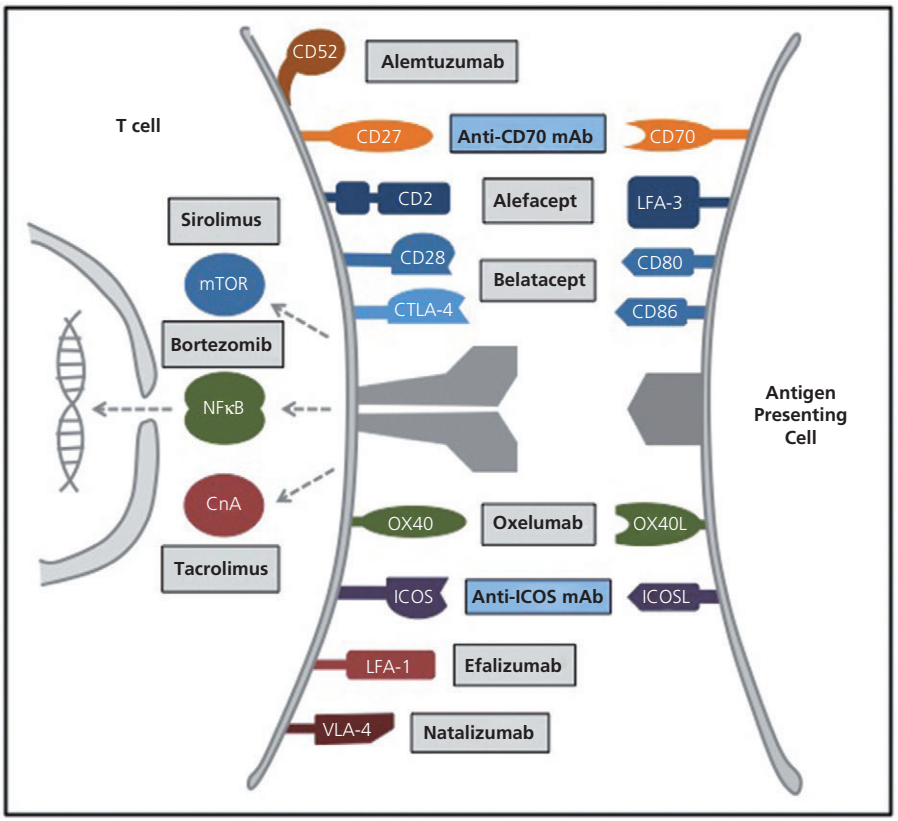

Figure 9.5. Current and experimental therapeutic targets for inhibition of alloreactive memory T-cell responses. Given the fact that donor-reactive memory T cells can arise via prior sensitization, heterologous immunity, and autoimmunity, therapeutics are being developed to specifically target alloreactive memory T cells. These include: alemtuzumab, anti-CD52 monoclonal antibody; alefacept, LFA-3 Ig fusion protein; anti-OX40L mAb, anti-OX40 ligand monoclonal antibody; oxelumab, anti-OX40 monoclonal antibody; efalizumab, anti-LFA-1 monoclonal antibody; natalizumab, anti-VLA-4 monoclonal antibody; bortezomib, protease inhibitor; sirolimus, mammalian target of rapamycin (mTOR) pathway inhibitor; and tacrolimus, calcineurin A (CnA)-NFAT pathway inhibitor. tissues, inhibited infiltration of memory T cells into donor tissue and synergized with costimulation blockade in inhibiting memory T-cell-mediated graft rejection in experimental models [114,115]. Furthermore, Kirk and colleagues reported that targeting the CD2/LFA-3 adhesion pathway abrogated the ability of $CD2^{hi}$ Tem cells to mediate CD28 costimulation blockade-resistant rejection. Finally, memory T cells may be at least partially susceptible to the effects of regulatory T cells, especially when their ability to induce neutrophil migration into allografts is simultaneously blocked [116,117].

Summary

In sum, the immune history of a given transplant recipient profoundly influences the quantity and quality of pretransplant alloimmunity and in many cases has a direct impact on graft survival. Identification and quantification of immunologic parameters underlying the relative strength of alloimmunity in a given transplant recipient may allow tailored immunosuppression in order to minimize infectious complications and maximize overall patient health following transplantation.

CHAPTER 10

Fundamental Concepts Regarding Graft Injury and Regeneration: Tissue Injury, Tissue Quality, and Recipient Factors

Chatchai Kreepala, Konrad S. Famulski, and Philip F. Halloran
Alberta Transplant Applied Genomics Centre, Department of Medicine, Division of Nephrology and Transplant Immunology, University of Alberta, Edmonton, AB, Canada

Introduction and definitions

> Who has seen the wind? Neither you nor I but when the trees bow down their heads, the wind is passing by.
>
> *Christina Rossetti, 1830–1894*

Injury is like the wind. We perceive it by its effects: dysfunction, inflammation, histologic changes, and molecular changes of the "injury-repair response". These are manifestations of the response to wounding in the tissue, rather than direct consequences of the injurious agent. The concept is that each tissue has a programmed injury-repair response that is its own variant of wound healing, highly organized and stereotyped. The extent of this response tells us whether injury has occurred recently. Most of the dysfunction is due to the dedifferentiation of the tissue that is necessary for the repair of injury: it is difficult to repair a machine while it is working. The key teaching points in this chapter are outlined in Table 10.1.

We reviewed the problem of delayed graft function (DGF) more than a decade ago [1] and will concentrate on new knowledge since that time. In the interim, donor aging/tissue quality and recipient aging and co-morbidities have emerged as progressively more serious concerns, and use of donation after cardiac death (DCD) donors have introduced a new level of acute injury. However, improved cross-matching and recognition of early antibody-mediated rejection (ABMR) [2] has largely eliminated the influence of undetected sensitization and immunologically mediated DGF, except when the decision is taken to transplant positive cross-match organs (Table 10.2). The consequences and clinical approaches to alloantibody sensitization are dealt with specifically in Chapters 68 and 89. This leaves a triad to consider: acute injury, tissue aging, and recipient factors. The present chapter focuses on this triad, in the context of kidney transplants, but the principles are relevant to all transplants. The kidney has proven to facilitate our understanding of acute injury and recovery given the ready availability of functional markers (e.g. creatinine), its accessibility for biopsy, and the availability of a support system (dialysis) to allow patient survival during periods of severe dysfunction and ultimate recovery.

Acute kidney injury (AKI) per se can induce irreversible changes (particularly when it is severe and leads to infarction) but usually has relatively little impact on long-term graft survival once it recovers. Biopsy studies have shown that late graft loss is primarily due to recipient death and to kidney failure from diseases that develop post-transplant: ABMR, rejection from non-adherence, recurrence of primary diseases, BK, etc [3]. Thus AKI that recovers to normal function is usually not a risk factor for late graft loss, once covariates such as donor aging and recipient co-morbidity/aging are considered [4,5]. For example, among potential standard criteria donors (SCD), elevated donor terminal creatinine is not a risk factor for late graft loss [6]. Similarly, prolonged cold ischemia time (CIT) increases the rate of DGF, but has no effect on long-term outcomes after adjusting for covariates [7]. Even among extended criteria donor (ECD) kidney transplants, there is little or no effect of cold ischemic time on late graft survival [8].

Brain injury and brain death place stress on all tissues, including severe hemodynamic and endocrine-metabolic disturbances in the donation after brain death (DBD) and perhaps hormones and other factors are released into the circulation by severe brain injury [9]. Brain death leads to an initial hyperdynamic stage from the Cushing reflex—a response to hypothalamus ischemia, causing an increase in sympathetic outflow that results in increased systolic blood pressure, widening pulse pressure, and bradycardia. This hyperdynamic response would present in a short period, due to catecholamine effects increasing systemic vascular resistance, and functionally reduces left ventricular output followed by impaired cardiac performance and multiple organ dysfunction [10]. In addition, there would be alteration of the hypothalamic–pituitary–adrenal axis, resulting in the depletion of antidiuretic hormone (ADH), cortisol, and thyroid hormone. Inadequate ADH production can cause central diabetes insipidus, resulting in hypotonic polyuria (urine volume >3 L/day or >5 mL/kg/h) [11] and hypernatremia (serum sodium >145 mEq/L with plasma osmolality >295 mosmol/kg) [11]. Evidence suggesting adrenal insufficiency with low baseline cortisol levels and improper response to ACTH stimulation is common following brain death. In addition, "euthyroid sick syndrome" (low free T3 but normal TSH) can also be found after brain death. In an attempt to counteract all of the effects described above, administration of triple therapy with desmopressin (or vasopressin), methylprednisolone, and a single dose of

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Table 10.1. Key points on acute injury, tissue quality/aging and recipient aging/co-morbidity: the DGF triad and the ECD paradox

1 "DGF ≠ AKI": Early graft dysfunction as observed clinically is a complex differential diagnosis, including infarction, technical problems, and ABMR
2 AKI
- recovery following AKI is usual, with few late consequences; however, occasionally, adequate function is not recovered if AKI is severe
- AKI triggers a complex injury-repair program ("wound healing") with parenchymal, stromal, microcirculation, and inflammatory cell components, involving many thousands of molecular changes
- Inflammation in AKI is inherent in wound healing and probably does not "extend" injury
- AKI probably does not increase immunogenicity and rejection of MHC mismatched tissue

3 Quality/aging
- Older brain dead donor organs are often "older" than their age suggests due to age-related disease, e.g. hypertension
- Older organs are smaller (loss of mass) and the remaining elements are "old": fragile, with impaired repair ability

4 Recipient age is a powerful factor that is underestimated because co-morbidities (e.g. left ventricular dysfunction) are hard to capture
5 The ECD paradox: tissue aging/quality and recipient aging/co-morbidity interact
- The outcomes of ECD kidneys are heavily influenced by the practice of allocating them to high-risk recipient. The understandable practice of allocating only low-risk organs to young persons with no co-morbidities means that high-risk organs are intrinsically linked to high-risk recipients, making risks difficult to dissociate, i.e. some apparent donor risks are actually recipient risks

6 Graft survival is not programmed by early function once organs establish function. Most kidney failures are now due to diseases: antibody-mediated rejection, rejection from non-adherence, recurrent disease, and miscellaneous diseases (BK, PTLD, etc.)
7 Animal models are misleading and must be regarded as an unreliable basis for conclusions
8 Registry analyses are useful but their inherent limitations must be borne in mind

Table 10.2. Delayed graft function: biological variables, outcomes and potential interventions

Biological variables	Early phenotypes	Late function e.g. 1-year GFR	Late deterioration of function and progression to failure (mostly due to recipient death or post-transplant diseases (ABMR, rejection from non-adherence, recurrent disease, BK, PTLD, etc.)	Potential interventions
Kidney quality (age, hypertension, diabetes, etc.)	"DGF" "SGF" Histologic	Reduced late function	Not usually progressive loss of function	Selection; allocation
Recipient age, co-morbidities, LVEF	Imaging changes Molecular AKI signal in biopsies	Patient survival Graft survival Not typically loss of function except during intercurrent recipient illnesses	Not usually progressive loss of function	Selection; allocation
AKI: brain death hypotension organ removal preservation implantation post implantation		AKI per se may cause permanent loss of nephrons that fail to recover	No progressive loss of function	Prevent AKI; manage AKI to permit and optimize recovery; no current treatment

either triiodothyronine or levothyroxine has been advocated to help promote hemodynamic stability in deceased donors. This has been claimed to be useful in cases of cardiovascular instability with adequate volume status and where high doses of vasoactive agents are used [12]. However, convincing evidence of benefit from such therapies is lacking [12–14].

Brain injury can damage the kidney by circulatory disturbances (ischemia) and possibly by humoral factors such as cytokines, but whether such cytokines can cause renal endothelial or parenchymal injury is not proven. Brain injury induces an inflammatory response, perhaps mediated through NF-κB activation, leading to IL-6 production in glial cell with subsequent release of IL-6 into the systemic circulation. Mitogen-activated protein kinases (MAP kinases) are likely involved in the process of the systemic inflammatory signal, leading to the local changes in the kidneys that resemble the acute-phase response [9,15]

Post-operative vasospasm due to arterial manipulation and hypotension due to under-filling, third spacing, and poor left ventricular performance all contribute to kidney ischemic injury, although they are difficult to capture in databases. Thus the donated kidney brings with it injuries and stresses that begin at brain death but continue post-operatively. Moreover, some measures taken to protect other organs—volume depletion to protect the heart and prevent pulmonary edema—may adversely affect the kidney. Ultimately many influences converge to create tissue injury, which is likely more complex than simply oxygen deprivation (hypoxia) and hypoperfusion (ischemia).

One of the challenges of organ transplantation is the necessity of evaluating and transplanting tissue that has been subjected to both chronic injury (e.g. aging and diseases) and acute injury into older recipients with co-morbidities, and supporting it during the injury-repair period to obtain a favorable outcome. This creates the **ECD paradox**: the clinical necessity of avoiding allocation of older organs into young person, plus the rising unmet need for organs in older people on waiting lists, links acute injury, donor and recipient aging, and co-morbidity together. Moreover, these three problems may interact in synergy rather than simple addition: the older recipient with poor left ventricular ejection fraction has difficulty perfusing the transplant kidney with high resistance due to aging and AKI. New understanding and reliable tests for predicting

post-operative organ performance in relationship to biologic donor aging/tissue quality are needed: demographic factors and biopsy histology correlate with post-operative course but actually have poor predictive value [16–20].

Definitions

Acute kidney injury (AKI) is defined here as the phenotypic changes induced by stresses such as ischemia or toxins, including the molecular changes reflecting the response to injury (wound healing). AKI manifests as dysfunction, but there are other causes of dysfunction, including some pure vasomotor states that do not induce parenchymal damage, for example the effect of ACE inhibitors and vasoconstrictor effects of calcineurin inhibitors (CNIs). According to the definition used here, AKI implies reversible injury. More extreme forms of ischemia can induce infarction: patchy cortical necrosis, complete cortical necrosis, or global infarction. As it is used here, AKI specifically excludes such conditions, which are nevertheless in the differential diagnosis, along with disruption of the arterial and venous anastomoses, renal artery stenosis, ureteric obstruction, etc.

The injury-repair response: the transcript changes in the tissue induced by injury are a response of the tissue. The injury-repair response is a state in the tissue best assessed by molecular examination of **biopsies** (molecular assessments) [21,22] but which can be inferred by **biomarkers** in urine or blood, at least some of which are products of the genes induced by injury in the kidney. Many biomarkers for transplants are derived from those used in native kidney AKI, but they need to be validated and calibrated in the transplant setting.

The strategies of the injury-repair response are:

1 stabilize the site to protect the host;
2 restore the tissue to its previous state if possible;
3 achieve the best possible stable state (e.g. atrophy–fibrosis) if it is impossible to restore the previous state;
4 activate inflammation/innate immunity for host defense and repair.

Delayed graft function (DGF) is defined as any observed serious impairment in function of the kidney initially after transplantation from any cause. The causes of DGF include anastomosis problems, cortical necrosis, ureteric obstruction, and antibody-mediated rejection, as well as AKI. Thus, *DGF is not synonymous with AKI*. A typical convention in registry analyses is to define DGF as any dialysis in the first week because these data are easily collected by registries, but the clinical definition is more comprehensive. DGF can be defined clinically by many functional assessments: urine output, GFR assessments, imaging, or dialysis dependency. Remember that some recipients have underlying residual native kidney function and are dialysis independent, and thus may not meet dialysis dependency definitions for DGF, even if the transplant has no function.

Slow graft function (SGF) is defined as a significant degree of early dysfunction from any cause that fails to meet DGF criteria. SGF has most of the same correlates as DGF, and usually reflects AKI and displays a typical injury-repair response, albeit milder than that seen in dialysis-dependent kidneys [1]. Patients have urine output but allograft function is impaired without requirement for dialysis. Serum creatinine may rise then slowly decrease, reflecting the lack of a steady state, in the first week after transplantation [23]. Some useful definitions for analysis include serum creatinine >3 mg/dL at day 5 or 7 after transplantation [23]; or serum creatinine of the recipient decreasing less than 70% on day 7 after transplantation (compared to the predialysis level before transplantation) [24]. However, dialysis independence is part of all definitions of SGF, but the decision to dialyze is to some extent arbitrary.

Actually, function is a continuum and dichotomizing continuous data is not a good idea, because this loses information. DGF is a continuum with SGF, and every kidney transplanted has some degree of injury, as we showed in functioning mouse kidney isografts from live donors [22]. Thus interventions that convert DGF to SGF (e.g. pulsatile perfusion) may not represent any major change in the state of the transplanted tissue [1].

Primary non-function (PNF) is defined as failure to ever achieve enough allograft function to avoid dialysis. It is thus a retrospective diagnosis, and should be broken down to indicate whether the etiology is ABMR, surgical complications, or simply failure to recover from apparent AKI, often after 3 months of observation [25]. When investigators describe DGF, it is important to know whether they are including PNF, and if not how they are excluding it.

Graft ischemic time describes the time between organ cooling or vascular clamping and the time of vascular clamp release during implantation procedures. It can be divided into three periods: **warm ischemia time (WIT); cold ischemia time (CIT); and anastomosis time**. WIT refers to the time from asystole (in cases of donation after cardiac death; see below), or from the time of cross-clamping of the renal artery (in cases of living donation or donation after brain death) until cold organ preservation. CIT refers to the time from when the organ is cooled with preservation solution (after organ procurement) to the release of the vascular clamp of anastomosis [26]. It is also useful to record the time taken for the vascular anastomosis, which when accurately recorded is a powerful predictor of DGF [27].

Extended criteria donor (ECD) and the ECD paradox: ECD, as defined by the Scientific Registry 3 of Transplant Recipients, are deceased donors older than 60 years or donors aged 50 to 59 with at *least two* of the three following criteria: (1) serum creatinine >1.5 mg/dL prior to transplantation, (2) history of hypertension, (3) brain death due to cerebrovascular causes [28]. Kidneys with good characteristics, not fulfilling the definition of ECD, are called **standard criteria donor (SCD)** kidneys.

ECD kidneys were found to have >1.7 times more risk of graft loss than SCD kidneys [28], but this was partly due to the recipient co-morbidities and the ECD paradox (the policy of allocating ECD kidneys into high-risk older recipients). Because recipient co-morbidities are difficult to capture in databases (e.g. left ventricular dysfunction), the ECD paradox overestimates the impact of ECD donor issues and underestimates older-recipient issues.

Marginal donor kidney (MDK): the term MDK not only describes donor tissue quality, as in ECD, but also includes clinical injury variables in its definition. In general, MDK means kidneys with one or more of the following pretransplant factors: donor age >55 years, donor history of hypertension/diabetes longer than 10 years' duration, donation after cardiac death (DCD), or cold ischemia time longer than 36 hours [29]. However, some have considered the risk of transmitting infectious disease and/or malignancy, the histology on biopsy (glomerulosclerosis and interstitial fibrosis), and pretransplant renal function as the criteria for MDK [28]. In this way, MDK can describe both living and deceased donors, whereas ECD only applies to deceased donors [30]. An organ not fulfilling the criteria for MDK is referred to as an **ideal donor kidney (IDK)** or optimal donor kidney.

Thus, the definition of ECD is based on age and age-related co-morbidity, while MDK includes other risks. We will confine our comments here to ECD. Additional clinical considerations of ECD donations can be found in Chapter 53.

Donation after cardiac death (DCD) or **non-heart-beating donor (NHBD):** DCD refers to donation after pronounced irreversible circulatory arrest, which results in prolonged warm ischemia and damage to the organs. In contrast to a deceased donor who has been pronounced brain dead and the heart is still beating (**donation after brain death; DBD**), DCD places more stress on the procured organs.

Five categories of DCD donors were proposed by the International Workshop on DCD Donation in Maastricht [31]:

I dead/cardiac arrest outside the hospital;
II dead (outside the hospital) after resuscitation attempted without success;
III awaiting cardiac arrest (situation after brain death in which active care, particularly inotropic drugs or ventilator, was discontinued);
IV cardiac arrest while brain dead (situation of cardiac arrest during the process of brain death declaration or just before organ retrieval);
V unexpected cardiac arrest in a hospital inpatient.

Another clinical classification based on the timing of circulatory death is simplified for use in

the general practice. They are classified into "uncontrolled DCD donors" and "controlled DCD donors". The **uncontrolled DCD** refers to a donor who died suddenly and unexpectedly before or during transfer to hospital, or unsuccessful cardiovascular resuscitation for a hospital inpatient. This corresponds to donors in categories I, II, or V of the Maastricht classification. Meanwhile, **the controlled DCD** corresponds to donor in category III or IV of the Maastricht classification, which refers to donors who underwent imminent cardiac death due to termination of active care, cardiac arrest during the process of brain death declaration, or immediately prior to organ retrieval in the operating room [32]. The uncontrolled DCD have uncertain time of brain and cardiac death, and they would have longer WIT. On the other hand, the controlled DCD have potentially shorter WIT and experience lower rates of DGF and PNF [32].

Outcomes of transplantation of DCD kidneys have been evaluated for short- and long-term graft function compared to DBD kidneys. The results concluded that the incidence of DGF is significantly higher in DCD (40–80%) [33–36] when compared to DBD kidneys (17–39%) [33–36]; also the incidence of PNF is as high as 15–25% in DCD kidneys [37], while it has been reported that DBD kidneys experience PNF with an incidence of 2–6% [34,38]. However, the long-term graft function (1 and 5 years), slope of GFR decline, and percentage of graft survival are similar in DCD and DBD kidneys [33–36]. This indicates that sublethally injured organs in DCD can recover and achieve function as well as DBD kidneys.

The main concern in DCD kidney results is PNF or severely compromised long-term function due to various degrees of infarction, from focal cortical necrosis to global infarction. The clinical decisions in the use of DCD kidneys, particularly category I and II, would be helped by tests to identify irreversibly injured organs, because changes such as infarction take time to be manifest. Proposed viability tests include enzymatic indicators of proximal tubular cells such as glutathione-S-transferase (GST), which is markedly higher in DCD kidneys that will never function. However, whether such tests are valid for DCD is unclear, because the injury in DCD is so proximal to organ removal that the injury changes do not have time to appear. (See Section Are AKI biomarkers useful in the clinic?). Additional discussions of DCD donations can be found in Chapters 22.

Population lessons—causes and consequences of delayed graft function

DGF represents a complex interaction between acute injury, pre-existing aging, and recipient aging, including the ECD paradox. This complexity cannot be studied in experimental animals, because aging involves different processes in those species compared to human tissue. In general, the understanding of transplant AKI benefits from the available population studies, from native kidney AKI and aging studies, and from experimental models, provided the interpretation is very conservative and the limitations are acknowledged [39,40]. Compared to these early studies, contemporary data places increasing emphasis on donor and recipient aging and on the use of ECD.

The injury-repair response following ischemia in the transplant and native kidney are similar. One example in support of this is the common kidney injury biomarker findings in both disease states [41,42] (see Section Are the AKI biomarkers useful in the clinic?). However, the injury-repair response in kidney transplants may be altered by tissue perseveration/handling (e.g. hypothermic storage, preservation solution, and pulsatile machine perfusion) as well as by composite risk of donor and recipient factors.

Many features of the associations of DGF in renal transplantation were established before 1990. Hypothermic storage at 0 to 4 °C is still used to decrease tissue metabolic rate during the ischemic process. However, hypothermic techniques require use of preservation solutions to protect organs against ischemic injury. Preservation solutions have been developed based on biologic changes of ischemia and aim to:

1 prevent cellular edema by minimizing the osmotic gradients between extracellular and intracellular compartments [43];
2 delayed cell destruction by providing oxygen free radical scavengers and buffers to maintain physiologic pH [43];
3 maximize organ function by using the correct potassium (K^+) concentration to prevent cellular depolarization and diminished cellular ATP due to high concentration of extracellular K^+ [44,45]. This led to the development of solutions such as UW (University of Wisconsin) solution and HTK (histidine, tryptophan, and ketoglutarate). However, studies comparing the use of UW and HTK have failed to show a difference in graft or patient survival between the solutions [46].

Pulsatile machine perfusion reduces observed DGF compared with cold storage but has little effect on survival [47]. Long-term differences in survival reported in some studies may be due to accidental imbalance in covariates [48].

The relationships among injury, inflammation, DGF, and outcomes are complex. Injury induces inflammatory changes, which may simulate T-cell-mediated rejection (TCMR) and can be misinterpreted [49]. Thus AKI can produce tubulitis, interstitial inflammation, and probably endothelial lesions ("v-lesions") [49]. While immunologic factors played a role in the past due to poor cross-matching [50], such factors are only important now when a choice is made to deliberately transplant across a positive cross-match. The recognition of early ABMR in sensitized renal transplant recipients

as a syndrome distinct from TCMR and from AKI [51], and advances in cross-matching have largely eliminated DGF due to undiagnosed ABMR. DGF due to immune factors or tissue quality (older donors) has associations with reduced long-term outcomes, whereas pure AKI does not, for example CIT [1]. For example, studies of paired kidneys from one donor reveal that both kidneys generally perform badly when either has DGF, emphasizing the importance of donor-related factors, rather than the DGF phenotype per se [52].

The DGF phenotype has long-term associations with reduced late graft and patient survival but associations must not be interpreted as "consequences" [53]. Observed early dysfunction (DGF or SGF) [54] includes many adverse covariates that give strong correlations with late graft and patient survival but are not consequences of the DGF or SGF, for example the ECD paradox. These associations complicate the assumption that interventions that improve early function will affect late outcomes [53]: an increase in GFR from 5 to 10 may mean that the definition of DGF is not met but this is actually not a major change in the injury state of the parenchyma, and does nothing to alter the recipient's risks due to the ECD paradox.

Independent of covariates impacting tissue quality and recipient health, DGF has no long-term impact once the kidney recovers [4,5]. CIT is a case in point. Multivariate analysis of factors affecting functional graft survival suggested that even though CIT is a powerful risk factor for DGF, it was not an independent risk factor for graft survival [7]. Analysis of a paired DBD kidney cohort, derived from the national Scientific Registry of Transplant Recipients between 2000 and 2009, suggested that paired donor transplant graft survival, with and without DGF, was similar. These results suggest that DGF, specifically induced by prolonged CIT, has limited effect on long-term outcomes [7]. Lesson from other paired kidney analyses revealed many recipient characteristics were associated with DGF: recipient sex (male), African-American race, obesity, diabetes, HLA mismatch, and duration on waiting lists, as well as panel reactive antibody (more than 10%).

While clinicians hope that better management of modifiable recipient and transplant risk factors, such as obesity, waiting time, and CIT, will reduce the occurrence of DGF, the effects of interventions are often disappointing. For example, waiting time may reflect co-morbidity (e.g. ischemic heart disease) that is not reduced by simply reducing the time [55]. Perfusion should provide benefits over cold storage, but its impact on observed early, reversible graft dysfunction is rather limited and not accompanied by improvement in late survival or function [56,57].

AKI probably does not program late graft deterioration

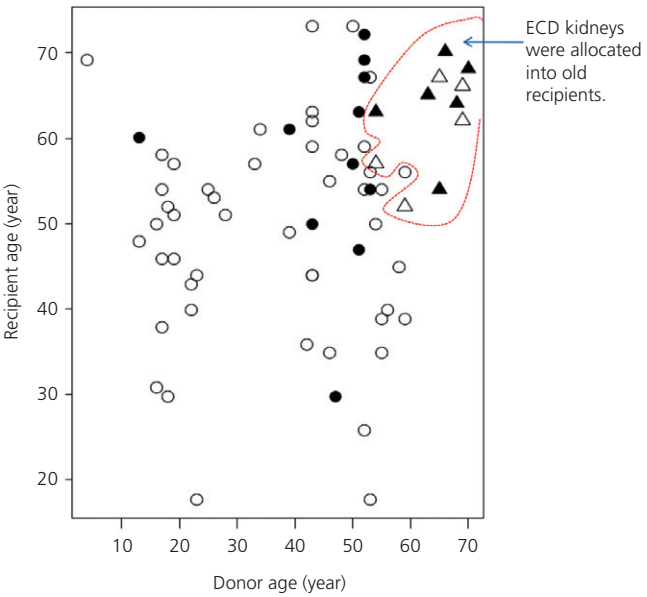
The causes of late graft loss are now better understood due to the use of prospective biopsy studies since 2005. The main causes of late graft loss in kidneys that are biopsied for clinical indications are ABMR (sometimes complicated by non-adherence) and recurrent disease, with smaller numbers being due to polyoma virus nephropathy and other causes [3,58,59]. In other words, late deterioration is due to diseases, not mysterious fibrosis [60]. The finding of atrophy–fibrosis without a disease is common because disease diagnoses are easily missed in kidneys with extensive atrophy–fibrosis, but this does not imply a primary fibrosis process.

Role of the interaction of donor age with recipient age and the ECD paradox

Donor and recipient age may act together to affect renal allograft survival: risk of late allograft failure increases via an interaction between donor and recipient age. Donor aging is undoubtedly important: kidneys lose cells/tissue elements (e.g. loss of renal mass and function, i.e. nephrons and GFR) [61]. We found that AKI molecules measured in implantation biopsies predict only early function in kidneys (manifested by DGF), but tissue quality/aging affects early and late function [4], influenced by donor age and age-related diseases.

The role of donor tissue aging/quality and of recipient aging/co-morbidities in graft survival is complex [4]. The ECD paradox means that ideal kidneys from young donors are generally allocated to young recipients to maximize utility [62]. Thus older donor age carries a major burden of recipient co-morbidity that cannot be fully captured in registries. The older kidneys, which are most likely to have DGF, are selectively given to the highest-risk recipients (Figure 10.1). The relationships among AKI, donor age, recipient age, and graft survival in population studies [63,64] must be interpreted with caution because of the hard linkage of high-risk kidneys from older donors used as the only solution for many high-risk older recipients with co-morbidities.

Transplant survival was lowest in elderly recipients [65], mainly because of death with a functioning graft, as expected. However, recipients' intercurrent illnesses and ICU admissions are also a risk to the survival of the graft, and may compromise immunosuppressive management. Thus recipient co-morbidities increase not only the risk of patient death but of graft failure during medical illnesses.



Legend; ○ =SCD with early graft function, ● = SCD with graft dysfunction, Δ = ECD with early graft function, ▲ = ECD with graft dysfunction.
SCD - standard criteria donors, ECD - extended criteria donors

Figure 10.1. The ECD paradox. Ideal kidneys from young donors are generally allocated to young recipients. Meanwhile, transplants from older donors allocated into older recipients are at a high risk for early dysfunction. Thus, interpretation of early graft dysfunction (DGF or SGF) is confounded by a relationship between the donor and recipient age.

Graft failure in young recipients who received older-donor kidneys is increased compared to young recipients who received young donor kidneys (relative risk = 1.97; $P = 0.001$) [66], although the reason for this is not clear. Recipients of older-donor kidneys have inferior graft function, which may have a greater negative impact on young recipients (i.e. increased risk of cardiovascular-related morbidity and mortality, because of their longer life expectancies compared to older recipients). Some evidence suggests renal dysfunction is an independent risk for coronary artery disease, congestive heart failure, and hypertension [67–70], although it is not clear whether renal function is an independent risk factor after Framingham risks [71] have been adjusted. However, the decision to give an older kidney to a young recipient may be driven by medical risks in the recipient.

Because transplant recipients have survival and quality-of-life advantages over patients remaining on waiting lists, the organ shortage forces clinicians to transplant from ECDs. Recognizing the detrimental effects of older-donor kidneys on graft survival, preferential allocation of young organs to young recipients is understandable, thereby improving graft and patient survival. The justice, utility, and fairness of such practices are beyond the scope of this chapter. Problems of older-donor tissue and older recipient age are strongly linked and probably interact, for example the high-resistance kidney from an ECD may be poorly perfused in the elderly recipient with reduced left ventricular ejection fraction.

In summary, donor age (particularly that of deceased donors), must be taken into consideration:

1 Young adult kidneys are best for every recipient, young or old. Transplanting "old for old" [72] makes sense to utilize older kidneys but it is not ideal for the older recipient, although it is usually better than dialysis.
2 Older deceased kidneys should be allocated (not discarded), but are not a good solution for young recipients, giving rise to the ECD paradox.
3 The phenotype of aging includes loss of functioning mass and aging changes in the remaining tissue, which could be manifest as fragility ("injurability") and poor repair on injury.

Biology of aging is not linear

The effects of time on human tissue include growth and development and aging. The ideal donor is not an infant but a young adult—hence the U-shaped distribution of risk. Empirically derived equations (e.g. Schold [73] and Kidney Donor Risk Index [KDRI] [74]) that express risk of failure based on kidney characteristics all include donor age but expressed as a complex equation to describe the U-shaped distribution. The complex effects of aging on the graft reflect factors such as graft mass [75], somatic cell senescence [76], vascular resistance, function, vulnerability to injury, and potential for repair. For this discussion, aging is considered to begin when young adults have completed their growth and development.

Experimental models

Lessons and limitations of experimental models

Animal models, both small and large, can be misleading because they do not simulate the risks observed in humans, for example tissue quality/aging and recipient factors. Even the biology of aging and somatic cell senescence is different in small animals compared to humans. Thus interventions that have produced beneficial effects in rat and mouse models of AKI seldom translate into successful human trials.

One strong assumption based on small animal models is that "inflammation" is injurious. In fact inflammation is essential to wound repair. Manipulation of experimental models can be misleading in this regard: many concepts arising from manipulation of experimental animals do not translate into human applications. Although in rats and mice injury sometimes triggers long-term kidney deterioration, this involves processes such as focal glomerulosclerosis that are unique to these models and not relevant to humans. Moreover, contrary to the widespread assumption, it is not proven that injury predisposes to rejection: in most circumstances rejection and injury are additive (see Section Clinical treatment of AKI).

The biology of injury repair at tissue and organ level

The nephron is a worm-like unit, subject to highly sophisticated developmental and homeostatic programs, responses, and regulation, including renal hemodynamics. Autoregulation is the mechanism that maintains the renal plasma flow (RPF) and GFR constant over a wide range of arterial blood pressure, mediated by the interaction of myogenic stretch receptors response and tubuloglomerular feedback [77].

Cessation of movement of columns of fluid caused by interruption of glomerular filtration alters the function of renal primary cilia (another sensor of movement in renal tubules) [78]. Fluid movement through these tubes provides signals to renal epithelial cells to maintain their normal differentiation state. The ability of renal primary cilia to sense fluid flow also has an important role for epithelial differentiation during renal injury and repair. They contain the movement-sensing mechanoreceptor-like proteins (e.g. polycistins), which play an important role in communicating changes in extracellular milieu from cilia to the intracellular environment, leading to the regulation of epithelial cell differentiation, proliferation, migration, and adhesion [78].

Cessation of arterial blood flow causes immediate oxygen deprivation in cells (i.e. hypoxia with accumulation of metabolic products), but also many other effects such as interruption of the movement of columns on fluid inside capillaries and tubules. In the kidney, reduction in arterial blood delivery causes relatively greater ischemia in the outer cortex compared to the inner cortex and medulla. (Thus after relatively severe ischemia a rim of cortical necrosis can result in the outer cortex.) Severe reduction in blood flow causes high-energy phosphate depletion and subsequent failure to maintain physiological ion gradients across the cell membrane. ATP depletion stops ATP-dependent transport pumps, resulting in mitochondrial swelling and outer membrane rupture, with release of cytochrome c and apoptosis-inducing factor (AIF), which is also involved in initiation of apoptosis [79].

After ischemic renal injury, the modes of cell death—necrosis and apoptosis—depend primarily on the severity of the insult and the resistance of the cell type. Necrosis, histologically characterized by loss of membrane integrity, cytoplasmic swelling, and cellular fragmentation, usually occurs after more-severe injury [80]. Apoptosis is characterized by cytoplasmic and nuclear shrinkage [80]. Apoptosis predominates after less-severe injury and leads to the formation of apoptotic bodies that are rapidly cleared by phagocytosis. This process is initiated by signaling from proapoptotic proteins (Bax and Bid) in response to cell stress and/or proapoptotic cytokines [81].

Of the regulatory factors, the proapoptotic transcription factor p53 has been shown to be induced at the mRNA and protein levels. Inhibition of p53 by pifithrin-α suppresses ischemia-induced

apoptosis by inhibiting transcriptional activation of Bax and mitochondrial translocation of p53. However, pifithrin-α is an unlikely candidate for therapeutic consideration in humans because systemic inhibition of p53-dependent apoptosis is likely to promote survival of damaged or mutation-bearing cells in other organ systems [81,82].

Injured renal tubular epithelial cells respond by secreting chemokines (e.g. CXCL1), cytokines (e.g. IL6, IL18), and other inflammatory mediators [83], and express ITGB6, which activates latent TGF-β [84–86] bound to the extracellular matrix. The inflammation in AKI is probably beneficial as a component of wound repair, but is often assumed to be an extension of the injury—often termed "maladaptive" but more appropriately termed "injurious". It actually makes little sense that a tissue that is wounded would automatically increase its wound. It is more appropriate to conceptualize the early inflammatory changes as the activation of innate immune mechanisms in response to wounding—stabilizing the site, clearing debris, and looking for infection. In mouse kidney transplant isografts, macrophages accumulate over the first week [87] and persist in decreasing numbers for many weeks. They have many potential roles, for example removing debris. Effector memory T cells also accumulate in injured tissue, but their role is not clear.

The histological changes associated with AKI are most pronounced in the corticomedullary junction of the kidney. Some morphologic features of ischemic AKI in humans include: (1) proximal tubular regeneration, with loss of brush borders; (2) patchy distal tubular necrosis; (3) regeneration; (4) pigmented (heme) granular casts; (5) Inflammation; and (6) nucleated cells in the vasa recta [88]. Compared to the histology of native kidneys with AKI, transplanted kidneys with AKI are said to have fewer tubular casts, occasional necrosis of complete tubular cross-sections, and less tubular dedifferentiation and regeneration. In addition, there might be more calcium oxalate crystals, and more microcalcification and isometric vacuolization (possibly reflecting calcineurin inhibitor toxicity in some cases). Arteriolar hyalinization and arterial fibrous intimal thickening are increased in older donors and thus are associated with DGF [89], although the chronologic age is probably a stronger association. In general, histologic changes of aging in renal biopsies at implantation correlate with, but do not reliably predict, transplant outcomes. Imaging by ultrasound detects increased echogenicity of cortex and loss of corticomedullary differentiation in kidneys with AKI, probably reflecting edema, but this feature is non-specific [90,91].

In indication biopsies of transplanted kidneys with AKI, there are characteristic AKI transcript changes that correlate with depression of GFR, whereas the tubular changes called "acute tubular injury" by histology do not correlate [21] (see below).

Thus the injury-repair response probably does not cause additional stress on the tissue any more than the inflammation in a wound produces stress on the wounded tissue—it is a component of the program. Renal tubular cells continue to undergo repair, migration, and proliferation, and attempts at cellular and tubule integrity are re-established. The GFR begins to improve as cellular differentiation continues and normal cellular and organ function returns [92]. Some morphologic changes persist into the recovery phase and are not correlated with function, whereas brush border changes and detachment of individual tubular epithelial cells subside as function returns [93,94].

The response to damage in renal cells is integrated by the response of the nephron. The nephron is best conceptualized as having an intelligence system, receiving information and responding with a series of potential responses including:

1. temporary shutdown without a wound repair response, e.g. pure vasomotor dysfunction;
2. temporary shutdown and a wound repair response that brings the unit back to quality standards;
3. permanent shutdown and atrophy–fibrosis and global sclerosis of the glomerulus, possibly with ultimate disappearance.

Figure 10.2 depicts the processes discussed above over time.

Molecular changes in AKI

The injury-repair response of kidney is analogous to wound repair, with epithelial and matrix remodeling being essential to restoring homeostasis. Indeed, the renal regeneration/repair process shares some features with renal carcinoma [81,95–99], including synthesis of extracellular matrix components cell growth and proliferation. (Cancer has been called "the wound that does not heal".) The inflammatory cascades are initiated by mediators such as proinflammatory cytokines, for example, TNF-α, IL-6, and TGF-β [83,100]. The principal elements of this injury-repair response are the dedifferentiation of the parenchyma, appearance of repair and embryonic programs in the parenchyma, remodeling of the matrix and microcirculation, a wave of cell cycling, and inflammation.

Although most dysfunction is due to massive de-differentiation, not cell death, various forms of cell death accompanies this process. Cell death is of several types: apoptotic, autophagic, and necrotic, and it is likely that injury can result in any of these. However, cell death may be more merely a direct than a consequence of injury: it may be part of the injury-repair process and critical for remodeling of damaged tissue elements. Apoptosis is critical in embryonic development programs and may sometimes be a part of the recapitulation of these developmental programs to remodel the tissue after injury [101].

Experimental transplant models: Gene expression profiles associated with the injury of kidney isografts

AKI induced by transplantation can be modeled in rodent kidney isografts, as reviewed [22]. The injury-repair induced transcripts (IRITs) in mouse kidney transplants reflect different types of injury suffered by the isografts (i.e. early, intermediate, and late) [22]. The early IRITs reflected the systemic influences (wounding, anesthetic), and the intermediate and late IRITs represented the local stress changes in the epithelium, reminiscent of ATN injury of a native kidney (Figure 10.3). In allografts, the IRIT expression profile (the early, intermediate, and late IRIT) was initially similar to isografts but diverged later due to TCMR [101].

Transcripts associated with the stress response, kidney development, cell cycle, and ECM processes were enriched in intermediate and late IRIT expression profiles. Transcripts associated with embryonic kidney and ureteric bud development were over-represented in intermediate IRITs, whereas the mesenchyme-associated transcripts were prominent in late IRITs, alongside ECM components and TGFβ1/fibrogenesis-related transcripts.

A detailed inspection of the post-transplant time course of gene expression showed that the isografts displayed a mild but complex active injury-repair response and loss of epithelial features (KT1, KT2), accompanied by inflammatory features (QCATs, GRITs, QCMATs, and AMATs). Similar changes were observed in day 7 ATN (Figure 10.4) [102,103]. Note that the active injury-repair response is accompanied by secondary inflammation, particularly

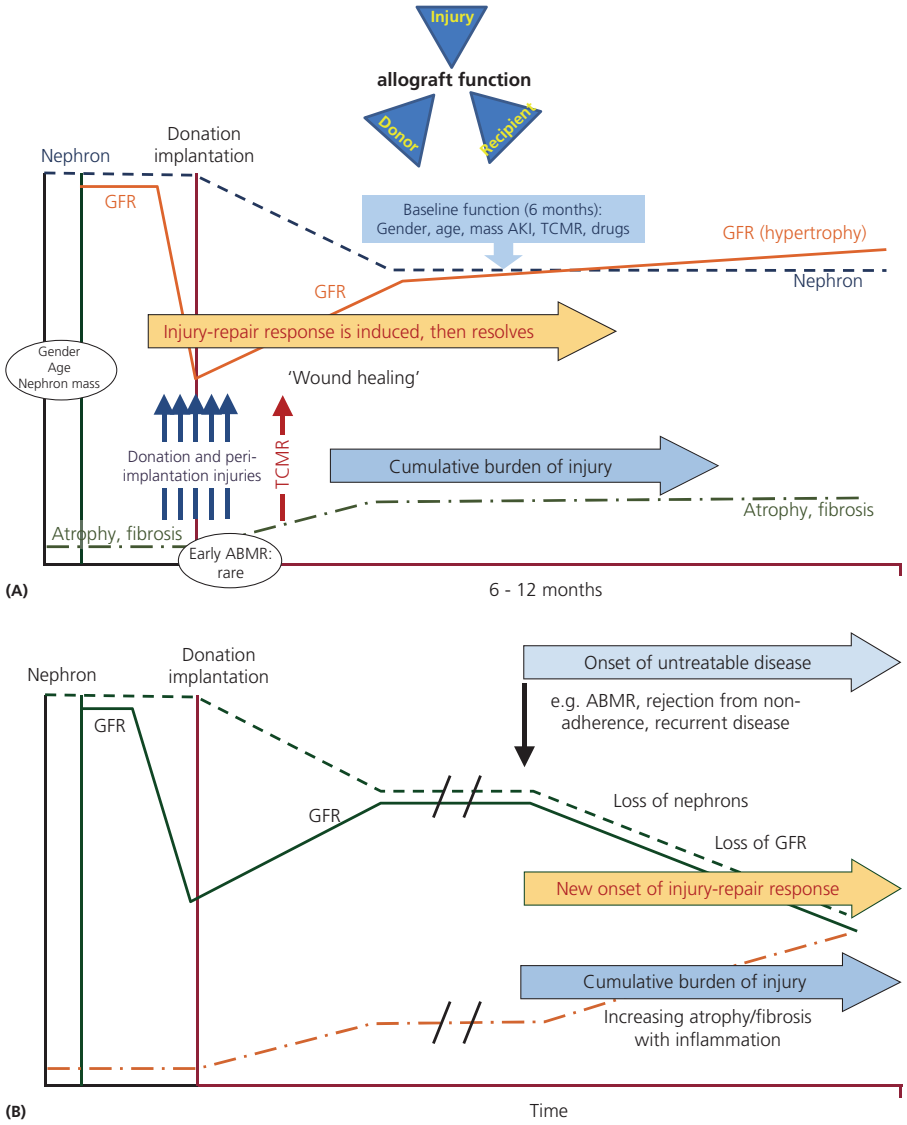


Figure 10.2. Conceptualizing the time course of a kidney transplant. (A) Stresses of the early transplant period induce the injury-repair response. The majority of changes in the kidney transplant reflect the resolution of the injuries associated with donation and implantation, plus damage during AKI, TCMR, and drug toxicity, followed by stabilization. Injury is often followed temporally by the injury-repair response and later nephron loss; the nephron loss is caused by the injury, not by the injury-repair response. The injury-repair response is adaptive and self-limited, like wound healing, and the early injury does not trigger relentless deterioration, but the active injury-repair response will usually leave at least some permanent burden of injury. (B) Despite early injuries, kidney transplants are stable until a disease appears. Kidneys that present with late (>1 year) onset of dysfunction can usually be shown to have a new disease operating. In addition, the issue of non-adherence should always be considered as a condition that must be corrected to prevent graft loss. Late deterioration should never be explained as the result of early remote injury. Atrophy scarring reflects the failure of the efforts of the injury-repair response to restore the damaged tissue to its previous state.

the IFNG effects and macrophage features even in the absence of rejection. However, as the healing process continues, their expression returns toward normal.

Allografts (Figure 10.4) display all the features of isografts, but after day 3 accumulate progressively more T-cell and macrophage transcripts accompanied by an augmented active injury-repair response (intermediate and late), ENDATs, and decreased KTs, coinciding with the emergence of the interstitial infiltrate and then rejection. Importantly, this study demonstrated that the increase in expression of the intermediate and late IRITs in the rejecting allografts with TCMR was independent of T-cell cytotoxic molecules, B cells, or immunoglobulins. Thus the mechanism of TCMR seems to involve triggering of the inherent injury-repair response to the nephron.

Accumulation and activation of monocyte–macrophage–dendritic cell populations (MMDC) is complex and closely related to the extent and type of injury [104]. The MMDC population has a number of potential roles in inflammation, phagocytosis, response to injury, and tissue remodeling [105]. There are two phenotypes of macrophage activation in the injury-repair response. Classical macrophage activation (CMA) is essentially driven by IFNG, whereas the alternative macrophage activation (AMA) is more complex. AMA is usually modeled in vitro by IL4 and IL13 [106] but can also be driven by activin A [105,107]. Each has a role in

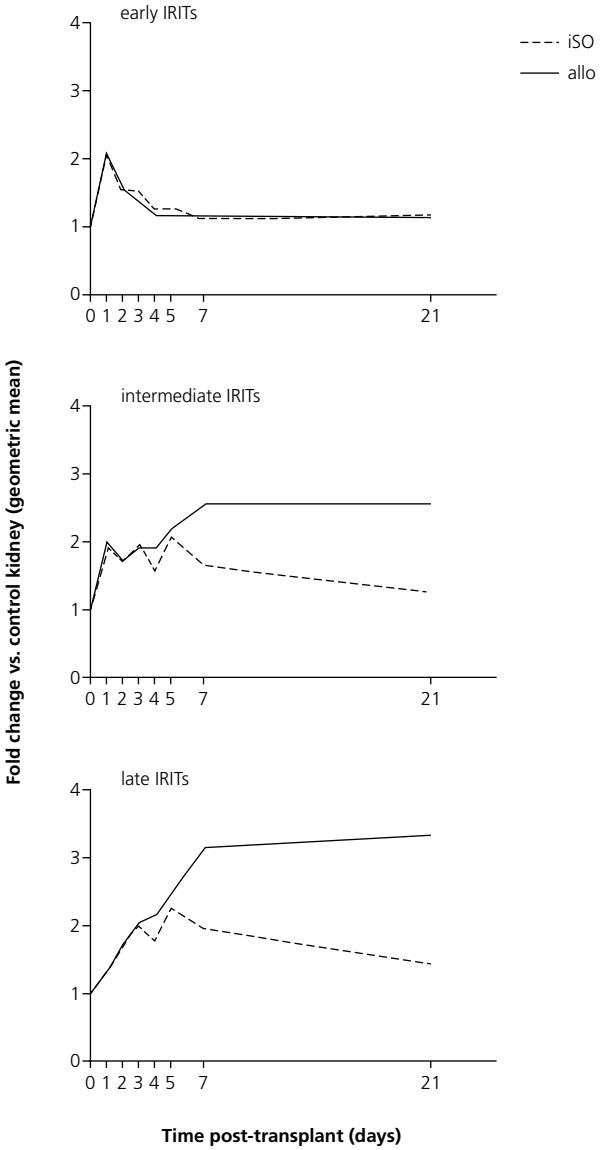

Figure 10.3. The heterogeneity of the injury-repair response in mouse isografts and allografts. Expression time course of injury and repair-induced transcripts (IRITs): early IRITs, intermediate IRITs, and late IRITs. Dashed lines indicate isografts, solid lines indicate allografts. Early IRITs showed transient peak at day 1 and are induced equally in isografts and allografts. They represent the systemic effects of anesthesia and wounding. Intermediate and late IRITs showed a broad peak of expression on days 1–5 in isografts and then decreased. In allografts, expression of intermediate and particularly late IRITs was markedly elevated after day 5 post-transplant. (Reproduced from Famulski et al. 2007 [22], with permission from John Wiley and Sons Ltd.)

the innate response against certain pathogens. There is a strong interest in AMA features because of their relationship to tissue injury [108] and tissue remodeling after injury [109]. In humans, the summarized expression of IFNG effects and alternative macrophage activation is seen in severe AKI to some extent, but it quantitatively characterizes the TCMR, perhaps due to the tissue injury [21].

Molecular changes associated with AKI in human kidney transplants

Post-transplant biopsies

We investigated the relationship of gene expression to kidney function in post-transplant indication biopsies [21], focusing on kidneys with AKI that had biopsies taken early post-transplant (within the first 6 weeks), and excluding those with histological evidence of rejection or specific diseases. These kidneys had poor function (eGFR) at the time of biopsy, but recovered their function after 6 month.

We identified the top 30 candidate genes of the AKI signal (Table 10.3), which represent stereotyped mechanisms in the injury-repair response (response to wounding) such as tissue development and cancer, particularly invasive and metastatic cancers, as well as fibrosis. The AKI signal correlated well with GFR and the AKI phenotype, while the histological changes of AKI had no associations with either kidney function or the phenotype. Thus kidney transplants with an early AKI represent a successful repair of the non-immune injury and their transcripts reflect a snapshot of the active injury-repair response that occurs in recovering kidneys [110].

Surprisingly, the AKI signal is a general feature of injured and diseased renal parenchyma, and thus is detected in transplants biopsied late post-transplant. The injury signal in late transplants was a better predictor of future graft loss than fibrosis, inflammation, or expression of collagen genes. At least 19 individual genes of the AKI signal were predictive of the future graft loss [111]. Thus the acute injury signal, defined in reversible injury, is present in many progressive diseases as a reflection of parenchymal distress. The association of the AKI signal with the risk of failure is dictated by the inducing insult, that is treatable/self-limited versus untreatable and sustained. Thus progression in troubled transplants is primarily a function of ongoing parenchymal injury by disease, not fibrogenesis.

Implantation biopsies

Both the local and systemic responses in the implanted kidneys had an early DGF phenotype. Furthermore, the high incidence of DGF was associated with the expression of genes associated with injury-repair response (IRITs) and inflammation [112].

The AKI signal has a predictive value for DGF in implantation biopsies, as shown in DBD kidneys [113]. The AKI signal score was significantly higher in kidneys with a future poor function compared to kidneys with a good function. Living donor kidneys and control kidneys had the lowest AKI signal scores.

In some reports, detection of inflammation at the time of implantation has been associated with post-transplant clinical outcomes, but inflammation is a feature of older kidneys with patchy scarring. Thus these reports need confirmation to adjust for such factors as ECD donors, high-risk recipients, and the ECD paradox. African-American recipient race, donation after death, increased donor age, acute rejection during the first three transplant months, the degree of HLA mismatching, and increased *CD25* and decreased *BCL2L1* gene expression individually predicted risk for poor graft function (serum creatinine $\geq$2.0 mg/dL) 6 months after transplantation [114]. In one study, high CD3 and low platelet endothelial cell adhesion molecule (PECAM) were associated with worse 2-year allograft function, and high TNF-α predicted worse death-censored and overall 2-year graft survival [4], but, after adjustment for clinical variables, none of the gene expression profiles was associated with distinctive clinical outcomes at 3 or 4 years post-transplantation.

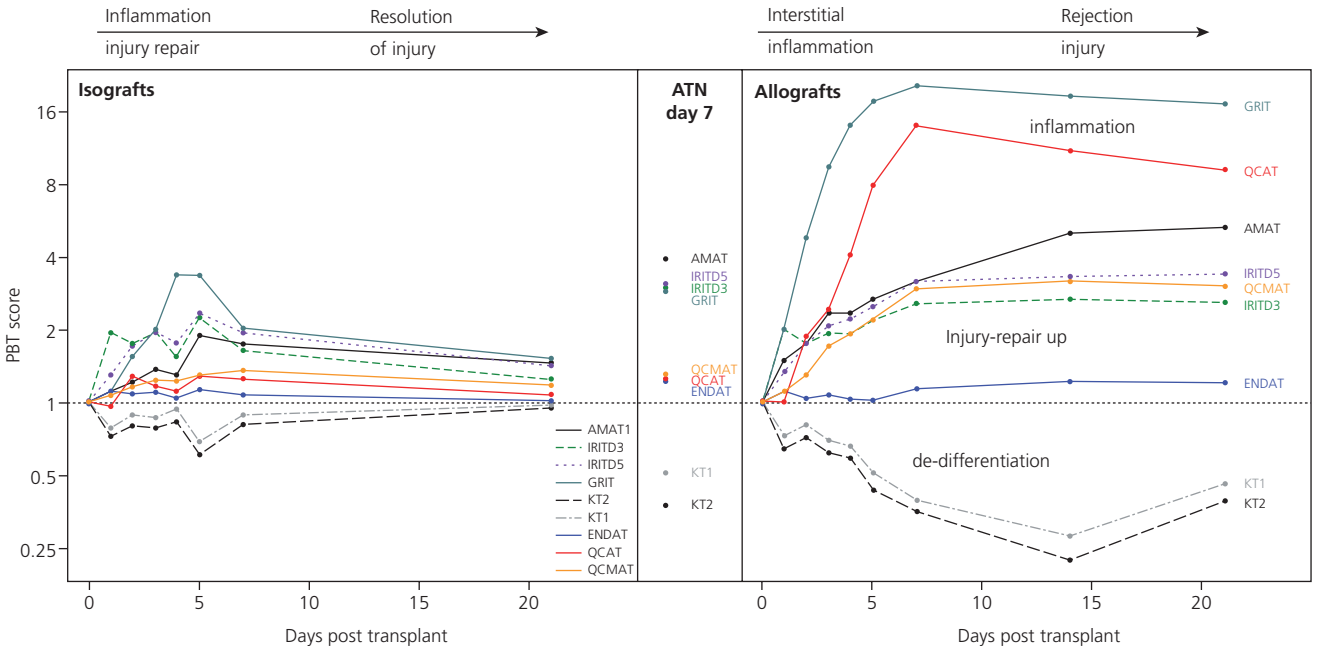

Figure 10.4. Time course of expression of pathogenesis-based transcript sets demonstrates close relationship between inflammation, injury-repair response, and tissue dedifferentiation. T-cell mediated rejection (right) triggers the same injury-repair (AKI) response as seen in isografts (left). When the injury resolves in the isografts, inflammation, injury response, and tissue dedifferentiation abate. However, in the highly inflammatory state (allografts) injury response and tissue dedifferentiation is prominent and continuous. Note that ischemic injury (ATN) demonstrates the injury response similar to that in allografts. AKI–QCAT, burden of effector/effector-memory T cells; AMAT1, alternatively activated macrophages; ENDAT, microcirculation (endothelial cell) response to injury; GRIT, interferon-gamma effects on the tissue and inflammatory cells; IRIT3, injury and repair-induced transcripts during the injury-repair response, peaking at day 3 in mouse isografts (intermediate); IRIT5, injury and repair-induced transcripts during the injury-repair response, peaking at day 5 in mouse isografts (late); KT1, parenchymal transcripts that decrease during the injury-repair response; KT2, solute carrier transcripts that decrease during the injury-repair response. QCMAT, burden of macrophages; (Reproduced from Halloran et al. 2010 [101], with permission from John Wiley and Sons Ltd.)

The belief that pure AKI in transplants leads to poor long-term graft outcomes is not supported by the molecular data. The impaired long-term survival of kidneys with DGF in registry data is not an effect of pure AKI, which is undesirable but inherently reversible.

Some key issues in AKI

Does inflammation increase/extend injury?

There has been a suspicion that inflammatory cells, as part of the injury response in the kidney, contribute to the tissue injury. As a result, many investigators have attempted to manipulate the injury response to mitigate the injury in experimental transplant models. At present, there is no evidence from humans that inflammatory cells create injuries in the minutes, hours, or days after organs have been injured. Just as in any wound-healing site, these cells are present and presumably have been recruited because they have benefits in the healing response. Wound healing is such a major program in multicellular organisms that it is difficult to improve, and apparent phenotype "benefits" from an intervention either may not be reproducible in other models or in the clinic, or are associated with adverse events at another time. However, given the strong interest in inflammatory cells, it seems likely that efforts to manipulate wound healing in the context of an injured organ will continue.

Does injury increase immunogenicity and either TCMR or ABMR?

In models of ischemia–reperfusion injury, AKI induces the proinflammatory compartment [115], which increases MHC expression and thus increases the "antigenicity" of the kidney, but whether this increases allorecognition of MHC "immunogenicity" is doubtful. ABMR can also masquerade as DGF and early AKI. However, AKI and DGF have not been shown to induce de novo HLA antibody formation and ABMR.

The DGF phenotype has many covariates (donor age, recipient age, brain death, sensitization, etc.) that render its interpretation difficult. The DGF phenotype is associated with more histologic diagnosis of TCMR [116], but these may be false positives due to injury-induced tubulitis and interstitial infiltrate, detected because kidneys with DGF are biopsied much more frequently than those with good function. Protocol biopsies of kidneys with the AKI phenotype show an increased frequency of inflammation resembling rejection [117], because injury induces interstitial inflammation and tubulitis and probably even endothelialitis (v-lesions) [49], all of which will give false-positive diagnoses of TCMR. The inflammation present in protocol biopsies, which some call "subclinical rejection", is in fact primarily a reflection of AKI [118]. In addition, rejection is not primarily determined by the characteristics of the donor tissue. The concept of rejection associated with DGF might be an observational artifact due to a high number of biopsies.

Table 10.3. Top 30 genes associated with AKI ordered by fold change in AKI biopsies versus pristine protocol biopsies

Gene* symbol	Gene name	Fold change: transplants with AKI vs. normal kidneys	Correlation with eGFR at biopsy in transplants with AKI†	Predictor of the AKI phenotype (AUC ≥0.7)	Predictor of future graft loss
ITGB6	integrin, beta 6	7.9	−0.69	yes	yes
SERPINA3	serine (or cysteine) proteinase inhibitor, clade A	6.1	−0.71	yes	
MTND6	NADH dehydrogenase, subunit 6 (complex I)	5.6	−0.51	yes	
OLFM4	olfactomedin 4	5.5	−0.74	yes	
PTX3	pentaxin-related gene, rapidly induced by IL-1 beta	5.3	−0.58	yes	
LCN2	lipocalin 2 (oncogene 24p3)	4.3	−0.57	yes	yes
VCAN	chondroitin sulfate proteoglycan 2 (versican)	4.1	−0.35‡	yes	yes
LTF	lactotransferrin	4.1	−0.63	yes	yes
SLPI	secretory leukocyte protease inhibitor (antileukoproteinase)	4.1	−0.70	yes	yes
ADAMTS1	a disintegrin-like and metalloprotease (reprolysin type) with thrombospondin type 1 motif, 1	4.0	−0.64	yes	
MEGF11	multiple EGF-like-domains	3.8	−0.68	yes	yes
CDH6	cadherin 6, type 2, K-cadherin (fetal kidney)	3.7	−0.72	yes	yes
PI15	peptidase inhibitor 15	3.6	−0.40	yes	
FCGR3A	Fc fragment of IgG, low affinity IIIa, receptor for (CD16)	3.4	−0.30‡	yes	yes
NNMT	nicotinamide N-methyltransferase	3.3	−0.56	yes	yes
S100A8	S100 calcium binding protein A8 (calgranulin A)	3.2	−0.11‡	yes	
SOD2	superoxide dismutase 2, mitochondrial	3.2	−0.61	yes	yes
ITGB3	integrin, beta 3 (platelet glycoprotein IIIa, antigen CD61)	3.0	−0.74	yes	yes
NFKBIZ	nuclear factor of kappa light polypeptide gene enhancer in B-cells inhibitor, zeta	3.0	−0.67	yes	yes
AKAP12	A kinase (PRKA) anchor protein (gravin) 12	3.0	−0.60	yes	yes
VMP1	likely ortholog of rat vacuole membrane protein 1	2.9	−0.71	yes	yes
ADAM9	a disintegrin and metalloproteinase domain 9 (meltrin gamma)	2.9	−0.57	yes	
PTPRC	protein tyrosine phosphatase, receptor type, C	2.9	−0.53	yes	yes
FOS	v-fos FBJ murine osteosarcoma viral oncogene homolog	2.9	−0.48	yes	
OSMR	oncostatin M receptor	2.8	−0.80	yes	yes
C9orf71	chromosome 9 open reading frame 71	2.8	−0.41	yes	
EGR1	early growth response 1	2.8	−0.48	yes	
CTSS	cathepsin S	2.7	−0.50	yes	yes
RARRES1	retinoic acid receptor responder (tazarotene induced) 1	2.7	−0.55	yes	yes
EVI2A	ecotropic viral integration site 2A	2.7	−0.32‡	yes	yes

* Non-redundant and annotated genes are shown. In case of multiple transcripts per gene, the one with highest fold change was selected.
† Spearman correlations of gene expression with eGFR at the time of biopsy were considered significant at $P < 0.05$.
‡ P value not significant.

Aging and somatic cell senescence in relation to organ injury

Older donor age is an issue for DGF and for long-term impairment of GFR, and is considered here in relation to DGF. Older organ age is a major determinant of early organ dysfunction, and a major concern leading to the discard of organs. Moreover, the ECD paradox mandates that organs from older donors are put into higher-risk recipients, making recipient death and co-morbidities complex associations of donor age. With living donors, kidneys from older donors do well, except for their decreased GFR, as expected. However, live donors with hypertension or renal disease are commonly excluded. (Some centers accept kidney donors with well-controlled hypertension and without any evidence of end-organ damage.)

In deceased donors, the duration of hypertension is an independent risk factor for graft survival. The 3-year graft survival rate was inferior when compared to donor-age-match controls (65% vs. 75%, relative risk = 1.36 for hypertension >10 years, $P = 0.001$) [20] (but again the ECD paradox must be considered). The negative impact of hypertension and diabetes on transplant outcome is probably a matter of severity and duration, for example donor hypertension duration >10 years.

Histology lesions from preimplantation biopsies, including glomerulosclerosis, interstitial, and fibrosis, and fibrous intimal thickening of small arteries have questionable predictive value for transplanted organ function beyond that of donor aging and demographic equations, leading some to argue that biopsies should not be performed to assess aging and/or quality [119]. In addition,

most published studies that evaluate tissue quality assessment methodology lack appropriate validation [119].

The problem of what to do with ECD kidneys has no easy answers: transplant two into one recipient, two into two recipients, or discard both [120]. The practice of transplanting two kidneys from an older donor into one recipient is not well supported by evidence: there are no trials of randomly transplanting two kidneys into one recipient versus transplanting them into single recipients. Studies of the outcome of double kidney transplants from ECDs into one recipient compared to transplantation of a single ECD kidney usually find patient- and graft-survival rates of double kidney transplant are similar to single kidney transplant (95% and 90%, respectively) [121,122]. In view of the donor shortage, ECD kidneys should probably be transplanted as singles (into two recipients) rather than doubles into one recipient, if at all possible, although two into one is preferable to discarding both kidneys.

This puts the biology of aging on the agenda for understanding organ transplant performance and organ injury. In essence, the problem is that older organs are "smaller"—they have lost functioning mass—and their remaining cells are "old"—their cells are more fragile and vulnerable to injury [123]. Older kidneys that are functioning adequately in the donor after brain death manifest more DGF than younger organs. The older deceased donor population is qualitatively different, with more hypertensive vascular disease, and thus has a second issue in organ quality, that is more advanced changes preceding death. In contrast, the living donor of the same age can be selected to avoid hypertensive disease and avoid renal insufficiency. These choices cannot be made in the deceased donor, where evaluation is very limited.

The molecular changes of aging include the progressive DNA damage in telomeres, TP53, and mitochondria [124]. As cells undergo senescence, their mitochondrial function is compromised, which leads to the protein, lipid, and DNA modifications [125], including glycation [126].

There are two main theories of somatic cell senescence [127]: the telomere shortening theory [128] and the P16INK4A (cyclin-dependent kinase inhibitor 2A, CDKN2A) theory [129]. Telomeres are the ends of chromosomes and they are shortened as the cells replicate because the ends cannot be completely regenerated in cell replication. The problem is the absence of telomerase in somatic cells.

In experimental animals, such as rats and mice, the telomeres are very long and do not shorten significantly with age. In the humans and in phylogenetically higher animals, telomeres are short and shorten with age. At a certain point, they become limiting and evoke the DNA damage response [130,131]. This is beneficial because it keeps somatic cells from excessive replication and thus acts as a defense against cancer. Indeed, any cancer must find a way of bypassing somatic cell senescence mechanisms, by strategies such as re-expression of telomerase or deactivation of TP53.

The main cell cycle regulator used by somatic cells as they enter senescence is CDKN2A. CDKN2A is expressed in somatic cells in culture, such as fibroblasts, as they experience replication-induced arrest. Somatic cells have a limited number of cycles, which is known as "the Hayflick limit". The Hayflick limit is caused by telomere shortening. Other limitations on cells in culture include oxidative stress, which damages many aspects of the cell. As cells enter replicative arrest, they express CDKN2A, which acts as an irreversible inhibitor of the cell cycle. Epigenetic factors also contribute to the aging process and CDKN2A expression [132–134]. A number of studies have shown that replicative senescence occurs in human, mouse, and rat kidneys. These issues have been reviewed [76,135]. Cellular senescence in pretransplant kidney biopsies is predictive of postoperative organ function [136].

Markers of somatic cell senescence as a measurement of biological age of the organ at the time of transplantation have yet to be proven to give more information than chronological age itself. Donor age strongly predicts injury and function during the first weeks. In order to use telomere length or CDKN2A measurements at the time of transplantation, to assess the true age of the organ, one would have to show that these measurements they are superior to demographic factors alone. The commonly used risk indices (Schold, KDRI), expressed as complex weighted equations, are strongly influenced by the donor age.

Is somatic cell senescence a factor in organ survival?

The stresses of organ transplantation induce replication and oxidative stress adds further somatic cell senescence to that caused by pre-existing aging. Thus organs with extensive atrophy and fibrosis manifest high levels of expression of CDKN2A, as shown by staining. Moreover, the expression pattern is abnormal, and is very extensive in the atrophic tubule cytoplasm, as well as nucleus. Expression of CDKN2A in renal transplants and native kidneys is associated with impaired organ function and supports the concept that some cell senescence changes that accompany aging are also induced by stresses due to injury and disease [4]. In addition, a study of implantation [4] indicated that only donor age and donor-age-related histology (particularly interstitial fibrosis) is associated with long-term graft function. This demonstrated that somatic cell senescence is a factor in organ survival. However, this study also found that injury/ischemic stress at implantation failed to correlate with long-term function [137].

Can the somatic cell senescence mechanisms be bypassed or treated by drugs?

The possibility of a temporary suspension of some of our anticancer controls to secure additional replicative capacity in acute injury should be considered [138] but the potential risks must be weighed. There is a link between somatic cell senescence mechanisms and cancer defense: the tradeoff for not getting cancer is that somatic cells are not immortal. Attempts to induce telomerase to prevent telomere shortening and to bypass CDKN2A are theoretically attractive to giving cells extra replicative ability. There are some encouraging results in CDKN2A knockout mice, but one must be concerned about bypassing the limits imposed on somatic cells as cancer defenses. Both at the whole animal level and in the organ, there could be consequences and risks for bypassing either the telomerase mechanism or the CDKN2A mechanism.

Clinical treatment of AKI

Are the AKI biomarkers useful in the clinic?

Studies have examined the aim of using of the molecular tools to correlate with and diagnose AKI, ideally before the onset of the functional disturbance. As mentioned before, the functional classification of molecular changes in AKI revealed changes in immunity and defense response, ligand-mediated signaling, cell proliferation, and differentiation, as well as apoptosis. Some genes are up-regulated but some are down-regulated after AKI [139,140]. For example, expression of IL-6 and IL-18 is elevated (the inflammatory biomarkers), as well as the expression of HAVCR1 (KIM-1),

Table 10.4. Potential biomarkers reported in the context of AKI

Biomarker name	Gene name	Testing Specimen	Molecular function	Biological process	Study type
Neutrophil gelatinase-associated lipocalin (NGAL)	*LCN2* Synonym: *NGAL*	Serum, urine	Iron ion binding Transporter activity	Regulation of apoptosis Innate immune response Siderophore transport	Native AKI Post-KT AKI
γ-glutamyl transpeptidase (γGT) (gamma-GGT 1)	*GGT* Synonym: *GGT1*	Urine	Acyltransferase activity Gamma-glutamyltransferase activity Protein binding	Glutathione biosynthetic process	Native AKI
Sodium/hydrogen exchanger 3 (Na(+)/H(+) exchanger 3)	*SLC9A3* Synonym: *NHE3*	Urine	Sodium :Hydrogen antiporter activity	Ion transport	Native AKI
Interleukin-6 (IL-6) (B-cell stimulatory factor 2 (BSF-2)) (Hybridoma growth factor interferon beta-2 (IFN-beta-2))	*IL6* Synonym: *IFNB2*	Serum	Cytokine activity Growth factor activity Il-6 receptor binding	Acute-phase inflammatory response	Native AKI Post-KT AKI
Kidney injury molecule 1 (KIM-1) (Hepatitis A virus cellular receptor 1 homolog (HAVcr-1))	*HAVCR1* Synonym: *KIM-1*	Urine	Receptor activity	Host–virus interaction	Native AKI Post-KT AKI
Interleukin-18 (IL-18) (Interferon gamma-inducing factor)	*IL18* Synonym: *IGIF*	Serum, urine	Cytokine activity Signal transducer activity	T-helper 1 type immune response Angiogenesis Cell–cell signaling Granulocyte macrophage colony-stimulating factor biosynthetic process Interferon-gamma biosynthetic process IL-2, IL-13, IL-17 biosynthetic process Positive regulation of NK T cell, activated T-cell proliferation Positive regulation of tissue remodeling Regulation of cell adhesion	Native AKI Post-KT AKI

the receptor for a signal generated by apoptotic cells. Meanwhile, GGT and SLC9A3 are down-regulated probably due to dedifferentiation of the epithelium. Biomarkers of AKI were detected either as the product in urine or blood [4] or as mRNA expression in human kidney [110]. Most of the candidate markers had been initially discovered in native kidney diseases and were subsequently found in the human post-transplant AKI (Table 10.4).

In transplanted kidneys, the top 30 up-regulated genes in post-transplant AKI are potential markers for predicting AKI [4]. In addition, HAVCR1 and IL-18 were elevated in kidney tissue in response to injury, suggesting a potential role as a biomarker of renal injury. Molecular markers of AKI have also been studied in preimplantation biopsies. The results indicated that individual gene members of the AKI signal (*OSMR*, *SOD2*, *NNMT*, *ITGB6*, *CTSS*, *ITGB3 CDH6*, *LCN2*, *SLPI*, and *VCAN*) also showed significant predictive ability of DGF at implantation (area under the curve, AUC >0.7) [141].

In DCD kidneys, lactate dehydrogenase (LDH) levels have been assessed as indicators of the extent of injury [142]. However, LDH is not commonly used because it is not specific to renal tissue (it can also be released from damaged erythrocytes). In current practice, viability markers based on glutathione-S-transferase (GST) and α-GST iso-enzyme, a lysosomal protein from proximal renal tubular cells, are more extensively used. These correlate with warm ischemic time and are markedly increased in DCD kidneys that will never function [110]. Nevertheless, no single biomarker is an ideal marker for AKI, which should have the ability to predict injury phenotype, be unique to the kidney, easy to detect at an early phase of injury, and be highly accurate, sensitive and specific, and inexpensive [4].

Many of the top 30 AKI transcripts are used by independently derived, molecular risk score classifications of graft failure, such as NMMT, ITGB6, and VCAN [143]. This indicates that the parenchyma and stroma reaction to acute stress is also evoked in the context of ongoing progressive diseases. The association between the molecular changes of AKI and progressive disease underscores the need to identify aggressive processes that are disrupting the parenchyma [144,145] and becomes an important tool for clinical progress [146]. The prominence of the AKI signal in kidney transplants with progressive disease, such as ABMR, has encouraging implications for potential treatments. If progression is due to injury from the ongoing effects of the primary disease, progression will stop if the disease-causing injury is arrested. If progression is an autonomous secondary process, such as dysfunctional fibrosis (or FSGS, as in rodents), it would be necessary to treat both the primary disease and the secondary autonomous process.

In particular, the clinicians charged with making decisions about the use of ECD kidneys would be helped by new tests of organ aging/quality, whether that is based on biopsies or body fluids. We have analyzed whether the AKI signal in implantation biopsies could be clinically useful as a predictor of future poor kidney function, in addition to the clinical risk (e.g. donor age). The addition of the AKI signal in implantation biopsies to demographic risk scores, such as the Kidney Donor Risk Index, was better than either using histology or clinical risk alone [147,148]. It remains to be seen whether biomarkers in body fluids will reflect the molecular changes in the tissue and permit quantitative estimates of AKI.

Therapeutics of AKI: Lessons from failure

Many agents and experimental compounds have been investigated for their potential prevention or treatment of AKI, but virtually all have failed in subsequent clinical trials (as summarized in Table 10.5). The strategies for managing injury in experimental models are based on a rationale consisting of three main points:

Table 10.5. Clinical trial results for prevention and treatment of ischemic AKI

Intervention	Pharmaceutical/ intervention categorization	Rationale	Experimental trial (animal study) results	Clinical trial (human study) results
Objective : To increase oxygen delivery to the injured renal tissue				
Dopamine	Vasodilator	Vasodilator	Prevention and treatment [158–160]	No benefit from treatment [161–163]
Fenoldopam	Vasodilator	Vasodilator	Prevention and treatment [163]	No benefit from treatment [164,165]
Furosemide	Diuretics	Decreased oxygenation requirement of renal tubules	Treatment [166–168]	No benefit from treatment [169–171]
Hemoxygenese, carbon monoxide release compounds, and bilirubin	Vasodilator/antioxidant	1. Vasodilator 2. Scavenging peroxy radicals and inhibiting lipid peroxidation	Prevention and treatment [172,173]	Lack of clinical trial
Endothelin antagonist	Vasodilator	Vasodilator	Prevention and treatment [174]	Lack of clinical trial
Atrial natriuretic peptide	Vasodilator	Dilating afferent arterioles while constricting efferent arterioles	Prevention and treatment [175]	No benefit from treatment [176]
Remote ischemic preconditioning (RIPC)	Procedure	Flow reperfusion mechanism of transient non-lethal ischemic organ protects another organ or tissue from a subsequent episode of lethal ischemia and reperfusion (AKI)		No benefit to protect against AKI [177] (The actual benefit by NCT00975702 trial will be finished at the end of 2012)
Objective : To decrease inflammation via the inhibition or elimination of proinflammatory cytokines, free radical oxygen species, apoptosis, expression of adhesion molecules, or leukocyte function				
Mannitol	Diuretics	A free radical scavenger	Prevention [178]	No benefit to protect against AKI [179–181]
Statin	Anti-inflammatory	Statins can induce the cellular accumulation of endothelial nitric oxide synthase; inhibit the expression of adhesion molecules and chemokines that recruit inflammatory cells; inhibit expression of procoagulant factors and ameliorate platelet hyper-reactivity Pathways/factors implicated in the cellular effects of statins include the cholesterol biosynthesis pathway, Ras/Rho, nuclear factor-kappaB, and activator protein-1-mediated proinflammatory pathways, and nuclear factors such as peroxisome proliferator-activated receptor and Kruppel-like factor-2	Prevention [182]	Insufficient clinical data (Lack of RCT [183])
Alkaline phosphatases	Anti-inflammatory/antisepsis	Alkaline phosphatase (AP) attenuates inflammatory responses by lipopolysaccharide detoxification and may prevent organ damage during sepsis Inhibits the up-regulation of renal inducible NO synthase, leading to subsequent reduced NO metabolite production	Treatment [184]	Insufficient clinical data (Lack RCT [185,186])
N-Acetylcysteine (NAC)	Antioxidant	Reduces oxygen free radical	Prevention and treatment [187–189]	No benefit to protect against AKI [190,191]
Caspase inhibitors	Antiapoptosis/necrosis	Inhibition of caspase	Prevention and treatment [192,193]	Lack of clinical trial
Minocycline	Antiapoptosis/necrosis	Inhibition of p53 and BAX	Prevention [82,194]	Lack of clinical trial
p53 Inhibitor	Antiapoptosis/necrosis	Inhibition of p53	Prevention and treatment [195]	Lack of clinical trial
PARP inhibitor	Antiapoptosis/necrosis	Inhibition of poly ADP-ribose polymerase (PARP) activation	Treatment [196]	Lack of clinical trial
Soluble thrombomodulin	Antisepsis	Down regulates VCAM-1, ICAM-1, E-selectin	Prevention [197]	No benefit from treatment [198,199]
Ethyl pyruvate	Antisepsis	Inhibits tumor necrosis factor-α (TNF-α), down-regulates iNOS	Treatment [200]	No benefit to protect against AKI [201]
Activated protein C	Antisepsis	Down-regulates VCAM-1, ICAM-1, E-selectin	Treatment [201]	No benefit from treatment [202]
Sphingosine 1 phosphate analog (FTY720)	Anti-inflammatory/ immunosuppression	1. Direct activation of S1P1Rs results in a reversible redistribution of lymphocytes (B and T cells) from the circulation to secondary lymph tissue and thus away from sites of inflammation 2. Protected from apoptotic cell death through activation of mitogen-activated proteinkinase/extracellular regulated kinase (MEK/ERK) and phosphatidylinositol 3-kinase (PI3K)/Akt signaling	Prevention [203,204]	No benefit to protect against AKI [205]

Table 10.5. (*Continued*)

Intervention	Pharmaceutical/ intervention categorization	Rationale	Experimental trial (animal study) results	Clinical trial (human study) results
α -Melanocyte-stimulating Hormone	Anti-inflammatory	Inhibits proinflammatory cytokine from leukocyte, inhibition of iNOS	Treatment [206,207]	Lack of clinical trial
Interleukin 10	Anti-inflammatory	Inhibits proinflammatory cytokine from leukocyte, inhibition of iNOS	Treatment [208]	Lack of clinical trial
Peroxisome proliferator (PPAR) -activated receptors	Anti-inflammatory	Peroxisome proliferator (PPAR) -activated receptors inhibit NF-κB, and down-regulate VCAM-1 expression	Prevention [209,210]	Lack of clinical trial
Inducible nitric oxide synthase inhibitors	Anti-inflammatory	Inhibits iNOS	Treatment [211]	No benefit from treatment [212]
Objective : To enhance renal tubular regeneration via growth factors or mesenchymal stem cell therapy				
Erythropoietin	Growth factors	Down-regulation of NF-κB and activator protein 1 (AP-1)	Prevention and treatment [148,213,214]	Lack of clinical trial
Hepatocyte growth factor	Growth factors	Hepatocyte growth factor (HGF) is a potent regenerative factor for many cell types including renal tubule, with mitogenic, motogenic, and morphogenic activities. Renal expression of HGF and its receptor, c-met, increase after ischemic ARF HGF modulates neutrophil-endothelial interaction by suppressed TNF-mediated endothelial ICAM-1 induction. HGF is also capable of suppressing de novo induction of E-selectin, another key molecule for leukocyte-to-endothelial adhesion	Prevention and treatment [215–217]	Lack of clinical trial
Insulin like growth factor (IGF-1)	Growth factors	IGF-IR signaling also activates phosphatidylinositol 3-kinase (P13-K), which in turn activates protein kinase B (PKB/Akt) that also prevents apoptosis. These pathways converge on the inhibition of caspases, especially caspase-3, which is then blocked from performing an apoptosis-initiating cleavage of poly(adenosine diphosphate ribose) polymerase (PARP) and blocked from degrading β-catenin, part of the cadherin cell-adhesion system	Prevention and treatment [218,219]	No benefit from treatment [220]
Stem cell	Procedure	Amplify adult mesenchymal stem cells in the laboratory or identify factor (or factors) and then reintroduce them into recipients at the time of injury to promote proliferation of renal tubular cells	Prevention and treatment [221–223]	Lack of clinical trial

1 to increase oxygen delivery to the injured renal tissue by improved renal blood flow or decreased oxygen demand in the repairing renal tubular tissue;
2 to decrease inflammation via the inhibition or elimination of proinflammatory cytokines, free radical oxygen species, apoptosis, expression of adhesion molecules, or leukocyte function;
3 to enhance renal tubular regeneration via growth factors or mesenchymal stem cell therapy.

The patterns from these models have been misleading. In fact, interventions in AKI models have produced essentially no successes in predicting human interventions. The recent enthusiasm for erythropoietin treatment of kidneys with AKI is a case in point, where experimental models indicated efficacy [149] and clinical trials failed [150].

Perhaps it is time to change this paradigm: the interventions that "improve" function in young rodent tissue now seem very unlikely to improve outcomes with human tissues, although we do not know why. Perhaps much of the dysfunction in these rodent models is actually due to a different event (from the human point of view, an irrelevant event) from what we see in adult humans, where the problems of injury, donor aging, and recipient morbidity are so much more complex.

Having said that, treating and even preventing AKI in the clinic is difficult because much of the serious injury occurs in the donor before organ removal and cannot be prevented. Moreover, the major limitation of successful therapeutics in clinical trials of AKI is the complexity of AKI biology and the parenchymal remodeling. Interventions that directly address the cell cycle, and thus anticancer defenses, raise concerns about safety and adverse effects. The injury-repair process is closely related to cancer pathways, and bypassing somatic cell senescence also bypasses mechanisms such as telomere shortening and CDKN2A, which are part of our anticancer defenses. This must be kept in mind during efforts to modify or "improve" the repair processes by suspending these mechanisms. Future strategies may require drugs targeting more specific disease pathways rather than broad treatments, but it will be important to anticipate the consequences of manipulating the repair mechanism.

Injury repair wound healing is a remarkable program in every tissue, and we have achieved very little in the clinic to actually improve on the natural program, even in terms of accelerating the healing of the sterile surgical wound. This should not be a source of discouragement, only of appreciation that the study of this area at the molecular level continues to be challenging.

Management of high-risk early allograft dysfunction

Detailed strategies to reduce and manage AKI are beyond the scope of this chapter, but obviously include the general principles of ICU care of the donor and recipient, for example fluid replacement with crystalloid or colloid for a central venous pressure 8–10 cmH_2O for maintaining organ perfusion while avoiding aggressive hydration [5,151]. Other pretransplant, recipient-directed therapies, such as ischemic preconditioning with carbon monoxide [152], vasodilatory agents (e.g. endothelin receptor antagonist, a selective adenosine A1 receptor antagonist, and calcium channel blockers) [153–155], have yet to be proven in clinical studies for treatment of allograft AKI [152–155].

Calcineurin inhibitors (CNIs; cyclosporine and tacrolimus) are nephrotoxic at least in part by dose-dependent reversible preglomerular vasoconstriction, reducing renal blood flow and GFR. They probably seldom induce DGF but can prolonged recovery time [156] and complicate management and interpretation of functional disturbances. Many clinicians delay introduction of CNIs, often with antibody induction, which is more difficult to diagnose in patients with early allograft dysfunction [156]. Studies that compared early and delayed CNI initiation after transplantation generally have found that the incidence of DGF, acute rejection, graft failure, and kidney function was similar in either early or delayed CNI initiation protocols [157]. Mammalian target of rapamycin inhibitor (mTORi) based regimens (sirolimus and everolimus) have been proposed as a replacement for CNIs, but they delay injury repair and prolong recovery from DGF. Based on the current available information, the combination regimen of antibody induction, minimization dosing of CNI, and use of mycophenolate mofetil and steroids is commonly used for patients who receive kidneys with high risk of, or manifesting, early dysfunction.

Summary

Early graft dysfunction (DGF or SGF) as observed clinically is a complex differential diagnosis, including infarction, technical problems, and ABMR. The causes of DGF include anastomosis problems, cortical necrosis, ureteric obstruction, and antibody-mediated rejection, as well as AKI. AKI is defined here as the reversible phenotypic changes induced by stresses such as ischemia or toxins, including the molecular changes reflecting the response to injury (wound healing). Thus DGF is not synonymous with AKI**.** There is usually recovery from AKI with few late consequences; however, occasionally, adequate function is not achieved following severe AKI. Inflammation in AKI is inherent in wound healing and probably does not "extend" injury. The allograft function is affected by the following triad: donor factors (tissue aging/quality), the injury insult at implantation, and the recipient aging/co-morbidity interaction. The outcomes of ECD kidneys are heavily influenced by the practice of allocating them to high-risk recipients (the ECD paradox). The interventions in AKI models have produced essentially no successes in clinic. Perhaps this is due to the situation that we see in adult humans, where the problems of injury, donor aging, and recipient morbidity are so much more complex. This must be kept in mind during efforts to modify or "improve" the repair processes by suspending these mechanisms. Future strategies may require drugs targeting more specific disease pathways rather than broad treatments, but it will be important to anticipate the consequences of manipulating the repair mechanism.

CHAPTER 11

Mechanisms of Allograft Tolerance

Raul Badell[1] and Allan D. Kirk[2]

[1] Department of Surgery, Emory University School of Medicine, Atlanta, GA, USA
[2] Duke University Medical Center, Durham, NC, USA

Introduction

The last 60 years have seen clinical transplantation evolve from an experimental therapy with poor outcomes to the standard of care for most end-stage organ diseases. However, despite outstanding 1-year graft survival rates exceeding 90% for most organs and associated excellent control of acute rejection, the field continues to be plagued by late graft loss and immunosuppressive toxicity-related morbidity and mortality [1]. The need for chronic immunosuppression combined with its adverse effects is evidence we have likely entered a period of diminishing returns, such that increased immunosuppression will minimally increase graft survival and markedly augment morbidity. As such, gains in graft survival will best be achieved by pursuing strategies promoting immune tolerance and favoring therapies that enhance physiologic immune adaptation to transplanted tissues rather than those that suppress immune effector function.

Tolerance, or the maintenance of allograft function without an evident immune suppressed state, has been a long sought goal of allotransplantation. It is known to be clinically possible in selected circumstances, as it has been observed that rare allograft recipients can be withdrawn from immunosuppression without apparent clinical consequence [2,3]. Indeed, several series of tolerant kidney transplant recipients have been reported in the literature [4–7], and up to 20% of highly selected liver transplant recipients achieve successful immunosuppression withdrawal [8–13]. These exceptional cases have demonstrated that operational tolerance is possible but stochastic; the ability to prospectively and reliably induce durable, allospecific tolerance remains elusive.

Although clinically rare, tolerance is readily achievable in controlled experimental animal models. The underlying immune mechanisms of allograft rejection and acceptance have become increasingly defined and exploited, such that experimental allograft tolerance is now commonly achieved in rodents and has been demonstrated in higher animals including pigs [14,15], dogs [16–18], and non-human primates (NHPs) [19,20] with increasing regularity. However, success in animal models has not reliably translated to humans. Indeed, human tolerance has been observed primarily in the setting of patient non-compliance or drug withdrawal due to complications [21]. Some generalizations have, however, emerged. We know tolerance tends to evolve with time, occurring with increasing frequency late after transplant. It likely requires some resilience of the targeted organ, as younger donor organs and organs with regenerative capacity, such as the liver, tend to be favored; this implies that there is an early engagement with the immune system that has the potential to damage the graft. Tolerance is facilitated by lesser degrees of MHC mismatch, suggesting that reduced donor-specific precursor frequency is salutary. Nevertheless, reliable methods of predicting tolerance do not exist [22], making the risk of rejection with weaning or discontinuation of immunosuppressive therapy prohibitive in stable transplant recipients on minimal immunosuppression. Thus, some patients likely are tolerant, but remain on immunosuppression for lack of a suitable means of recognizing their condition. The clinical application of tolerance is therefore in need of assays to recognize tolerance when it occurs.

This chapter will provide an overview of the predominant mechanisms by which tolerance is induced and maintained: chimerism, depletion, costimulation blockade, and regulation; and will introduce B-cell mechanisms of tolerance. It will highlight those therapeutic maneuvers that are translatable, and provide a framework with which to interpret clinical tolerance trials. Additional insights into tolerance with specific commentary on clinical tolerance trials can be found in Chapter 76.

Conceptual considerations

In 1953, Billingham, Brent, and Medawar published their landmark work showing that tolerance could be purposefully induced under experimental conditions [23], arguably giving birth to the discipline of transplant immunology and laying the foundation for essentially all subsequent research in the field. They showed that two of five adult mice injected as fetuses in utero with alloantigen from a donor strain failed to reject donor-specific skin grafts. Additionally, the passive transfer of sensitized lymph node cells into the tolerant mice led to rapid rejection of the tolerated skin grafts. The three non-tolerant mice rejected their skin grafts, two shortly after transplant and one following a long period of acceptance. These findings led Medawar to several prophetic conclusions that remain salient to current concepts of tolerance in transplantation.

Medawar summarized that "The conferment of tolerance is not of an all-or-nothing character; every degree is represented, down to that which gives the test-grafts only a few days of grace . . . ." Indeed, immunity is not an all-or-nothing phenomenon, but rather a spectrum of immunologic responses which fall between rejection and tolerance. Physiologic immunity has subsequently been found to require contextual signals that augment or suppress effector

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

responses to increase the appropriateness of an immune response. As in Medawar's experiments, tolerance in humans has been observed, but the natural history of most allografts is rejection—indicating that the conditions at the time of transplantation favor an aggressive immune posture. This is not to say that those conditions cannot be manipulated to evoke a "perfect storm" of tolerance, but rather that rejection is more likely given the combination of high allospecific precursor frequency, reperfusion injury, and established allospecific memory (all discussed below). Rejection likely looms even in operationally tolerant patients, because, by definition, a competent immune system must retain the ability to adapt to changing contexts, maintaining its dynamic nature as determined by innumerable and at times immeasurable variables [21]. In essence, tolerance is observational, unpredictable, and likely not indefinite in a high percentage of operationally tolerant individuals unless substantial alterations to the recipient immune response are made.

Medawar also declared, "The conferment of tolerance is immunologically specific." That is, mice made tolerant to allografts from one donor strain retained the ability to reject grafts from another strain. This specificity is crucial to any sustainable form of tolerance, as indiscriminate hyporeactivity would, in essence, manifest as a state of gross immunosuppression, and indiscriminate immunity would be best characterized clinically as septic shock. Specific immune engagement of antigen by antigen receptors must occur in the appropriate context to maintain the balance between tolerance and immunity [24]. The development of antigen-specific tolerance facilitates the maintenance of protective mechanisms and the capacity to respond to other antigens or potential pathogens.

Lastly, Medawar concluded, "Acquired tolerance is due to a specific failure of the host's immunological response. . . .The host itself retains the power to give effect to a passively acquired immunity directed against a homograft, which has until then been tolerated by it." In other words, allograft rejection or acceptance is determined by the immune system's interpretation of donor antigen, not ignorance of the donor antigen or an alteration of its properties by "residence in a tolerant host." It has been a common misconception that tolerance is a state of immunologic unresponsiveness, when in reality it is best defined as the absence of a detrimental immune response, but a response nonetheless, recognizing that immune activity can either augment or hinder graft acceptance. Antigen recognition must occur but with a non-aggressive outcome. It is not that antigen recognition fails, but rather the outcome resulting from recognition changes—a change in interpretation, not occurrence.

These concepts outlined by Medawar more than 60 years ago underscore our understanding of mechanisms of tolerance today. Tolerance requires specificity to alloantigen and results from a combination of effector and regulatory immune responses that can manifest as rejection at any time following transplantation. While protective immunity is theoretically maintained by selective suppression of effector reactivity to donor alloantigen alone, some component of overlap between the allo- and protective immune repertoires is inevitable. In such instances, the coexistence of tolerance and immunity will rely on a multitude of cross-reactive combinations, where allo-specific cells dispersed in a sufficiently stochastic manner allow for the elimination of the allospecific repertoire without commensurate elimination of pathogen-specific immunity (Figure 11.1). Because this is a random process, some cross-reactive cells will be very related and the potential for loss of a pathogen-specific response present, but more often than not immunity will be maintained.

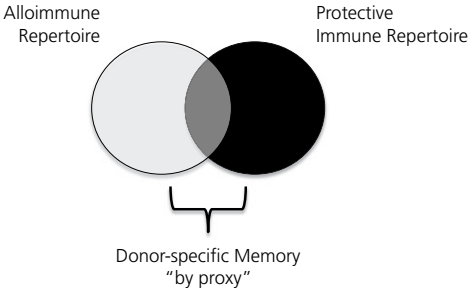

Figure 11.1. The relationship between alloimmunity and protective immunity. Overlap between the allo- and protective immune repertoires is inevitable, thus creating donor-specific memory "by proxy." In these instances, selective suppression of donor-specific effector reactivity has the potential to eliminate pathogen-specific immunity, and maintenance of protective immunity will depend on the random distribution of cross-reactive allospecific cells to facilitate coexistence of tolerance and immunity.

Successful induction of true tolerance will require the introduction of alloantigen to illicit specificity under circumstances that favorably tip the balance from rejection to tolerance. Initial alloantigen exposure with control of the destructive donor-specific response needs to be offset by a sufficient level of effector cell activation that results in compensatory responses favoring allograft acceptance. Current prevailing strategies of tolerance induction include chimerism, lymphocyte depletion, and costimulation blockade, with emerging interest in immune regulation techniques and B-cell-targeted therapies. These methods aim to manipulate the immune response through central and/or peripheral mechanisms of tolerance, essentially altering the context in the thymus, secondary lymphoid tissues, and periphery to favor acceptance (Figure 11.2). Given the complexity of the human immune response, and the required need to control the entirety of the immune response, it is likely that successful induction of clinical tolerance will involve a combination rather than a single one of these immune modulatory strategies. Indeed, as the mechanisms below are discussed, one will see that the practical implementation of these approaches frequently involves combinations of the various mechanisms (e.g. T-cell depletion and costimulation blockade to achieve chimerism, etc.).

Chimerism

Depending on context, hematopoietic stem cells (HSCs) can function in two ways: as expendable alloantigen to drive antigen-induced cell death (AICD), or for engraftment to induce chimerism. The former purpose is a peripheral mechanism that selectively eliminates alloreactive T cells via mechanisms such as costimulation blockade leading to AICD (discussed in the respective section), and the latter a central mechanism (requiring thymic or other primary lymphoid organ function) that relies upon donor HSC engraftment to achieve recipient marrow replacement. Both are intended to induce transplant tolerance.

Complete chimerism classically occurs in bone marrow transplantation (BMT), where all bone marrow-derived cells in a recipient are eliminated and replaced by donor cells. This form of hematopoietic cell engraftment provides the ideal condition for allograft acceptance, as evidenced by the successful persistence of

renal allografts with no requirement for immunosuppression in patients who developed renal failure after undergoing allogeneic BMT for treatment of hematologic malignancies [25]. However, the significant infectious and graft-versus-host disease-related morbidities of the myeloablative conditioning required for marrow transplantation precludes the application of this approach to induce tolerance in solid organ transplantation, with morbidity clearly exceeding that of standard immunosuppressive regimens. To achieve the same outcome with less morbidity, investigators have developed mixed chimerism [26,27], in which milder forms of non-myeloablative preconditioning do not completely ablate the recipient hematopoietic system. In instances of mixed chimerism, the recipient marrow is largely preserved but modified such that both donor and recipient hematopoietic components coexist [28].

Initial proof-of-concept studies in mice using lethal total body irradiation [26,29], and then more translatable non-myeloablative [30] techniques consisting of T-cell depletion and local thymic irradiation, successfully produced mixed chimerism and donor-specific tolerance. These strategies inspired subsequent successes in swine [31,32] and NHP models [33,34] and facilitated extension of a non-myeloablative preparative regimen to induce mixed lymphohematopoietic chimerism and solid organ allograft tolerance in humans [35]. In these instances, it is thought, by avoiding donor marrow rejection for some period of time, transferred hematopoietic cells populate the recipient thymus and marrow and facilitate central deletion of donor alloreactive T and B cells [29,36]. This non-myeloablative approach has the advantages of being less toxic, preserving immune competence, and lessening the risk for graft-versus-host disease. It does, however, depend on a rigorous early regimen that variably includes T-cell depletion, transient maintenance immunosuppression, and thymic or total lymphoid irradiation (TLI) to prevent marrow rejection [35,37].

Interestingly, although persistent mixed chimerism has generally been shown to be required in the murine studies that gave rise to this field, primate and human experience has established a tolerant phenotype despite the loss of chimerism. Thus, it remains unclear what mechanisms are dominant in humans. In mice, donor-specific tolerance requires permanent mixed chimerism and is maintained by central, intrathymic clonal deletion and not peripheral suppression or anergy, as the loss of donor-specific tolerance in the absence of donor antigen was thymus-dependent [38]. A costimulation blockade-based regimen has been used to achieve mixed chimerism and tolerance without T-cell depletion or myeloablation [39,40]. Following tolerization of the peripheral T-cell repertoire to achieve mixed chimerism, long-term tolerance is also maintained by intrathymic deletion, and regulatory cells do not play a role in maintaining tolerance in this model [41,42]. However, other mouse models using costimulatory blockade as conditioning for allogeneic BMT have been associated with less complete deletion of pre-existing donor-reactive T cells and appear to involve long-term peripheral regulatory mechanisms [36,43].

In contrast to the permanent mixed chimerism required in mice, the multilineage chimerism achieved in NHPs using an analogous regimen plus splenectomy has been shown to be transient [33]. Nevertheless, in the seminal studies of this approach, recipients have not rejected their allografts and developed donor-specific tolerance. Without splenectomy, all recipients developed alloantibody-mediated rejection [44], introducing the specter of humoral immunity as a barrier to tolerance. Long-term survival and more durable chimerism were salvaged by replacement of splenectomy by costimulation blockade (anti-CD154) [45]. The persistence of tolerance after loss of chimerism suggested that peripheral mechanisms might be responsible for the maintenance of tolerance in primates. Furthermore, sustained operational renal allograft tolerance achieved in multiple myeloma patients with ESRD after HLA-identical bone marrow and kidney transplantation [46], despite the loss of detectable hematopoietic chimerism, also suggests the presence of peripheral mechanisms in addition to (or instead of) the deletional tolerance demonstrable in mice. The detection of antidonor alloreactivity in vitro after loss of chimerism and the enrichment of $CD25^{+}CD4^{+}$ T cells both have implicated immune regulation as a mediator of tolerance in humans [47].

In 2008, Kawai et al. published the first consecutive series of HLA-disparate allografts intentionally transplanted without maintenance immunosuppression [48]. Following variable conditioning regimens and donor bone marrow infusion, four of five recipients of haploidentical live donor kidney transplants were weaned off immunosuppressive medication for greater than 2 years without rejection. In contrast to preparatory mouse studies where chimerism was a prerequisite for success, and similar to preceding NHP studies, durable mixed chimerism was not achieved. Four patients experienced humoral complications, highlighting the critical but poorly understood role of B cells. Interestingly, high levels of Foxp3 in the renal allografts of these patients suggest a role for regulatory T cells in the maintenance of unresponsiveness.

Several additional reports have linked chimerism and tolerance in humans. Scandling et al. described one of three patients rendered tolerant after HLA-identical marrow and kidney transplantation with persistent mixed chimerism [49], and Alexander et al. reported on an HLA-mismatched liver allograft recipient who spontaneously developed multilineage chimerism and tolerance in the setting of lymphopenia and infectious complications without HSC transplantation [50]. Despite these remarkable results, no true single tolerance regimen exists [51]. The only commonality amongst the various reports of chimerism and tolerance in humans has been profound and prolonged lymphopenia in all patients during initial alloantigen exposure. As such, a better understanding of lymphocyte behavior during lymphopenia and repopulation remains an important research focus (discussed below in the Depletion section).

The relationship between the actual induction and maintenance of chimerism and solid organ allograft tolerance remains a conundrum in the field. It is generally accepted that microchimerism (<1% donor chimerism) is distinct from macrochimerism (>1% of circulating cells), and is a property of transplant recipients and not a mechanistic harbinger of tolerance [52]. It is also important to recognize that all transplant recipients are chimeric, in that the organ itself is a massive amount of donor antigen residing within the recipient. What makes hematopoietic cells particularly important to the process when organs have many antigenic properties of these cells remains unresolved. Regardless, the persistence of macrochimerism, or lack thereof, has been an important variable in both preclinical animal models and clinical protocols using combined HSC and renal transplantation. While NHPs, unlike mice, do not seem to require long-lived macrochimerism for tolerance to solid organ allografts, both circumstances have been reported in humans [48–50]. A study from Northwestern University and the University of Louisville reported use of a non-myeloablative conditioning HSC transplant approach to establish complete chimerism and tolerance in renal transplant recipients [53]. The authors achieved durable chimerism in HLA-disparate HSC and renal

Figure 11.2. Mechanisms of (A) self tolerance and (B) alloimmunity to overcome for tolerance induction. (A) (1) A naïve T-cell pool is tailored for appropriate interactions with self-MHC through thymic selection. The result is a T-cell precursor frequency of autoreactive cells that is exceptionally low relative to the allospecific precursor frequency. (2 and 3) As productive antigen presentation is best achieved in the secondary lymphoid tissues, the stochastic meeting of a rare autoreactive cell that has escaped thymic selection with an activated APC derived from the periphery and presenting autoantigen in the secondary lymphoid organs is infrequent. (4) In the event that autoreactive T cells are successfully activated through autoantigen presentation, their migration back to their target antigen is also rare and stochastic in the absence of endothelial activation or chemotactic signals homing the activated cell to its peripheral antigen target. Chance encounters of non-activated autoreactive T cells with autoantigen in the periphery without the appropriate APC delivered presentation and costimulation results in anergy or apoptosis. (5) Activated T cells that fail to reach their target antigen eventually undergo apoptosis. (B) (1) A naïve T-cell pool with high allospecific precursor frequency derived from thymic selection in the absence of alloantigen brings any T-cell-activating event close to threshold for generating a significant immune response. Introduction of donor antigen in the recipient thymus through chimerism induction and/or depletion of donor-specific lymphocytes will counteract this mechanism of immunity. (2) Alloantigen presentation by self or donor type APCs in secondary lymphoid organs is easily enabled by a high frequency of allospecific T-cell help and can also be controlled by chimerism and/or lymphocyte depletion. Costimulation blockade has potential to interfere with T cell:APC interactions and prevent T-cell activation by inducing anergy or apoptosis. (3) Injured endothelium serves as a site of platelet binding and complement activation, thus activating endothelial cells and initiating chemotactic signals to attract lymphocytes for alloantigen encounter. Efforts to limit ischemia and reperfusion injury, and cellular adhesion attenuate this step of the alloimmune response. (4) Activated platelets encounter APCs (4.1), thus initiating mobilization (4.2) to regional secondary lymphoid tissues where costimulation blockade serves to disrupt activation. (5) CTLs encounter their target organ in sufficient numbers to cause rejection in a milieu rich in inflammatory cytokines (e.g. IL-2), both as a result of precursor frequency and chemotaxis. Depletion and costimulation blockade limit the productiveness of this response and prevent the attainment of a milieu that is supportive of cytotoxic lymphocyte activity. The role of regulatory and B-cell mechanisms are not depicted in this figure.

transplant recipients, and found that T-cell chimerism was associated with persistent donor chimerism and the ability to successfully wean subjects from immunosuppression while maintaining stable renal function. In addition, Ramakrishnan et al. have recently reported that durable whole blood (non-T cell, non-B cell) chimerism is insufficient at prolonging allograft acceptance or facilitating immune tolerance to renal transplants in an MHC-matched NHP model [54]. This study underscores the need for a multilineage requirement in that durable chimerism that lacks T-cell chimerism failed to protect subsequently transplanted renal allografts in primates. Thus, it may be prudent to closely adhere to the lessons learned from murine models and pursue strategies that reproducibly lead to chimerism that is both multilineage and stable.

Although the above referenced existing clinical protocols have been inspired by mixed chimerism, tolerance has been achieved without it, and rejection observed with it. There are differences in both the methodology and the mechanisms by which tolerance has been induced in the different animal models. In mice, where complete T-cell depletion is possible, mixed chimerism is long lasting and tolerance is based on central, clonal deletion. The maintenance of such tolerance does not depend on the presence of an organ allograft and it persists even after such a graft is removed. In monkeys and in humans, T-cell depletion is less complete and while central deletion may be involved early after HSC transplantation, maintenance of tolerance long-term, after peripheral chimerism has disappeared, may depend on the presence of the donor organ allograft and appears to involve control of peripheral donor-specific responses by regulatory T cells.

The last few decades of experience with BMT for the induction of chimerism and allograft tolerance has certainly begun to inform our understanding of the mechanisms necessary to achieve tolerance. However, chimerism has yet to reliably predict success in humans or primates, and the antibody response distinct from the T-cell response remains incompletely addressed (see B cell section). The relationships described above between chimerism and tolerance highlight the interdependence of the following individual methods of tolerance induction, and how a combination of these is most likely to lead to true, intentional tolerance.

Depletion

Targeted irradiation to lymphoid tissue crucial for the development of alloimmunity has been used to control the immune response after transplantation in animals [16,55–57] and in patients [58–60]. Lymphoid irradiation alone has had the effect of vigorous T-cell depletion, but more recently has been used as a means of immunosuppression to facilitate marrow engraftment and subsequent mixed chimerism [60] as discussed above. As a pretransplant conditioning regimen, TLI has induced tolerance in chimeric and non-chimeric humans, whereas post-transplantation irradiation has failed to produce stable chimeras or tolerance [61].

Depletional tolerance strategies all have a common aim of controlling allospecific T-cell precursor frequency. Between 1 and 10% of peripheral T cells are able to recognize alloantigen [62,63], and this far exceeds the frequency of T cells for any given nominal antigen. Lymphocyte depletion with polyclonal or monoclonal antibodies has been envisioned as a strategy to non-specifically reduce the precursor frequency, allowing peripheral mechanisms to proceed with less risk for allograft injury. $CD4^+$ and $CD8^+$ antigen-specific precursor frequency has been shown to impact T-cell proliferation, differentiation, and overall quality of the effector immune response [64,65]. However, the compensatory response to depletion, homeostatic repopulation, also has been shown to influence the character of an immune response, typically engendering a more activated phenotype [66]. These concepts are expanded upon in Chapter 9. To date, depleting antibodies have been clinically used both as induction and as rescue therapy of acute rejection [67]. The availability of depletional antibodies makes depletional strategies logistically attainable, but as we have learned more about the myriad types of, and responses to, depletion, its proper place in tolerance regimens has remained incompletely defined. In surveying the literature, it is important to

recognize that every approach to depletion has unique properties to be considered.

In 1997, Knechtle et al. reported that T-cell depletion by a CD3-specific immunotoxin in NHPs led to prolonged renal allograft survival and tolerance to donor skin grafts in five of six recipients, despite rejection of third-party skin grafts [68]. Prior to this study depletion with rabbit antithymocyte globulin (ATG) had been used to promote tolerance, but only in conjunction with donor bone marrow infusion [69,70]. The ability of immunotoxin to promote tolerance alone in contrast to ATG and TLI was attributed to improved selectivity and more efficient T-cell lysis in both the peripheral circulation and lymph nodes [33,71]. Interestingly, despite rodent studies to suggest that the presence of donor MHC class I or class II antigens in the recipient thymus given in combination with anti-T-cell therapy might promote tolerance [72–74], no additional tolerogenic effect was achieved by concomitant thymic donor lymphocyte injections.

Although immunotoxin showed initial promise as a singular tolerogenic agent, subsequent studies rendered it best as an adjunct to tolerance induction methods. As a single agent administered pretransplant it promoted allograft survival, inducing tolerance in at least one-third of recipients, but administered post-transplant (more clinically relevant) in combination with steroids and deoxyspergualin or mycophenolate mofetil (MMF), long-term unresponsiveness was produced more reliably than with immunotoxin alone [75]. Mechanistic examination of NHPs treated with immunotoxin revealed that donor-specific cytotoxic T-lymphocyte precursor frequency and responsiveness were suppressed, but not mixed lymphocyte reaction responsiveness or alloantibody production [76,77]. Histologic and serologic examination of NHPs receiving post-transplant immunotoxin showed alloantibody-mediated glomerular and arterial damage associated with expression of the co-inflammatory cytokines INF-γ and IL-2 [78], introducing the possibility of early T-cell allosensitization and promotion of antibody-mediated graft injury. Post-transplant immunotoxin-treated animals also were able to mount donor-specific antibody responses, further implicating humoral mechanisms as responsible for the failure of tolerance induction and providing rationale for the successful use of the B-cell-suppressive agent deoxyspergualin in combination with steroids and immunotoxin that reliably produced tolerance in NHPs [79].

These preclinical studies using the CD3-specific immunotoxin established the principle of profound T-cell depletion at the time of transplantation as a platform for promoting long-term unresponsiveness to allografts. Calne et al. used campath-1H (alemtuzumab), a CD52-specific antibody that depletes both T and B cells in human cadaveric kidney recipients in combination with cyclosporine to achieve allograft acceptance on low-dose maintenance immunosuppression [80,81]. Several subsequent randomized control trials validated the use of alemtuzumab as a depletional induction agent to achieve *prope*, or almost tolerance, followed by very-low-dose maintenance immunosuppression to guard against rejection [82,83]. The authors point out that operational tolerance has been difficult to achieve with any given protocol due to the enormous variation between donors and recipients of organ grafts of tissue matching, innate immune reactivity, and susceptibility to disturbance of a tolerant state by infections or allergic reactions; thus, they make the case for *prope* tolerance in which graft acceptance is maintained by a low, non-toxic dosage of maintenance immunosuppression [84]. Although this is a very acceptable clinical outcome, it is not clear if the mechanisms involved are related to tolerance, or just efficient immunosuppression. Regardless, it is clear that lymphocyte depletion alone of the level achievable with antibody preparations such as alemtuzumab, will not induce tolerance. This has been tested prospectively in a series of living-donor renal transplant recipients treated aggressively pretransplant with alemtuzumab to achieve complete elimination of T cells in the peripheral blood and marked depletion in the secondary lymphoid tissues [85]. Despite profound lymphopenia after alemtuzumab induction, all patients in this trial developed rejection episodes characterized by predominantly monocytic (not lymphocytic) graft infiltrates. These data underscore a prominent role for non-lymphocyte cell populations in allograft rejection regardless of lymphocyte depletion, or perhaps a need for very few T cells to incite a rejection response. Another seminal point drawn from these studies is that non-specific, polyclonal depletion is not homogeneous in that effector memory T cells have been found to be relatively resistant to depletion [86]. These cells are, however, sensitive to calcineurin inhibitors (CNIs), in part explaining the results of CNI-based *prope* tolerance trials. In addition, remaining T cells after depletion undergo homeostatic repopulation, and this has been recognized as a barrier to the development of tolerance [66,87]. B cells too have been implicated in depletion-resistant rejection due to elevated levels of BAFF (a factor integral to B-cell homeostasis) in renal transplant patients treated with alemtuzumab [88]. Thus, vigorous depletion alone is not a reliable means toward tolerance.

Depletional studies have informed us of important mechanisms salient to the development of tolerogenic protocols. We have learned that allograft dysfunction is not solely determined by T-cell cytotoxicity, and that depletional agents have inhomogeneous effects on macrophages, T cells and B cells. Differences in the immune repertoire present prior to depletion (memory vs. naïve) and differential homeostatic expansion kinetics likely influence the ultimate effect of depletion. Overall, lymphocyte depletion is best viewed as a component of other approaches to tolerance, yet it does facilitate reduced maintenance immunosuppressive requirements in many patients. The lessons learned from depletional strategies to tolerance are likely to lead to improved strategies toward clinical tolerance in organ transplantation.

Costimulation blockade

In 1975, Lafferty and Cunningham's two-signal hypothesis of T-cell activation offered at least the possibility that an immune response under the proper circumstances could promote tolerance rather than being obligatorily hurled toward antigen destruction [89]. This conceptual breakthrough inspired decades of subsequent work amassing considerable experimental evidence that costimulation blockade facilitates tolerance induction [90–93]. Costimulation blockade is based on the paradigm that specific immune responses require two signals for optimal activation [94]. In the absence of a facilitating costimulatory signal, antigen stimulation induces anergy or apoptosis. Thus the provision of signal 1 via antigen exposure, combined with signal 2 or costimulation molecule inhibition, has the effect of eliminating cells in an antigen-specific manner. Costimulation blockade has been used in robust preclinical models to facilitate the protolerant mechanisms at play during peripheral antigen encounter, either with the graft itself [95–98] or with infused hematopoietic cells [99], and has also been used as a means to facilitate chimerism [45,100]. This model has subsequently been modified to include a "signal 3" [101], that being cytokine-induced signals controlling postactivation expansion.

As it has been increasingly recognized that costimulatory signals are critical for optimal T-cell activation, proliferation, and differentiation, there has been an explosion in the study of costimulatory molecules and their roles in enhancing antidonor T-cell responses and facilitating tolerance following transplantation. Amongst the multitude of costimulatory pathways described [102], the best-characterized and perhaps most important interactions occur between CD40 and CD154 (CD40L) in the TNF:TNFR family, and CD80 (B7-1)/CD86 (B7-2) and CD28 of the immunoglobulin superfamily. The exact mechanism by which these molecules exert their effects remains incompletely defined; however, inhibition of these pathways using transgenic knockout mice, monoclonal antibodies, or fusion proteins has demonstrated profound effects on the immune response [103].

Lenschow et al. first reported that CTLA4Ig, a soluble fusion protein of CTLA4 that binds the B7 molecules, blocked pancreatic xenoislet rejection and induced donor-specific tolerance in mice [104]. Similar survival of mouse pancreatic islet allografts was subsequently obtained targeting the CD40:CD154 pathway with an anti-CD154 antibody [105]. Larsen et al. then showed that long-term acceptance of skin and cardiac allografts in a more stringent mouse model required simultaneous but not independent blockade of the CD28 and CD40 pathways [95]. These instances of tolerance induction in select rodent transplant models following blockade of the CD28 and CD40 costimulatory pathways have been replicated in NHP transplant models [96,97,106], but identification of clinically applicable strategies that consistently induce tolerance in large animal preclinical models has so far been elusive [19,20,107]. Furthermore, a pilot study using a humanized CD154-specific antibody in human renal transplantation raised concerns about the efficacy of this strategy, as data showed that five of seven patients experienced rejection episodes [108].

The reasons for the apparent discrepancies between the results in rodents, primates, and humans remain unclear, but may, in part, be due to the increased complexity of the human immune system and the more diverse and longer-term environmental exposure that humans experience compared with laboratory animals [19,20,107]. Though not completely understood, further studies have identified mechanistic barriers to the development of tolerance by way of costimulation blockade [102,109]. They include duplicitous positive and regulatory effects of some costimulatory pathways and heterologous immunity mediated by alloreactive memory T cells [110], the nature of which is covered in detail in Chapter 9.

The discovery that CTLA4, which binds CD80 and CD86 more avidly than CD28 and competitively inhibits rather than enhances T-cell activation, presented one of the first mechanistic challenges for tolerance induction by B7 costimulatory blockade [111,112]. Because blockade of B7 might inhibit differential signaling pathways, modulation of T-cell costimulation in attempts to promote allograft tolerance proved to be more complex than simply blocking primary positive costimulatory interactions. As a result, it is not surprising that blocking CD28:B7 alone has neither been universally effective in generating tolerance in rodent transplant models nor has it been able to induce tolerance in NHPs [20,113]. Blockade of the CD40:CD154 pathway has also had its share of challenges. Despite initial enthusiasm for CD154-specific antibodies, thromboembolic complications in NHPs and humans almost led to abandonment of strategies aimed at targeting the CD154 side of this pathway [108,114]. Fortunately, alternative targeting of CD40 has been efficacious in preclinical studies [115–119] and CD40-specific agents are currently in clinical development [120]. However, the CD40:CD154 story highlights that although costimulatory molecules are generally viewed through their effects on T cells, receptor-ligand interactions are bidirectional with potential for significant immune and non-immune consequences. Both inadvertent inhibition of negative regulatory mechanisms or non-T-cell and non-immune bystander effects of costimulation blockade could negatively impact tolerogenesis.

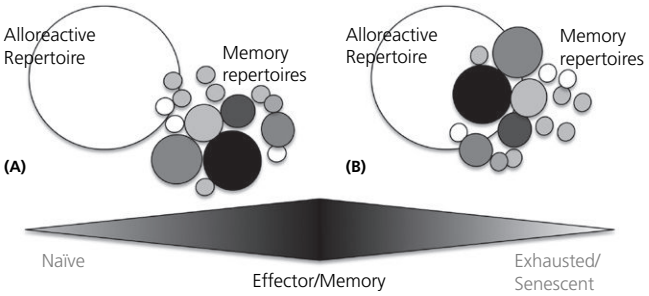

Figure 11.3. High frequencies of donor-specific memory present a barrier to tolerance induction. In scenario A, a low frequency of alloreactive memory repertoires favors tolerance induction, as costimulation blockade potently blunts naïve donor-specific T-cell responses. Conversely, the high frequency of donor-specific memory in scenario B presents a barrier to costimulation blockade-based tolerance induction strategies.

Blockade of T-cell costimulatory pathways can potently blunt naïve donor-specific T-cell responses following transplantation, but the presence of donor-reactive memory T cells poses a sometimes insurmountable barrier to long-term graft survival and tolerance induction [109] (Figure 11.3). Memory T cells can reject allografts independent of secondary lymphoid organs [121] and are known to be relatively resistant to a variety of therapeutic interventions [86,122], including costimulatory blockade [110,123–125]. In addition, $CD4^+$ and $CD8^+$ precursor frequency plays a critical role in determining the ability of T cells to mediate rejection in the setting of costimulation blockade following transplantation [64,65]. More recently, the presence of high frequencies of donor-reactive T-cell memory have been reported to impair tolerance induction to kidney allografts in NHPs [126]. Thus, a high frequency of alloreactive memory T-cell populations in transplant recipients may obviate the need for costimulation and play a large role in mediating costimulation blockade-resistant allograft rejection and tolerance prevention [109,127].

The complexity of costimulatory pathways presents both challenges and opportunities in employing costimulation blockade to promote transplant tolerance. Costimulatory molecules regulate multiple aspects of the alloimmune response, from priming of naïve cells to the development of memory and regulatory T cells, and have both negative and positive effects that may function to either augment or attenuate antigen-specific T-cell responses. It has become clear, as with other immunosuppressive methods, that a costimulation blockade alone approach to the generation of tolerance is not feasible. However, with the recent introduction of belatacept [128], a high affinity CTLA4Ig for clinical use, costimulation blockade can be folded into clinical regimens to be tested in humans, and like depletional antibodies, the clinical availability may drive investigation over more theoretically attractive approaches.

Several possible alternative approaches may harness the therapeutic potential of targeting T-cell costimulation to achieve tolerance. Negative costimulatory molecules present a physiologic

means of dampening or terminating immune responses and maintaining peripheral tolerance. The best-studied is CTLA4, as it plays a key role in immune regulation [129] and its signaling has been required for tolerance induction in several studies [130–132]. Strategies aimed at enhancing CTLA4 signaling may prove useful given the potency of this endogenous tolerogenic pathway. Alternatively, selective targeting of memory T cells in conjunction with costimulation blockade has successfully neutralized this costimulation-resistant population to prevent allograft rejection in NHP renal and islet transplant models [133,134]. The targeting of numerous other costimulatory molecules has shown in rodents to evoke at times dramatic effects. However, the cataloging of each costimulation blockade approach is beyond the scope of this chapter, and these additional pathways have been extensively reviewed elsewhere [93,102,109,135,136].

Recent history has seen a shift in the use of costimulation blockers primarily as a tool for tolerance induction toward exploitation of their potential as primary maintenance drugs in CNI-free regimens [92]. Encouraging clinical results from studies in renal transplantation targeting the CD28 pathway using belatacept [128,137,138] suggest that costimulation blockade may someday be a component of the future therapeutic regimen that provides transplantation tolerance.

Regulation

As Peter Medawar conjectured from his early description of "actively acquired tolerance," the mechanisms of tolerance are probably reversible, continually being threatened by emerging effector cells, inflammatory cytokines, and revolving contexts with general inflammatory conditions and pathogen exposures. Thus it is logical that active suppressive mechanisms are involved in the maintenance of tolerance. For allograft survival following transplantation, let alone tolerance induction, it is critical that both the innate and adaptive immune responses be controlled. Whether immune cells promote rejection or facilitate tolerance depends on both the origin of the cells and temporal conditions in transplant recipients. Although leukocyte populations such as macrophages, dendritic cells, B cells, and T cells can mediate destruction of transplanted tissues, they can also promote graft survival and tolerance [139]. The topic of regulation is considered in depth in Chapter 8.

Early experiments over 20 years ago showed that, under certain circumstances, $CD4^+$ T cells could prevent damaging immune reactions [140–143]. Studies showed that rats with long-term allograft survival off drug-based immunosuppression had T cells that could actively prevent graft rejection [144,145], and that the adoptive transfer of such a population of cells in a rodent model conferred donor-specific tolerance [146]. This form of cellular regulation in transplantation was later found to be associated with $CD4^+$ T cells that express CD25, the α-chain of the IL-2 receptor [147–149], and that $CD4^+CD25^+$ T cells could suppress T-cell proliferation [150]. Ultimately, murine studies implicated Foxp3 as the transcription factor needed to direct $CD4^+$ T cells to become regulatory cells [151–153]. These regulatory cells have been found to be increased in the circulation and within the grafts of operationally tolerant liver and kidney transplant recipients [154–159].

$CD8^+$ T cells [160–162], $CD4^-CD8^-$ T cells [163], natural killer T cells [164], and $\gamma\delta$ T cells [165] comprise more newly identified T-cell populations with regulatory activity, but $CD4^+CD25^{hi}Foxp3^+$ regulatory T cells (Tregs) remain the best characterized with the most promising experimental results. They function to maintain immune tolerance to self-antigens and provide negative feedback mechanisms to keep immune reactions in check [166]. Tregs are classified as either naturally occurring cells centrally selected in the thymus [167], or induced cells that encounter antigen in the periphery in a tolerogenic environment and differentiate into induced Tregs [168]. Various cellular mechanisms by Treg cells to inhibit the effector immune response have been described [169]. They include direct cellular contact inhibition of effector T-cell proliferation [170] and the induction of cytolysis or cell cycle arrest and apoptosis of target cells such as antigen presenting cells (APCs) [171–173]. Tregs also indirectly induce suppression via paracrine regulation by secreting the suppressor cytokines IL-10, TGF-β, and IL-35 [148,174], or consumption of the proliferative cytokine IL-2 [150,175]. Furthermore, constitutively expressed CTLA4 on Tregs can block T-cell access to necessary costimulatory signals for activation due to a higher affinity for CD80/CD86 than CD28, and can lead to attenuated T-cell proliferation via CD80/CD86-mediated activation of indoleamine 2,3-dioxygenase in APCs [176].

Upon initial alloantigen encounter after transplantation there are usually insufficient Treg cells to prevent the rejection of an allograft, particularly in the presence of a high frequency of donor-specific memory T cells [122]. This imbalance favoring alloantigen-reactive T cells will shift the immune response toward allograft destruction. However, with initial control of the effector alloimmune response, Treg cells can be peripherally induced or thymus-derived cells expanded in the prolonged presence of alloantigen—thus theoretically tipping the balance toward regulation [177–179]. This balance between destruction and regulation provides an opportunity to manipulate the alloimmune response in favor of tolerance either before or after transplantation by inhibiting the activity of effector T cells and/or increasing the relative frequency or functional activity of donor-specific Tregs [180–183].

Non-T-cell regulatory immune cell populations have arisen as potentially important mediators of allograft tolerance. Interest in B-cell-mediated tolerance arose from clinical findings of higher B-cell-associated gene expression in tolerant human kidney transplant recipients [184–186]. Human regulatory B cells identified as $CD19^+CD24^{hi}CD38^{hi}$ have the ability to secrete the proregulatory cytokine IL-10 [187–189], but their exact role in alloimmunity remains to be defined. Regulatory macrophages characterized by their morphology, cell-surface phenotype, and their ability to suppress T-cell proliferation in vitro also produce IL-10 and are thought to dampen proinflammatory immune responses [190,191]. Though dendritic cells play a critical role in the generation of antigen-specific effector T cells, they too have been described to promote tolerogenic responses [192,193].

It is probable that the overall interactions of the regulatory-cell-mediated mechanisms described above, rather than their individual effects, determine their promotion of allograft protection and tolerance. As reviewed by Wood et al. [194], hypothetically, early in the immune response to an allograft, hematopoietic progenitor cells attracted to the graft by innate inflammatory mechanisms may initiate immunomodulatory activity and create a microenvironment favoring the generation of regulatory macrophages and dendritic cells. Such a tolerogenic microenvironment could then serve to peripherally induce Tregs upon the arrival of returning activated T cells from secondary lymphoid organs, aided by modulation from thymus-derived Tregs and regulatory B cells. These processes are all dependent on aid from immunosuppressive therapy to help tip the balance away from destruction of the allograft to tolerance

while alloantigen-specific regulatory mechanisms are allowed to mature.

Key to the discussion of regulatory mechanisms of tolerance is the net in vivo effect of current immunosuppressive strategies on effector cell populations and the generation of immunomodulatory cell populations, as it is variable and dependent on the combination and timing of agents used. For example, lymphocyte depletion has the potential to reduce the number of effector cells and allow for repopulation with regulatory cell subsets to prevent rejection, as has been observed with alemtuzumab induction [195–197]. On the other hand, maintenance therapy with CNIs and antiproliferative agents (e.g. MMF) can inhibit both effector and regulatory cells. The effect of anti-CD25 antibodies on Tregs is debated, and sirolimus has been shown to support Treg generation ex vivo and promote function in vivo [198,199]. Data suggests that CTLA4Ig worsens outcomes in Treg-dependent models of transplantation by blocking CTLA4-mediated inhibition of T-cell activation [200–202]. Thus, the potentially competing components of different immunosuppressive protocols need to be thoroughly considered in efforts targeted at promoting regulatory mechanisms of tolerance.

Attempts at clinical translation of regulatory cell therapies in transplantation based on proof-of-concept preclinical animal studies [203,204] are underway and revolve around the transfer of Treg cells into transplant recipients with or without the aid of various immunosuppressive agents. The infusion of Tregs into transplant recipients, however promising experimentally, is clinically limited by their low frequency in vivo, prompting the need for isolation and expansion in vitro [205]. In vitro strategies include expansion of natural Tregs, induction of adaptive Tregs from precursor cells, and Treg generation by ectopic gene expression [206]. Current clinical experience has been limited to the BMT population [207–209], but the upcoming European Union "ONE Study" proposes the use of immunomodulatory cells, including expanded recipient natural Tregs in living-donor kidney transplantation. Nonetheless, the first trials of Treg cellular therapy in clinical HSC transplantation have been promising and provide a basis for future trials in solid organ transplantation.

B cells

Traditionally, T cells have been primarily blamed for allograft rejection, but humoral mechanisms mediated by alloantibodies have been recognized to play a significant role in antibody-mediated rejection (AMR) [210,211], the mechanisms of which are covered in depth in Chapter 6. AMR is thought to account for 2–10% of rejections with a greater incidence in sensitized patients [212], is characterized by donor-specific antibody formation [213] and histopathologic complement deposition [214], and correlates with poor long-term allograft survival. Studies within the last few years have provided increasing evidence that antibody-dependent and antibody–independent B-cell-mediated immune responses are a formidable barrier to the development of allograft tolerance.

Much of our knowledge of mechanisms of B-cell tolerance derives from studies of B cells in autoimmunity [215,216]. The random assembly of B-cell receptors through V(D)J genetic recombination leads to large receptor diversity, with as much as 20–50% autoreactivity [217–219]. Physiologic self-tolerance is achieved via both central and peripheral mechanisms. Central tolerance tends toward the elimination of high-affinity autoreactive B cells by clonal deletion or receptor editing [220–222]. Self-antigen stimulation of autoreactive B-cell receptors leads to receptor internalization and arrest of B-cell maturation. Alternatively, cell death of autoreactive cells can occur through increases in proapoptotic factors such as Bcl2-like protein 11 and inhibition of B-cell survival proteins [223,224]. For autoreactive B cells that escape clonal deletion, continued expression of *RAG* genes responsible for V(D)J recombination lead to receptor editing and new receptor combinations that overcome autoreactivity [225–227]. Peripheral tolerance mechanisms include anergy induction in low-affinity transitional B cells that escape central mechanisms via well-described molecular changes that raise activation thresholds and turn on intrinsic regulatory pathways of autoreactive B cells [228,229]. Low-affinity autoreactive B cells can also be rendered clonally ignorant by emerging extrinsic B-cell mechanisms responsive to homeostasis of the peripheral B-cell population [230], such as competition for a follicular growth factor with limited availability known as TNFSF13B [231]. Further insight into these central and peripheral mechanisms of physiologic B-cell regulation will guide the development of methods to achieve B-cell tolerance.

Current B-cell-targeted therapies for AMR fail to effectively control B-cell-dependent effector immune responses. Non-selective alloantibody removal by plasma exchange is limited by a compensatory homeostatic response of antibody production induced by hypogammaglobulinemia, and generalized humoral suppression with agents such as rituximab (anti-CD20), bortezomib (proteasome and plasma cell inhibitor), and eculizumab (anti-C5) does not achieve stable immune suppression or tolerance amid safety concerns [232–234]. Thus, the need for emerging therapies for B-cell tolerance is clear, but as with T cells, B-cell tolerance has been more difficult to achieve in humans than in animal models. Nonetheless, observations derived from animal models of allograft transplantation have served as the foundation for modern clinical strategies that aim to achieve allograft tolerance by targeting B cells [19,20,235].

Neonatal tolerance has been observed between cattle with shared placental circulations [236] and in mice after fetal infusions of alloantigen, possibly by clonal deletion of alloreactive B cells [23]. Human monochorionic dizygotic twins with different blood groups also develop neonatal tolerance to each other's blood group in utero [237]. Similar B-cell tolerogenic mechanisms presumably facilitate successful ABO-incompatible transplantation in infants, as they do not produce ABO-specific antibodies until 5–6 months of age and therefore are at low risk of hyperacute allograft rejection [238]. Human ABO-incompatible heart transplantation has been performed in infants without hyperacute rejection or ABO-incompatibility related problems [239]. The mechanisms responsible for this observation seem to involve transient deletion of ABO-specific B cells dependent on the presence of alloantigen, as B cells specific for the previously mismatched ABO epitope reappeared in recipients subsequently transplanted with an ABO-compatible heart graft [240]. Thus, in contrast to neonatal tolerance, which seems to involve centrally based mechanisms, allograft tolerance seems to require peripheral antigen. Additional treatment of this topic can be found in Chapter 112.

A 2004 study of ABO-incompatible heart transplant recipients suggested that B-cell tolerance to donor-specific blood group antigens can develop spontaneously [241]. Although these patients did not develop tolerance to donor HLAs, the development of B-cell tolerance to ABO blood group antigens provided the first demonstration that neonatal tolerance could be acquired in humans. ABO-incompatible transplantation has also been attempted in renal and liver transplantation [242,243], with most success in

pediatric recipients less than 1 year of age [244,245]. Further understanding of tolerogenic mechanisms in infants will greatly enable the development of strategies for achieving B-cell tolerance to allografts in adult patients.

The role of B cells in mixed chimerism protocols is unclear. Mixed chimerism of multilineage hematopoietic cells is associated with centrally mediated tolerance of T cells and B cells to donor allografts [246]. In one of the clinical mixed chimerism studies discussed above [48], renal allograft tolerance was achieved in four of five patients but one recipient experienced allograft loss due to acute AMR and two others developed alloantibodies despite transient mixed chimerism, indicating that tolerance can coexist with some level of B-cell reactivity to donor alloantigens. Though the relationship between transient mixed chimerism and B-cell-mediated tolerance has not been established, given the transient nature of the chimerism achieved, long-term tolerance is unlikely to result from clonal deletion of B cells alone. In humans, therefore, it is probable that other mechanisms of peripheral B-cell tolerance are involved.

Lymphocyte depletion non-specifically reduces the number of T-cell and B-cell precursors specific for alloantigen. However, plasma cells and some B-cell subsets resistant to lymphocyte-depletion therapy might pose an important barrier to the induction of allograft tolerance [85,247]. While depletional therapies have generally reduced rejection rates, their effects on B-cell tolerance have not been evaluated. In fact, some depletional agents might be associated with increased rates of AMR [248,249], as homeostatic proliferative activation of T cells might promote T-cell-mediated B-cell antibody production. Thus, the linear notion that partial B-cell depletion can reduce B-cell function and minimize AMR might be fundamentally flawed and requires further study.

Moreover, substantial depletion of T cells and B cells has been associated with increased production of TNFSF13B [88], a cytokine critical for B-cell survival, maturation and differentiation [250–252]. Increased TNFSF13B production is perhaps a response to homeostatic pressure to replace depleted lymphocytes and might lead to paradoxical B-cell activation in the setting of B-cell lymphopenia. Modulating B-cell homeostasis and survival via targeting of TNFSF13B has potentially important implications for transplantation tolerance. For example, ablation of B-cell clones in combination with controlled repopulation using TNFSF13B inhibitors might facilitate the induction of transplantation tolerance, because the newly emerged B cells could undergo induction of tolerogenic mechanisms in response to exposure to donor antigens.

An exploratory mechanistic study analyzed the gene-expression profiles in subsets of peripheral blood lymphocytes in 25 spontaneously tolerant kidney transplant recipients from the Immune Tolerance Network registry [184]. In comparison to patients with stable graft function on immunosuppression and healthy controls, gene expression of tolerant patients suggested that allograft tolerance was strongly associated with an increased expression of multiple genes involved in B-cell differentiation. This subset of B-cell-related genes or "B-cell signature" was consistent with the up-regulation of CD20 messenger RNA in urine sediment cells and the elevated numbers of naïve and transitional B cells in spontaneously tolerant kidney transplant recipients. Similarly, a study from the Indices of Tolerance European Union consortium [185], which analogously screened 11 operationally tolerant kidney transplant recipients, cohorts of immunosuppressed recipients exhibiting allograft injury and healthy controls, found that peripheral blood from tolerant patients contained higher levels of B-cell-related genes than peripheral blood from the other patients. These results suggest a critical role for B cells in the regulation of the alloimmune response in transplant-tolerant kidney graft recipients.

Summary

The field of transplantation remains burdened by a requirement for chronic immunosuppression, making immunologic tolerance a most appealing solution to combat poor long-term allograft outcomes. Rejection is an aggregate phenotype influenced by multiple interrelated pathways, all of which must be mollified to achieve donor-specific tolerance. Thus, a combination of the current strategies reviewed in this chapter is most likely to comprise the first consistent tolerance-inducing protocol. While purposeful mixed chimerism approaches have had early successes that thus far appear unrelated to durable mixed chimerism, a single proven regimen has not been developed. Lymphocyte depletion alone does not lead to tolerance and, in fact, alters homeostasis in ways that may promote immunity. Costimulation pathways have clear and potent influence over immune responsiveness, but are most relevant for naïve responses. Although the CD28:B7 pathway has advanced to the clinic in the form of belatacept, it will surely require adjuvant therapies if it is to be used as a tolerogen. Increasingly, identified regulatory and B-cell mechanisms are bound to factor significantly in future tolerance studies, and ongoing coordinated clinical efforts to identify larger numbers of operationally tolerant transplant recipients and study them should shed light on the mechanisms responsible for transplantation tolerance.

CHAPTER 12

Xenoimmunity

Peter J. Cowan and Anthony J.F. d'Apice
Immunology Research Centre, St Vincent's Hospital Melbourne and Department of Medicine, University of Melbourne, Melbourne, Victoria, Australia

Introduction

Xenotransplantation involves the transplantation of organs across species lines. While technically inclusive of all combinations of donor and recipient species combinations, the field of xenotransplantation has driven almost exclusively toward the pig to human combination as the most clinically relevant combination. Clinical xenotransplantation using pigs as donors has great potential to solve the shortage of human organs, tissues and cells that currently limits allotransplantation. The major barrier to clinical xenotransplantation is immunological rejection of the graft. Unless this key obstacle can be overcome, other important issues such as physiological compatibility [1] and infectious risk [2] become irrelevant.

Most of this textbook is about allotransplantation, and when we think of immunity in transplantation our minds naturally focus on those mechanisms that are critical in allotransplantation, specifically cellular and humoral adaptive (or acquired) immunity (discussed in depth in Chapters 5 and 6, respectively). In such a transplant into a non-sensitized recipient, the first obvious sign of the immune response is the onset of what was initially termed first-set rejection, typically manifesting after about a week, and the main mechanism is a T-cell-mediated delayed type hypersensitivity response. That xenotransplantation should be approached with a different mindset should be obvious when we note that the timing of the first manifestations of rejection is completely different, occurring within minutes. This is due primarily to the binding of preformed antibodies and a heightened innate immune response. Elements of the innate immune system are known participants in both allo- and xenotransplantation (see Chapter 7), but their involvement in xenotransplantation is far more primary. While an allograft excites some activation of the innate immune system due to the tissue damage associated with the transplant procedure, the xenograft is itself a source of molecular differences that are powerful and rapid activators of innate immunity. However, that is just the beginning of a complex story in which there are not only critical differences but also important similarities between xenoimmunity and alloimmunity. As such, the student of xenotransplantation will find this chapter to be complemented by the chapter on physiologic immunity (Chapter 2), and the chapters on fundamental alloimmunity (Chapters 5–7), particularly when concerning the later forms of xenograft rejection.

Dissecting the mechanisms of xenoimmunity has relied on a number of small and large animal models, each with their own blend of contributing factors and with widely varying degrees of relevance to clinical pig-to-human xenotransplantation. As an exhaustive discussion of these models is beyond the scope of this chapter, most of the focus here will be on the pig-to-non-human primate (NHP) preclinical model. These discussions complement those in Chapter 15, which outlines pig and primate large animal models in general.

Rejection of porcine vascularized xenografts

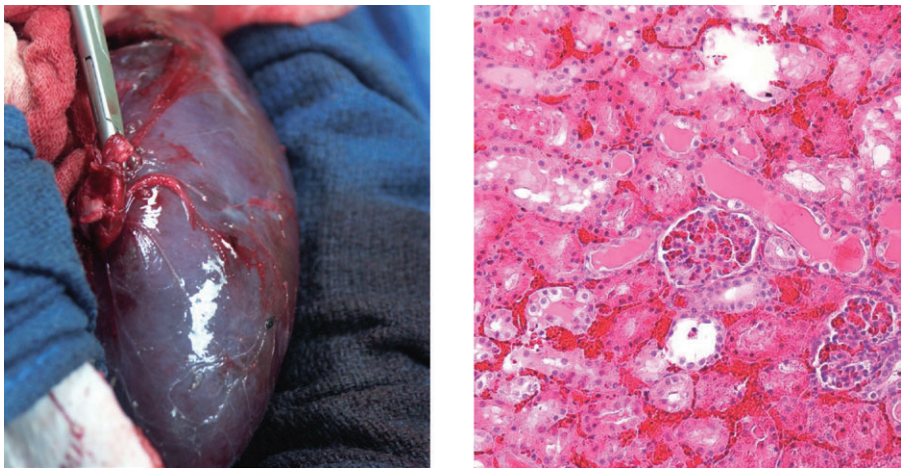
Trying to prevent the rejection of solid organ xenografts is like peeling an onion—it is only as each layer is removed that the next one becomes fully apparent. The study of porcine heart and kidney xenografts has been pivotal to understanding the rejection process because they are the only organs that can be coaxed to survive for longer than a week in NHP recipients. This section will draw mainly from the cardiac and renal pig-to-NHP literature to describe the phases of rejection, the mechanisms responsible and the approaches being taken to promote long-term xenograft survival.

Hyperacute xenograft rejection

Anti-αGal antibodies and complement: the key mediators of hyperacute rejection

Hyperacute rejection (HAR) is an extremely potent process in which porcine xenografts sustain terminal injury within minutes to hours of transplantation into untreated recipients (Figure 12.1). Like HAR of blood group ABO-incompatible allografts, HAR of xenografts is due to differences in glycosylation between the donor and the recipient. Most species, including pigs, express a glycosyltransferase called α1,3-galactosyltransferase (also known as GalT) that synthesizes the terminal carbohydrate structure galactose-α1,3-galactose-β1,4-*N*-acetyl-glucosamine (Galα1,3-Galβ1,4-GlcNAc) on glycoproteins and glycolipids. This moiety, called the αGal epitope, differs from the blood group B antigen only by the absence of a fucose residue attached to the penultimate galactose. αGal is present in abundance on the surface of most pig cells, notably on vascular endothelial cells where the estimated density is more than 10 million epitopes per cell [3]. In contrast, humans and their closest relatives, the apes and Old World monkeys, lack αGal expression due to frameshift and nonsense mutations in the coding region of the GalT gene [4]. Continual exposure to αGal on gut bacteria induces the development of anti-αGal IgM and IgG antibodies in these species [5]. In humans, anti-αGal is made by up to 1% of B cells [6], comprises about 80% of preformed ('natural')

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.



(A) (B)

Figure 12.1. Hyperacute xenograft rejection. The gross (A) and histological (B) appearance of hyperacute rejection of a pig-to-baboon kidney xenograft is shown, minutes after implantation. Note the vascular congestion seen grossly and indicative of pangraft thrombosis, and the substantial haemorrhage evident histologically indicative of a primary disruption of vascular integrity.

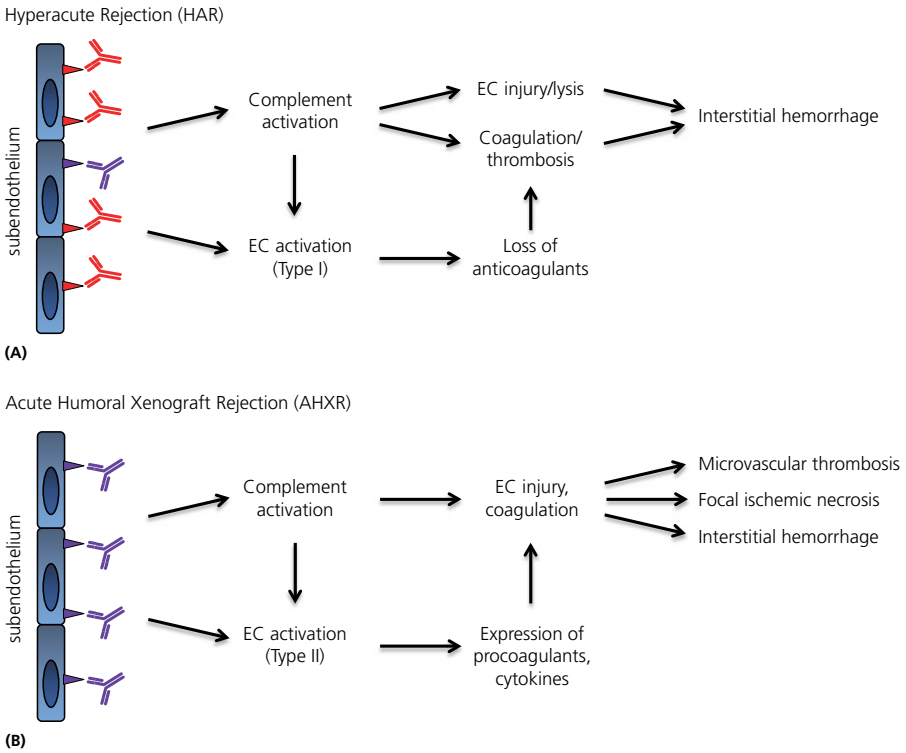


Figure 12.2. The phases of organ xenograft rejection. (A) Hyperacute rejection is initiated by the binding of preformed anti-αGal antibodies (red) to xenograft endothelial cells (EC), triggering a chain of events that culminate in vascular injury and massive interstitial haemorrhage. (B) Acute humoral xenograft rejection, exemplified here in a GTKO xenograft, is an extended process in which binding of elicited non-Gal antibodies (purple) drives a gradual conversion of the endothelial environment from anticoagulant to procoagulant.

antipig IgM [7], and is the most abundant naturally occurring IgG [8]. The corollary is that all humans possess high levels of preformed cytotoxic antibodies to an antigen that is densely expressed on the surface of pig blood vessels—a recipe for disaster for porcine organ xenografts.

Binding of anti-αGal IgM antibodies to the vascular endothelium of the xenograft triggers the classical pathway of complement activation, which in turn activates the coagulation cascade (Figure 12.2A). The resulting pathogenesis is striking at both the macroscopic and microscopic levels. Grafts change colour soon after

reperfusion, becoming mottled and dark, and initial signs of function (if any) rapidly disappear. A detailed histopathological analysis of hyperacutely rejected cardiac xenografts identified thrombosis of veins and venules as the initiating event, followed by the development of congestion, oedema and massive interstitial haemorrhage [9]. These features are the hallmarks of HAR. Immunohistochemical analysis of the early stages of HAR showed significant deposition of IgM, activated complement components and platelet aggregates, with expression of P-selectin but little evidence of endothelial cell lysis or apoptosis [10]. The overall picture is consistent with type I activation of endothelial cells, a protein synthesis-independent process involving the opening of cellular junctions, exocytosis of the platelet ligand P-selectin from Weibel–Palade bodies and loss of cell-surface anticoagulants [11]. The mediators of type I activation of xenograft endothelial cells are antibody binding and sublytic activation of complement [12,13]. At the later stages of HAR, numerous apoptotic endothelial cells are observed [10], potentially promoting further thrombosis by exposure of phosphatidylserine [14] and release of tissue factor-bearing microparticles [15].

Homologous restriction and membrane complement regulators: quality versus quantity?

One could speculate that cross-species incompatibilities contribute to the failure to efficiently regulate complement activation in HAR. In general, complement efficiently lyses 'non-self' cells from different species but not 'self' cells [16]. An early hypothesis to explain this phenomenon, known as homologous restriction, was that membrane-bound complement regulatory proteins (CRPs) from one species are unable to inhibit complement of another species [17,18]. Like humans, pigs express CD46 (membrane cofactor protein), CD55 (decay accelerating factor or DAF) and CD59; perhaps the devastating rapidity of HAR could be partly explained by an inability of these porcine CRPs to inhibit activation of primate complement. However, more recent studies have shown that homologous restriction is a patchy rather than a universal phenomenon, and that the three pig CRPs regulate human complement with efficiency similar to their human homologues [19,20]. It is also salient that ABO-incompatible human allografts can be hyperacutely rejected [21] in the presence of an autologous complement regulatory system. The ability of human (h)CRPs to prevent HAR of transgenic porcine xenografts (see below) is probably due to an elevated overall capacity to regulate complement, rather than the correction of an intrinsic molecular incompatibility.

Prevention of HAR

Conventional immunosuppression is not designed to deal with high levels of preformed antibodies and is thus ineffective against HAR [22]. A number of studies have shown that treatment of the recipient to prevent HAR requires targeting one or both of its essential components, complement and anti-αGal antibodies. For example, systemic treatment with cobra venom factor to deplete complement delayed the rejection of a cardiac xenograft from less than 1 hour to 6 days [23]. Similarly, depletion of anti-αGal antibodies by immunoadsorption delayed the rejection of renal xenografts to a mean of 7 days, although all grafts ultimately rejected when circulating anti-αGal returned [24]. While these approaches have provided valuable insights into the mechanisms of HAR, they are of limited practical benefit in the longer term because they usually afford only transient protection and may compromise the recipient's resistance to infection.

A technique that is theoretically superior to systemic therapy—and that is unique to xenotransplantation—is genetic modification of the donor. Two groups pioneered this approach in 1994 with the generation of transgenic pigs expressing hDAF [25] or hCD59 [26], followed later by pigs expressing hCD46 [27,28] or combinations of the hCRPs [29–32]. With rare exceptions [33], organs from hCRP-transgenic pigs are protected from HAR, whether or not other treatments are employed [27,28,30,31]. There are theoretical arguments for the use of particular hCRPs: DAF and CD46 because they regulate complement upstream of CD59; CD46 because it regulates the alternative pathway more effectively than DAF [28]; CD59 because of the importance of the membrane attack complex, and because thrombin can bypass regulation by DAF and CD46 by directly activating C5 [34]. However, it is not yet clear which hCRP or combination thereof will provide optimal complement regulation beyond HAR.

The second major breakthrough in genetic engineering of the donor pig was the deletion of the GalT gene [35–40]. The resulting GalT knockout (GTKO) pigs lack αGal expression but otherwise appear to be completely normal, and as expected develop anti-αGal antibodies [41]. GTKO renal and cardiac xenografts are protected from HAR in the pig-to-NHP model [42–47], confirming the central role of αGal in the rejection process.

Preformed antibodies to non-αGal determinants

While anti-αGal is the predominant natural antipig antibody in humans and higher primates, preformed antibodies with other specificities have been detected by incubating sera from non-sensitized individuals with endothelial cells or peripheral blood mononuclear cells from wild-type and GTKO pigs [48–51]. It has been suggested that many of these natural 'non-Gal' antibodies recognize carbohydrate targets expressed in pigs but not in humans [52], such as the Hanganutziu–Deicher antigen [53]. Preformed non-Gal IgG and IgM antibodies vary considerably in titre and are capable of inducing complement-dependent lysis and antibody-dependent cellular cytotoxicity (ADCC) to porcine cells [50]. However, the consistent survival of GTKO xenografts beyond 24 hours in the pig-to-NHP model suggests that they rarely play a role in HAR.

Acute humoral xenograft rejection

When HAR is averted, conventional immunosuppression usually prolongs the survival of pig-to-NHP cardiac and renal xenografts for days to weeks. Most xenografts are rejected during this period by a second antibody-dependent process known as acute humoral xenograft rejection (AHXR) (Figure 12.2B), also referred to as acute vascular rejection (AVR) or delayed xenograft rejection (DXR) [54–57]. The interchangeable terms for this phase of rejection reflect a degree of uncertainty about the underlying mechanisms, but a role for even low levels of antigraft antibodies seems quite well established. The immunopathological and histopathological signs of AHXR include antibody and complement deposition, microvascular thrombosis, focal ischaemic necrosis and interstitial haemorrhage, and endothelial cell changes ranging from swelling to severe damage and apoptosis [47,56,58]. Perivascular infiltration by lymphocytes and macrophages may also be observed, but usually only when immunosuppression has been relatively ineffective. The occurrence and severity of the features of AHXR are somewhat variable depending on the genetic background of the donor (e.g. hCRP-transgenic and/or GTKO), the immunosuppressive regimen and even the type of organ.

Just as type I activation of xenograft endothelial cells is integral to HAR, type II activation is a key element in the pathophysiology of AHXR [59]. Type II activation is a protein synthesis-dependent process triggered by a range of factors, typically proinflammatory cytokines such as TNF-α and IL-1 [11]. The mechanism involves activation of the transcription factors NF-κB and AP-1 and subsequent expression of proinflammatory proteins including chemokines and adhesion molecules; the resulting cytokine- and leukocyte-mediated injury to endothelial cells favours thrombosis [11]. Type II activation of porcine endothelial cells can be initiated by the binding of xenoantibodies even in the absence of complement activation [60].

The T-cell-dependent xenoresponse

As discussed in Chapter 5, donor antigens can be presented to recipient T cells by two pathways: direct, in which the T-cell receptor (TCR) engages mismatched MHC–peptide complexes on donor antigen-presenting cells (APCs); and indirect, in which recipient APCs take up and process donor molecules and present antigenic fragments within self-MHC to the TCR. The T-cell response in allotransplantation stems from a mixture of direct and indirect presentation, with the direct pathway predominating in acute allograft rejection [61]. (The significance of a third pathway [semidirect presentation] to allograft rejection remains unclear [62].) In contrast, the balance in acute xenograft rejection appears to be shifted in favour of indirect presentation [63,64]. Numerous porcine proteins and carbohydrates released by injury to xenografts provide the source material for the processing of xenoepitopes that can be presented by the indirect pathway. That is not to say that direct presentation does not play a role—the human TCR is capable of recognizing swine leukocyte antigen (SLA, the porcine equivalent of MHC) [65], and in vitro data suggest that porcine lymphocytes can directly activate human T cells [66]. The overall stimulus for T-cell activation is powerful, and among the consequences, T-cell help to B cells will be of major significance to the development of AHXR.

Identity of the antibodies and antigens responsible for AHXR

Elicited anti-αGal antibodies are the predominant cause of AHXR of αGal-positive xenografts [67]. When these antibodies are neutralized, AHXR can be induced by non-Gal antibodies, either preformed high-titre IgG or elicited IgG and IgM [68,69]. Non-Gal antibodies are also responsible for AHXR of GTKO organs [70]. The relevant non-Gal xenoantigens have not been unequivocally defined. Candidate carbohydrate xenoantigens include *N*-glycolyl-neuraminic acid (NeuGc), *N*-acetyl-neuraminic acid (NeuAc), and the T and Tn antigens [71]. The number of protein xenoantigens, on the other hand, could number in the hundreds or even thousands. Almost all pig proteins exhibit amino acid sequence differences to their human homologues and are thus potentially immunogenic. The induced non-Gal antibody response has been examined in NHP and human recipients of porcine xenografts. One NHP study showed that induced non-Gal antibodies to GTKO cells are encoded by a restricted number of germline progenitors and may bind to a carbohydrate epitope structurally related to αGal [48]. In human recipients, non-Gal antibodies to a large number of unidentified pig proteins were continuously produced, apparently from multiple B-cell clones, for as long as the xenograft remained in the recipient [72].

Possible effects of non-Gal antibodies on endothelial cell function

In addition to activating endothelial cells and mediating ADCC, elicited non-Gal antibodies may contribute to AHXR by interfering with critical vasculoprotective mechanisms. One group searched for xenoantigens by using sera from sensitized baboons, enriched in non-Gal IgG, to screen porcine endothelial cell expression libraries [73]. Four targets of non-Gal that were consistently identified were endothelial membrane proteins involved in the regulation of complement (CD46 and CD59) and thrombosis/ inflammation (endothelial protein C receptor and CD9). Although the ability of the sera to inhibit the function of these proteins was not assessed, it seems conceivable and perhaps even likely that the non-Gal antibody response can promote AHXR by blocking the natural defence systems of xenograft endothelial cells. This strengthens the argument for expressing the corresponding human proteins in pigs, as has been done for CD46 and CD59.

Prevention of AHXR

The deletion of αGal significantly prolongs the survival of cardiac and renal xenografts [74], but AHXR of GTKO organs has proven extremely difficult to prevent. Conventional immunosuppression capable of protecting renal allografts did not protect GTKO xenografts, which succumbed to the induced non-Gal antibody response [44]. This outcome highlights that drugs designed to suppress the acute T-cell alloresponse, which involves predominantly direct presentation, are less effective against the mostly indirect xenoresponse. More success has been achieved with costimulation blockade-based regimens, in particular those employing anti-CD154, with survival of GTKO ± hCD46 hearts for up to 8 months [43,75] and GTKO composite kidney–thymus grafts for nearly 3 months [42]. However, immunohistochemical analysis of the xenografts at rejection or recipient death indicated that non-Gal antibodies were not completely negated by these protocols. It is conceivable that molecular incompatibilities unique to the xenograft context, which will be discussed in the following two sections, promote a disproportionate response to even relatively low levels of xenoreactive antibodies.

Role of innate immune cells

As discussed in Chapter 7, an important component of innate immunity is the ability of innate immune cells to recognize and respond to pathogen-associated and damage-associated molecular patterns (PAMPs and DAMPs, respectively), primarily through Toll-like receptors [76,77]. The process of transplantation generates DAMPs irrespective of whether the donor is of the same or a different species. Where xenotransplantation differs from allotransplantation is that human innate immune cells appear to directly recognize porcine cells as foreign, largely because of differences in cell surface glycosylation [78,79]. There is also evidence that molecular incompatibilities affect particular cellular interactions, which will be discussed further below.

NK cells

Natural killer (NK) cells injure and lyse target cells by a variety of mechanisms. Although the role of these cells in solid organ allotransplantation has not been fully defined, data suggest that they are activated by the transplant process and contribute to acute rejection by producing inflammatory cytokines such as interferon gamma (IFN-γ) [80–82]. NK cells express a set of activating and inhibitory receptors, and their cytolytic activity is determined by

the balance of interactions between these receptors and ligands on the target cell. In the human allograft setting, the key NK receptors include the inhibitory killer-cell immunoglobulin-like receptor (KIR) family and NKG2A, which bind self but not allogeneic MHC class I, and the activating NKG2D receptor, which recognizes several 'stress' ligands that are up-regulated on allografts [83–85].

Several in vitro studies suggest that the human NK cell response to xenografts is more pronounced than that to allografts. FcγRIII-mediated ADCC, while considerably reduced by the elimination of αGal [86], is likely to remain a problem due to elicited non-Gal IgG antibodies [87]. Human NK cells are also capable of direct perforin/ granzyme B-mediated cytotoxicity to porcine endothelial cells [88]. Furthermore, there is evidence that pig cells provoke an exaggerated human NK cell cytotoxic response [89]. Gene sequence analysis indicates that SLA class I will not transmit an inhibitory signal to human KIRs and NKG2A [90]. In contrast, several activation pathways are fully operational (Figure 12.3). Human NKG2D efficiently binds ULBP1 expressed on pig endothelial cells, triggering NK cytotoxicity [91], and may bind an additional, as yet unidentified, porcine ligand(s) [92]. NKp44 also transmits an activating signal from an unknown porcine ligand [93]. The involvement of the human C-type lectin NKRP1A, which binds *N*-acetyllactosamine (NAcLac) and (with apparently lower affinity) αGal [94], is less clear. As the substrate of α1,3-galactosyltransferase, NAcLac might be expected to be exposed at increased levels in GTKO animals, but this has been demonstrated only in mice [94,95] and not in pigs [96]. However, irrespective of the role of NKRP1A, the balance between inhibitory and activating NK signals in xenotransplantation appears to be tilted towards activation.

A logical genetic strategy to attenuate human NK cell xenoreactivity is to change this balance by expressing inhibitory ligands on porcine tissue and/or deleting activating ligands. The latter is a more challenging proposition because of the number and diversity of activating ligands, some of which remain unknown, so most work in this area has focused on the expression of inhibitory signals. The most advanced example of this approach is the generation of transgenic pigs expressing the non-classical human MHC class I molecule HLA-E [97], following promising in vitro proof-of-concept studies [98,99]. HLA-E was used because it binds the inhibitory NK receptor NKG2A and is a poor inducer of allogeneic T-cell responses. Endothelial cells from the transgenic pigs were partially protected from human NK cell-mediated cytotoxicity in vitro in an NKG2A-dependent manner [97]. Determining in vivo efficacy will probably require crossing the HLA-E transgene onto an appropriate genetic background in which other more profound xenoimmune mechanisms have been addressed (e.g. GTKO ± hCRP-transgenic). The use of GTKO donors may itself reduce the NK cell xenoresponse, because several studies have demonstrated that human NK cells directly recognize αGal on pig endothelial cells, although this remains controversial [87].

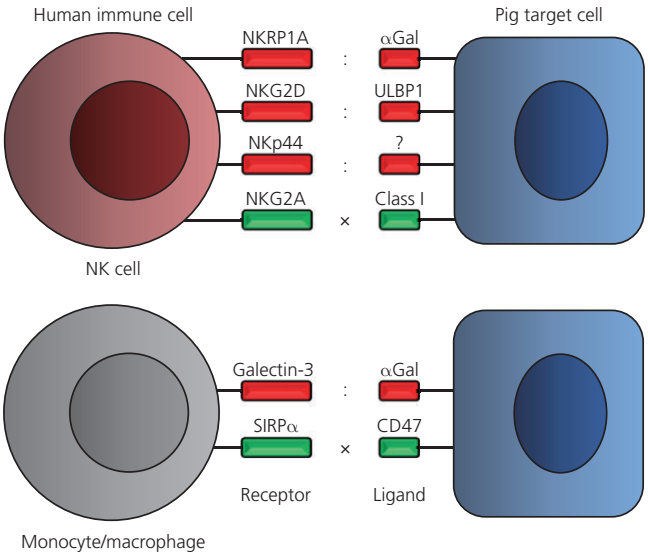

Figure 12.3. The heightened reactivity of human innate immune cells to porcine targets. Interactions between activating receptor/ligand pairs (red) are preserved, while key inhibitory interactions (green) appear to be non-functional due to molecular incompatibilities.

Macrophages

Infiltration by macrophages is a common feature of acute antibody-mediated renal allograft rejection [100], although evidence for a direct role in the rejection process is lacking [82]. Macrophages express receptors for Fc and complement and are therefore likely to be involved in antibody- and complement-dependent mechanisms of xenograft rejection. Human monocytes have been shown to directly recognize αGal on pig endothelial cells via the galectin-3 receptor [79]. Furthermore, as is the case for NK cells, cross-species molecular incompatibility may reduce the threshold for activation of human macrophages by porcine cells (Figure 12.3). SIRPα is a highly polymorphic macrophage inhibitory receptor that recognizes CD47 as a marker of 'self' on other cells [101]. In the absence of a functional SIRPα/CD47 interaction, macrophages are capable of phagocytosing haematopoietic cells [102]. Although human SIRPα was shown to bind porcine CD47 in vitro [103], subsequent studies indicated that this interaction does not send a negative signal and thus does not prevent human macrophages from engulfing porcine cells [104]. Consistent with this, expression of human CD47 on porcine cells inhibited their phagocytosis by human macrophages in vitro [104] and protected them from rejection in a mouse tumour model [105]. These results suggest that transgenic expression of human CD47 in pigs may be a useful strategy to prevent macrophage-mediated destruction of xenografts. The benefits of this approach are likely to be greatest for cellular xenografts such as haematopoietic stem cells (for tolerance induction) and islets.

Neutrophils

The role of neutrophils in allograft rejection remains largely unknown [82], but the fact that they are recruited and activated by antibody- and complement-mediated mechanisms argues for at least a secondary involvement in the rejection of xenografts. In addition, in vitro studies have shown that human neutrophils directly recognize, adhere to and activate pig endothelial cells in the absence of antibody and complement [106,107]. Should this interaction prove to be significant in vivo, it will be difficult to prevent. There are few treatment options to control neutrophil number and/or activity that do not leave the recipient susceptible to opportunistic infection. Genetic modification of the donor to express human CD47 may be beneficial because neutrophils, like macrophages, are known to express SIRPα, although the incompatible human

SIRPα/pig CD47 interaction seems to be of greater significance for macrophage activation. Identification and deletion of the porcine molecule(s) directly recognized by human neutrophils, which does not appear to be αGal [107], is another avenue.

Dysregulated coagulation

Graft endothelial cells are activated by a range of mechanisms including ischaemia–reperfusion injury (IRI), antibody binding and complement activation [108]. In extreme circumstances, the procoagulant effects of endothelial cell activation can result in allograft loss. Thrombotic microangiopathy (TMA), a complication of renal allotransplantation, is an example of this. TMA in renal allografts is triggered de novo by immunosuppressive drugs or acute antibody-mediated rejection, and is characterized by vessel wall thickening and microvascular thrombosis [109]. It is frequently associated with a reduced capacity to regulate the alternative pathway of complement activation. Renal allograft recipients with mutations affecting the circulating alternative pathway regulators factor H and factor I appear to be at increased risk of de novo TMA [110]. This not only reflects the interplay between the complement and coagulation pathways, but also points to some of the unique problems that may be faced by organ xenografts. The routes to activation of complement in xenotransplantation are more numerous and varied than in allotransplantation, and induced antibodies have been shown to target regulators of complement expressed on porcine endothelial cells [73].

Indeed, while severe coagulation is rare in allotransplantation, it is relatively common and difficult to deal with in xenotransplantation. Dysregulated coagulation is one of the major current challenges in organ xenotransplantation [74,111–113]. TMA is frequently observed in rejected cardiac and renal pig-to-NHP xenografts [114,115]. Even when the humoral response appears to have been effectively suppressed, TMA still develops and is a major cause of xenograft failure [43,45,116]. TMA in xenografts is often accompanied by the development of consumptive coagulopathy, characterized by thrombocytopenia (often profound), a falling fibrinogen concentration, increased levels of D-dimer and thrombin-antithrombin complex, and prolonged clotting time. Coagulopathy is common in renal xenograft recipients [30,117–120], and can only be treated by removal of the graft [118]. Recipients of cardiac xenografts seem to be less prone to developing the condition [121,122], although not without exception [116]. It has been suggested that these different outcomes may be due to differential gene responses in the endothelium of renal and cardiac xenografts, with up-regulation of von Willebrand factor (vWF) and P-selectin (favouring platelet deposition) in the former and of plasminogen activator inhibitor-1 (favouring fibrin deposition) in the latter [123].

Dysregulated coagulation also plays a major role in lung and liver xenotransplantation. Long-term function of lung xenografts has not yet been achieved in the pig-to-NHP model. Xenoreactive antibodies, complement activation, pulmonary macrophages, shedding of vWF by pulmonary endothelium and poor control of coagulation have all been suggested to play a role in the rejection process [124,125]. The maximum reported graft survival, achieved using vWF-deficient donor lungs depleted of macrophages, was 4.5 days [126], but in most cases survival has been measured in hours [127–129]. Even the combination of GTKO/hDAF-transgenic donors and depletion of pulmonary macrophages failed to extend graft survival beyond 2 days [130]. The main histological features of pulmonary xenograft rejection are micro- and macrovascular thrombosis, neutrophil infiltration and oedema [126,129]. The development of consumptive coagulopathy is even more rapid and consistent than in kidney xenotransplantation, although why pig lung xenografts should be particularly susceptible to coagulation remains unclear.

Coagulopathy in the form of severe thrombocytopenia is a major problem in pig-to-NHP liver xenotransplantation. Baboons transplanted with GTKO/hCD46 livers died or had to be euthanased within 7 days, not due to rejection but rather to bleeding problems resulting from a sharp and prolonged drop in platelet count within an hour of transplantation [131]. At necropsy, the grafts showed only patchy injury at the macroscopic and microscopic levels [131,132] and liver function was relatively normal [133]. The degree of platelet deposition in the livers did not appear to be extensive enough to account for the severity of thrombocytopenia, which was instead hypothesized to be due to rapid platelet activation and subsequent formation of platelet–leukocyte aggregates in the circulation [134]. An alternative mechanism, proposed on the basis of ex vivo perfusion studies, is that pig liver sinusoidal endothelial cells and Kupffer cells rapidly and efficiently phagocytose human platelets in an antibody- and complement-independent manner [135–137].

Expression of tissue factor by recipient platelets and monocytes

In vitro and in vivo studies indicate that tissue factor is up-regulated on pig endothelial cells activated by elicited anti-αGal and/or non-Gal antibodies (Figure 12.4), even in the absence of complement, contributing to intravascular coagulation and the development of consumptive coagulopathy [138]. More recently, it has been proposed that the induction of tissue factor expression on recipient platelets and monocytes may also play a significant role. Human platelets and monocytes up-regulate tissue factor expression and activity simply by contact with pig endothelial cells, in the absence of antibody and complement [139]. Rejected GTKO pig-to-baboon cardiac xenografts showed tissue factor expression on recipient macrophages in thrombosed vessels and in the interstitium [116]. Time-course analysis of circulating cells in baboon recipients of GTKO/hCD46 porcine renal xenografts revealed several quite

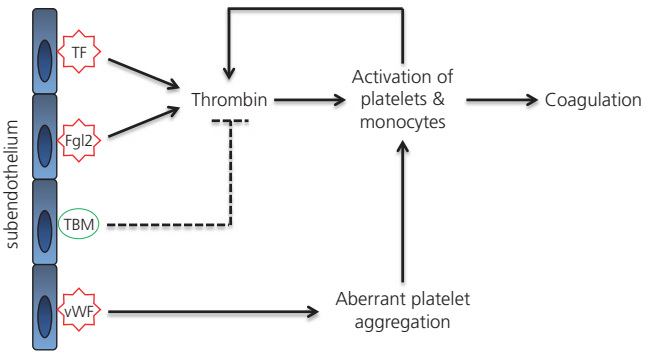

Figure 12.4. The potential mechanisms of dysregulated coagulation in solid organ xenotransplantation. Expression of tissue factor (TF) and the direct prothrombinase fgl2 by activated xenograft endothelial cells drives thrombin generation, which is poorly controlled by pig thrombomodulin (TBM). In addition, human platelets aggregate in response to pig von Willebrand factor (vWF) in the absence of shear stress, and are activated by contact with pig endothelium.

distinct stages: up-regulation of tissue factor on platelets within a day of transplantation, followed by the appearance of increasing numbers of platelet–leukocyte aggregates, and finally expression of tissue factor by monocytes, accompanied by the onset of thrombocytopenia and other features of coagulopathy [120]. Recipient tissue factor was also detected in the native heart and liver at necropsy. These events occurred in the apparent absence of a significant humoral response, leading the investigators to hypothesize that: (1) platelets are activated to express tissue factor soon after transplantation in response to inflammation and contact with xenograft endothelium; (2) monocytes subsequently express tissue factor after being activated by thrombin and/or by adhesion to activated platelets; and (3) the resulting systemic exposure of recipient tissue factor triggers consumptive coagulopathy [120]. However, the failure of other groups to observe this very early and profound coagulopathy in GTKO renal xenograft recipients [140] suggests that it may be model dependent rather than universal.

Tissue factor-independent coagulation: direct prothrombinase activity

Pig endothelial cells express an enzyme called fgl2, which directly converts human prothrombin to thrombin [141] (Figure 12.4). Fgl2 expression and activity is induced in porcine endothelial cells by proinflammatory cytokines including human TNF-α [141,142]. Rejected pig-to-baboon renal xenografts showed up-regulated fgl2 expression in association with fibrin deposition in small vessels and glomerular capillaries [141]. Interestingly, co-localization of fgl2 and fibrin was also observed in rejecting human renal and mouse cardiac allografts [143,144]. This suggests that fgl2 is a common inflammation-mediated mechanism for tissue factor-independent coagulation in acute rejection of solid organ transplants, although it should be noted that this view is not universally shared [144].

Molecular incompatibilities in the control of coagulation and inflammation

Coagulation and inflammation are powerful interlinked processes that require multiple levels of regulation [145,146]. The vascular endothelium maintains an anticoagulant and anti-inflammatory surface by expressing a range of regulatory proteins. Tissue factor pathway inhibitor-1 (TFPI-1) sequesters factor Xa and factor VIIa/tissue factor and is the primary physiological regulator of the initiation phase of coagulation [147]. Antithrombin inhibits multiple coagulation serine proteases including factor Xa and thrombin [148]. Thrombomodulin (TBM) binds thrombin and alters its specificity from procoagulant and proinflammatory substrates, such as fibrinogen and protease activated receptors, to protein C; activated protein C (APC) inhibits the propagation phase of coagulation by inactivating factors Va and VIIIa [149]. The endothelial protein C receptor (EPCR) enhances APC generation by the TBM/thrombin complex and mediates many of APC's anti-inflammatory and cytoprotective effects [150]. TBM also has direct, APC-independent anti-inflammatory effects via its lectin-like domain [151,152].

Some of these regulators (TFPIα and antithrombin) are circulating proteins that associate with the endothelial cell surface via heparan sulphate proteoglycans, while others are integral endothelial membrane proteins. In transplanted organs, the latter group (TFPIβ, TBM and EPCR) will be of donor origin—a distinction that is irrelevant in allotransplantation, but potentially critical in xenotransplantation if the regulators do not function efficiently across the species barrier. This was first highlighted by in vitro studies in the 1990s suggesting that pig TFPI does not bind human factor Xa and that this failure may contribute to uncontrolled coagulation in xenografts [153,154]. More recently, however, a recombinant form of pig TFPI, expressed in transfected cells, was shown to bind and inactivate human factor Xa and factor VIIa/tissue factor as efficiently as human TFPI [155]. Furthermore, even if there is a degree of incompatibility, it should be corrected to some extent by association of recipient-derived TFPIα with xenograft endothelium.

There is more compelling evidence for a molecular incompatibility affecting the protein C pathway. Pig TBM binds human thrombin but is a poor cofactor for activation of human protein C, with only 1–10% of the activity of human TBM [156–158]. It is quite conceivable that this level of impairment will have a detrimental impact in vivo (Figure 12.4), considering that the protein C pathway is a key regulator of coagulation and inflammation within the microvasculature [149] and that microvascular thrombosis is a feature of xenograft rejection [9,58]. Expression of human TBM in pig endothelial cells in vitro suppressed classical and direct (fgl2) prothrombinase activity and delayed cell-mediated clotting of human plasma [142,159]. Pig EPCR has been less well studied, although it has been reported to bind human protein C in vitro [160]; targeting of this regulator by induced antibodies [73] may prove to be a more significant problem than molecular incompatibility.

Another incompatibility defined in vitro may promote platelet adhesion and aggregation in xenografts. Human platelets spontaneously aggregate upon contact with porcine vWF (Figure 12.4), in the absence of shear stress, due to an aberrant interaction between human platelet glycoprotein Ib (GPIb) and the *O*-glycosylated A1 domain of vWF [161–163]. The in vivo significance of this heightened platelet response is not known. The use of donors severely deficient in vWF expression had no obvious impact on coagulation or graft survival in a pig-to-baboon renal xenograft model [164], suggesting that porcine vWF is not a major contributor to dysregulated coagulation. However, the only treatment of the recipients in this study was depletion of natural antipig antibodies by immunoadsorption prior to transplantation. Any effect of the vWF deficiency may have been difficult to distinguish in the face of the ensuing humoral response, which was severe and caused rejection of all grafts within 5 days [164].

Approaches to control dysregulated coagulation

Intravascular thrombosis in short-term ex vivo pig organ xenoperfusion models can be inhibited by pharmacological antithrombotic drugs including APC [165], desmopressin, which reduces vWF content [166], and tirofiban, a platelet GPIIb/IIIa receptor inhibitor [167]. In vitro experiments suggest that statins may also be useful by blocking the up-regulation of tissue factor in activated pig endothelial cells [168]. Anticoagulation in vivo is more challenging because the dosage must be balanced against an increased risk of bleeding. The pig-to-NHP model has been used to test many anticoagulant and antiplatelet agents, including warfarin, antithrombin, APC, heparin, aspirin, and clopidogrel [45,169–173]. While there was evidence for limited benefits in several of these studies, it would be fair to say that pharmacotherapy will not be the complete answer to controlling thrombosis and prolonging xenograft survival [174]. This may be partly a reflection of progressive damage to xenograft endothelium by mechanisms such as ADCC that are not directly influenced by anticoagulation.

Perhaps the best prospect for solving the coagulation problem is genetic modification of the donor pig. This has already been partly addressed by deleting αGal and expressing hCRPs, which reduce

the stimuli for endothelial cell activation and coagulation. However, these modifications alone appear to be insufficient because dysregulated coagulation is still evident in baboon recipients of GTKO ± hCRP-transgenic xenografts [116,120]. The next logical step is to express human anticoagulant and antiplatelet molecules to correct molecular incompatibilities and/or to provide a supraphysiological level of control of thrombosis within the xenograft. The beneficial effects of expressing human TFPI and TBM have been demonstrated in murine transplant models [175,176]. Both proteins have also been expressed in transgenic pigs [168,177–179], but in vivo efficacy data are not yet available.

Another molecule of interest is the ectonucleotidase CD39, which plays a critical thromboregulatory and anti-inflammatory role on vascular endothelium [180]. CD39 sequentially degrades extracellular ATP to ADP and AMP, which is then hydrolysed to adenosine by CD73. It therefore removes proinflammatory (ATP) and prothrombotic (ADP) signals, while concurrently promoting the generation of adenosine, which has a generally dampening effect on the activity of both innate and adaptive immune cells [181,182]. Like several other anticoagulant/ anti-inflammatory molecules, including heparan sulphate [183], TBM [184] and EPCR [185], CD39 is lost from the endothelium during inflammation, promoting vascular injury [186]. Over-expression of CD39 is therefore an attractive prospect in xenotransplantation. Proof-of-concept studies using transgenic mice have shown that expression of human CD39 protects hearts and kidneys from transplant-related vascular injury [187,188]. A preliminary report suggests that the addition of human CD39 to a GTKO/hCRP-transgenic background was not sufficient to prevent AHXR of pig-to-baboon renal xenografts, although the level of CD39 expression was reportedly low [189].

Chronic xenograft rejection

Reports of chronic xenograft injury are relatively rare because few organ xenografts have survived long enough for this type of injury to develop. Chronic vasculopathy, considered to be a characteristic feature of chronic allograft rejection, was observed in GTKO pig-to-baboon cardiac xenografts that survived for between 78 and 179 days [47]. In another study, a GTKO pig-to-baboon renal xenograft that survived for 81 days under an immunotolerance protocol showed evidence of chronic glomerulopathy, similar to that observed in clinical allotransplantation [190]. Possible reasons proposed for the development of glomerulopathy were unstable induction of tolerance, injury by preformed non-Gal antibodies and dysregulated coagulation. However, the mechanism of chronic xenograft rejection is likely to remain obscure until more consistent long-term survival is achieved.

Rejection of porcine islet xenografts

Pig islet xenotransplantation covers a broad range of procedures in which there may be different sources of tissue (embryonic, fetal, neonatal, young, adult), different routes of delivery (intraportal, renal subcapsular, intraperitoneal, subcutaneous, omental), and different methods of immunoprotection (immunosuppression, encapsulation). Many of these factors have been discussed in recent reviews [191,192]. This section will focus mainly on intraportal transplantation of neonatal or adult pig islets into NHP, because it is the model that is most widely used and most closely reflects current clinical islet allotransplantation practice. Additional discussions of this topic can be found in Chapter 15.

The instant blood-mediated inflammatory reaction

Intraportal transplantation brings islets directly into contact with the circulation, provoking an immediate thrombotic/ inflammatory response termed the instant blood-mediated inflammatory reaction (IBMIR). This phenomenon, first recognized in allotransplantation [193], is characterized by rapid activation of complement and coagulation, adherence of activated platelets to the islet surface, entrapment of islets in clots, and infiltration by activated neutrophils and monocytes [194]. The proposed mechanisms include binding of natural antibodies, islet expression of tissue factor and chemoattractants such as MCP-1, exposure of thrombogenic molecules such as collagen, and the absence of membrane regulators of complement and coagulation [195–197]. IBMIR is thought to be the major factor responsible for the early destruction of approximately half of the islet allograft mass [198,199].

IBMIR is also well described in pig-to-NHP islet xenotransplantation [200–202] and in pig-to-human in vitro models [200,203,204]. In fact, IBMIR is likely to be more severe in xenotransplantation because of higher levels of natural antibodies and the hyperactive innate immune response to xenogeneic cells [205]. This is supported by the observation that the number of pig islets required to consistently reverse diabetes in NHP (25 000–100 000 islet equivalents per kg body weight) [206–208] is much higher than the number of human islets used to similar effect in clinical allotransplantation.

Acute cellular rejection of pig islet xenografts

Intraportal islet xenografts surviving the initial innate onslaught of IBMIR are subjected to an adaptive immune response that is predominantly dependent on, and mediated by, T cells [191]. In the absence of immunosuppression, adult pig islets are destroyed within 3 days by acute cellular rejection, with $CD4^+$ and $CD8^+$ T cells and macrophages most prominent in the infiltrate [201]. With T-cell-targeted immunosuppression including costimulation blockade, intraportal islet xenografts from wild-type pigs are capable of restoring insulin independence in diabetic monkeys for several months [206,209,210].

The role of αGal in pig islet xenograft rejection

Expression of αGal on pig islet β cells appears to correlate with their maturity, with neonatal β cells expressing significant levels and adult β cells virtually none [211]. Adult pig islet preparations therefore contain little αGal, apart from that expressed on residual contaminating non-endocrine cells, and do not seem to be susceptible to anti-αGal antibodies [191,206]. This interpretation is supported by a pig-to-monkey study that showed no apparent survival benefit for GTKO adult islet xenografts, although the numbers were too small to draw definitive conclusions [207]. In contrast, αGal clearly plays an important role in the rejection of neonatal porcine islets. Xenografts from neonatal GTKO pigs showed significantly improved engraftment and induced less intrahepatic inflammation in diabetic monkeys than wild-type grafts [212].

Strategies to protect pig islet xenografts

Islets are somewhat different to organs in that there are a far smaller proportion of patients for whom the benefits of transplantation outweigh the side-effects of immunosuppressive drugs. It is therefore critical to develop strategies to reduce the level of immunosuppression required in islet xenotransplantation, or even to eliminate it altogether. For intraportal porcine islet xenografts, a major goal is to protect the islets from early inflammatory and thrombotic

mechanisms, as this would enable transplantation of fewer islets and reduce stimulation of adaptive xenoimmunity. A combination of pharmacological and genetic approaches will probably be necessary. One treatment option to regulate complement and coagulation is low molecular weight dextran sulphate [203,207]. On the genetic side, deletion of αGal has clear benefits for neonatal islet xenografts [212], and expression of hCD46, while not preventing early attrition, significantly prolonged adult islet xenograft survival [207]. Certain genetic modifications designed to protect organ xenografts, such as the expression of various human anticoagulant molecules described earlier, should also benefit islet xenografts.

The induction of tolerance is another avenue that has produced promising results recently. Diabetic monkeys transplanted with adult pig islets under the cover of anti-LFA-1, anti-CD154 and low-dose rapamycin showed xenoantigen-specific T-cell tolerance, and maintained insulin-independent normoglycaemia for more than 140 days [208].

Another strategy to protect pig islets from IBMIR and the xenoimmune response is to encapsulate them in alginate-based compounds, allowing passage of nutrients and insulin but preventing entry of antibodies and immune cells. The potential of encapsulated pig islets to correct diabetes for long periods, without immunosuppression, has been demonstrated in monkeys transplanted either intraperitoneally with microcapsules [213] or subcutaneously with a macroencapsulation device [214]. A Phase IIb clinical trial of microencapsulated pig islets is currently in progress in New Zealand, but full results are not yet available.

Rejection of other types of porcine xenograft

Neuronal cell xenografts

Transplantation of pig dopaminergic tissue into the brain has long been proposed as a therapy to relieve the symptoms of Parkinson's disease. In a clinical trial in the 1990s, 12 patients were transplanted with fetal pig neuronal cells, half under the cover of cyclosporine and half receiving grafts that had been treated with the Fab fragment of a monoclonal antibody directed against MHC class I [215]. Although there was evidence of improved function in some recipients, neither immunosuppressive strategy was able to prevent rejection, despite the brain being considered a relatively immune-privileged site. In contrast, a study in mice showed that embryonic pig neuronal cell xenografts were protected from rejection by short-term costimulation blockade with CTLA4Ig, anti-CD154 and anti-LFA-1 [216]. More recently, Parkinsonian monkeys were transplanted with fetal neural tissue from transgenic pigs expressing human CTLA4Ig from a neuron-specific promoter, under immunosuppression with cyclosporine, mycophenolate and steroids. Preliminary data indicated prolonged engraftment (up to 17 months) and significant improvement in locomotor function in monkeys receiving CTLA4Ig-transgenic cells, but not in those receiving control non-transgenic grafts [217]. A relatively high incidence of post-transplant lymphoproliferative disease in the recipients suggests that adjustment of the immunosuppressive regimen and/or further genetic modification of the donor is still required.

Corneal xenografts

The prospects for xenotransplantation of pig corneas have been reviewed recently [218,219]. The relatively few pig-to-NHP corneal xenotransplantation studies performed to date have shown that corneal xenografts are not subject to HAR, as might be expected for an avascular tissue transplanted into an immune-privileged site, but usually succumb to a largely T-cell-mediated rejection process over weeks to months [220–223]. The corneal endothelium appears to be the primary target of the immune response [221], and decellularization of corneal xenografts reduces the frequency of rejection [223]. The role of αGal and non-Gal antigens in corneal xenograft rejection has not been determined, but the expression of αGal on corneal keratocytes and endothelial cells [218] and the sensitivity of the latter to lysis by complement-fixing antibodies [224] suggest that GTKO ± hCRP-transgenic xenografts may have a survival advantage.

Reducing the immunosuppressive burden

Systemic immunosuppression, with its attendant complications and side-effects, is a greater challenge in xenotransplantation than in allotransplantation because of the severity of the xenoimmune response. Xenotransplantation of porcine solid organ xenografts will not enter clinical practice unless the degree of immunosuppression required can be reduced to a manageable level, similar to or less than that used in allotransplantation. Three potential solutions to this problem are outlined below.

Induction of accommodation

Pig-to-NHP xenografts have occasionally been observed to survive and function normally despite the presence of circulating xenoantibodies and immunohistochemical evidence of antibody and complement deposition on graft endothelium [67,225,226]. This is an example of accommodation, an incompletely understood phenomenon in which vascularized organ allografts or xenografts acquire resistance to acute humoral injury and rejection [227,228]. Little is known about the mechanism or durability of accommodation in the pig-to-NHP model. Evidence from other models suggests that sublethal injury to grafts, particularly as a consequence of antibody binding, can trigger the activation of protective pathways that lead to resistance to humoral immunity. These pathways include up-regulation of the complement regulators DAF and CD59 [229,230] and cytoprotective molecules such as A20 and heme oxygenase-1 [231]. Certain genetic strategies designed to inhibit humoral rejection of porcine xenografts, for example transgenic expression of hCRPs, might therefore be expected to promote the development of accommodation. However, there is no evidence so far that this is the case, and accommodation of pig-to-NHP xenografts remains elusive.

Induction of tolerance

The T-cell-mediated xenoresponse has proven to be a formidable barrier in pig-to-NHP solid organ xenotransplantation. Even the combination of genetically modified donors and intensive T-cell-directed immunosuppression has not resulted in a clinically applicable outcome. This has led to the suggestion that the induction of T-cell tolerance (the mechanisms of which are discussed in additional detail in Chapter 11) will be essential to the success of any treatment regimen for clinical xenotransplantation [232]. The two approaches to tolerance induction are mixed chimerism and co-transplantation of thymic tissue. Both methods have been used to establish that human T cells can be tolerized to porcine xenografts, albeit in highly manipulated humanized mouse models [233,234]. In the more challenging pig-to-NHP model, stable mixed chimerism has been difficult to achieve, even with intensive preconditioning of recipients and massive doses of wild-type pig haematopoietic stem cells (HSCs) [235]. There is some evidence that natural

xenoantibodies may present an obstacle to HSC engraftment. The use of GTKO donors reduced the number of cells required to achieve the same level of transient chimerism, and prolonged the period of cellular hyporesponsiveness as measured by mixed lymphocyte reaction [236]. In a more recent study also using GTKO HSCs, the degree of transient bone marrow chimerism and nonresponsiveness to pig cells inversely correlated with the level of preformed non-Gal antibodies in the recipients [237]. Only the two baboons with relatively high pretransplant titres of non-Gal IgG failed to demonstrate chimerism or pig-specific hyporeactivity, and both rapidly rejected pig kidneys transplanted soon after bone marrow infusion [237]. Another possible reason for the failure of porcine HSCs to stably engraft is destruction by macrophages and NK cells due to the previously discussed SIRPα/CD47 and KIR/SLA cross-species incompatibilities, respectively. It remains to be seen whether transgenic expression of human CD47 and HLA-E on donor cells will enhance the establishment of mixed chimerism.

Transplantation of porcine vascularized thymic tissue, either as thymic lobes or 'thymokidneys' (kidneys in which autologous thymic tissue is engrafted before renal xenotransplantation), has produced more promising results. Initial experiments using αGal-positive thymokidneys showed some evidence of thymopoiesis and T-cell hyporesponsiveness in vitro, but xenografts were rejected within 30 days upon the return of anti-αGal antibodies [238]. The use of GTKO donors markedly prolonged thymokidney survival in baboons to up to 83 days, among the longest recorded for a life-supporting xenograft in the pig-to-NHP model [42]. The immunosuppressive regimen included thymectomy, splenectomy, whole body irradiation (WBI), antibody-mediated T-cell depletion, mycophenolate mofetil, anti-CD154 and low-dose steroids. Unfortunately, this regimen caused a high incidence of early post-operative complications, mainly infectious. Several animals died with functional grafts that appeared relatively normal by histology, with minimal signs of rejection [42]. Modifying the protocol to eliminate WBI and steroids reduced the incidence of early complications and increased mean graft survival time from 34 to 51 days, although maximum graft survival was not prolonged [140]. Adjustments to the T-cell depletion strategy did not lead to further improvement, even with recipients selected on the basis of low levels of preformed non-Gal antibodies [239]. Nevertheless, these studies provide a tantalizing hint that the thymic transplantation approach, perhaps in combination with mixed chimerism, will eventually lead to long-term tolerance to porcine xenografts. It will first be necessary to overcome the many challenges of the model and to find a substitute for anti-CD154, which appears to be essential for success but is not currently available in a clinically applicable form.

Graft-mediated (local) immunosuppression

A novel strategy with obvious appeal for xenotransplantation is to engineer transplanted tissue to secrete immunosuppressive proteins in the local environment of the graft. Most of the data supporting the efficacy of local immunosuppression have come from small animal islet allograft models involving adenoviral or transgenic expression of CTLA4Ig [240–243]. Similar data from the pig-to-NHP model are limited to the observation that transgenic expression of CTLA4Ig appears to be required for the long-term engraftment of porcine neurons in Parkinsonian monkeys [217]. On a cautionary note, strong and ubiquitous transgenic expression of porcine CTLA4Ig resulted in a high mortality rate in pigs due to compromised humoral immunity [244]. Tissue-restricted and/or regulated expression of the transgene may be the solution to this problem.

Limitations of the pig-to-NHP model

While demonstration of efficacy in the pig-to-NHP model is generally regarded as an essential prerequisite for moving to the clinic [245], it should be borne in mind that the model is not without limitations. First, NHP may share some antigens with pigs that humans do not possess. For example, NHP and pigs express NeuGc, also known as Hanganutziu–Deicher antigen [96,246], whereas humans do not and develop anti-NeuGc antibodies [247]. The true relevance of these antibodies may not be known until xenotransplantation enters clinical practice [248]. Second, NHP appear to have a more 'hypercoagulable' phenotype than humans [249], suggesting that we may be setting the bar too high when it comes to solving the problem of thrombosis in solid organ xenotransplantation. Finally, NHP have a higher insulin demand than humans, implying that higher doses of pig islets will be required to achieve insulin independence in the pig-to-NHP model than may be needed in human recipients [250]. These and other considerations have led some in the field to call for the commencement of clinical trials sooner rather than later [71].

Summary

When considered as a whole, the immunological challenges that must be overcome before xenotransplantation can enter the clinic seem almost insurmountable. The xenograft is glycosylated in a way that makes it immediately recognizable as foreign, attracting the attention not only of a high level of preformed antibodies but also the cells of the innate immune system. The multitude of protein and carbohydrate antigenic differences provokes a powerful T-cell xenoresponse that seems to be quite different to the alloresponse. Furthermore, xenoimmunity operates on a background in which innate immune cells are more prone to activation, and several key mechanisms that regulate coagulation and inflammation are compromised by molecular incompatibilities. It is therefore hardly surprising that drugs designed to prevent allorejection are considerably less effective against xenorejection.

Balancing these 'cons' is one unique and powerful 'pro'—the ability to genetically modify the donor to remove stimulatory signals, correct molecular incompatibilities and bolster graft-protective defences. Even the relatively few modifications tested in the pig-to-NHP model to date have significantly prolonged maximum survival of heterotopic and orthotopic cardiac xenografts to 8 months [75] and 2 months [251], respectively, renal xenografts to 3 months [42], islet xenografts to 13 months [207], and neuronal cell xenografts to 17 months [217]. Several new transgenic pigs await in vivo testing [97,252–254], and increasingly sophisticated methods are being developed to precisely and efficiently manipulate the porcine genome [255–257]. These advances, together with improved immunosuppressive regimens aimed at inducing tolerance, give cause for cautious optimism that clinical xenotransplantation will indeed be 'the next medical revolution' [74].

CHAPTER 13

In Vitro Models of Alloreactivity

Charles A. Su, Anna Valujskikh, William M. Baldwin III, and Robert L. Fairchild
Department of Immunology, Cleveland Clinic, Cleveland, OH, USA

Introduction

Transplantation is inherently an in vivo procedure. Allogeneic transplantation performed as a curative procedure for end-stage heart, lung, liver, or kidney disease, or for diabetes is quickly followed by a sequence of complex inflammatory processes and immune interactions invoked to reject the graft. First, the time of ischemic storage imposed on the donor tissue dictates the intensity of early inflammation primarily through production of reactive oxygen radicals that stimulate the production of acute-phase cytokines by graft endothelial cells and other cells in the graft during reperfusion [1,2]. Second, these oxygen radicals and cytokines not only mediate direct graft tissue injury but also potently amplify the inflammatory response by stimulating the production of leukocyte chemoattractants and up-regulating the expression of adhesion molecules on the graft endothelium that synergize to direct the trafficking of cellular components of innate immunity (i.e. neutrophils, monocytes, macrophages, and dendritic cells) into the graft and their activation to express functions mediating graft tissue injury (covered in Chapter 7). Third, this innate response to the initial inflammation in the allograft is quickly followed by the infiltration of endogenous memory T cells expressing receptors specific for donor alloantigens, and the activation of these memory T cells within the graft further exacerbates the intensity of the inflammation and the tissue injury [3,4]. This initial inflammatory response also activates graft passenger leukocytes, primarily interstitial dendritic cells, to emigrate from the graft and traffic to secondary lymphoid organs of the recipient where alloantigen-reactive T and B lymphocytes are activated to clonally expand and differentiate into effector cells [2,5]. These primary effector T cells traffic to the graft where they are re-activated to express programmed functions that mediate acute and/or chronic graft tissue injury. These processes are covered in depth in Chapter 5 [6]. Activation of B cells expressing surface immunoglobulin receptors for donor antigens results in their differentiation into antibody-producing cells, plasmablasts, or plasma cells, and binding of the antibody to the target donor antigens on the graft endothelium and other cells results in tissue injury through several different mechanisms (see Chapter 6 for additional detail) [7,8].

Many of these processes, such as ischemia–reperfusion injury as well as the continuum of the response from innate to donor antigen-specific mediated inflammation and the resulting graft tissue injury, are best studied using in vivo models as they encompass multifactorial components and interactions that cannot be reproduced using in vitro approaches. There are, however, many instances in which in vitro approaches have provided a great many insights into the in vivo responses mounted against transplanted cells and organs. This overview will detail what we have learned from using in vitro approaches to investigate the presence and characteristics of alloimmune responses.

Stimulation of alloreactive T-cell proliferation

Initial studies investigating the nature of T-cell alloreactivity established the ability of cells expressing allogeneic MHC molecules to activate and drive the proliferation of T cells in vitro [9–11]. This resulted in the development of mixed lymphocyte reactions (MLR) to assay the presence and intensity of T-cell reactivity to allogeneic stimulator cells. In this assay, naïve T cells are cultured with stimulator cells expressing allogeneic class I and/or class II MHC molecules. The allogeneic stimulator cells are normally inactivated through irradiation or treatment with a mitotic inhibitor to allow detection of T-cell activation and proliferation more accurately. T-cell receptor engagement of allogeneic class I or class II MHC molecules by $CD4^+$ or $CD8^+$ responder cells results in activation of the T cells to produce growth factors, primarily IL-2, and to express high-affinity receptors for the growth factors. This results in cell cycle progression and proliferation of the alloreactive T cells. T-cell proliferation was initially detected in these assays by adding ^{3}H-thymidine during the last 24 hours of the culture and then assessing the amount of ^{3}H-thymidine incorporation into the DNA of the cells as an indication of the proliferation of the cells. The proliferation of naïve or antigen-unprimed T cells is optimally observed 4–5 days after initiation of the culture whereas proliferation of memory T cells is observed within 1–2 days of culture initiation.

More recently, the use of ^{3}H-thymidine to assess T-cell proliferation has been replaced by labeling the responder T cells with a fluorescent dye that is retained within the responder cells; the most commonly used dye for this purpose is carboxyfluorescein succinimidyl ester (CFSE) [12]. CFSE is a derivative of carboxyfluorescein

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

diacetate succinimidyl ester (CFDA-SE). CFDA-SE, which is non-fluorescent, is highly cell permeable and enters the cytoplasm of cells. Intracellular esterases remove the acetate groups and convert the molecule to the fluorescent derivative, CFSE, which is retained within cells by covalently coupling to intracellular lysine residues and other amine sources. As the responder T cells divide, the amount of the dye retained in each daughter cell is decreased by half for each cycle of proliferation (Figure 13.1). Thus, non-dividing and dividing cells are easily detected as indicated by the level of CFSE dilution measured on a flow cytometer. When performed with appropriate controls, where the responder T cells are cultured with autologous/self cells as stimulators so that the level of spontaneous proliferation is assessed, this can be a powerful approach not only for detecting alloantigen-reactive responder T-cell proliferation but also for determining the number of distinct cycles of proliferation and dissecting the characteristics of the non-dividing and dividing T cells. Elegant studies by Wells and colleagues [13], using a polyclonal T-cell receptor (TCR) agonist, plate-bound anti-CD3 mAb, to activate CFSE-labeled T cells, indicated that the frequency of T cells entering the proliferating cell pool is regulated by the TCR stimulus, but that the addition of CD28-mediated costimulation regulates both the frequency of responding cells and the number of mitotic cycles. In addition, this approach can be combined with antibody staining to detect the expression of specific cell surface molecules, for example cellular activation markers such as CD11a, CD44, and/or CD69, or intracellular cytokine production, so that cells in each cycle of the proliferative response can be interrogated for specific markers of activation and differentiation [14]. The CSFE labeling approach has been widely used to investigate the alloantigen-induced proliferation of T cells isolated from various animals as well as human transplant patients [15–17].

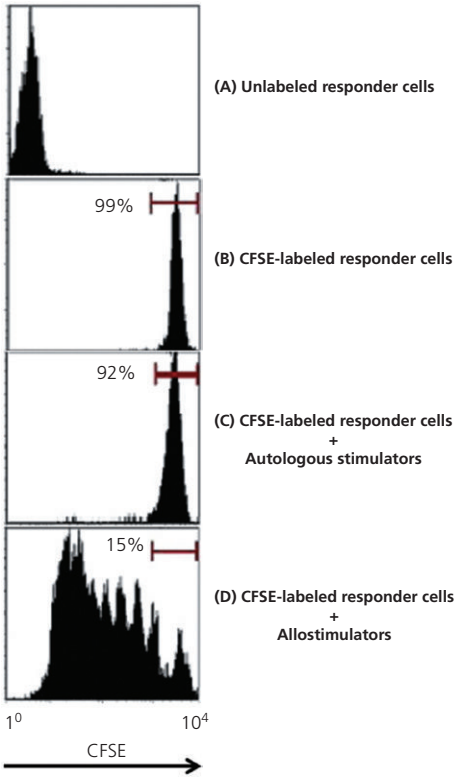

Figure 13.1. Detection of alloreactive T-cell proliferation by in vitro CFSE dilution. Equal numbers of unlabeled (A) or CFSE labeled (B–D) responder T cells are aliquoted into culture plates. Responder T cells are then stimulated with media alone (B), or autologous (C), or allogeneic stimulator cells (D). Three days after culture, responder cells are harvested and their proliferation assessed by dilution of CFSE using flow cytometry.

In addition to proliferation, functional characteristics of T cells following activation by allogeneic stimulator cells in culture can be measured through a number of different approaches. These approaches include assessing the production of cytokines by enzyme-linked immunosorbent assay (ELISA) in the supernatants of MLR cultures or cytolytic assays using radioactive- or CFSE-labeled allogeneic target cells. In addition, enzyme-linked immunosorbent spot (ELISPOT) assays can be performed to enumerate alloreactive T cells producing specific cytokines in response to allogeneic stimulator cells (Figure 13.2). In this assay, the responder T cells and allogeneic stimulator cells are cultured on filters that are coated with an antibody specific for the test cytokine. After 24–72 hours of culture, the cells are washed from the filters and a second antibody to the test cytokine is added, except in this case the antibody is coupled to a chromagen that converts a substrate to a color that is retained by the filter as a spot. A reader is then used to count the spots, which represent the number of alloreactive T cells producing the specific cytokine. These approaches have indicated that in unmanipulated cultures, alloantigen activation of $CD4^+$ and $CD8^+$ T cells promotes differentiation to IFN-γ producing cells and that $CD8^+$ T cells also differentiate to express FasL and undergo perforin/ granzyme B-mediated lysis of allogeneic target cells. It is important to note, however, that the composition of the MLR cultures can be manipulated to drive alloantigen-specific T cells to perform other functions, as is discussed below.

Seminal studies by Lafferty and Cunningham [18] led to the hypothesis that alloreactive T-cell activation requires the delivery of two signals. In vitro and in vivo studies provided support for this

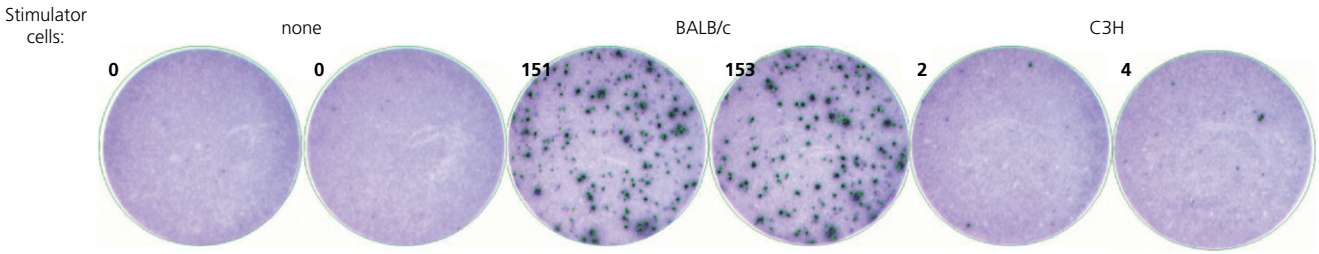

Figure 13.2. ELISPOT assay. Spleen cells isolated from B6 (H-2^b) recipients of BALB/c (H-2^d) heart allografts were tested in a recall response against BALB/c and third-party SJL (H-2^s) stimulator cells by IFN-γ ELISPOT assay. Duplicate wells are shown with 100 000 cells plated in each well. Numbers represent spots per well.

hypothesis in that the activation of naïve T cells to proliferate and differentiate into cells expressing distinct functions required both signaling through the TCR complex and through what are now termed costimulatory molecules [19]. In vitro approaches have been used to identify the key costimulatory molecule interactions that are required for the activation (or inhibition) of alloantigen-specific naïve and memory T cells during stimulation with alloantigen-presenting cells.

In vitro approaches were initially used to demonstrate the synergistic activity of an agonist monoclonal antihuman CD28 antibody with anti-CD3 antibodies in activating human T cells to produce IL-2 and proliferate, thus identifying the requirement for CD28 stimulation for optimal activation of human T cells [20–22]. Subsequent studies demonstrated that alloreactive human T-cell activation was dependent on CD28-B7 (i.e. B7-1/B7-2 or CD80/CD86) interactions by transfecting B7-deficient allogeneic stimulator cells to express the ligand for CD28 [23]. A second ligand for B7 molecules, CTLA-4, expressed by T cells was identified by Peter Linsley and colleagues [24] and a generated fusion protein, CTLA-4Ig, inhibited human alloreactive T-cell proliferation in MLR and the delivery of CD4 T helper cell signals for in vitro antibody production by B cells. These studies provided seminal clues leading to the initial observation of Turka and colleagues that administration of CTLA-4Ig could prolong the survival of MHC-mismatched Norway cardiac allografts in Lewis rat recipients [25]. Over the course of 20 years, these initial in vitro studies, defining the molecular structures and properties of CD28 and CTLA-4 expressed by T cells and their interactions with CD80/86 molecules on antigen-presenting cells, have led to the development of a new modified form of CTLA-4Ig, belatacept, that has shown efficacy in improving graft outcomes in renal transplant patients [26,27].

Since the identification of CD28-CD80/86 mediated costimulation, it has been further appreciated that there are many more costimulatory ligand–receptor pairs that can positively or negatively influence the activation of alloreactive T cells [19]. The identification and function of these additional positive and negative costimulatory molecules on T cells and their ligands on antigen-presenting cells has required extensive in vitro investigation using approaches similar to those used to delineate the structures and functions of the CD28/CTLA-4 molecules and their cognate ligands, CD80/CD86.

Presentation of alloantigens to T cells

Alloantigen is recognized by T cells through three different presentation pathways to induce proliferation, expression of activation markers, and expression of specific functions that contribute to graft injury [28–32]. Depending on the specificity of the TCR, alloreactive T cells can recognize peptide/ allogeneic class I or class II MHC complexes on donor antigen-presenting cells through the direct pathway or can recognize donor allogeneic peptides that are presented by MHC complexes on self-antigen-presenting cells through the indirect pathway. In the latter case, peptides from graft allogeneic MHC molecules or allelic variants of other proteins are acquired, processed, and presented by host- or self-antigen-presenting cells. In addition, host-antigen-presenting cells may acquire intact peptide/ allogeneic MHC complexes, most likely through exosomes released by graft cells, which are incorporated into the membrane and presented through the semidirect pathway to T cells expressing receptors specific for the allogeneic peptide/ MHC complex.

The presence of T cells specific for alloantigen presented through the direct versus indirect presentation pathways can be detected and investigated through many different in vitro approaches. Essentially, these approaches must involve the use of purified T cells that will respond during culture with the appropriate antigen-presenting cells and source of antigen. For alloreactive T cells responding through the direct pathway, this simply involves culture of the purified T cells with antigen-presenting cells expressing allogeneic class I and/or class II MHC molecules, for example those isolated from an allogeneic donor or allogeneic tumor cells. For detection and/or measurement of T cells responding through the indirect pathway, purified syngeneic antigen-presenting cells are added with a source of allogeneic proteins or peptides, cell-free tissue homogenates from allografts, or synthetic peptides from allogeneic MHC molecules or other target proteins. These cultures can be used to measure proliferation of the responder T cells as discussed above or their activation to produce cytokines that can be detected by ELISA or ELISPOT assay. Using these in vitro approaches to investigate T cells isolated from MHC mismatched allograft recipients, Benichou and colleagues [31] demonstrated that the majority (>90%) of alloreactive T cells isolated from the time of transplantation to the time of acute graft rejection responded through the direct alloantigen presentation pathway.

For reasons discussed below, the frequency of T cells in a repertoire that will respond to peptide/ allogeneic MHC complexes is in the order of 1 in $10–10^4$ cells, whereas the frequency of T cells that will respond to allogeneic peptides presented by self-MHC molecules is the same as that for T cells responding to other foreign peptides presented by self-MHC molecules, that is $<1:10^5$ cells. Thus, the alloreactive T-cell response through the direct presentation pathway is much stronger than the response through the indirect presentation pathway and is normally the major component of the strong, initial alloimmune response to allografts which constitutes the need for potent immunosuppression in transplantation.

Analysis of alloreactive precursor frequencies

The number of available α and β chain gene segments for somatic recombination and the additional diversity generated by junctional insertion of nucleotides can result in the generation of more than 1×10^{13} different α/β TCRs, or T-cell clones, in the thymus [33]. This high number of T-cell clones ensures the optimal chance of immune protection against most pathogens that an individual will encounter. In addition to generating such a vast diversity in potential protective reactivity to pathogens, however, the repertoire must be culled to remove those clones that have high reactivity to self-peptide/MHC complexes so that the risk of autoimmune disease is attenuated. During development of the T-cell repertoire in the thymus, TCRs that engage self-peptide/MHC complexes with high affinity induce signaling that results in thymocyte death, preventing the T-cell clone from escaping the thymus and seeding the peripheral T-cell repertoire. These events are detailed in Chapter 2. Alternatively, thymocytes expressing TCR that cannot engage self-peptide/MHC complexes are not given the signals needed for cellular survival and such "useless" clones are also removed from the repertoire. It is only thymocytes expressing TCR that engage self-peptide/MHC complexes with "intermediate" affinity that are given the appropriate intracellular signaling which promotes cell survival and seeding of the clone into the peripheral T-cell repertoire.

With respect to alloimmune responses, it is important to realize that during development thymocytes are only deleted for strong reactivity to self-peptide/MHC complexes, not for strong reactivity to peptide/allogeneic MHC complexes. Because the evolution of the T-cell receptor has endowed it with inherent affinity for peptide/MHC complexes, the reactivity of TCR selected for engagement of self-peptide/MHC complexes is strong for peptide/allogeneic MHC complexes and accounts for the strong response to antigen-presenting cells expressing peptide/allogeneic MHC complexes in cultures and in allografts. Determining the actual frequency of the peripheral T-cell repertoire in mice and in humans that is reactive to defined allogeneic MHC molecules has been an actively investigated area of T cell and transplant immunobiology. Initial studies were performed using limiting dilution analyses of murine and human $CD4^+$ or $CD8^+$ T cells in proliferation or cytotoxicity assays with defined allogeneic stimulator cells [34–38]. These approaches determined the frequency of T cells responsive to any different MHC haplotype difference to be on the order of 0.2–2%. Using a different approach, T-cell clones generated from T cells responding to immunization with several model protein antigens were tested for activation by proliferation to a panel of allogeneic antigen-presenting cells with different MHC haplotypes and all clones were shown to have reactivity to one or more of the allogeneic stimulator cells [39]. More recently, the CFSE proliferation approach has been used to determine the frequency of T cells for allogeneic MHC molecules [40,41]. Overall, the precursor frequency of T cells for allogeneic peptide/MHC complexes is three to four orders of magnitude greater than the precursor frequency of T cells specific for a foreign peptide/self-MHC complex which is typically $1:10^5$–10^6, and this accounts for the strength of the alloreactive T-cell response. This is covered in detail in Chapter 9.

These studies have prompted investigation of the structural nature of the interaction of the T-cell receptor for a peptide/allogeneic MHC molecule as would occur during direct alloantigen presentation [42]. Until these studies, it was unclear if the TCR heterodimeric protein on $CD8^+$ T cells engaged the allogeneic MHC molecule with some degree of flexibility regardless of the peptide presented in the groove of the α helices of the class I MHC molecule or if the interaction of the T-cell receptor with the allogeneic class I MHC molecule was also dependent on specific peptides presented in the groove. Initial crystallographic studies indicated that the T-cell receptor protein interacts in a similar manner with peptide/self class I MHC complexes as it does with a peptide/allogeneic class I MHC molecule, with the T-cell receptor heterodimer sitting at a diagonal angle on the plane of the peptide/MHC complex and the CDR3 regions of the T-cell receptor engaging the peptide [43]. However, T-cell receptor interaction with the peptide/allogeneic class I MHC complex may occur in some instances with more flexibility in the docking angle [44]. Furthermore, at least one T-cell receptor reactive to a peptide/self class II MHC complex is also reactive to peptides presented by both allogeneic class I and class II MHC complexes [45] (see Chapter 9). Crystallography analyses, performed in conjunction with in vitro T-cell activation assays discussed above, have been used to demonstrate a T-cell receptor from human T cells reactive to viral peptide/HLA-B molecules that also reacts to allogeneic peptide/allogeneic HLA-B complexes with the same engagement structure, indicating that in some cases the structural basis of TCR alloreactivity is through molecular mimicry rather than an alteration in the physical interaction of TCR with peptide/MHC [46].

Naïve versus memory T-cell proliferation to alloantigens

The arsenal of T lymphocytes within an individual comprises both naïve and memory T cells, with the proportion of memory T cells increasing with age, reflecting an accumulation of antigenic experiences. Naïve and memory T lymphocytes are functionally, spatially, and temporally distinct entities in transplantation. Unlike their naïve counterparts, memory T cells are able to mount a faster and stronger immune response upon re-exposure to the same antigen due to their higher frequency, elevated functional avidity for the antigen, and their low requirement for costimulation [4,47]. Whereas naïve T lymphocytes are restricted to secondary lymphoid organs, memory T cells are themselves heterogeneous and two memory subsets have been identified in humans and rodents. These subsets are designated (1) central memory T cells that localize primarily to lymphoid tissue, and (2) effector memory T cells that localize to both lymphoid and non-lymphoid tissues [48]. Importantly, clinical studies have indicated that memory T cells are more resistant to T-cell depleting induction immunosuppression therapies that effectively deplete naïve T cells [49,50].

The presence of pre-existing memory T cells with reactivity to allogeneic MHC molecules in the transplant recipient is now widely recognized as a major barrier to tolerance induction and maintenance [47]. The generation of allospecific memory T cells results from previous exposure to alloantigens via prior transplantation, blood transfusions, or pregnancy. However, individuals without prior alloantigen sensitization also contain alloreactive memory T cells. Generation of allospecific memory independent of direct alloantigen exposure in such individuals is thought to occur via heterologous immunity (covered in depth in Chapter 9), in which memory T cells induced through prior environmental exposures, such as viruses, bacteria, and vaccines, cross-react to and become activated by an unrelated antigen, such as an alloantigen [51,52]. Proof of this principle has been demonstrated in mice after exposure to such pathogens as lymphocytic choriomeningitis virus (LCMV) and *Leishmania* parasites [53,54]. Studies using in vitro approaches in rodents, non-human primates, and humans have provided important insights into how memory T cells differ from naïve T cells in their response to alloantigens.

In vitro studies using mouse models have demonstrated that, on a per cell basis, antigen-specific memory T cells have less stringent activation requirements and have enhanced activation compared with antigen-specific naïve T cells. The development of TCR transgenic mice in which $CD4^+$ or $CD8^+$ T cells express a defined TCR specific for a given peptide antigen/MHC complex has enabled the side-by-side comparison of memory and naïve T cells specific for a defined alloantigen. Using such TCR-transgenic systems, it has been shown that $CD8^+$ memory T cells specific for alloantigen undergo more rapid activation than naïve $CD8^+$ T cells upon in vitro stimulation with cognate antigen, despite equivalent levels of TCR and CD8 [55]. Analyses of culture supernatants by ELISA reveal that memory $CD8^+$ T cells secrete IFN-γ and IL-2 much more rapidly and in greater quantities than their naïve counterparts. Furthermore, in vitro chromium release assays used to measure cytolytic activity have shown that memory, but not naïve, $CD8^+$ T cells are potently cytolytic [55,56]. While naïve T cells require CD28/B7-mediated costimulation provided by professional antigen-presenting cells (APCs), such as dendritic cells, memory cells may be fully activated in the absence of costimulation via the CD28/B7 or CD40/154 pathways and are more permissive to activation by different non-professional APCs, such as resting B

cells and macrophages [57]. These findings have been supported by in vitro work in which memory, but not naïve, allogeneic $CD8^+$ T cells were able to become activated, expand, and differentiate into cytotoxic T cells by co-culture with endothelial cells [58].

In contrast to laboratory mice, significant numbers of alloreactive memory T cells are present in monkeys and humans prior to transplantation. As an example, in a study of 48 cynomolgus monkeys caught in the wild, memory T cells (distinguished by surface CD95 expression) were found to comprise approximately 48% of all T cells and were equally divided between central and effector memory T cells [59]. Naïve and memory T cells were isolated from the peripheral blood of these monkeys and tested for their ability to mount an alloresponse against allogeneic irradiated donor peripheral blood mononuclear cells via in vitro ELISPOT assays to enumerate cytokine-producing cells. While only a few naïve T cells were able to respond, the pre-existing endogenous memory T cells mounted a potent direct alloresponse characterized by high frequencies of T cells secreting IFN-γ and IL-2. Furthermore, similar to the results seen in mouse studies, the kinetics and overall magnitude of inflammatory cytokine production by memory T cells in these in vitro assays was overwhelmingly greater than that seen for purified naïve T cells. These data in non-human primates provide support for the kinetically and functionally enhanced behavior of memory T cells relative to their naïve counterparts in a more physiologic setting by studying the naturally generated endogenous alloreactive memory T-cell repertoire.

Clinically, the presence of donor-reactive memory T cells in the peripheral blood of patients prior to transplant is associated with delayed graft function and poor long-term outcome of the allograft. The detrimental effect associated with the presence of these cells is further complicated by the observation in patients that effector memory T cells are relatively insensitive to induction immunosuppression with T-cell depleting agents such as alemtuzumab or rabbit antithymocyte globulin, which effectively deplete naïve T cells [49]. In 1999, Heeger and colleagues pioneered the use of in vitro ELISPOT to detect donor-specific IFN-γ-producing lymphocytes in the peripheral blood of patients prior to kidney transplantation [60]. ELISPOT assays detect cytokine production at single-cell resolution and only by cells with a history of immunologic priming, thus representing a measure of effector/memory donor-specific immunity. IFN-γ production detected in this assay was specifically a manifestation of endogenous memory T cells and the pretransplant frequency of these donor-specific memory cells has been found to strongly correlate with the post-transplant risk of developing acute rejection episodes [60,61]. The utility of this assay as a measure of the strength of pretransplant alloreactivity and predictor of graft outcome highlights the importance of pre-existing donor-reactive memory T cells independent of the number of antigen mismatches at MHC loci. Nonetheless, while the information collected from ELISPOT assays is clinically valuable, the assay cannot be performed within the time frame required for use in the context of deceased donor transplants.

An alternative in vitro method, the panel of reactive T cells, or PRT, assay has been developed as a variation of the traditional ELISPOT assay. In the PRT assay the peripheral blood T cells of transplant candidates are tested for reactivity to a panel of allogenic stimulator cells rather than to donor-derived stimulator cells. This allogeneic stimulator panel consists of B-cell lines generated from the spleen cells of several different donors, which together encompass greater than 90% of the human HLA antigens. The alloreactive response of patient endogenous memory T cells during culture with each of the allogeneic B-cell lines is measured by enumerating the T cells producing IFN-γ using ELISPOT assays and a positive pretransplant PRT has been found to correlate with acute renal graft rejection even in the absence of humoral allosensitization [62,63].

Skewed functional development of alloreactive T cells in vitro

In addition to interrogating the frequency of T cells for MHC allogeneic stimulator cells, in vitro approaches have been useful for driving alloantigen-reactive T cells to different functional phenotypes in order to test the impact of the expressed functions during alloreactive responses.

Seminal studies by Mossman and colleagues [64,65] had indicated that during in vitro activation of antigen-specific $CD4^+$ T cells, the T cells differentiate into either cells producing IFN-γ and lymphotoxin-α (LT-α) (i.e. type 1 cytokines) that are associated with delayed-type hypersensitivity responses or into cells producing IL-4, IL-5, and IL-10 (i.e. type 2 cytokines), which are associated with allergic responses, and that this differentiation depended on the co-factors included in the T-cell activation cultures. In vitro alloantigen activation of murine $CD8^+$ T-cell clones stimulated IFN-γ and LT-α production, suggesting that alloimmune $CD8^+$ T-cell-mediated responses may share functions associated with delayed-type hypersensitivity [66]. Subsequent studies from other laboratories indicated that factors produced and/or expressed on the membranes of antigen-presenting cells directed this skewing of antigen-specific $CD4^+$ T-cell differentiation into Th1 or Th2 cells [67,68]. The antigen-presenting cell function-dependent T-cell differentiation to Th1 versus Th2 cells was consistent with the model that antigen-presenting cells activating $CD4^+$ T cells for cell-mediated/delayed-type hypersensitivity responses would receive signals at the immunization site to express functions, including production of IL-12, that skew the population towards Th1 differentiation. Similarly, antigen-presenting cells activating $CD4^+$ T cells for allergic responses would receive signals during allergen immunization that induced production of factors, including IL-4, that skew differentiation to the Th2 functional phenotype [67,68]. In each case, the dendritic cell-derived signals activate transcriptional factors that skew the functional differentiation of responding T cells, with T-bet skewing to the IFN-γ-producing Th1 phenotype and GATA-3 skewing to the IL-4-producing Th2 phenotype [69]. More recently, immunologists have defined several other functional subsets of $CD4^+$ T cells, including those that express the transcriptional factor FoxP3 and mediate regulation of immunity (i.e. Tregs) and those that express the transcriptional factor RORγT and produce IL-17 and IL-23 (i.e. Th17) [69].

The discovery of antigen-specific $CD4^+$ T-cell differentiation profiles prompted studies by the transplant immunology community to investigate the ability of different functional phenotypes of alloantigen-specific T cells to mediate graft injury. Culture of purified human $CD4^+$ T cells with allogeneic stimulator cells in the presence of IL-2 or TGF-β promoted alloreactive T-cell development to cells producing IL-2 and IFN-γ whereas the presence of IL-4, IL-10, or anti-TGF-β antibody promoted $CD4^+$ T-cell development to IL-4 and IL-10 producing cells [70]. The impact of this T-cell functional differentiation on allograft outcome was addressed in studies by Orosz and Bishop laboratories comparing the abilities of in vitro differentiated alloreactive Th1 versus Th2 cells to mediate rejection in a mouse model [71,72]. These $CD4^+$ T cells were differentiated in culture with allogeneic stimulator cells and the

appropriate cytokine co-factors and neutralizing antibodies and were then transferred to cardiac allograft-bearing SCID mouse hosts. In each of these studies, Th2 cells were as effective as Th1 cells in mediating rapid rejection of the heart allografts and the alloreactive Th2 cell-mediated rejection was accompanied by heavy eosinophil infiltration of the allograft. Other laboratories used similar approaches to demonstrate the ability of alloreactive T cells skewed to Th1 versus Th2 effector functions to mediate rejection of allografts by different histopathology [73–75]. Recent studies have focused on the ability of donor-reactive $CD4^+$ and $CD8^+$ T cells producing IL-17 to mediate allograft rejection and have shown the ability of such cells to provoke graft injury in experimental models and in clinical transplants [76–78]. Overall, these studies have indicated the abilities of in vitro differentiated $CD4^+$ T cells to mediate graft injury although the specific histopathology of injury may be different based on the functions expressed by the T cells within the graft. However, during alloantigen-priming in allograft recipients, the donor-reactive $CD4^+$ and $CD8^+$ T-cell response is largely, though not entirely, skewed to an IFN-γ-producing Th1 phenotype, most likely because of the inflammatory environment created during surgical tissue stress and ischemia–reperfusion injury imposed on the graft.

It is important to note the many studies that have used in vitro approaches to derive T cells expressing regulatory functions of alloimmune responses [79–81]. These studies have tested factors promoting this differentiation, the specificities of the regulatory T cells, and the functions expressed by the regulatory T cells to inhibit alloreactive responses. A common in vitro approach to test regulatory T-cell functions is measuring their ability to suppress the proliferation of alloreactive effector T cells in response to allogeneic stimulatory cells or polyclonal mitogens. Often this approach uses CFSE-labeled effector T cells to assess decreases in the proliferation of the responding alloreactive T cells. In addition, several laboratories are now using in vitro approaches to grow large numbers of T regulatory cells for infusion into pancreatic islet and organ graft recipients in experimental models as well as in clinical transplant patients [82–85].

Summary

While transplantation remains an inherently in vivo procedure, in vitro models have been a critical tool in investigating and elucidating the fundamental mechanisms of the immune system's recognition of and response to alloantigens. The development of in vitro approaches such as the MLR have been essential to our understanding of the capacity for self-peptide/MHC selected recipient T cells to recognize allogeneic MHC molecules. Modifications of the MLR and its coupling to ELISA and ELISPOT assays have offered powerful tools, which have captured not only the ability of alloreactive immune cells to proliferate in response to alloantigen, but also express potent effector functions including cytokines, growth factors, and cytolytic molecules, which contribute to graft injury and dysfunction in vivo. The knowledge gleaned through use of such in vitro models to study alloreactive T-cell responses have extended well beyond transplantation to encompass basic immunologic principles, including the costimulatory requirements of immune cells, the fundamental differences between naïve and memory T cells, and the development and differentiation of various T-cell subsets. Importantly, not only have such in vitro studies provided novel insights for targeted clinical therapy in transplantation, but the adaptation of these in vitro tools, as in the PRT assays, are now used regularly prior to human transplantation to effectively assess the likelihood of acute rejection and patient outcomes before the surgery is even begun. Though major strides have been made in the field of transplantation immunology during the past few decades, the immune response to a surgically transplanted allogeneic organ is a complex process and many additional questions remain unanswered. In vitro models will continue to be a necessary and valuable asset to fully understand mechanisms of allograft rejection and the development of targeted therapies to improve transplant patient outcomes.

Introduction

The understanding of alloimmunity in man has been facilitated by experimentation in animals. These studies have provided not only opportunities to develop surgical techniques but also platforms for identifying the mechanisms of alloimmune injury and the effects of immunosuppressive strategies. Initial studies primarily focused on rodent models of transplant injury, in both rats and mice. Rat models have provided significant insights into immune responses in both vascularized and neovascularized settings. Mice have shown great utility, with the strong knowledge of their immune system, the substantial availability of reagents, and, critically, the ability to genetically manipulate these hosts and donors, providing enormous information about the biology of rejection and innate immune injury. In this chapter, we will review the history of the use of animal models in transplantation, the biology and potential for therapeutic intervention in ischemic injury, define the models of alloimmune-mediated injury and agents used to ameliorate those injuries, and, finally, compare and contrast these small, preclinical models with larger animals models, including the use of non-human primates prior to the delivery of agents into humans. This chapter complements Chapters 13, 15, and 16, which deal with in vitro, large animal, in silico, models of transplantation, respectively.

In establishing a model of alloimmune injury to investigate, it is critical to understand that the immunogenicity among the transplanted organ and tissue types varies widely. While the extent of antigen presentation and specificity of tissue antigens are involved in the potency of rejection responses, the microenvironment of the allograft and access to draining lymph nodes have critical impact on the alloresponse. In rodent models of transplantation, the most rigorous rejection response is seen in skin, a non-vascularized transplant, followed in order of decreasing immunogenicity by heart, kidney, and islet grafts [1,2]. Thus findings in the stringent skin model will likely apply to less stringent models, but prolonged graft survival in a less stringent model may not be observed in the context of a more immunogenic organ.

Another key consideration in establishing a model is the critical contribution of the strain of both host and recipient. For example, kidney transplants in mice may enjoy prolonged graft survival in the absence of any immunosuppression depending on recipient strain [3]; when the donor strain is derived from Balb/c strain (H-2^d) and recipient is C57BL/6 (H-2^b), the complete MHC mismatch does not result in vigorous rejection while the reverse combination does. The use of isolated MHC class I or II mismatch results in prolonged graft rejection response with associated vasculopathy in heart allografts [4]. While the use of small animal models, in the context of inbred strains, have provided unique insights and understanding into rejection and non-immune injury, it is also important to recognized their applicability to the outbred human may have limitations. In the following sections, we will attempt to highlight the key features of each model as well as potential applicability to the human condition.

Evolution of solid organ transplant models in rodent models

The history of animal models in transplantation studies is rich, filled with solid discoveries as well as anecdotes. While a detailed discussion of this history is beyond the scope of this chapter, it is covered in some depth in Chapter 8. The use of experimental rodent models for transplant studies was clearly launched by pivotal surgical and medical advances and propelled by a high level of technical skills given the physical challenges of working with small animal organs. The French surgeon Alexis Carrel established the "vascular anastomosis," which allowed his inaugural kidney and heart transplants in dogs, and he was recognized for this by receiving the Nobel Prize in 1912 [5]. The development of inbred mice by George Snell in the 1930s, from consecutive brother–sister mating, minimized genetic variability between mice and allowed more controlled transplant experiments, including Medawar's mouse skin transplants. Snell termed the underlying genes, which remain central to alloimmunity, "histocompatibility (H)" genes. With Peter Gorer, Snell established that the major locus was identical to a locus encoding "antigen II," thus the term histocompatibility locus 2, or H-2 in mice. Jean Dausset working with antibodies in the sera of patients who had received blood transfusions, delineated the genetically determined homologue of the H-2 system in man, namely the major histocompatibility complex or HLA. Alloimmunity research in mice and humans thus became mutually complementary. This association was highlighted by the award of the Nobel Prize to both

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Snell and Dausset in 1980. The severe limitation of transplant research in having only brief acceptance of organs in unmanipulated adult animals was addressed by the availability of the first antirejection drugs. Antimetabolite 6-mercaptopurine (6-MP) and the imidazole derivative azathioprine were identified by Hitchings and Elion and became available in the 1960s [6], followed by cyclosporine [7,8] (see Chapter 17).

The development of rodent models was clearly influenced by technical (i.e. surgical skills) and diagnostic challenges (i.e. rejection), and, as these were overcome, many groups were able to utilize small animal models for their specific organ system and particular areas of interest. Islet transplantation was pioneered by Lacy in 1967, when he established a collagenase-based isolation procedure to procure islets from rat pancreata [9–11]. Importantly, he showed that implanting islets in the subcapsular space of rat kidneys was a relatively simple model that corrected the metabolic defect of insulin production in autoimmune diabetic or streptozocin treated animals. In contrast to islet transplants in which the largest challenge was the isolation of islets, in solid organ mouse transplant models progress was limited by the technical skill required (i.e. heart <kidney <liver, small bowel).

Rodent heterotopic cardiac transplantation was described in 1964 [12] in a rat model that severely restricted blood flow to the lower extremities and resulted in paraparesis and paraplegia. A revised and quickly adopted heterotopic abdominal approach in mice resulted in 90% graft and recipient survival [13] (Figure 14.1). While mouse abdominal cardiac transplants are "non-physiologic" and "non-loaded" due to the unique directionality of intracardiac blood flow, they have been widely utilized for tolerance studies, as they have low surgical costs, relatively low requirement for personnel, and a wide availability of genetically inbred mouse strains. Importantly, the low spontaneous acceptance rate of hearts compared to other solid organs (i.e. liver, kidney) facilitated analyses of potential tolerance-inducing strategies. Assessment of rejection using palpation, as originally described, continues to be used. However, assessment of contraction force from "0" (cessation of graft contraction) to "4" (vigorous graft contraction) has been criticized for being too subjective, insensitive in detecting ear¬ly changes post-transplant, and unsatisfactory for evaluation of long-term graft survival [13,14]. The gold standard for diagnosing cardiac rejection clinically and experimentally remains histology, but is not feasible for serial studies due to the small size of the rodent heart [15]. The addition of electrocardiography [16], nuclear magnetic resonance [17], ultrasound, coronary perfusion studies, and biochemical and molecular markers of rejection have all refined rejection diagnosis [18], but obviously add complexity and cost.

Mouse kidney transplantation was first described by Skoskiewicz and Russell in 1973 [19], with modifications by Kalina [20] and Zhong [21]. However, this model remains confined to relatively few transplantation centers compared to cardiac transplantation in mice, due to the surgical challenge of anastomoses presented by small-caliber vessels (the mean mouse renal artery diameter is 0.3 mm) and higher technical failure rates. The conventional method includes harvesting of the left kidney as a donor graft only, whereas the right kidney is generally considered unsuitable for transplantation due to the short length of the right renal vein and difficulty of anastomosis to the vena cava of the recipient. Anastomoses are performed end-to-side to the abdominal aorta and vena cava and urinary reconstruction is established by suturing a small bladder patch to the bladder dome (Figure 14.2). As the murine kidney is quite sensitive to ischemia–reperfusion injury (IRI), the time of anastomosis and warm ischemia is generally confined to less than 35–40 minutes. While the use of a transplant into a bilaterally nephrectomized recipient (i.e. survival model) simplifies the

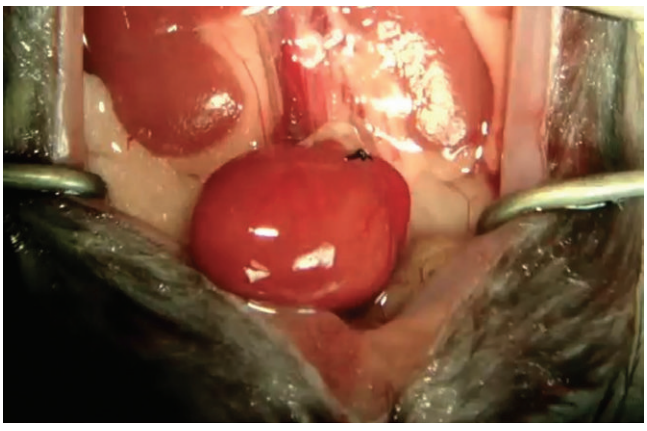

Figure 14.1. Vascularized heterotopic heart transplant in the mouse. This figure demonstrates the infrarenal placement of a cardiac allograft in a mouse. The heart is vascularized through the aortic root, and beats such that survival can be assessed by manual palpation of the animal's abdomen. However, the ventricles do not fill; as such, there is no contribution to cardiac output, and recipient survival is not dependent on graft survival. (Photo courtesy of Jean Kwun.)

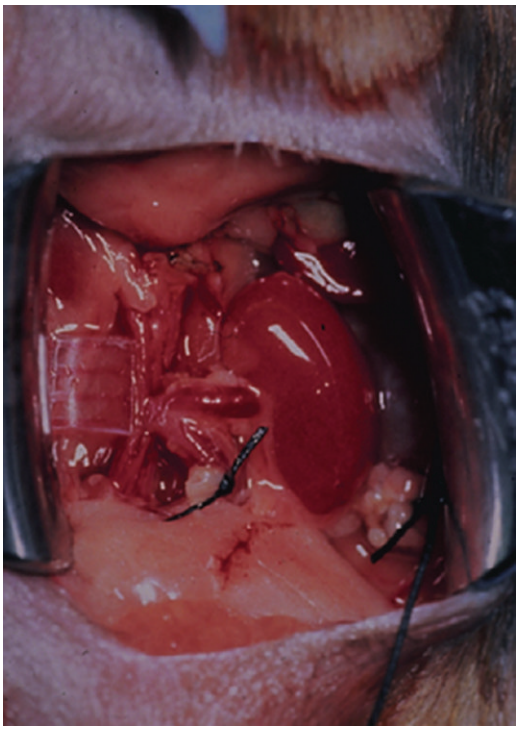

Figure 14.2. Vascularized kidney transplant in the mouse. This figure demonstrates the end-to-side vascular anastomoses and ureter/dome of bladder anastomosis that typifies the technique in mice. This can be a survival model, followed by serum creatinine, if recipient native nephrectomy is performed. If the native kidneys are left in place, the graft can be studied independent of survival.

diagnosis of rejection, this approach is clearly associated with a higher mortality rate if there is prolongation of warm ischemic time and a subsequent delay in graft function. Alternatively, a two-stage procedure can be performed, leaving the right native kidney in place until day 7. This approach, while having a lower mortality rate, may have some subtle effects on the alloimmune response and subsequent graft survival due to intrinsic immunoregulatory factors of the native kidney during alloantigen exposure [22]. While rejection can be determined biochemically through monitoring of serum creatinine, histology also remains the gold standard. This is particularly important with a spontaneous acceptance rate of approximately 30% in mouse kidney transplants using the B6 (H-2^b) to Balb/c B6 (H-2^d) strain combination [2,3].

While rat heart and kidney transplants continue to be the mainstay models in experimental rodent transplantation, the unique physiologies and immunological responses of other organs have resulted in the establishment of nearly all solid organ transplant models in mice. Surprisingly, it was not until 1991 that Starzl's group reported orthotopic liver transplantation in mice [23], based on techniques described in the initial rat liver transplants performed in the 1970s [24–26]. A higher level of spontaneous liver transplant acceptance is also well recognized, particularly in the rat model, in which low responder strains such as PVG or Dark Agouti (DA), accept completely MHC-mismatched livers for greater than 100 days [27].

Other critical models of solid organ transplant models, which have also proven to be particularly formidable challenges for tolerance induction, are those of small bowel and lung. The differential susceptibility of particular organs to tolerance induction appears to occur in organs in which there is a greater microbial exposure and activation of innate immunity [28]. Zhong described development of the heterotopic mouse intestinal transplantation in 1993 [29,30]. However, these grafts were non-functional as they were excluded from normal gastrointestinal passage and a definite endpoint for rejection was more difficult to define as the nutrition of the host was maintained by the native alimentary tract. This was addressed by the development of orthotopic small bowel transplantation in 2005 [31]. Orthotopic lung transplants have also been described in the rat [32,33] and the mouse [34,35].

Availability of strains

The unique ability to manipulate the genome of mice has facilitated an enormous series of studies that have unique opportunities to manipulate the donor and recipient and provide insights into specific arms of the immune response [36]. These genetic manipulations include the specific deletion of various components of the alloimmune response (Table 14.1). A detailed discussion of these strains and available resources for such mice is beyond the scope of this chapter but is reviewed in [37]. These strains can be used as both donors and recipients of transplants, and can test the requirements of host immunity and/or responses to donor antigens or proteins. Additionally, there is an extensive series of knockout strains that have cytokine deletions as well as critical signaling molecules in immunity. These include Janus kinases (JAK), non-receptor tyrosine kinases involved in immune and hematopoietic tissues. Deficiency of JAK3 is the defect in human severe combined immunity [38]. The signal transducers and activators of transcription (STAT) proteins are activated in response to a large number of cytokines, growth factors, and hormones, and bind to the promoters of specific target genes. Through the use of deficient mice, STAT4 and STAT6 have been identified as essential for Thl and Th2-responses and have provided novel agents to dissect alloreactive responses to solid organ transplants [39,40] (see Chapter 5). Lastly, mice deficient in specific cytokines have been similarly utilized to identify the possible roles of Th1 versus Th2 responses [41–46] (see Chapter 2).

Table 14.1. Genetically modified mice with immune defects

Strain name (abbreviation)	Defect	Immune defect	Background strain
Nude	*Foxn1*^{nu} mutation	Absent thymus, T cell depleted	H-2^d
RAG deficient (RAG$^{-/-}$)	VDJ recombinase deficiency or absence	Absent antigen-specific cellular or humoral immunity	H-2^b
Severe combined immunodeficiency (SCID)	Mutation in protein kinase, DNA activated, catalytic polypeptide (*Prkdc*)	Absent B and T cells, complement activation impaired	H-2^b
μT-deficient (μT$^{-/-}$)	Gene for membrane exon for IgM μ chain absent; IgM receptor on pre-B cells absent	B cell depletion Humoral immunity impaired	
β_2 microglobulin deficient (β_2m$^{-/-}$)	β_2 microglobulin gene disrupted	Absence of intact class I expression, CD8 T cell depletion	H-2^b
$A^b\beta$ deficient ($A^b\beta^{-/-}$)	Disruption of $A^b\beta$ gene	Absent class II expression; CD4 T cell depletion	H-2^b
CD4 deficient (CD4$^{-/-}$)	Disruption of CD4 gene	Absent CD4 T cells	H-2^b
CD 8 deficient (CD8$^{-/-}$)	Disruption of the CD8α gene	Absent CD8 T cells	H-2^b
Beige (*bg*^{j}/*bg*^{j})	Spontaneous mutation	NK cell depletion; cytotoxic T cell and macrophage function affected	
op/op	Osteopetrosis	m-CSF and monocytes depleted	
Interleukin 2 receptor, gamma chain deficient (*Il2rg*$^{-/-}$)	Mutation in IL-2 receptor gamma chain	NK cell development defect; abnormal signaling for IL-s, 4, 7, 9, 15, and 21	
Prf1 deficient (Prf1$^{-/-}$)	Perforin 1 mutation	Defect in NK and CD8$^+$ T lymphocyte function	

In summary, compared to rat models, mouse models require a more advanced level of microsurgical skill and are performed by a limited number of laboratories. Allograft rejection is much less intense in mouse models compared to rat models, even when comparing the extent of MHC class mismatches. Moreover, as noted above, there is more variability in graft survival in mice compared to the rat model. However, their relative smaller size makes them a more cost-effective approach and more scientifically elegant due to the large number of genetically modified strains available.

Models of alloimmune injury: acute injury

Acute cellular rejection

In the development of our understanding of the host immune response, acute cellular rejection has been a critical area of investigation. As already alluded to, strain differences can lead to differences in immunoreactivity. Additionally, the type of graft is

important and the microenvironment also impacts on the extent of response.

Skin transplantation remains one of the technically easy models of transplantation. The ease of transplantation allows for rapid screening of immunomodulatory strategies as well as mechanistic insights. Skin grafts have been used as a primary test of donor-specific hyporesponsiveness in preclinical studies of tolerance. Of all tissues and organs transplanted, it is the most immunogenic and provides a high degree of immune stringency. However, these grafts are non-vascularized and may undergo ischemic degeneration and necrosis, making them more susceptible to the immune response [47]. Rejection is also affected by the presence of tissue-specific antigens, which are critical targets of the immune response [48]. In addition, skin contains specific professional antigen-presenting cells (Langerhans cells), which have the capability of migrating from the graft and efficiently activating T cells. Finally, the size of the organ may also impact on graft rejection, such that the quantity of donor tissue as well as donor APCs may affect host responses [49]. More careful and detailed studies using specific mouse strain combinations comparing heart, islet, and skin rejection suggests that neither the number of resident APCs or tissue-specific antigens impact on the quantity of T-cell host response; rather, graft microenvironment and size may be more important in determining susceptibility to rejection [50]. Critical studies by Singer and Rosenberg using skin allografts have demonstrated fundamental insights into the distinct roles of CD4 and CD8 T cells during the rejection of class I disparate skin grafts in mice (reviewed in [51]).

The use of mouse kidney allografts to study rejection is discussed in detail below in the section on chronic graft injury, because, as already noted, these allografts enjoy prolonged survival in the absence of immunosuppression compared to skin and heart allografts amongst the same donor/recipient combinations. These models have provided more of a platform for assessing chronic immune injury. More recently, these models have been utilized to assess antibody-mediated injury and the impact of viral nephritis on graft function and survival. However, with strain manipulation, a more acute pattern of rejection may be seen. Indeed C57BL/6 kidneys transplanted into fully mismatched Balb/c recipients were rapidly rejected over a 2-week period; rejection was mitigated however by treatment with anti-CD45RB, which resulted in improved allograft and recipient survival, histology, and renal function [52]. Only a limited number of these recipients demonstrated true donor-specific hyporesponsiveness to a skin allograft while all rejected third-party skin. This novel blockade strategy is undergoing further studies in non-human primates with the goal of understanding mechanism of action and providing a preclinical platform.

Location of antigen engagement

Another critical concept explained almost exclusively by mouse models is the understanding of where and how antigen is engaged. While for many years the prevailing impression was that antigen engagement occurred within the allograft, it is now understood that secondary lymphoid organs, including spleen, lymph nodes, and mucosal lymphoid tissue, not only provide the proper environment for antigen presentation, but are necessary to initiate rejection. These studies utilized cardiac allografts transplanted into wild type, alymphoplastic (*aly/aly*) mice that lacked lymph nodes and Peyer's patches, and splenetomized *aly/aly* mice, which are totally devoid of secondary lymphoid tissue, as well as *Hox11*$^{-/-}$ mice which are asplenic. In spite of the absence of either lymphoid tissue or spleen, *aly/aly* and *Hox11*$^{-/-}$ mice rejected heart allografts, albeit modestly delayed in the former [53]. However, the splenectomized *aly/aly* mice accepted cardiac allografts indefinitely and failed to develop donor-specific antibodies. Thus, fully vascularized allogeneic organ transplants are unable to induce a productive immune response in the absence of secondary lymphoid tissue. In contrast, skin allografts are not rejected by *aly/aly* recipients, while *Hox11*$^{-/-}$ recipients do reject these allografts, demonstrating the importance of antigen location in defining the immune response. While these studies seem fairly convincing, studies in splenectomized lymphotoxin α-deficient and β-receptor deficient mice (two strains that lack lymph nodes and Peyer's patches) demonstrate efficient rejection of skin and cardiac allografts, albeit with delayed kinetics compared to wild-type recipients, suggesting that secondary lymphoid tissue is not an absolute requirement for allograft rejection [54]. Moreover, in small intestinal allografts, the presence of donor lymphoid tissue is a significant factor in mediating host immune responses [55]. These studies identify a key feature of immunogenicity, that is donor lymphoid tissue in the case of small bowel, but also the minimum requirements to mediate allograft rejection.

Allorecognition

A formidable number of studies have utilized mouse transplant models to identify the process of allorecognition that is necessary and sufficient for transplant rejection. Initially, direct recognition was considered the only mechanism by which an allograft could be rejected. However, it is now clear now that the indirect pathway may mediate rejection, as demonstrated in rat studies utilizing immunization with MHC molecules followed by skin grafting [56,57]. In mice depleted of CD8 T cells, donor grafts lacking class II MHC (I-A^{b} deficient mice) are rapidly rejected with evidence of CD4 T cells sensitized to donor peptides indirectly presented in the context of class II antigens on host recipient cells [58]. Again, using MHC class II deficient mice as well as class II deficient mice engineered to have an intact CD4 compartment due to expression of class II only in the thymus, Steele and colleagues demonstrated that indirect recognition is responsible for B-cell activation and alloantibody production [59]. This pathway has also been associated with chronic rejection responses and is viewed as less amenable to current immunosuppression [60].

Minor histocompatibility antigens

Minor histocompatibility antigens, immunogenic peptides derived from polymorphic self-proteins, are sufficient to trigger rejection responses (reviewed in [61]). In this setting, there is usually considerable identity of donor and recipient MHC antigens such that MHC/peptide complexes are essentially identical whether presented directly by donor, or indirectly by recipient, DCs. Additionally, there is a low frequency of alloreactive T cells that recognize minor antigens, resulting in slower and delayed graft rejection relative to the process of rejection mediated by direct recognition. The classic minor antigen is the male H-Y antigen and has been most frequently studied in mouse skin transplant models. These studies have demonstrated the requirement for CD4C MHC class II-restricted T helper cells to synergize with CD8^{+} MHC class I-restricted cytotoxic T cells [62]. Using IL-17 deficient mice (IL-17$^{-/-}$) as recipients of minor mismatched skin allografts, Vokaer et al. demonstrate that minor skin grafts have prolonged survival, and in this model Tregs can promote a Th17-mediated neutrophil-dependent pathway of graft rejection [63].

Th deviation in transplant rejection

A key consideration studied in mouse models has been the contribution of Th1 versus Th2 T cells in transplantation. Th1-derived cytokines were postulated to promote rejection by mediating delayed-type hypersensitivity (DTH) and cytotoxic responses and via antibody-dependent cellular cytotoxicity (ADCC). Th2 cytokines, on the other hand, were postulated to protect from rejection by suppressing DTH and macrophage activation, with antibody production deviating to IgE and non-cytotoxic IgG subclasses. These hypotheses were initially supported by transplant studies that correlated cytokine expression to transplant outcomes. However, the complexity of immune deviation and redundancy of cytokines in rejection was identified using cytokine knockout mice (reviewed in [64]). For example, IL-2-deficient mice were shown to be perfectly capable of rejecting islet allografts and fully mismatched heart allografts [46], indicating that a signature Th1 cytokine was not necessary for rejection. And interestingly, tolerance induction using CTLA4Ig required expression of IL-2 [65]. Double knockouts of IL-2 and IL-4 were also capable of rejecting islet and heart allografts, suggesting that remaining signaling through the γ-chain of the IL-2 receptor could mediate rejection responses, via IL-15, 7, or 9 [43]. Similarly, long-term survival under the cover of costimulatory blockade (CSB) requires IFN-γ as this therapy was ineffective in IFN-$\gamma^{-/-}$ recipients [66]. Moreover, IFN-$\gamma^{-/-}$ mice rejected completely mismatched or class I mismatched allografts, but were unable to reject class II mismatched grafts [67]. Thus, while IL-2, IL-4, and IFN-γ contribute to acute rejection, they are not required. Similarly, as will be discussed below, the association of Th2 responses with long-term graft survival is another oversimplification, in that the unopposed actions of IL-4 in IL-$2^{-/-}$ or IFN-$\gamma^{-/-}$ mice does not lead to prolonged graft survival [45,46,65,66]. Overall, these studies exemplify how unexpected findings in the mouse models have provided unique insights into the role of Th immune deviation and its contributions to the transplant immune response.

Th17 cells and their function in transplant rejection and tolerance is of recent interest. The prevailing notion is that Th17 cells are a barrier to transplant tolerance and may have an antagonistic response to Treg differentiation. For example, inhibition of IL-17 prolonged rat cardiac allograft survival [68], and there have also been correlations of IL-17 expression with chronic injury in lung transplantation in rats [69]. More direct support comes from the observation that Tbet-deficient mice (Tbet$^{-/-}$) which lack an intact Th1 response, rapidly and vigorously reject cardiac allografts with associated IL-17 producing CD4 T cells within the graft [70]. Similarly, CSB is ineffective in Tbet$^{-/-}$ mice, and is associated with CD8$^+$ IL-17 producing T cells [71]. However, whether IL-17 producing T cells are important mediators of immune injury in clinical transplant remains under debate. It is unclear whether, in the setting of an active Th1 response, Th17 cells play a role in rejection and, moreover, whether Th17 cells are responsive to conventional immunosuppression remain inconsistent (reviewed in [72]). Finally, the ability of Tregs to control Th17 cells in transplantation remains unanswered.

The functional capacity of Tregs has been explored extensively in animal models with the general goal of enhancing the activity of these cells by either (1) ex vivo expansion with adoptive transfer or (2) providing conditions within the host to facilitate this population's role in suppressing allogeneic immune responses. In the former approach, human CD4 T cells were cultured and polyclonally stimulated ex vivo; the resulting Tregs were sufficient to suppress vasculopathy in a chimeric humanized arterial allograft in mice [73]. An alternative approach by the same group involved enrichment of alloreactive induced Tregs by stimulation of recipient CD4$^+$ T cells with donor antigen-presenting cells under defined culture conditions. In this case, the Tregs were effective in prolonging survival of MHC-disparate skin grafts in mice [74]. Similarly, human CD45RO$^-$CD25$^-$CD4$^+$ T cells, cultured under similar conditions, were effective in suppressing vasculopathy in a human arterial allograft model [74]. Treg adoptive transfer following ex vivo expansion and maintenance in culture with indirect allospecificity has also been beneficial in inducing long-term survival of completely MHC-disparate mouse cardiac allografts [75]. Alloantigen-specific expansion of FoxP3$^+$CD25$^+$CD4$^+$ Tregs in the presence of bone marrow-derived dendritic cells led to recipient hyporesponsiveness to cardiac allografts in mice but had no effect on third-party donor grafts [76]. Thus, there are some convincing data in preclinical models to demonstrate feasibility of this approach which may be applicable to man.

The manipulation of the recipient in order to facilitate Treg expansion has been a focus of a number of studies in tolerance induction (see below). These studies demonstrate the importance of recipient immunosuppression in affecting outcome. For example, a number of have implicated the use of mTOR inhibition as beneficial in mediating long-term survival in the setting of CSB [77,78] and in development of Tregs in man (reviewed in [79]), but the benefit is not observed consistently [80]. Alternatively, treatment of recipient mice with antilymphocyte serum and donor pancreatic lymph node cells results in the proliferation and expansion of FoxP3$^+$ Tregs and supports islet allograft survival [81]. Treatment with IL-2/anti-IL-2 complexes was associated with in vivo expansion of FoxP3$^+$ Tregs in mice, and in concert with G-CSF treatment expanded myeloid-derived suppressor cells and led to a significant delay of MHC class II disparate skin grafts [82]. These data support a potential strategy in human subjects, although it may be difficult in practice to support these approaches. A cautionary note is that recent studies indicate inhibition of the B7/CD28 pathway using CTLA4Ig in mice may alter Treg homeostasis and be detrimental in situations where graft prolongation is dependent on Tregs [83].

Innate immune mechanisms of allograft injury

The role of NK cells in acute rejection is an area of intense investigation, and covered specifically in Chapter 7. The mechanisms by which innate immunity triggers and collaborates with adaptive responses is key not only to initial clinical management but long term as well, where innate responses are not the primary focus of immunosuppressive therapy. Studies in rats have shown that depletion of NK cells fails to impact the kinetics of rejection [84,85]. However, NK cell activation has been identified in acutely rejecting rat cardiac allografts [86] and specific subsets may contribute to rejection responses to mouse cardiac allografts [87] through direct recognition of alloantigens. This was functionally demonstrated when CD28-deficient (CD28$^{-/-}$) mice that received anti-CD154 antibody rejected cardiac allografts [88] and depletion of their NK1.1 cells allowed indefinite survival [89]. Blockade of NKG2D, the activating immune receptor expressed on the surface of NK and CD8 T cells, similarly prevented rejection in CD28$^{-/-}$ recipients [90]. NK cells have also been shown to directly mediate graft rejection, as evidenced by the fact that IL-15 (an NK cell activating cytokine) precipitates rejection of skin transplants in RAG knockout mice (which lack B and T cells) but not RAG-common gamma chain (γc, CD132)-deficient mice, which also lack NK cells [91].

Macrophages may also participate in acute allograft rejection (reviewed in [92] and covered in Chapter 7) and a number of studies have utilized mouse models to investigate this pathway. Genetic deletion of CCR1 [93] was associated with prolonged survival of both MHC class I and class II mismatched heart allografts in mice; deletion of CCR5 [94] was associated with improved rejection of class II mismatched heart allografts. In both instances, macrophage infiltration was reduced. Treatment of recipient mice with DTCM-glutarimide, which inhibits macrophage function, prolonged survival of fully mismatched heart allografts [95]. Treatment with liposomal clodronate, an agent that eliminates macrophages, improves renal allograft function and reduces inflammation in a rat model [96]. Conditional depletion of macrophages in the transgenic CD11b-DTR mouse resulted in marked reduction in inflammation of kidney allografts [97]. Collectively, these studies demonstrate the proinflammatory function of macrophages in acute rejection.

Acute antibody-mediated injuries

Antibody mediated-rejection is an increasingly recognized means of graft failure (see Chapter 6) With the recognition that antibody-mediated injury is a critical cause of late kidney allograft loss [98] and also a key feature of ongoing injury in heart transplantation [99], there is now a critical need for the study of mechanisms in animal models of injury. Colvin and colleagues have provided a sequence of events in man based on non-human primate (NHP) models [100]. In the context of small animal models, the focus of this current decade has been on mouse models, to define the pathogenesis of antibody development, injury mechanisms, biomarkers, and potential therapeutic interventions.

Acute antibody-mediated rejection (AMR) is a difficult entity to recapitulate in mice. Passive transfer of antibodies to donor-specific MHC proteins into $RAG^{-/-}$ mice does not result in a dramatic antibody-mediated injury response and this is titer dependent [101]. Use of monoclonal antibody against a specific MHC determinant passively transferred into a $RAG^{-/-}$ recipient with donor-specific cardiac allograft has similarly failed to induce substantial injury, although there is evidence of antibody deposition on capillaries [102].

The passive transfer studies do provide some interesting insights into the development of antibody-mediated injury. There are limitations, however. The use of monoclonal antibodies focuses on either class I or II determinants and in man there is frequently a combination. Moreover, in humans, anti-class II antibodies are the predominant type in late graft failure. In mice, class II molecules are not expressed on resting endothelium and are up-regulated only when there is inflammation; in man, class II protein is constitutively expressed. Finally, $RAG^{-/-}$ lack intact cellular responses, which may facilitate B-cell activation as well as produce key cytokines to alter MHC expression in allograft tissue and activating other inflammatory cells in the rejection response.

An alternative model, reported by Bickerstaff and colleagues, is the use of CCR5 knockout mice ($CCR5^{-/-}$) [101]. In this model, A/J cardiac allografts transplanted into $CCR5^{-/-}$ are rapidly rejected with minimal cellular infiltration but intense deposition of C3d in the large vessels and capillaries of the graft, characteristics of AMR. Donor-specific antibody titers were substantially elevated compared to wild-type recipients and adoptive transfer of this serum led to rapid humoral rejection of donor-specific heart allografts. Similarly, accelerated rejection is also seen in isolated class I differences, and this response is clearly dependent on continual production of antibody and not cytotoxic T cells [103]. These results are not organ specific as A/J kidney allografts transplanted into $CCR5^{-/-}$ mice are rapidly rejected with histologic evidence of antibody deposition [104]. Use of μ-chain-deficient mice $CCR5^{-/-}$ doubly deficient mice as recipients of kidney allografts abrogates this response, demonstrating the dependence of antibody-producing cells to mediate organ rejection.

While these models have focused on capillary deposition of antibody and complement, arterial injury may also be seen. Using segments of human mesenteric artery interposed into the abdominal aorta of beige/SCID mice accompanied by transfer of anti-class I HLA antibody results in complement deposition and neointimal formation [105]. These results are difficult to put entirely into context of a cardiac allograft as there is disruption of the vasa vasorum in the adventitia and this effect is not accounted for in the model of injury development. This will be discussed further below in the context of chronic antibody-mediated graft injury.

Complement activation

The key role of complement activation leading to endothelial injury has been examined as an alternative potential pathway to ameliorate antibody-mediated injury (also see Chapters 2 and 7). Complement inhibition has been the focus of animal studies to mitigate acute injury. First reported in 1995 in a pig-to-primate xenograft cardiac transplant model of hyperacute rejection, anti-C5 antibody prevented the development of hyperacute rejection, allowing normal function and the absence of histologic injury [106]. Subsequent studies in mice demonstrated a similar beneficial effect. In this model, Balb/c mice were first grafted with C3H skin, and 7 days later, received a cardiac allograft from the same donor strain as the skin. This resulted in accelerated graft loss by day 3 post-transplant. A combination of low-dose cyclosporine, cyclophosphamide, and anti-C5 antibody resulted in prolonged graft survival of >100 days, with normal histology despite the presence of systemic and intragraft antidonor antibodies and complement, with immunological alterations in both the graft and the recipient, were required for successful graft accommodation to occur [107].

Blocking complement activation using soluble complement receptor 1 (sCR1) demonstrated similar findings in hyperacute rejection models following presensitization. For example, Pruitt and Bollinger demonstrated an amelioration of vascular injury in Lewis recipients presensitized with ACI skin and subsequently transplanted with ACI kidneys [108]. Similarly, in DA recipients of Lewis kidneys treated with soluble complement receptor 1 (sCR1) there was reduced vascular and cell-mediated injury compared to untreated control allografts [109]. Cobra venom factor, which mitigates C3 activity, suppressed hyperacute rejection in presensitized Lewis recipients of ACI heart allografts [110]. The genetic absence of terminal component of complement C6 also resulted in modification of vascular injury in cardiac transplantation. In this model, PVG rats ($RT1^c$) were genetically modified to lack C6 and were recipients of ACI hearts after sensitization by skin allografts. The lack of this terminal complement component showed reduced antibody and cellular-mediated injuries compared to wild-type recipients [111]. Finally, blockade of C5 convertase, in association with CTLA4Ig significantly prolongs survival of completely mismatched cardiac allografts in mice, by also apparently blocking T-cell-mediated graft rejection [112]. Thus, acute antibody-mediated injury, in the context of pre-existing antibodies in both rats and mice, whether kidney or cardiac allografts, appears to be ameliorated by strategies that limit complete activation of the complement

cascade. Such provocative data have supported recent clinical trials in humans (reviewed in [113]).

It is important to note, however, that early complement components are important anti-inflammatory mediators. Deficiency of C1q is associated with autoimmune phenomena, perhaps due to its role in clearing apoptotic bodies by macrophages [114]. Indeed, deficiency of C1q may alter alloimmune responses as C1q-deficient mice reject cardiac allografts with a tempo faster than wild-type recipients [115]. This study indicates the complex role of early complement proteins.

BK polyomavirus nephropathy

A vexing problem in kidney transplantation is BK polyomavirus infection. The virus has a tropism for urogenital epithelium and may become reactivated or transmitted from the donor allograft in the context of over-immunosuppression. The resulting infection leads to a proinflammatory response within the kidney allograft that histologically mimics acute cellular rejection with associated allograft dysfunction [116]. Treatment is primarily by immunosuppressive withdrawal and, in some circumstances, antiviral therapy, which may include cidofovir, limited in its effectiveness by intrinsic nephrotoxicity [117]. Monitoring has improved the opportunity for earlier detection and intervention. However, critical questions remain in understanding the pathogenesis of this disease, intervening against the strong CD8 cytotoxic T cell and associated profibrogenic responses [118], and identifying new antiviral therapies. These issues could be further addressed using animal models of disease.

Finding an appropriate small animal model has been difficult due to the specificity of BK virus to human tissue. BK infection similar to that in man has been reported in cynomolgus monkeys during studies of novel immunosuppressive strategies [119] and also in squirrel monkeys [120]. A mouse model of polyomavirus nephropathy has been described more recently [121]. In these studies, C57BL/6 mice were subcutaneously inoculated in the hind footpad with mouse polyomavirus (Mpy) wild-type strain A2. Peak infection was detected at day 4 postinoculation and was associated with the expansion of $CD8^+$ cytotoxic T cells, as detected by MHC class I tetramers containing viral peptide epitopes as well as by measuring viral peptide stimulated IFN-γ production. While there was no detectable virus in blood by 6 months postinfection, there was detectable virus in some solid organs including the kidney at that time point.

In the transplant setting, kidneys from either C57BL/6 ($H\text{-}2^b$; isografts) or C3H/HeJ mice ($H\text{-}2^k$; allografts) were transplanted into C57BL/6 recipients with associated bilateral native nephrectomy. Acute infection with MPy at day 1 post-transplant accelerated kidney allograft failure compared to uninfected allograft recipients, and had no effect on isograft function and recipient survival. Examination of the kidney demonstrated increased tubular cell loss, inflammation, and interstitial edema in infected allografts compared to isografts or uninfected allografts, associated with elevated viral loads within the kidney in infected recipients. Moreover, there was an enhanced antidonor cytotoxic T-cell response, which may lead to allograft destruction. This model could provide new insights into the immunologic and viral factors that lead to graft failure in human PVN. Interestingly, IFN-γ inhibits replication of BK in this model by blocking viral replication and diminishing viral protein expression [122]. The use of mouse models of infection may thus provide substantial insights into viral replication, viral persistence, and therapeutic effects, while also defining the pathogenesis of progressive allograft injury in man [123]. While informative, these studies do not precisely mimic human infection, which may be quiescent for years prior to reactivation or may present as a primary infection.

Models of alloimmune injury: "chronic" injury

Long-term graft survival remains a critical issue in all solid organ transplants. Key features of this disease include allograft fibrosis, ongoing inflammation, and vasculopathy. Small animal models have provided a number of unique insights into the human condition, providing further information regarding therapeutics, biomarkers, and pathogenesis (reviewed in [124]). A key issue in this field is finding the proper model to emulate the specific human disorder being studied.

Kidney chronic injury

In the kidney, late allograft failure was referred to for many years as "chronic rejection" and subsequently as "chronic allograft nephropathy" ("CAN") [125]. This term relates to the characteristic histologic features of interstitial fibrosis (IF) and tubular atrophy (TA). Numerous investigators began to consider these findings a disease entity and a cause of late graft failure even in the absence of tissue for histologic diagnosis. Consequently, in current clinical practice, the term "CAN" has been eliminated and specific pathological investigation into the cause of IF/TA and functional failure are emphasized [126]. Thus, finding ideal models may be limited to those with IF/TA but recognizing that for etiologies such as BK or antibody-mediated injury, more specific models as described herein, apply.

The rat models were the first to be developed, likely due to the relative technical ease. As already discussed, strain manipulation is key, providing a more stable model of prolonged allograft failure. First reported in 1969 by White et al., the use of only minor MHC mismatches led to prolonged graft survival [127]. The most common model is the F344 graft into a Lewis recipient coupled with immunosuppression of low-dose cyclosporine A (CsA; 5 mg/kg/d) for 10 days [128]; here, the donor and recipient are matched at class I and class II with minor and non-MHC antigen disparities. The kidney is fully vascularized, heterotopically placed in the abdomen with a full connection of the transplant ureter to the recipient bladder, with a staged or simultaneous bilateral nephrectomy that results in survival on the transplanted graft. Within 12 to 16 weeks post-transplant, segmental or global sclerosis is seen with increasing tubular atrophy, intimal proliferation, and gradual luminal occlusion of cortical vessels. There is renal function deterioration accompanied by the development of nephrotic range proteinuria at 24 weeks. Numerous studies of this model have emphasized a proinflammatory response including T-cell and macrophage activation of the host [128,129]. Prolonged administration of CsA in this model was associated with worse interstitial fibrosis, while mycophenolate treatment was associated with a down-regulation of proinflammatory cytokines [130]. Impressive amelioration of this injury and histologic abnormalities were seen with CSB, specifically a single dose of CTLA4Ig [131,132]. The development of injury in this model may be further mediated by a reduction in nephron supply provided by a single kidney transplant, as retention of one native kidney mitigated the development of proteinuria and the allograft glomerulosclerosis [133], suggesting that in this model inadequate nephron mass is contributory to chronic injury.

However, such studies underestimate the potency of the alloimmune response operating in this model, and, in particular, underestimate the humoral component.

Mouse kidney transplants were limited in development due to the need for microsurgical expertise. The key operative challenges were the relatively small caliber of blood vessels and the ureteral connection, which was successful using a dome to dome anastomosis. While initially developed for the study of acute rejection of the kidney, it became clear that these models rejected with altered kinetics and severity compared to rat models as well as similar strain combination skin allografts [134]. B10.D2 (H-2^{d}) kidneys transplanted into B6AF1 (H-$2^{b/a}$) mice enjoyed prolonged survival over a period of weeks. Some recipients survived >1 year post-transplantation. These animals were shown not be tolerant based on in vitro assays of donor-specific responsiveness and the ability to mediate immunologic injury by treatments that heightened donor reactivity [135].

The factors related to this hyporesponsiveness and the potential use of these models to study more chronic tempo rejection have more recently been studied in depth. Mannon and colleagues demonstrated that prolonged graft survival in mice was associated with poor allograft function and histologic features of chronic immune injury including IF/TA [3]. Studies using class I and class II MHC knockout strains in which intact MHC molecules were absent on donor tissue demonstrated modestly altered kinetics of graft failure, and modest reductions in severity of these responses when either donor class I [136] or class II was absent [137]. The complete absence of donor MHC, however, resulted in significant improvements in function and the reduction in IF/TA changes [137]. These studies further demonstrated the critical components of both the cellular and humoral immune responses to mediate chronic allograft injury. They also utilized renal function as measured by inulin clearance as a more sensitive measure of injury.

A number of studies have examined the role of recipient hyporesponsiveness to kidney allografts, investigating the role of the kidney microenvironment. An interesting phenomenon is that recipient $CD8^{+}$ T cells down-regulate the cell surface expression of the TCR and, as such, may have altered immune activation [138]. Spontaneous acceptance, with graft survival greater than 60 days in the absence of immunosuppression seen in DBA/2 kidneys transplanted into C57BL/6 recipients, is associated with up-regulation of host TGF-β expression but not IL-10 [139]. This expression pattern was not seen in cardiac allografts of the same strains which rapidly rejected [140]. Furthermore, these kidney allografts are infiltrated by $FoxP3^{+}$ regulatory T cells (see Chapter 8), with up-regulated expression of IDO and regulatory dendritic cells [141]. These studies suggest immune regulation in recipient mice with both more immediate and, perhaps, more sustained responses, which allow for prolonged survival but still have ongoing immune responses that result in a chronic injury pattern of IF/TA.

Therapeutic interventions in chronic graft injury in the kidney

Based on data implicating the renin–angiotensin system (RAS) in fibrosis models in other kidney diseases [142], and the stimulation of the profibrogenic cytokine TGF-β by RAS activation [143], numerous studies have evaluated the impact of RAS blockade on mitigating the chronic injury. These studies have typically utilized the rat model of chronic fibrosis and glomerulosclerosis with F344 grafts into Lewis recipients, described above. Treatment with angiotensin receptor blockade, initiated at the time of transplantation, was associated with a reduction in urinary protein, glomerular capillary pressure, and glomerulosclerosis [144,145]. There were also reductions in proinflammatory cytokines and interstitial inflammation [144]. These effects were specific to this class of agent as blood pressure reduction using alternative agents did not show similar benefits [146]. These studies indicate the potential benefit of RAS inhibition in long-term graft failure, a clinical therapy already approved in humans.

It would seem to follow that regardless of injury, the long-term complications of both immune and non-immune mediated injuries are the developments of allograft fibrosis and tubular atrophy. Thus an alternative to treatment would be the use of antifibrotic agents. These agents attack the development of collagen formation by either stimulating matrix degradation or slowing or abrogating deposition. There have been limited preclinical studies in transplantation with these agents and these have been reviewed [147]. However, some are quite encouraging. The use of prolyl-4-hydroxylase inhibition (PHI), to limit formation of active collagen chains, ameliorated chronic injury in a mouse model of kidney allograft fibrosis, with a significant improvement in renal function and reduction in interstitial fibrosis and inflammation [148]. However, these agents have broader impacts within the kidney, including the overexpression of hypoxia-inducible factor and many downstream genes [149], which, in and of itself, may have a modulatory impact on inflammation.

The limitations of this approach may not seem obvious at first, but there are several difficulties in using these agents. Most studies have engaged therapy in the immediate post-transplant period, which prevents fibrotic injury but requires all recipients to be treated de novo. In practice, this would not be acceptable in man. The toxicities of these agents, including failure of wound healing, are obvious. The PHIs have potential effects on other biological pathways, including the induction of erythropoietin [149]. Thus, intervening at the time of developing injury would be more reasonable, but the biomarkers for fibrotic injury in transplant recipients remain an enigma. Finally, the instigating events of fibrosis are not affected by these strategies, leading to an uncompensated activation of profibrotic and repair pathways, a futile situation for the recipient's graft.

Cardiac vasculopathy

Chronic allograft vasculopathy, the leading cause of late heart allograft failure, has been studied extensively using mouse models of cardiac allotransplantation. This lesion is characterized histologically by intimal proliferation with luminal stenosis of epicardial branches and small vessels. In rats, heterotopic cardiac allografts between MHC class I compatible strains (RT1.A and/or RT1.E) develop intimal proliferation if surviving at about 30 days post-transplant [150] to as far as 120 days in the Lewis to Fisher-344 recipient [151]. These combinations likely differ in other MHC loci as evidence of acute rejection and myocardial inflammatory cell infiltration occur. Using ACI donors and (LEW×BN)F_1 recipients, which differ in both MHC and non-MHC antigens, grafts that survived 20 to 50 days developed arterial intimal fibrosis, which was modestly affected by brief CsA treatment [151,152]. A more detailed study of rat strains and the development of this histology was carried out by Cramer et al. [153]. Here, syngeneic control grafts demonstrated minimal abnormalities compared to strain combinations with MHC class I incompatibilities, which displayed variable levels of acute inflammation as well as intimal fibrosis. Non-MHC incompatible combinations had lesions more consistent

with mild-to-moderately severe allograft rejection, with concomitant development of myocardial fibrosis, and concentric myointimal changes in medium-to-large intramyocardial arteries. These differences demonstrate the critical dependence of strain on model outcome, with vascular lesions less prominent in recipients with more active acute rejection and less common in class I disparate recipients or syngeneic controls.

The pathogenesis of these vascular lesions has been studied extensively. Infection with CMV may mediate endothelial cell injury, vascular smooth muscle proliferation, and subsequent intimal thickening [154,155]. As implied above, an earlier inflammatory stage precedes vascular injury, and macrophages play a critical role, responding to up-regulation of MHC class II and ICAM-1 on endothelial cells [156,157] with associated up-regulated intragraft MCP-1 [158] and induction of nitric oxide production [159]. Strategies to limit mononuclear cell infiltration in the rat are limited. Further successful attempts have been utilized in a limited fashion in mouse models discussed below.

While donor-specific antibody has been strongly implicated in the pathogenesis of cardiac vasculopathy in the rat, modulation of T-cell responses have shown significant success. CSB, typically used in the early post-transplant period, has shown dramatic impact in late injury. Using the Lewis to Fisher-344 model, and a single dose of CTLA4Ig 2 days post-transplant, graft survival extended to nearly 70 days with a reduction in proinflammatory and macrophage-related cytokines as well as a reduction in the frequency and severity of arteriosclerosis [160], demonstrating the prominent role of T-cell activation early on in the development of chronic injury. Similarly, blockade of the CD40–CD154 pathway has ameliorated both acute and chronic injury in this rat model with prolonged graft survival [161]. Mitigation of chronic injury in this model has also been successful using a hematopoietic chimerism approach by transplantation of T-cell-depleted allogeneic marrow, demonstration the potential of this approach to affect long-term outcomes [162]. Other successful strategies include the use of genetically engineered dendritic cells that over-express indoleamine 2,3-dioxygenase [163], the oral delivery of donor-specific antigens [164], and treatment with synthetic peptide corresponding to residues 75–84 of the alpha1 domain of the HLA-B7 molecule [165]. These various approaches have all demonstrated significant modulation of the T-cell response and subsequent vasculopathy. However, further development in clinical trials has not occurred.

Murine models of transplant vasculopathy have also been studied and have provided some very specific insights that are available through the use of genetically engineered donor organs and recipients. A number of proposed models currently exist and their utility is apparent. Heterotopic transplantation of B10.A hearts into B10.BR recipients reproducibly develops intimal proliferative lesions, characteristic of transplant coronary vasculopathy in the absence of immunosuppression, over a period of 4–6 weeks [166]. This combination differs in the D and L loci of MHC class I, but are identical for the K locus of class I, class II, and minor MHC proteins (see Chapter 4 for detailed discussions of MHC molecule structure and function). Additional strain combinations that elicit the presence of vasculopathy over 4–7 weeks include transplants with isolated MHC class II differences (bm12 [H-2^{bm12}] into C57/BL6 [H-2^{b}] and bm6 [H-2^{bm6}] into C57/BL6 [H-2^{b}]) as well as multiple non-H-2 differences between donor and recipient (129/J [H-2^{b}] into C57BL/6 [H-2^{b}]) [4,167]. Complete MHC disparity between donor and recipient may also be used but requires adjuvant immunomodulation. For example, transplantation of CBA/CaJ [H-2^{k}] hearts into C57BL/6 [H-2^{b}] will develop vasculopathy under coverage of combined anti-CD4/anti-CD8 therapy [168]. Chronic vasculopathy will also develop in DBA [H-2^{d}] into C57BL/6 [H-2^{b}] recipients following prolonged treatment of anti-CD4 [169] or gallium nitrate [170,171], an immunomodulatory semimetallic element that inhibits T-cell and macrophage activation in part by affecting iron transport. Long-term acceptance of these allografts under gallium treatment is associated with production of TGF-β within the recipient and suppressed donor-specific DTH responses [172].

The critical role of alloantibody has been further evaluated in these models. While a B10.BR heart into a B10.A recipient does not develop arteriopathy, the addition of passive transfer of polyclonal antidonor antibodies leads to coronary lesions in a dose-dependent fashion [173]. B10.BR hearts transplanted to C.B-17 SCID mice results in arteriopathy, again only with the addition of anti-B10.BR serum [173]. Similarly, B10.BR hearts transplanted in $RAG^{-/-}$ mice lacking both B and T cells that further received passive transfer of monoclonal IgG2a anti-H-$2K^{k}$ also develop arteriopathy [174] and this response was dependent on continued administration of donor-specific serum. Moreover, reconstitution with passive transfer of IgG2b antibody into immunoglobulin knockout mice (C57BL/6 Igh-6) may recapitulate antibody-mediated injury of cardiac allografts [175]. While intimal thickening may occur in the context of donor-specific anti-class I antibodies, these responses are not dependent on complement fixation [176]. These data support the notion that chronic injury may occur in humans in the absence of detectable complement activation histologically.

The contributions of both antigen-dependent and independent mechanisms of rejection have been evaluated in these models. The dependence of rejection on CD8 cytotoxic T-cell responses has been demonstrated in both class I and class II mismatched models using CD8-deficient mice [177] or via CD8 depletional antibody therapy [168]. Costimulatory blockade of the CD40–CD154 pathway but not CD28/B7 alone has been effective in ameliorating vasculopathy [178,179], but this is a strain-dependent response [180]. Innate immune responses are also contributory. Carrageenan depletion of macrophages in the recipient ameliorates vasculopathy in C57BL/6 into (C57BL/6xBalb/c) F_1 recipients, suggesting macrophages as end-effector cells in a final common pathway that may be independent of B- or T-cell immunity [181]. Innate immune responses contributed by NK cells was also apparent using CCR4-deficient recipients [182] or in the context of parental to F_1 transplants [183], or in mice genetically deficient in mature NK cells (γ chain knockouts) [184]. Finally, non-antigen-dependent factors include oxidant stress [185], up-regulation of adhesion molecules [186,187], and the presence of viral infection [188].

Chronic vascular and glomerular injury also can be caused by non-MHC specific antibodies, suggesting an autoimmune phenomenon associated with injured tissue. In the rat model, these include cardiac myosin [189], other non-MHC antibodies in cardiac allograft failure in the rat [190], antibodies to perlecan and type IV and VI collagens responsible for glomerulopathy in the F344 into Lewis recipient [191], and antimesangial cell antibodies [192,193]. In the mouse, antibodies to vimentin [194] have also been identified as pathogenic. Further understanding of the contribution of antibody responses to structural proteins in chronic injury is needed.

While these studies highlight the development of vasculopathy, Bishop and colleagues have studied the development of graft

hypertrophy and fibrosis. Their studies, using an MHC complete mismatch cardiac allograft (H-2^b into H-2^d) with anti-CD4 antibody induction, have highlighted a novel pathway of fibrosis, mediated by IL-6 [195] and the downstream effector CTGF [196] and Th17 cells [197]. These studies and the use of this model may help to determine novel therapeutic targets in inflammatory-mediated cardiac hypertrophy. Finally, fibrosis is markedly reduced in heart allografts in IL-$17^{-/-}$ mice treated with [198] or without CSB [199], suggesting a detrimental effect of IL-17 in this development of chronic injury.

Vessel allografts—an alternative model for accelerated arteriosclerosis?

As an alternative to heterotopic cardiac transplants as a model of graft arteriosclerosis, a number of investigators have utilized the implantation of arterial "jump" grafts attached to the recipient aorta. Models exist in both rat and mouse recipients. In the former, combinations have included DA ($RT1^a$) into Wistar Furth ($RT1^u$) without immunosuppression for a 1 to 5-month period [200], Lewis ($RT1^l$) to F344 ($RT1^{lv}$) grafts over a 75-day period without immunosuppression [201], Brown Norway($RT1^n$) into Lewis [202], and PVG ($RT1^c$) into DA ($RT1^a$) [203]. A cellular inflammatory response was commonly seen, with intimal and adventitial infiltrates containing T cells and macrophages. Murine models have provided more intense scrutiny of these immune responses. An initial report using B10.A into C57BL/6 recipients highlighted the vascular injury, and smooth muscle cell proliferation within 30 days in the absence of immunosuppression and further demonstrating the technical feasibility of this mouse model [204]. However, the elegant use of genetically modified mice highlighted the need for both intact cellular and humoral arms of the immune response, particularly B cells, macrophages, and $CD8^+$ T cells [205] to mediate this inflammatory intimal fibrosis.

While these data provide interesting clues to the cellular and antibody-mediated injuries, and this model is easy to reproduce, these grafts have some significant differences from fully vascularized allografts. As already noted, the vasa vasorum, a network of microvasculature in the adventia that supplies nutrients and oxygen to the arterial wall, is disrupted in these grafts. This lack of physiological underpinning has significant implications and may alter the development of this lesion, making the findings less biologically relevant [206]. The lack of interstitial dendritic cells also implies that the direct pathway of allorecognition is relatively absent, necessitating only indirect pathway activation of recipient T cells. This is in contrast to the dual pathways that are activated in vascularized organ rejection. These limitations have made this model less biologically relevant in examining graft arteriosclerosis and the intact organ models are favored.

Bronchiolitis obliterans syndrome and lung allografts

Past mechanistic studies of chronic lung injury, called bronchiolitis obliterans syndrome (BOS), were limited by the availability of small animal models. A commonly used approach is the heterotopic tracheal allograft. Here, a section of trachea is implanted under the skin in a pocket of a recipient mouse [207]. In general, MHC incompatible strains are used and some immunosuppression, typically CsA, is provided over a 4-week period. Tracheal allografts developed epithelial injury and cellular infiltrates with both CD4 and CD8 T cells by 2 weeks post-implantation with epithelial denudation and luminal obliteration by 6 weeks and, finally, dense collagenous scarring by 15 weeks [208,209] with a broad outpouring of T-cell cytokines [210]. Severity of immune response is based on MHC mismatch with a primary response against MHC class I antigens which is both cellular [211] and humoral [212]. Further investigation has identified the epithelium as a key target of immune injury in which epithelial regeneration is an active process, providing a self-renewing source of antigens [213,214]. This targeted injury is further augmented by viral infections, including CMV [215]. TGF-β and IL-13 may also play a role as a profibrogenic cytokine [216,217]. Like other models of chronic allograft injury, costimulatory blockade ameliorates the development of this lesion [218]. Finally, inhibiting fibrocyte migration using anti-CXCL12 attenuates the histologic features of BOS [219].

While this is a facile model to study airway injury, there are limitations to a model which is physiologically passive without ventilation and hence does not recapitulate the intact lung model. Secondly, this is a neovascularized graft, and lacks the development of a microcirculation, which has now been identified as a key contributor to allograft injury [220]. Finally, the morphology of the trachea differs from the bronchioli and cannot be compared to small bronchioli after orthotopic lung transplantation [221]. Hence, a number of laboratories have developed a rat fully vascularized heterotopic lung transplant model and later a mouse model. These models differ in donor and recipient strain combination and include Wistar Kyoto into F-344 [222,223], F-344 into Wistar Kyoto [224], Lewis into F-344 [225], and Brown Norway into Lewis [226,227]. These models typically show a progression of inflammatory T-cell-mediated injury leading to fibrosis and airway occlusion and may require low-dose CsA treatment with injury evolving over months [226,228,229], although this has not been consistently reported [223,230]. Additional insults, including charcoal installation [226] and viral and bacterial infections [225], have stimulated more aggressive injury. The inconsistent results of these models are still unclear but do not appear to relate to surgical technique. The lesions may require two insults and may relate to strain variation from vendors [224].

A more elegant model of orthotopic transplantation in the mouse has been developed. Here, MHC-incompatible C57BL/6 left donor lungs are transplanted into Balb/c recipient [35]. Extensive inflammatory cell infiltration by CD4 and CD8 T cells as well as monocytes are seen in the first 7 days post-transplant, and marked graft edema. Treatment with dual costimulatory blockade using anti-CD154 mAbs and CTLA4Ig results in severe vascular rejection with interstitial fibrosis, while airway epithelium remained intact [231]. Using a staged pneumonectomy and right donor lung, recipient's survival depends on the transplant and both functional and histologic features of rejection may be quantitated [232]. In this model, rejection is independent of secondary lymphoid organs [233]. These studies demonstrate the feasibility of orthotopic lung transplantation in the mouse, with an emphasis on acute rejection. Further changes in the donor and recipient strains has provided more consistent findings of BOS, such as lungs from C57BL/10 (H-2^b) mice transplanted into C57BL/6 recipients, where only minor MHC disparities exist. Here, there was a rapid onset of BOS features within 2 weeks post-transplant which is ameliorated by neutralizing IL-17A [234]. The use of CsA with steroids in a Balb/c allograft into a C57BL/6 recipient resulted in BOS after about 10 weeks with an acute inflammatory injury consistent with rejection, although pulmonary function measurements did not correlate to the extent of severity of late histologic abnormalities [235]. These promising studies in a technically

difficult surgical model may provide new insights into the mechanisms of injury mediating BOS.

The toxicity of immunosuppressive agents

The role of the calcineurin inhibitor CsA as an immunosuppressant and its mechanisms of action are discussed in Chapter 17. In its early clinical use, CsA was found to mediate dose-dependent renal failure and was initially seen in renal transplant recipients (reviewed in [236]). With its accepted use, nephrotoxicity was also demonstrated in the native kidney, in recipients of non-renal organs, as well as patients treated for autoimmune diseases [237]. These clinical observations led to a detailed analysis of a rat model of nephrotoxicity whereby Sprague Dawley rats treated with 12.5 mg/kg CsA daily for 3–10 weeks developed reduced renal function and the histologic features of "striped fibrosis" with tubular degeneration along the thick ascending limb of the loop of Henle, as well as fibroblast proliferation and collagen deposition in the outer medulla [238]. These findings were exacerbated by a low-sodium diet but unaffected by unilateral nephrectomy. Other rat stains have been used including Wistar [239] and PVG [240] with similar responses, indicating that this is not a strain-specific phenomenon. Doses of CsA utilized include 5–25 mg/kg/day, for an average of 4 weeks [239], and nearly every model emphasizes the use of low-sodium diet to enhance the vasoconstrictive process.

Mechanistic studies using this toxicity model have identified several critical classes of mediators, including angiotensin II [241–246]. Indeed, spironolactone [247] or angiotensin receptor blockade [242] treatment ameliorated the renal injury in this model. Similarly, vasoconstrictive eicosanoids like thromboxane A_2 [248–252] and leukotrienes [240,253] have been shown to be up-regulated in this model, and inhibition of these pathways not only improves renal function but histology as well. Other implicated molecules include endothelin [254] and nitric oxide [255–257].

The profibrogenic effects of CsA have been associated with the induction of PDGF and TGF-β within the kidney [239,258–260], as well as CTGF [261]. The functional impact of TGF-β in this model was further demonstrated by mitigation of the CsA-induced fibrosis following treatment with the pirfenidone [262] as well as anti-TGF-β antibodies [259]. Furthermore, as angiotensin II expression has been linked with the induction of TGF-β, several studies have demonstrated a reduction in TGF-β when the angiotensin pathway is antagonized [242,263]. HMG-CoA reductase treatment has also been associated with a reduction in renal fibrosis and interstitial inflammation in nephrotoxicity of this model [264]. While TGF-β is a unifying theme for the development of fibrosis in this model, antagonists of this pathway may have unintended consequences as TGF-β has strong immunomodulatory actions as well.

Due to the tubular injury mediated by CsA, it should come as no surprise that apoptosis occurs during exposure. This has been demonstrated in the nephrotoxic rat model by TUNEL staining [265]. Up-regulation of proapoptotic genes also occurs within the kidney of nephrotoxic rats [266] as well as a mouse model [267]. Reversal of this expression as a potential therapeutic strategy may ameliorate injury [268–270]. Additional modulation of the fibrotic injury may also occur via nestin expression, which may be found in the interstitium of kidneys following CsA nephrotoxic injury [271]. Depletion of macrophages at the time of injury was similarly associated with improved renal function and reduction in interstitial fibrosis following CsA treatment [272].

Endoplasmic reticulum (ER) stress has been identified as a potential mechanism mediating the injury of CsA on human tubular epithelium in vitro [273]. Indeed, prolonged treatment with CsA in the rat is associated with the ER stress that accompanies the apoptosis of the epithelium [274] and autophagy of epithelial cells following CsA treatment [275]. Moreover, protection of ER from CsA-mediated stress improves renal function and the histologic features of CsA toxicity in the rat [276]. These studies suggest a novel mechanism that could be an alternative therapeutic avenue to ameliorate CsA-mediated tubular injury.

While most of the mechanistic data regarding CsA nephrotoxicity has been obtained using rats, there have been a number of reports utilizing a mouse model. Similar to transplant models, a mouse model provides the advantages of smaller animal size, the convenience of genetically manipulated models, and greater understanding of the immune response and reagent availability for the mouse. However, mice are resistant to this treatment [277,278] and as such require additional maneuvers. A reduced sodium diet of 0.01% is combined with 30 mg/kg/day subcutaneous administration of CsA in ICR mice, and, by day 28 of treatment, these animals developed the characteristic lesions associated with CsA nephrotoxicity [279]. In contrast, a normal sodium diet, even with 100 mg/kg/day treatment, had no impact on renal function or structure, even out to 56 days of treatment. Associated with this injury is an increase in apoptotic tubular epithelium and up-regulated gene expression for apoptotic proteins [267], much like that seen in the rat model. These reports provide the possibility of an alternative model to study CsA injury. Whether there are differences in nephrotoxicity mediated by tacrolimus as compared to CsA has yet to be explored.

Small animal models of transplantation tolerance

Animal models, and in particular rodents, have been extensively studied for more than 50 years, in the pursuit of predictable and robust transplant tolerance strategies that might be successfully applied clinically. Discussions on the mechanisms of tolerance and on the clinical application of tolerance protocols can be found in Chapters 11 and 76, respectively. Despite our contemporary focus on rodent models, the field of transplantation tolerance has been critically dependent on both small and large animal models. Indeed our foundation of tolerance understanding has benefited greatly from integration of species observations. J.B. Murphy showed, as early as 1914, that foreign tissues could grow on the chorioallantoic membrane of the chick embryo due to immunoincompetence, which could be reversed by the concomitant administration of adult spleen cells [280]. The evolution of transplant tolerance studies continued with large animals observations in 1945 by R.D. Owen, noting that dizygotic cattle twins display red cell chimerism–mosaicism. This was followed by Medawar's observation that dizygotic cattle twins generally had a natural "tolerance" for each other's skin allografts [281]. The association of transplantation tolerance and utility of small animal (i.e. rodent) models was, however, firmly established in 1953 when Medawar's group reported that tolerance could be established with the adoptive transfer of lymphocytes to fetal mice that could subsequently accept skin transplants from the same donor [282].

Transplant tolerance tends to be operationally defined in small animal models, usually with an allogeneic graft being accepted 100–150 days after cessation of therapy. Tolerance is more firmly

established if the animal is unable to reject a graft from the same donor, yet retains the ability to reject "third-party" tissues or organs. Due to technical limitations in small animals, often a donor-specific skin graft is used a second graft challenge. While the skin graft remains a "gold standard" as it is the most sensitive to rejection, skin tissue is very immunologically different from the first graft. Indeed, it has been suggested that acceptance of a skin graft may be too rigorous a criterion for tolerance, as the number of T cells required to elicit skin graft rejection is 6000 times smaller than that required for heart rejection [50].

While the use of small animals in transplant studies has greatly expanded our understanding of tolerance, it is clear that they have not provided a "Rosetta stone" to unravel the tolerance phenomenon, nor have they become a substitute for large animal (i.e. swine), non-human primate (NHP), or clinical studies in patients. While tolerance in mice was demonstrated by Medawar's experiments, it was evident even in 1953 that transplant tolerance in inbred strains of mice was influenced by complex factors beyond his mouse model, as graft survival could be permanent or transient and it was highly strain specific. Furthermore the induction of tolerance by Medawar in mice depended on the presentation of allogeneic antigens to fetal mice before they were immunologically mature, a situation that may be rarely clinically relevant. However, his pioneering experiments in the 1950s unequivocally demonstrated that alteration of recipient immunity could lead to acceptance of adult tissues, and, in doing so, launched the field of "immunoregulation." Despite their limitations, small animal models continue to provide valuable insights in transplantation tolerance. Advanced technologies continue to provide not only novel therapeutics that require validation in small and large animal models, but also unique genetically modified mouse models that can be used to test specific potential pathways or more accurately reflect human systems.

Limitations of small animal models in tolerance studies

There is little doubt that tolerance insights have come from mice and transplant studies have been revolutionized by the use of genetically engineered transgenic, knockout, and mutagenized mice [283–288], as well as monoclonal antibody probes for lymphocyte membrane markers [289]. However, tolerance appears to be more readily achieved in small, inbred animals compared with large, outbred animals and even robust animal models seem less challenging than patients. The biology of tolerance, even in mice, is complex. Of note in Medawar's classic experiments of central tolerance, only three of five mice became tolerant of skin grafts after perinatal injection of donor tissue, and one of these three animals lost the skin graft between days 75 and 91 after transplantation [290]. It is apparent that while small animals and rodents remain "economical" for identifying potential strategies of tolerance induction, there are complex factors that alter their validity for human transplant tolerance approaches. Immune systems of rodents differ from those of larger animals and certainly primates (Table 14.2), with differences in MHC organization, age-related decline in T-cell regeneration, T-cell repertoire diversity, B-cell and T-cell development in response to different regulatory factors, differences in cytokine and chemokine repertoires, cytotoxic effector cell bias in rejection, and homeostatic T-cell proliferation and memory T-cell expansion in response to depletional strategies [291–293]. It is also well known that many inbred mouse strains commonly used for experimental purposes represent extreme immunological phenotypes, including their tendency to generate Th1 as opposed to Th2 responses [294]. Perhaps the most relevant difference is animal longevity, which results in primed T cells and the formation of memory T and B cells in long-lived "antigen-experienced" primates and humans as compared to short-lived rodents, which tend to remain "antigen naïve" [290,295–297]. Tolerance strategies based on CSB, for example, are therefore very successful in rodents and less efficacious in animals with a higher proportion of memory cells [298].

Table 14.2. Comparison of rodent models to non-human primate models used in experimental transplantation research

Feature	Non-human primate	Rodent
Handling	Difficult especially larger animals	Relatively easy
Cost per animal	High	Low
Access to strains	Restricted	Widely available
Robustness	High	Low
Transgenic models	Not available	Available
Technically challenging	More	Less
Mimic human immune system	Foundations similar	Foundation and applicability
Lifespan	1–3 years	20–40 years
Physiologic readouts	Complex	Simple
Breeding	Easy	Very difficult (not done)
Availability of reagents	Limited/ non-specific	Wide variety/strain specific
Spontaneous mutations	Uncommon	Several
Useful for testing therapeutics	More applicable	Less applicable
Similarity to human anatomy	Similar	Distant
Physiology similar to humans	Similar	Distant
Nutrition	Complex regimen	Simple regimen

Transplant tolerance in small animals

Central transplant tolerance

Self-reactive T cells and B cells are eliminated in primary lymphoid organs in mice and humans, namely thymus and bone marrow [287,299,300]. While the thymus is essential for T-cell maturation and the induction of "central" tolerance to self-antigens through clonal deletion, self-reactive T cells can exit the thymus and are capable of potentially causing autoimmune disease (see Chapter 2). Immunoregulation thus necessarily includes "peripheral tolerance" mechanisms, primarily anergy [301], peripheral deletion [302], and regulatory T and B cells that can down-regulate the activity of autoreactive cells [303,304]. While the thymus' capacity for deletion of antigen-reactive T cells has been shown following intrathymic administration of islets in mice [305], intrathymic delivery of allopeptide may be limited by involution of thymus in adults. The transient presence of donor antigen may also account for the lack of graft protection observed clinically using donor cells in heart transplant patients [306].

Mixed chimerism transplant tolerance

Mixed lymphohematopoietic chimeras result from irradiated mice (and larger species), reconstituted by a mixture of T-cell depleted host and donor bone marrow. A form of central tolerance, both host and donor lymphoid and hematopoietic elements remain in these animals for the lifetime of the recipient and transplanted donor tissue is subsequently accepted without immunosuppression [307]. Mixed chimeric tolerance is robust in small animal recipients that can accept highly immunogenic skin and small-bowel grafts across extensive major and minor histocompatibility antigen barriers

[308,309]. Mechanistically, the tolerant state involves deletion of reactive cells as well as peripheral regulation mechanisms [310–314]. Requirement for pretransplant host conditioning, including sublethal irradiation, the use of myeloablative agents, and limited longevity of mixed chimerism, have limited the clinical application of this strategy except for specific patients such as those with hematological malignancies and concurrent renal failure [315]. Mixed chimerism follows T-cell-depleting monoclonal antibodies, but local thymic irradiation appears to be more durable in mice than non-human primates, in which chimerism appears to be transient [316,317]. Work in rodent models has thus focused on replacing toxic conditioning to reduce host morbidity, such as high-dose MHC mismatched bone marrow and only a single injection of anti-CD40L and cytotoxic T-lymphocyte-associated antigen 4 immunoglobulin (CTLA-4 Ig) [318]. Potentially, the use of donor-derived embryonic or mesenchymal stem cells, which possess immunoregulatory capacity, may increase the efficiency of mixed chimerism strategies [319–322]. While conceptually central tolerance is attractive, its translation into the clinic has been slow because the conditions necessary for achieving mixed hematopoietic chimerism have not yet been achieved using protocols with clinically acceptable toxicities.

Peripheral transplantation tolerance

Costimulatory molecule blockade

As self-antigen reactive cells can escape thymic deletion, additional mechanisms exist to regulate the functional capacity of T cells with potential autoreactivity that have emerged into the periphery. Peripheral tolerance is a broad term applied to naturally arising mechanisms that lead to the anergy, deletion, or regulatory cell suppression of self-reactive T cells in the periphery. Investigations using mouse transplant models have been critical in identifying mechanisms of peripheral tolerance to alloantigens, and, more importantly, developing clinically relevant strategies to exploit these mechanisms. Peripheral immune responses in mice are attenuated by "damping" receptors on T and B cells and promoted by costimulation. Damping receptors have been extensively studied in mouse transplant models and include molecules such as CTLA-4 [323], T-cell immunoglobulin mucin family (TIM) members [324], programmed cell death receptor (PD1) and its ligand PDL-1 [325,326], and on B cells, Fc, and other inhibitory (ITIM) receptors [327,328].

The blockade of the CD28-CD80/86 costimulation at the time of alloantigen recognition has been shown in experimental mouse models to be a robust and effective strategy for inducing peripheral tolerance. A second costimulatory pathway of importance is the CD40 (found on APCs)/CD40L (CD154) (found on T cells) pathway, which plays a pivotal role in the development of $CD4^+$ T-cell responses [329]. Signaling through CTLA-4 appears to be an essential pathway for graft acceptance [330]. $CD4^+CD25^+$ T regulatory cells have been shown in mice to express constitutively surface and cytoplasmic CTLA-4 (CD152) [331] and blockade of CTLA-4 with anti-CTLA-4 antibody led to acute rejection of skin allografts [332]. Early studies demonstrated that the partial inhibition of T-cell function by blocking signal 1 (anti-CD4 and anti-CD8 mAbs) or signal 2 (anti-CD40L or CTLA4Ig) induced long-term allograft survival in mice [333]. Inhibition of signaling through the CD80/CD86 (B7)-CD28 pathway using a CTLA-4 Ig fusion protein containing the extracellular domain of human CTLA-4 fused to human immunoglobulin Fc chain was shown to be effective in transplanting skin and cardiac allografts [334]. Experimental mouse models using CTLA-4 Ig were pivotal in more recent pharmacotherapeutic development targeting the B7:CD28/CTLA4 pathway by a high-affinity CTLA-4 Ig fusion protein variant termed LEA29Y (belatacept), which was FDA approved for use in clinical renal transplantation in 2011 [335–337].

There are adjunctive strategies that can enhance the effect of CSB in rodent transplant models. $CD4^+$ T cells appear to be more susceptible to CSB than $CD8^+$ T cells and in some mouse models allograft survival following costimulatory molecule inhibition is augmented by reduction or depletion of $CD8^+$ T cells [291]. In the mouse skin allograft model, treatment with anti-CD40L mAb and donor-specific transfusion of cells (DST) prolonged survival of skin grafts by inducing the deletion of alloreactive $CD8^+$ T cells [338–341]. CTLA-4Ig therapy has also been combined with an infusion of donor alloantigen or anti-CD40L antibody [342], as induced tolerant states in rodents tend to be more robust when CSB is combined with donor antigen presentation. While the use of calcineurin inhibitors can block CSB-induced tolerance under some conditions [77,343], rapamycin has been shown to enhance CSB effect and increase long-term acceptance of completely major and minor mismatched skin transplant models [77]. While CTLA-4 and CD40L are primary targets for mouse CSB transplant studies, there are additional CSB targets. In a mouse cardiac allograft model, mice deficient in the induced costimulatory molecule ICOS ($ICOS^{-/-}$) showed prolonged allograft survival [344,345]. Programmed death-1 (PD-1) and its ligands PDL-1 and PDL-2 (homologues of B7) have also been tested in mouse transplants. In a cardiac allograft model, mice treated with a PD-L1 Ig fusion protein showed prolonged allograft survival, and in some cases permanent survival [346].

T-regulatory cells

Donor-specific immunoregulatory activity exists within the lymphocyte compartment of rodent transplant recipients, and its role in transplant biology is specifically considered in Chapter 8. Suppressor or regulatory T cells are critical to the induction and maintenance of donor alloantigen unresponsiveness in vivo: this may represent an important strategy to exploit for therapeutic transplant tolerance. Peripheral regulation of immune response by lymphocytes was suggested in the 1970s, using mouse skin transplant models [347–349]. Purified splenic T lymphocytes from mice made tolerant prior to skin transplantation, transferred donor-specific unresponsiveness into antilymphocyte-treated secondary recipients, often permanently. Controversy over the existence of $CD8^+$ "suppressor cells" subsided with the emergence of strong evidence for $CD4^+$ regulatory T cells. It has been known for some time that short-term administration of blocking anti-CD4 and anti-CD8 monoclonal antibodies can produce a "dominant" form of tolerance in mouse skin allograft recipients, in that donor-specific nonresponsiveness is transferable using multiple serial transfers of lymphocytes into sequential generations of naïve recipient mice. This phenomenon is referred to as "infectious tolerance" [347,350]. However these early studies of infectious tolerance were described in mice with minor histocompatibility mismatches and infectious tolerance is less evident or absent in mice transplants with major genetic disparities.

The majority of $CD4^+$ regulatory cells (Treg) in normal individuals are so-called natural or nTreg cells which develop in the thymus. Regulatory $CD4^+$ T cells can also be induced (iTreg) by various strategies. The expression of CD25 (IL-2R alpha) expression has been used to more specifically identify and enrich subpopulations

of $CD4^+$ T cells that demonstrate powerful regulatory activity in mice [351]. $CD4^+CD25^+$ T cells capable of regulating responses to alloantigens in vivo, can be isolated from mice pretreated with donor-specific transfusion (DST) and anti-CD4 monoclonal antibody [352]. The importance of a key transcription factor in $CD4^+$ regulatory T-cell function was dramatically demonstrated using homologous mutant scurfy mice, which lack the forkhead transcription factor 3 (Foxp3). Selective ablation of $CD4^+Foxp3^+$ Treg cells resulted in "catastrophic" multisystem autoimmunity [353]. In addition to Foxp3, a number of molecules have been found in mice to be expressed by T cells with regulatory activity, including CD62, CD103, and GITR [291,351]. Alloantigen-specific $CD4^+CD25^+$ regulatory T cells are able to prevent skin graft rejection initiated by not only $CD4^+$ but also $CD8^+$ T cells [291]. Other populations of regulatory cells clearly exist, including $CD8^+$, $CD8^+CD28^+$, $TCR^+CD4^-CD8^-$ ("double negative"), and natural killer T cells. Thus $CD4^+CD25^+$ cells may only represent one subset of important regulatory cells in rodent transplant models [354,355]. Regulatory T cells in mouse models are responsive to cytokines in the microenvironment. IL-10 and TGF-β play key roles in the suppressive activity of alloantigen-specific $CD4^+CD25^+$ regulatory T cells. Tregs isolated from recipients pretreated with an anti-CD4/DST tolerizing protocol and co-transferred with naïve effector cells into T-cell deficient mice failed to prevent skin graft rejection when treated with an anti-IL-10 receptor antibody; in the absence of anti-IL-10R antibody treatment, all grafts were accepted [332]. Similarly, TGF-β1 mRNA was expressed at high levels in accepted cardiac allografts from DST-treated rats [356].

Role of the graft microenvironment in tolerance

It is increasingly evident that the donor graft has a capacity to interact or avoid recipient immune responses to allow acceptance or enhance tolerance. Antigens placed in the anterior chamber of the eye are not attacked by the immune system, demonstrating that tissues can hold back damaging immune effector systems [357]. Spontaneous acceptance of liver and kidney allografts and more recently embryoid bodies in mice without any added immunosuppression supports the existence of tissue-based protective mechanisms [134,358,359]. In co-transplantation experiments, the donor kidney was required not only to induce but also to maintain tolerance to co-transplanted heart allograft from the same donor. Interestingly, adoptive transfer of $CD25^+$ cells from heart–kidney recipients to heart-only recipients produced short-term, but not long-term, tolerance, suggesting ongoing education of Tregs in the kidney [22]. Factors, including heterogeneous genetic backgrounds, the nature of the solid organ transplanted, and concurrent ischemia or infections, which increase innate inflammation, can alter the development of tolerance. Experimental mouse models will need to address these factors to provide data relevant to the clinical transplantation.

Ischemia–reperfusion injury

Tissue ischemia is an inevitable consequence of solid organ transplantation. It is increasingly recognized that the initial injury incurred by the graft during organ procurement and implantation is a significant contributor to graft outcome.

History of cold preservation

In 1849, Loebel attempted the first perfusion of an isolated organ [360]. Then in 1895, Langendorf developed a simplified device for organ perfusion. Lindbergh and Carrel were the first to propose hypothermic preservation and later created a perfusion apparatus for this. It was not until 1964 that Belzer with Najarian, while at the University of California at San Francisco, began work on hypothermic perfusion techniques for use in the deceased donor kidney transplant program [361]. In 1969, Collins helped convert the practice of transplantation from an emergency procedure to a semielective one by developing the first effective cold storage solution using rabbit models [362,363]. This solution proved to be of great help in extending times of successful kidney preservation, but unfortunately was not suitable for prolonged periods and for hepatic tissue [360]. In early 1980, Belzer and Southard developed the University of Wisconsin (UW) solution [364]. The UW solution has seen several improvements but, despite being superior to many other solutions, was not suitable for organ storage much beyond 24 hours. Not surprisingly, cold ischemia time is the single most important predictor of delayed graft function (DGF) following kidney transplantation [365]. After transplantation into the recipient, reinstitution of blood flow (reperfusion) leads to further tissue injury through generation of free radicals that further contributes to DGF [366]. The sum of injuries resulting from "warm" and "cold" ischemia is referred to as ischemia–reperfusion injury (IRI) [367]. Although most grafts with DGF will go on to have acceptable function, the long-term survival of these grafts is significantly worse than in those with immediate function [368]. By negatively influencing graft half-life, IRI contributes to the growing problem of donor organ shortage through the number of patients requiring re-transplants. The organ shortage problem has prompted the use of expanded criteria donors; however, by their nature, ECD organs are more prone to IRI and therefore DGF [369,370]. More recently, the use of pulsatile perfusion has been demonstrated to improve renal function and is also associated with improved graft survival in human kidney allografts [371]. Thus, IRI has become a major focus of experimental transplantation research.

Cold ischemic injury

Animal models have been developed to further investigate the mechanisms and potential treatments of IRI [372–374]. For cold ischemia, the organ (e.g. kidney) is removed, flushed, and stored at low temperature under conditions similar to cold preservation for human transplantation [375]. After a variable period of time, the kidneys are then re-implanted and reperfusion ensues. Before development of the mouse transplant models and transgenic technology, cold ischemia (bowel, heart, lung, liver, and kidney) was predominantly studied in dogs, rabbits, and rats [376–378]. Recently, the mouse model has overtaken all other animals as the choice model for studies of IRI. Together, these experimental models have contributed immensely to our understanding of the mechanisms of cold ischemic injury [360,374,379,380]. In particular, animal models were instrumental to the development of organ cold preservation solutions [381]. Despite how well the cold ischemia model is representative of events during human organ transplantation, much of what we know of transplant IRI stems from studies using the warm ischemia model [367,382]. This is despite the fact that the distribution and pattern of injury may substantially differ from that of cold ischemia–reperfusion models.

Pathophysiology of IRI

IRI is a dynamic process, which involves two distinctive yet interrelated phases of injury: ischemic organ damage and inflammation-mediated reperfusion injury. Cellular injury can arise from passive

or active mechanisms. Passive mechanisms include depletion of cellular ATP/GTP [383], intracellular acidosis, and hypothermia [360,384]. The active phase of cellular injury begins with reperfusion and leads to activation of both innate and adaptive immune pathways [385,386]. A key feature of IRI is the accumulation of reactive oxygen species (ROS), believed to arise from the decoupling of the electron transport system in mitochondria as a result of IRI-mediated damage. Although multiple cellular and molecular pathways contribute and regulate tissue damage, the crosstalk between innate and adaptive immune systems plays a significant role in the pathogenesis of liver IRI. The evolving model states that the initial tissue injury from ischemia–reperfusion serves as an "adjuvant" for alloimmune response to the organ through activation of innate immune mechanisms [386].

The ischemic-injured cell faces one of two fates: either recovery from sublethal injury with regeneration the epithelium [387] or cell death by apoptosis or necrosis [388–391]. Apoptosis is a common feature of IRI [373,382]. The importance of cell death to the pathogenesis of IRI is highlighted by the fact that inhibition of apoptotic pathways at the outset of IRI ameliorated tissue damage and limited organ dysfunction [392–397]. This is perplexing because apoptosis is regarded as an immunologically silent mechanism of corpse disposal [398]. In this context, a "surge" of dead cells may overwhelm endogenous clearance mechanisms [399], enabling apoptotic cells to undergo secondary necrosis [400,401]. These necrotic cells, unlike apoptotic cells, spill their intracellular contents into the extracellular milieu and instigate a sterile inflammatory response (SIR) [402] through activation of the innate immune response [386,403,404] (see Chapter 7). This "collateral damage" inflammatory response is the key element of organ dysfunction (reviewed in [405–407]) and may be triggered in part by endogenous "danger" signals or alarmins, which are released from cells that are distressed, damaged, or dying an abnormal death in order to alert the immune system [408–410]. Danger or damage-associated molecular pattern (DAMP) molecules are normal cell or extracellular matrix components, which are released by cellular injury or action of proteases at the site of tissue damage, respectively [411]. Inflammatory signals may be transduced from injured cells and initiate tissue damage via the IL-1R-Myd88 pathway [409], or TLR4 in kidney ischemic injury [412] and renal epithelium may directly contribute by directing renal inflammatory responses.

The immune response of IRI

Innate immune cells such as NK and NKT cells are part of the early infiltrate in the mouse kidney after IRI [413]. While NKT cells lack rearranged T-cell receptors (TCR), these cells respond to lipids, glycolipids, or highly hydrophobic peptide antigen presented by the atypical MHC class I molecule, CD1d (see Chapter 2). Blockade of CD1d or depletion of NKT cells or use of mice deficient of NKT cells markedly mitigates ischemic injury in the mouse kidney [414]. In addition, NK cells may trigger syngeneic tubular epithelial cells to undergo apoptosis, and adoptive transfer of NK cells may worsen renal IRI in NK cell-, T cell-, and B cell-null mice [415]. Deletion of CD39 on NK cells, which is associated with marked decreases in phosphohydrolysis of ATP and ADP to AMP with accompanying modulation of purogenic receptors, mitigates warm ischemic injury in the liver in mice [416]. Taken together, these results demonstrate NK cells and NKT cells contribute substantially to IRI.

Animal models have been further used as critical tools to dissect the contributors of damage and injury in IRI (Table 14.3). For example, treatment of uninephrectomized rats prior to renal ischemia with anti-CD11a and anti-CD11b resulted in improved renal function and inflammatory infiltrates [417]. There is now overwhelming evidence suggesting that T cells serve as direct mediators of IRI. In CD4 and CD8 doubly deficient mice subjected to renal ischemia, there was significantly improved renal function, reduced neutrophil infiltration, and markedly decreased tubular atrophy scores compared to wild type, suggesting a protective effect of T-cell depletion on renal IRI [418]. Similarly, T-cell-deficient mice are also protected from renal [419] as well as hepatic [420] ischemic injuries, indicating the requirement for $CD4^+$ T-cell responses to mediate injury [420]. The protective effect of costimulatory blockade of the CD28/B7 pathway provides further evidence for the role of T cells in the pathogenesis of IRI [372,421].

Table 14.3. Pathways identified in ischemia–reperfusion injury using small animal models

Pathways in IRI and repair	Model	Reference
Derangements in medullary blood flow	Rat warm IRI	[480,481]
Macrophages	Mouse warm IRI; siRNA	[482]
B cells	Mouse warm IRI	[483,484]
T cells	Rat and mouse warm/cold IRI; NUDE; SCID; $Rag1^{-/-}$; adoptive transfer; $CD4^{-/-}$; $CD8^{-/-}$	[372,420,485–488]
NKT cells	Mouse warm IRI; $Jalpha18^{(-/-)}$	[489,490]
Toll-like receptors	Mouse warm IRI; $TLR4^{-/-}$	[317,412,423,491]
Neutrophils	Mouse warm IRI	[492]
ICAM-1	Mouse warm IRI; $ICAM\text{-}1^{-/-}$	[492]
Complement	Mouse warm IRI; $Cr1^{-/-}Cr2^{-/-}$	[413,483,493–496]
Selectins	Mouse warm IRI and bowel transplant; P-selectin knockout	[156,497,498]
Origin of cells replenishing dying tubular epithelial cells	Mouse warm IRI; fate-tracing; bone marrow chimera	[387,441,442]
Apoptosis	Inhibitors; knockout mice	[396,413,499,500]
Fibrosis	Mouse warm IRI; fate-tracing	[444,501,502]
Hypoxia-inducible factors	Mouse warm/cold IRI; inhibitors; knockout mice	[503–506]

Targeting IRI

As outlined in Table 14.3, the complexity of IRI and the connection of adaptive to innate immunity have made IRI a therapeutic focus beyond cold storage solutions and ex vivo machine perfusion. We have already noted the role of antiapoptotic strategies to limit IRI. Numerous studies have demonstrated a cytoprotective effect of carbon monoxide (CO) in IRI in rat liver [422,423], kidney [424–426], lung [427], and small bowel [428,429], as well as other organs and tissues (reviewed in [430]). Inflammatory cell infiltration may be mitigated by sequestering lymphocytes in secondary lymphoid organs, preventing them from entering the ischemic organ using a sphingosine 1 phosphate analog, which induces lymphopenia in mice and protects them from ischemic injury in the lung [33] and kidney [431–433]. As adenosine is a vasodilator in many tissues, selective activation of adenosine A_{2A} receptors has been shown to reduce tissue injury in the heart, liver, spinal cord, lung, and brain (reviewed in [434]). Inhibition of HMG-coA reductase has similarly been shown to ameliorate IRI in mouse kidney and with the known safety profile in man may be useful therapeutic adjunct [435]. Matrix metalloproteinases that degrade matrix molecules are also involved in propagating IRI, and following genetic deletion in the mouse have a negative impact on IRI [436]. Thus, animal studies, using genetic deletion strategies or depletion of protein or

receptor blockade demonstrate a variety of molecules that contribute to ischemic tissue injury.

One of the major limitations of targeted therapies is the potential for non-specific, off-target effects. RNA interference (RNAi) is an emerging strategy that offers high inhibitory activity, limited duration of action, minimal toxicity and precision that has been studied in IRI [437]. For example, siRNA targeting the transcription factor p53, a molecule that regulates apoptosis in renal IRI, ameliorates ischemic tissue injury in the mouse [438,439]. This strategy is already in clinical trials in man. An attractive alternative to delivering siRNA into the recipient is to add it to the organ preservation solution before transplantation.

Tissue repair after renal IRI

A remarkable feature of the kidney is its ability to repair itself after injury, but the extent of organ recovery is dependent on the extent and severity of injury as well as regulation of inflammation [440]. Tubular epithelial cell (TEC) proliferation is a hallmark of tubular repair. Shortly after the injury phase following IRI, the normally quiescent kidney tubular cells enter the cell cycle [441]. The origin of the cells repopulating the injured kidney remains controversial and the use of mouse bone marrow chimeras from green fluorescent protein transgenic mice helped establish that bone marrow-derived cells do not make a significant contribution to the restoration of the tubular epithelium after an ischemic insult [442,443]. Further, fate-tracing techniques using specific renal cell promoters and mouse IRI model have revealed that TECs are the primary source of cells that regenerated the tubular epithelium after IRI in the adult mouse kidney [387]. When IRI is mild and limited, repair pathways can restore the kidney to its normal structural and functional state. However, when the repair is more severe or is superimposed on baseline kidney abnormalities, the repair process can lead to fibrosis and chronic kidney disease. After severe injury, the proximal tubule cellular response is impaired with its proliferative response altered due to cell cycle arrest at the G2/M phase of the cell cycle, resulting in generation of profibrotic factors, including cytokines, growth factors, and matrix proteins [444,445].

The biomarker of acute kidney injury, kidney injury molecule-1 (Kim-1), a member of the immunoglobulin gene superfamily, was identified initially in a rat model of kidney IRI [446]. Subsequent studies in vitro indicate that it is a non-myeloid phosphatidylserine receptor that transforms epithelial cells into semiprofessional phagocytes [447] and is shed into the urine during injury [448]. While not considered a target for therapy, it was the use of small rodent models that was critical in the identification of its potential as a biomarker for acute kidney injury, leading to a revolution in the goal of interventional trials in man. Similarly, IL-18, produced by monocytes, has been identified as another potential therapeutic pathway but also as a biomarker of acute ischemic injury [449,450].

The limitations of existing animal models of IRI

Due to the advances in our understanding of IRI and success in rodent models, a number of strategies have been identified as potential clinical therapies but these have failed to advance meaningfully to the bedside, particularly in acute kidney injury. The lack of progress may be due to a number of issues with the models, including the fact that: (1) the pathogenesis of IRI in animal models is generally less complex than it is in humans because patients often have multiple causes of injury and multiple organs are dysfunctional; (2) IRI in humans is often in the setting of sepsis, and it has been difficult to establish good models of sepsis and IRI in animals; (3) many of the tested strategies in IRI may be applied too late because serum creatinine has been used as the biomarker for onset of acute kidney injury; and (4) therapies tested in donors are difficult to initiate in human trials due to human subjects' protection issues, for recipients as well as donor families and donor intent.

The most widely used experimental model is renal vascular pedicle or renal artery clamping for a variable length of time, with subsequent reperfusion. The rat was the model substrate but with the advent of transgenic technology there has been a shift towards using mice over the past decade. Unfortunately, this model has come under much criticism. First, the morphological findings in the animal models are not equivalent to those in the human biopsy specimen of "acute tubular necrosis" (ATN) [451]. Paradoxically, in the limited human biopsy samples that have been studied, there is limited necrosis. The appearance of ATN in the renal transplant is very similar to that of non-transplant ATN, that is limited parenchymal injury and manifest renal dysfunction [452]. The IRI is very susceptible to variability in the mouse due to the experimentalist, and even subtle variations in temperature. Because hypothermia has a protective effect, animal body temperature control is critical as the renal temperature is expected to drop upon clamping and more so if the kidney in left exposed [453]. There are also strain differences in responses in mice. Additionally, one must remember the fundamental differences between human and animal kidneys. Unlike the human, the rat kidney has a well-developed medullary outer stripe and surrounding complex vascular bundles, which include the thin descending limbs of the short Loop of Henle, versus simple vascular bundles without inclusions in human kidney. On the other hand, rodents possess unilobar and unipapillary kidneys, both in contrast to humans [454,455]. Overall, regardless of the limitations, animal models of IRI have significantly improved our understanding of kidney injury.

Xenotransplantation

With the success of allotransplantation and the ever-growing shortage of human organs, the field of xenotransplantation has seen a renewed interest. This topic is specifically covered in Chapter 12, but several aspects relate to small animal models, as xenotransplantation is, by definition, a species-specific endeavor. However, a number of hurdles still remain in this field. These include host immune response against the xenograft, the physiological incompatibility between animal tissue or organs and the human system for things such as growth factors and other protein compatibility, and the potential to transfer infectious agents from the donor to the recipient or the general population [456].

Choice of species

Although non-human primates are phylogenetically closer than other species to humans, they are not considered to be a suitable source of organs because of ethical issues, the high risk of cross-species transmission of infections to humans, difficulties in breeding, and organ size disparities [457]. For these and several practical and biological reasons, pigs are considered to be the preferred organ donor for humans. Pig organs are more comparable in size to that of humans, easily bred at large scales, and amenable to genetic modifications that could enhance their use as an organ source (reviewed in [458]). Given that pigs maintain blood glucose levels that are similar to those of humans and porcine insulin is effective

in humans, they are also considered an ideal source of islets of Langerhans for transplantation in humans. These strengths of this organism are, however, offset by the fact that the human xenogeneic immune response to pig tissues is particularly strong and presents a large immunological hurdle.

Immunological barriers to transplantation

The immunological response to xenotransplantation in humans includes both the humoral and cellular arms of the immune system. The antibody-mediated processes include hyperacute rejection (HAR) and delayed xenograft rejection (DXR), which rapidly attack vascularized organs from pigs that have been transplanted into untreated primates [456]. HAR was the first immunological barrier to xenotransplantation and is primarily mediated by so-called anti-Gal antibodies, which are IgM directed against α-linked galactose moieties Gal1α1-3Gal present on the graft endothelium [459]. This antibody is naturally produced in the recipient in the absence of clear immune challenge akin to antibodies to blood-group antigens [460]. The antigen is synthesized by the enzyme α1,3-galactosyltransferase (α1,3GT), which exists in lower mammals and New World monkeys but not in Old World monkeys, apes, and humans [461]. Thus, in phylogenetically distant, discordant combinations of donor and recipient, such as pig-to-primate, complement activation is immediate following reperfusion upon binding of anti-Gal antibodies to the graft endothelium, leading to endothelial injury and subsequently to thrombosis and necrosis of the xenograft [461]. In phylogenetically concordant combinations, such as hamster-to-rat, where anti-Gal antibodies are not present, complement likely contributes to delay rejection once antigraft antibodies are generated [456]. For this reason, pigs were developed with a targeted mutation in the α-galactosyltransferase gene (GTKO) [462,463]. The initial pig-to-primate GTKO cardiac xenografts demonstrated no hyperacute rejection with a median survival of 78 days [464,465]. Other strategies to prevent hyperacute rejection have included immunoadsorption of xenogeneic antibody by extracorporeal perfusion of the recipient using a species-specific organ such as the liver [466].

DXR is usually observed when HAR is prevented either by removal of anti-Gal antibodies or inhibition of complement activation [467]. It is characterized by infiltration of the graft by NK cells, monocytes, and granulocytes, and by endothelial cell activation with fibrin deposition and platelet aggregation [468, 469]. The key features of DXR are vascular endothelial cell activation and natural antibody (IgG anti-αGal)-mediated activation of Fc receptors on the cells mentioned above. These effector cells, upon ligation of Fc receptors, release their granule contents to mediate antibody-dependent cell cytotoxicity (ADCC). By its nature, DXR represents a key immunological barrier to successful clinical xenotransplantation.

Cell-mediated xenotransplant rejection

The xenograft is also subject to cell-mediated rejection. Xenografts can illicit potent antigen-specific T-cell responses that remain an important barrier to successful xenotransplantation [470]. As antibody responses do not seem to be largely associated with the rejection of xenogeneic islets, elucidating the cellular response in this model has extended our understanding of cellular responses focused on the antiporcine cellular responses [471]. With the addition of CSB such as CTLA4Ig or anti-CD40L, porcine xenoislet survival has improved substantially [472]. Moreover, fetal porcine islet-like cells placed under the renal capsule of nude mice demonstrate a limited and reduced inflammatory injury compared to wild-type mice [473], demonstrating the dependence of intact T cells in islet xenograft rejection. In support of this conclusion, recent studies in pig-to-non-human primates [474] and pig-to-mice [475–478] have shown improvement in xenograft survivals using CSB with anti-CD40L, or combination therapies affecting multiple pathways.

Whereas the alloimmune response targets MHC antigens, the response to a xenograft may target a wide variety of proteins and carbohydrates that differ in their molecular makeup. Akin to the allogeneic T-cell responses, the T-cell response to xenogeneic cells involves two distinct pathways: direct and indirect [471]. In the indirect pathway, xenoantigens are taken up, processed, and presented by recipient APCs in the context of the recipient MHC and does not involve any cross-species interactions with regard to signal 1 and signal 2. On the other hand, the direct pathway results from recipient CD4 and CD8 T cells interacting with donor (xenogeneic) MHC molecules on the surface of passenger (xenogeneic) APCs. This will only lead to productive T-cell activation if the interspecies molecular interactions for both signal 1 and signal 2 are compatible. In man, antiporcine responses in unprimed recipients are quite strong [479].

Prospects for xenotransplantation

Xenotransplantation remains the most viable option for increasing organ transplantation rates. Small animal models have highlighted some of the biology of these responses and demonstrated both humoral and cell mediated immunity pose formidable barriers to bringing xenotransplantation to clinical use in humans. The recent advances in pig transgenic technology and recent successes in preclinical models using non-human primates pose significant promise for entry into the clinic [458].

Summary

This chapter has highlighted the many contributions of small animal models in expanding our knowledge of transplant immunology. Key clinical challenges include late graft injury, antibody-mediated injury, and the elusive goal of tolerance. Table 14.2 has highlighted the key considerations between small and larger NHP models and their characteristic features. The opportunity to genetically manipulate mice has been one of the key features supporting their use in studies. Congenic markers have assisted in adoptive transfer experiments that have highlighted critical immune component features. The availability of reagents, including antibodies and molecular reagents, has provided a powerful complement to the genetic approaches. However, there are shortcomings in these smaller animals. The vascularized procedures are challenging technically and are limited to labs with skilled microsurgeons. Mimicking human disease in a compressed time period is difficult. The nature of the immune response is also substantially different from that of man, with a dramatically less diverse T-cell repertoire and smaller clone size, which affects not only the strength of the immune response but also its nature and variability. The role of heterologous immunity is another key consideration as housing for mice is pathogen free, while humans are constantly facing an immunological assault. However, in the continuum of our understanding, both types of models have afforded key insights into alloimmunity. As such, we should consider the small animal model as a valuable contributor to clinical therapies.

Introduction

In 1954, a team of surgeons lead by Dr. Joseph Murray ushered in the modern era of transplantation with the successful transplantation of a kidney between identical twins [1]. One year earlier, Billingham, Brent, and Medawar published their landmark work describing the acquisition of tolerance to allogeneic cells [2]. Standing on the shoulders of these giants, over the past 60 years, clinical investigators have seen remarkable advances in surgical technique, perioperative care, and immunosuppression, allowing for steady improvement in patient outcomes [3,4]. Yet, many challenges still lie ahead. We have only just begun to achieve durable tolerance of grafts in the clinic [5–7], and thus, for the most part, we still ask our patients to trade one chronic condition for another: life-long immunosuppression. As we continue to tackle these issues for the benefit of patients, we must carefully navigate the pathway from the laboratory to the clinic. While mouse models have proven their worth countless times in aiding in the elucidation of new biological and therapeutic concepts, experiments in large animals have been and remain the best option for translation towards human trials. This chapter will provide an overview of commonly used large animal models in transplantation and the relative strengths and weaknesses of each, with the intent of demonstrating the value of large animal models in the translation from theory to therapy. This chapter serves to complement Chapters 13, 14, and 16, which address in vitro, small animal in vivo and in silico models of transplantation, respectively.

Why use large animals?

Animal experimentation has been a workhorse of medical progress since the times of Aristotle and Erasistratus, providing a rational basis for the translation of treatments and techniques to humans [8]. Indeed, the use of animals for the perfection of surgical technique dates to at least the 12th century when Ibn Zuhr (Avenzoar) performed a tracheostomy in a goat [9]. While human experimentation should not be void of novelty, it is impossible to provide the necessary and proper background so that patients may make truly informed decisions about their participation in research unless the method has previously been tested in a model with a reasonable chance of predicting at least the safety of the planned intervention. Typically, animal models have provided this foundation on which human experiments can be ethically based.

Despite the fact that animal models have often failed to be entirely predictive of a regimen's success in humans, they remain the best means for the prediction of safety. The complexity of immunity and rejection has prevented the development of any in vitro model capable of mimicking, let alone predicting, even basic immune responses. Thus, animals continue to provide the best models for advancing therapies toward clinical application. However, given the failure of animal models to predict *all* aspects of a therapy's effect in humans, experiments should be designed and interpreted with this limitation in mind.

The ethical principles guiding animal experimentation of all types, but particularly those of large animal experimentation, have become increasingly complex as modern society has recognized the rights of animals to humane treatment. The literal interpretation of Thomas Aquinas' assertion, "Animal non habet jus", translated as "Animals do not have rights", is no longer socially palatable. While his statement seems stark and uncaring at face value, more careful examination of Aquinas' humanity-centric philosophy reveals no disregard for animals' wellbeing, but rather elevates the position of humans and allows a rational justification for animal experimentation [10]. Modern views on the ethics of animal experimentation, primarily over the past half century, have led to significant regulation to ensure the proper use of animals. Specific guidance for ethical animal experimentation can be found in the *Guide for the Care and Use of Laboratory Animals* [11] and in the publications from the American Association for Laboratory Animal Care [12]. Many academic institutions and journal publishers require adherence to these guidelines. The principles of reduction, replacement, and refinement are at the heart of all ethical animal experiments. Animal models should only be used when no suitable replacement exists and all techniques should be maximally refined in terms of the animals' welfare. The number of animals used should be the minimum needed to answer the question posed in the experiment. However, no experiment is ethical if it cannot answer the question posed. Thus reducing the numbers of animals used to the point of failing the experimental objective is less ethical than a successful experiment that uses more animals.

Animal experimentation in mice offers several distinct advantages over the large animal models. Mice offer sufficient biologic similarity and easy genetic manipulation at a relatively inexpensive cost making them ideal for pathway determination and mechanistic studies. In contrast, large animal models are significantly more

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

expensive and, with the exception of inbred miniature swine (see below), their genetic diversity makes definitive mechanistic studies difficult. However, the impracticalities of large animals for mechanistic studies are, at the same time, what makes them the best option for preclinical studies. The additional complexity of a large animal model adds unanticipated variables that make these experiments best suited to examine practicality, safety, and generalized efficacy. That is not to say, however, that experiments should be void of measurements to confirm consistency with overarching hypotheses. With regard to transplantation and immunology, specifically, murine models have several potential drawbacks. Laboratory mice bred in pathogen-free environments and studied at 4–8 weeks of age have largely naïve immune systems [13]. This is likely responsible for the observation that many therapies that have been rigorously studied in mice, including methods that readily induce tolerance in mice, fail in more complex animals [14,15], or even in mice exposed to pathogens [16]. Unlike all large animal species so far tested, mice do not constitutively express class II antigens on vascular endothelial cells, which may explain the greater importance of class II matching for transplant outcome in large animals than in mice [17,18]. The specific genetic background in which treatments are tested has also been shown to affect the efficacy of therapy [19]. The genetic diversity and immunologic experience of outbred large animal models helps to avoid many of these shortcomings. Thus, experiments in a large animal model, most frequently in non-human primates (NHPs), have become a de facto requirement prior to initiation of human clinical trials in transplantation [15,20].

Due to the immense complexities of the immune system, therapies may fail in translation to large animal models or, subsequently, to humans. This is rarely a failure of the model itself, but is more likely to be due to one or a few critical differences that were not initially appreciated. Differences in drug distribution or metabolism can lead to apparent failure of a therapy that may have been quite successful had appropriate dose adjustments been made. In the era of modern biologic and antibody-based therapy, it is especially worth noting that relatively minor differences in molecular structure can have profound effects on the ability of the drug to exert the desired effect. As noted previously, the diversity of immunologic experience is a major advantage to large animal models and can significantly affect therapeutic outcomes via heterologous immune interactions. The quantification and control of this experimental parameter is particularly challenging. Finally, the practicalities of caring for the animals during therapy cannot directly replicate what is available clinically. Wound care in surgical models is often difficult. Monitoring and vascular access are also challenging in conscious animal models. Innovation in cage design has allowed for indwelling catheters in NHPs; however, these cages are not always available and are not without flaws.

A final issue with large animal models is that of time, both in terms of the age of the animal and in survival outcomes. Animals are often used at a relatively young age, consistent with adolescence, for practical reasons. Evidence suggests that these young animals have a predominately naïve T-cell repertoire that will slowly mature towards a memory phenotype with age [21–24]. This more closely resembles human children of the same absolute age rather than the human adults that comprise the bulk of the clinical transplant population. With regards to indefinite graft survival in animal models, convention in mouse models has established 100 days as indicative of acceptance, while several years has been used for larger animals. While this is intuitive in terms of the shorter overall lifespan of these animals compared to humans, where grafts are expected to last a decade or longer, there are no data to support that graft survival should be interpreted proportionally to expected lifespan. Thus, it is best to refrain from interpreting data from these studies as indicative of longer-term graft survival.

Despite the challenges and drawbacks of large animal models noted above, they remain the best predictors of generalized efficacy and safety of therapies being considered for clinical translation.

Common large animal models

In transplantation, the most commonly used large animal models are dogs, pigs, and NHPs. Each species has sufficient anatomic and physiologic similarity to humans for experiments that are both technical and pharmacologic in nature. The immune responses between these species are similar, being predicated on a network of T cells responding to similarly organized major histocompatibility complexes (MHCs). Because of this, the histology and tempo of unmodified allograft rejection is similar to what is expected in humans. Despite these similarities, these models also differ from each other and from humans in ways that prevent them from fully predicting clinical outcomes.

Before discussing each animal model individually, several generalizations can be made. Drug metabolism and absorption can and often does vary widely between species, preventing the direct translation of drug-response curves and toxicities to humans or other animal models. However, when drug distribution has been appropriately adjusted, the physiologic response and efficacy of most drugs is similar between the large animal models and humans.

In human studies of transplantation, the degree of relatedness and degree of MHC matching between donors and recipients is typically known. While the relative effect on outcome of MHC matching between human transplant pairs varies with the organ being transplanted, generally, better-matched pairs have better results. The same can be said for animal models, but MHC typing in large animals is often more difficult and therefore frequently omitted. Failure to control for variable MHC disparity in animal studies potentially introduces a significant confounding factor in the interpretation of experimental results.

While a full review of MHC genetics is beyond the scope of this chapter, a basic review focusing on the differences between species is worthwhile. In depth treatment of the structure of human MHC can be found in Chapter 4. The human MHC, also known as human leukocyte antigen (HLA), is composed of over 260 genes on chromosome 6p21.3 [25]. While many of these genes are associated with immune functions, the classical genes associated with antigen presentation and pertinent to this discussion include the class I molecules HLA-A, HLA-B, and HLA-C, as well as the class II molecules HLA-DP, HLA-DQ, HLA-DR. Individuals inherit two alleles of each gene from their parents. The highly polymorphic nature of these genes results in wide diversity of HLA molecules within the population. The overall structure of the MHC locus in the three animal models presented here is similar, although there are some significant genetic differences worthy of discussion.

The canine MHC, termed dog leukocyte antigen (DLA), is well defined. Located on chromosome 12, the dog MHC contains four complete class I antigens: DLA-88, DLA-12, DLA-64, and DLA-79. The class II region contains DLA-DRB1, DLA-DQB1, and DLA-DQA each of which is polymorphic. An additional class II gene, DLA-DRA, appears to be monomorphic [26]. Since the initial structure of the canine MHC was elucidated, several additional

alleles have been discovered through large surveys of various dog breeds [27]. Two highly polymorphic satellite markers, one near each of the class I and class II loci have been found and shown to be useful in determining the inheritance of DLA haplotypes within families, allowing for the selection of littermates with specific DLA matching for transplantation studies. Because these markers do not identify specific genotypes, however, they are currently unsuitable for pairing of unrelated animals [26]. Sequencing of the entire canine genome has been achieved [28] and direct sequencing of DLA-DRB1 to confirm allelic identity has been used [29], raising hope that more complete genotyping may be possible to improve pairing for transplant studies in unrelated dogs.

A major advantage of porcine models over dogs and NHPs is the more extensive knowledge of the pig MHC, or swine leukocyte antigen (SLA), and the ability to genetically modify pigs, either through breeding or through viral transfection. Located on Chromosome 7 [25], the SLA has been well defined with three known classical class I genes, notated SLA-3, SLA-2, and SLA-1 (corresponding to SLA A, B, and C series proteins that had been previously defined by serology). The class II region has also been well defined. Similar to the DLA, SLA-DRA is monomorphic while SLA-DRB, SLA-DQA, and SLA-DQB are highly polymorphic [30–32]. Knowledge of the SLA and of its functional importance has been aided by the breeding of MHC-defined miniature swine, increasing the validity of transplantation experiments in swine substantially. The ease of breeding pigs has made genetic manipulation of swine relatively straightforward. This has been a particular boon to the field of xenotransplantation, where knockout pigs have been produced that do not express the Gal xenoantigen [33,34]. Additional genetic modifications have included the up-regulation of complement modulators [35,36]. The use of these transgenic pigs will be discussed elsewhere in this book.

Non-human primates have become the favored large animal model in most modern transplantation studies, as new biologic therapies with a high degree of receptor specificity are being tested. While monkeys cannot readily be inbred to the same extent as mice, dogs, and pigs, they cannot be considered truly outbred either. The majority of NHPs used for transplantation research are from dedicated colonies with limited interbreeding. Until recently, techniques for establishing genetic disparity of NHP have been relatively limited, consisting mostly of mixed lymphocyte reactions and analysis of the DR region either serologically or by PCR. Significant effort has been placed into understanding the structure of the rhesus macaque MHC, with the fruits of this labor now coming to bear. The rhesus MHC, located on chromosome 4, is significantly larger than the human MHC, owing to significant duplication in the class I A and B genes, known as mamu-A and mamu-B (rhesus macaques lack a homolog of HLA-C). The class II genes are also duplicated, but to a lesser extent. The duplication of these genes results in expression of up to four mamu-A genes and fourteen mamu-B genes per chromosome, dramatically increasing the complexity of heterozygous individuals [37]. Furthermore, cloning strategies have revealed a hierarchical expression of these genes rather than the codominant expression seen in humans [38], effectively rendering allele-specific DNA-based typing ineffective at predicting the expression of MHC molecules. Two recent advances have significantly improved our capability of determining relatedness in macaques. The first was the identification of several DNA microsatellite probes, allowing for the determination of autosomal and sex chromosome inheritance between generations of macaques, enabling accurate pedigrees to be drawn of macaque breeding groups [39,40]. While this method lacks allele-specific determinations of the MHC, the inheritance of complete MHC haplotypes is able to be determined. The second major advance was the development of massively parallel pyrosequencing for comprehensive analysis of MHC expression [41]. Pyrosequencing was able to confirm the extreme complexity of the macaque MHC noted above. The technique allows for determination of the complete MHC type for any animal when planning transplantation experiments. The application of these two technologies allows for experiments to be designed with knowledge of MHC disparity between animals, greatly increasing the validity of the results.

Canine models in transplantation

Dogs have held a traditional place in surgical training and the development of surgical technique. Thus, it is not surprising that dogs represented the predominant model in early transplantation research. Many of the technical issues pertaining to surgical transplantation were worked out in the canine model. Indeed, early techniques for renal [42], heart [43], liver [44,45], lung [46], intestinal [47,48], bone marrow [49], pancreas [50,51], and pancreatic islet transplant [52] were all tested in dogs. The canine model can also lay claim to the first successful use of immunosuppression in the experiments by Calne [53]. While social pressure to avoid the use of domesticated animals in research has lessened the role of the canine model, it continues to be used, with recent studies in heart [54], renal [55], pancreatic islet [56], liver [57], and intestinal transplantation [58]. Extensive use of dog models in experimental bone marrow transplantation has been and continues to be carried out by the Storb group in Seattle [59,60], who have also utilized this model in studies of organ [61] and composite tissue [62]. Its use will not be considered extensively here as dog experimentation has lessened considerably in solid organ transplant investigation, and occupies little place in the translational study of modern biologic-driven regimens.

Porcine models in transplantation

Swine have been used for many years as laboratory models for complex human disorders because of the similarity of their anatomy and physiology to those of humans. Porcine models of disease may be spontaneous, inherited, induced, or transgenic. Domestic swine—particularly miniature pigs—are used for research in the areas of physiology, pharmacology, toxicology, radiology, surgery and organ transplantation, traumatology, pathology, embryology, gastroenterology, nephrology, neonatal surgery, and cardiovascular research. Several laboratories have studied the MHC of swine [31,63–65] and there have been a number of workshops held to standardized nomenclature of the SLA system [66–68]. In addition, there are now a large number of monoclonal antibodies available for studies of swine cell surface antigens [69–73], making swine a versatile animal model with regard to characterization and manipulation of cell populations, surpassed only by mouse and human.

In addition, swine are one of the few large animal species in which breeding characteristics make genetic experiments possible. Swine have a relatively large litter size (three to ten offspring) and a short gestation time (114 days). They reach sexual maturity at approximately 6 months of age, and sows have an estrous cycle every 3 weeks (cf. dogs, which have an estrous cycle only twice per year). These breeding characteristics have made it possible for the laboratory of one of the authors (DHS) to develop MHC homozygous

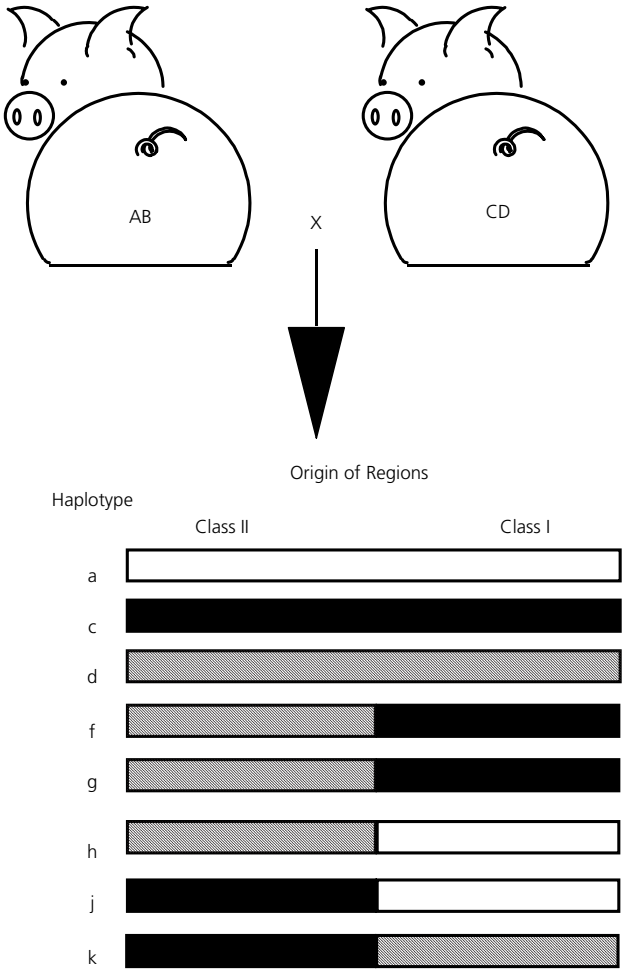

Figure 15.1. Origin of haplotypes of miniature swine.

lines of miniature swine in a relatively short time and have also made it possible to isolate new MHC recombinants, to breed them to homozygosity, and to carry out short-term backcross experiments in order to identify and study the segregation of genetic characteristics [74–76]. These miniature swine thus represent the only large animal model in which MHC genetics can be reproducibly controlled [77]. As such, they have been particularly useful in assessing the effects of selective MHC matching on rejection and/or tolerance induction.

At present, three lines bearing homozygous SLA haplotypes, SLA^{a}, SLA^{c}, SLA^{d} and five lines bearing intra-SLA recombinant haplotypes are maintained (Figure 15.1). All of these lines differ by minor histocompatibility loci, thus providing a model in which most of the transplantation combinations relevant to human transplantation can be mimicked. Thus, for example, transplants within an MHC homozygous herd simulate transplants between HLA identical siblings, while transplants between herds resemble deceased donor or non-matched sibling transplants. Likewise, transplants between pairs of heterozygotes can be chosen to resemble parent into offspring or one-haplotype mismatched sibling transplants. In addition, one subline of the SLA^{dd} animals was chosen for further inbreeding, in order to produce a fully inbred line of miniature swine. When this subline reached a coefficient of inbreeding of >94%, reciprocal skin grafts among the offspring were not rejected, defining thereby the first histocompatible strain of large animals [78]. Subsequent studies have utilized these highly inbred animals as donors for adoptive transfer of lymphoid populations, something that has previously been possible only in inbred rodents [79].

Studies of organ allograft tolerance

The partially inbred lines of miniature swine have been extremely useful in studies of organ transplant rejection and tolerance. When studies on the spontaneous induction of renal allograft tolerance were carried out in selectively MHC-mismatched combinations, all class II mismatched grafts were rejected acutely [17]. In contrast, when transplants were matched for class II and differed for one haplotype at class I (e.g. $SLA^{ag} \rightarrow SLA^{ad}$, see Figure 15.1), spontaneous tolerance induction was observed in approximately 30% of cases, with allografts being accepted long term (>100 days) [17]. The spontaneous acceptors of class II matched, one haplotype class I mismatched allografts demonstrated a significant rejection crisis during postoperative weeks 2–4, which subsided spontaneously, and normal renal function was maintained long-term. Animals that accepted class I mismatched renal allografts did not ignore the MHC antigens on the graft, but rather became actively tolerized to these antigens. Thus, during the rejection crises, cytotoxic antibodies directed against the donor class I antigens were detected in the serum of acceptor animals, but these antibodies were almost entirely of the IgM class, suggesting failure of the usual IgM to IgG switch, which characteristically occurs in animals that reject a graft. Since the switch from IgM to IgG is generally thought to depend on T-cell help [80,81], these results suggested that in the absence of sufficient T-cell help, as might occur for single haplotype class I only mismatched kidney allografts, tolerance rather than rejection had been induced. It was therefore hypothesized that rather than indicating a failure of the immune system to recognize class I, acceptance of renal grafts across class I plus minor differences might be the result of *an active immunologic process leading to tolerance*. Consistent with this hypothesis, skin grafts from the original renal donor showed markedly prolonged survival (31.7 ± 20.4 days) over similar class I-mismatched skin grafts placed on control animals (11.67 ± 2.6 d). Although prolonged, all skin grafts were eventually rejected, probably due to skin-specific antigens rather than to a break in tolerance, since there was no concomitant impairment of renal function, nor anti-class I antibody formation. In retrospect, the active process leading to tolerance in these early studies was undoubtedly the induction of regulatory T cells, a hypothesis that has subsequently been demonstrated in more recent studies in this model [82–84].

In order to increase the incidence of tolerance induction, subsequent studies utilized a short course of treatment with cyclosporine A (CyA) for renal transplants across a two-haplotype class I mismatched, class II matched barrier ($SLA^{gg} \rightarrow SLA^{dd}$, see Figure 15.1), a combination in which recipients were known to uniformly reject renal allografts rapidly without immunosuppression. Instead, long-term, specific tolerance was induced in eight of eight recipients [85]. This result has subsequently been substantiated in more than 50 additional CyA-treated animals, all of which demonstrated long-term tolerance. This transplant combination and treatment protocol have become the "standard protocol" for subsequent studies of tolerance in miniature swine, and have provided numerous insights into the mechanism of tolerance in this model [82,86–93]. Studies of heart and lung allograft tolerance have also been carried out in the miniature swine model [94–97]. Importantly, unlike the situation for transplant tolerance studies in mice, essentially all of the findings

that have been made in swine models have been able to be translated to NHP [98–101], and in some cases to the clinic [5,101–103].

NHP models in transplantation

Non-human primates have emerged as the most commonly used animal group in translational transplantation research, owing to their high degree of homology with humans. This is especially true in the study of biologic agents such as monoclonal antibodies and fusion proteins with a high degree of specificity [104]. Several species of primates have been used, including baboons, macaques, and, rarely, chimpanzees. Chimpanzees have the highest degree of homology with humans, having served as donors for humans on historical occasions [105]. However, their endangered status and evolutionary stature call into question the ethicality of chimp research. Indeed, in 2011, the NIH strictly limited new studies involving chimpanzees. Baboons are commonly used in xenotransplantation studies, as their large size better accommodates porcine organs. Macaques (cynomolgus, rhesus, and pigtail) are the most widely used of the NHPs. The macaques are preferred due to their small size and relative ease of care. They exhibit sufficient homology with humans so that the majority of molecules will cross-react, with the notable exception of CD3. Macaques are now used as models in virtually all areas of transplantation.

Renal transplant models

Renal transplantation in macaques is relatively straightforward, and somewhat mimics the techniques used in the pediatric population. Both donor and recipient are heparinized during excision and implantation. The donor kidney is excised, ensuring sufficient length of the vessels and ureter. While either donor kidney can be used, the left kidney is preferable due to the length of the vasculature. The donor kidney is then anastomosed to the recipient aorta and vena cava, proximal to the bifurcation, typically on the right side. A primary ureteroneocystostomy is formed, typically on the posterior aspect of the bladder after the ureter is tunneled through the retroperitoneal space (Figure 15.2). The recipient's native kidney(s) are removed following completion of the transplant in order to prevent any period of true anuria [106,107]. It is worth noting that bilateral retroperitoneal dissection is particularly stressful for the animals. If possible, preparative nephrectomy of the left kidney on a date prior to the transplant allows for the dissection to be limited to the right side on the day of transplant, which is better tolerated. Planning the experiments in a "domino" fashion, where each animal is, in turn, a donor and then a recipient, allows for use of this nephrectomy as a donation and minimizes the number of organs that go untransplanted. In general, the transplant procedure is well tolerated by the animals and there are minimal complications, usually related to the ureteral anastomosis. In a study by Song et al., 182 transplants were performed in cynomolgus macaques with an overall complication rate of 10.4%. Notably, more than two-thirds of these were related to the ureteral anastomosis, which was performed as an end-to-end ureteroureterostomy in this study [108].

Skin transplant models

Skin transplantation in NHPs has been used to test a number of potential immunosuppressive strategies, including antilymphocyte globulin [109], adhesion molecule blockade [110], costimulation blockade via CD80 [111], and CD154 blockade [112]. Technically, the transplant varies little from skin transplants in the murine

Figure 15.2. Renal transplantation in non-human primates. (A) A retroperitoneal pouch is made by incising medial to the native ureter and dissecting laterally. (B) The vascular anastomosis is performed, starting with the vein. (C) After reperfusion of the kidney, a cystotomy is performed and a retroperitoneal tunnel is created from the bladder to the previously created pocket. The transplanted ureter is delivered through the tunnel and anchored inside the bladder.

model, except for the size of the animal. Typically, donor grafts are taken from the abdominal wall and implanted on the recipient's back. A unique aspect of skin transplantation in primates is the requirement for protection of the grafts during healing and afterwards. Soft bolsters should be used to maintain light pressure of the graft on the underlying tissue (Figure 15.3). Furthermore, the animals will be required to wear protective mesh jackets that shield the grafts from damage during grooming. Training the animals to wear the jacket comfortably requires a period of acclimatization and may take several weeks.

Islet transplant models

The equivalent of a non-obese diabetic (NOD) mouse strain does not exist for use in NHP models of islet transplantation. Rendering NHPs diabetic is accomplished by pancreatectomy or, more commonly, by the intravenous administration of streptozotocin. The diabetic state must be confirmed by the absence of native c-peptide production prior to transplantation. Alloislets are then procured via donor pancreatectomy and isolated in an analogous manner to the human method prior to their transplantation into a diabetic NHP recipient. The established site of islet transplantation is intrahepatic seeding by gravity-dependent infusion into the portal or mesenteric vein, although other sites such as the bone marrow, kidney capsule, peritoneal cavity, omentum, and muscle have and are being explored [113]. Daily fasting and postprandial blood sugars can be easily monitored after ear-stick training has been completed, and this also facilitates insulin injections when appropriate. The NHP model of islet transplantation has played a crucial role in the evaluation of costimulatory blockade-based regimens, including CTLA4, CD40, and CD40L (CD154) [114–120].

Heart and lung transplant models

Non-human primates are less often used as models for allogeneic heart and lung transplantation, though there are examples of both [121–123]. Allogeneic heart transplantation is usually performed using heterotopic placement of the graft in the abdomen of the animal with follow-up of contractility by palpation or ultrasound [124,125]. Implanted EKG electrodes have also been tested for use in determining graft rejection [54]. In contrast to the relatively uncommon studies of allogeneic heart or lung transplantation in NHP, primates are frequently the recipients of heart or lung grafts in studies of xenotransplantation, which will be discussed briefly below and in more detail in Chapter 12.

Vascularized composite allograft models

Recent advances in microsurgical technique and immunosuppression have made possible the transplantation of composite tissues as a functional unit. The clinical realization of such transplants has led to the development of NHP models to study the immunobiology of these grafts. Examples of composite grafts in NHP exist, such as hand transplantation in baboons [126] and transplant of the radial portion of the hand in rhesus macaques [127]; however, these grafts potentially negatively affect the function of the surviving recipient. Cendales et al. have developed a Rhesus macaque model which involves transplantation of a sensate osteocutaneous radial forearm flap containing portions of the radius, brachioradialis, medial and lateral antebrachial cutaneous nerves, palmaris longus, radial artery, cephalic vein, and the overlying skin [128] (Figure 15.4). This model preserves function for both the donor and recipient, allowing for the "domino" of donors and recipients or exchange of grafts between two individuals. A group from the University of

The flap dissection begins ulnarward to include the deep fascia and the palmaris longus tendon . (E) The flap is isolated on the proximal vascular pedicle. Reproduced from [128] Cendales LC, Xu H, Bacher J, Eckhaus MA, Kleiner DE, Kirk AD. Composite tissue allotransplantation: Development of a preclinical model in nonhuman primates. Transplantation. 2005 Nov 27;80(10):1447–54, with permission from Wolters Kluwer Health.

Maryland has developed a primate model of facial transplantation in cynomolgus monkeys utilizing a portion of the madibular bone, masseter muscle, overlying skin, common carotid artery, and external and internal jugular veins [129,130].

Xenotransplant models

Specifics of xenotransplantation will be covered in depth in Chapter 12. Brief treatment of two specific topics germane to the topic will be covered below.

Swine as xenograft donors

Pigs are now considered the most likely animal to be utilized as a xenograft donor for humans, in an attempt to overcome the shortage of transplantable organs (see Chapter 12). As xenotransplantation is, by definition, a species-specific endeavor, pigs have become the prevailing donor for most clinically relevant xenotransplant experiments, as well. Lines of gal knockout pigs (GalT-KO), in which the gene for the enzyme α-1,3-galactosyltransferase has been disrupted, have been produced through genetic engineering by several laboratories [33,131–133]. These animals do not express the ubiquitous Gal epitope on their cell surface glycoproteins and their tissues and organs can thereby avoid the major problems previously caused by the high levels of natural antibodies to Gal present in the serum of Old World primates and humans [134,135]. It is hoped that this genetic modification, along with other modifications involving addition of transgenes (Figure 15.5), will eventually make the pig an ideal xenograft donor.

Miniature swine may be particularly suitable as potential xenograft donors because of their size. These animals achieve adult weights of approximately 120–140 kilograms. It would therefore be possible to obtain miniature swine of appropriate size as an organ donor for any potential human recipient, from a newborn baby to a large adult. In contrast, domestic swine reach mature weights of over 450 kilograms, clearly larger than necessary for organ donation. Using a fibroblast line derived from one of the most highly inbred lines of miniature swine (see above), the α-1,3-galactosyltransferase gene was disrupted through homologous recombination and the corresponding knockout animals (GalT-KO) were then produced by nuclear transfer [132,136]. The availability of these highly inbred GalT-KO animals has made it possible to carry out a variety of studies directed at the induction of tolerance across the pig-to-primate barrier [137–142].

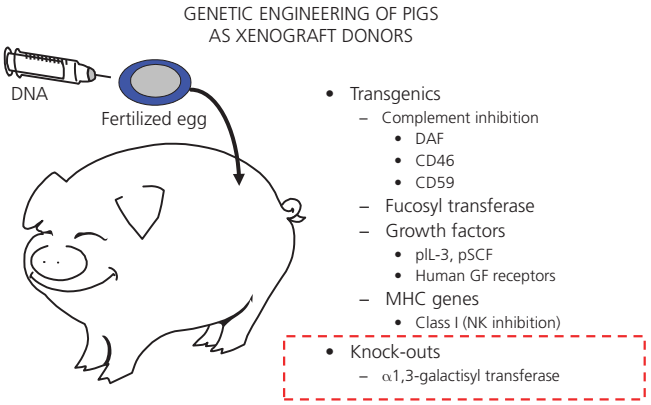

Figure 15.5. Genetic modifications of swine for use as xenograft donors.

Islet xenotransplantation

Cellularized xenografts, mainly islets, lack the endothelial component responsible for thrombotic dysregulation in vascularized xenograft models and, therefore, will likely be the first translatable platform for xenotransplantation. In large animal models these preclinical studies have been largely confined to NHP models of porcine islet xenotransplantation. Specific pathogen-free islets are primarily obtained from porcine sources due to ease of supply and similarities between human and porcine glucose homeostasis. Alternative sources include cows and tilapia. Non-human primate recipients are a robust model for translation. When compared to humans, non-diabetic cynomolgus monkeys are known to have lower levels of fasting blood glucoses and higher levels of insulin/c-peptide [143]. Some controversy exists regarding the timing of porcine islet isolation—fetal, neonatal, adult—with immature islets proving more resistant to ischemia [144]. Both neonatal and adult porcine xenoislets have been shown to be capable of producing prolonged insulin-independent normoglycemia when infused intraportally into diabetic rhesus macaques [145–148]. These feats required significant immunosuppression, including the use of CD154-specific monoclonal antibodies, although innate immunity was preserved with viral prophylaxis. As previously noted, xenotransplantation is uniquely amenable to the genetic modification of source pigs and, in the case of cellularized xenografts, ex vivo transfection. Identification of the gal epitope, Galα(1,3), Galβ(1,4),GlcNAc-R, as a major target of preformed xenoantibody has led to enhanced islet engraftment and function using gal-deficient neonatal porcine donors [148]. Further advances in the xenospecific immunity will elucidate more targets for genetic modification and likely reduce immunosuppressive requirements in the near future.

Perioperative care of non-human primates

Perioperative and follow-up care provided to NHPs can only approximate what is available for human patients. Routine animal care as well as treatment of any complications or clinical illness should be done in consultation with local veterinary staff. Careful attention should be paid to the animals' clinical status as changes in activity or appetite can represent early signs of rejection or deterioration. Recipients of renal or islet transplants and animals receiving nephrotoxic immunosuppression, such as high doses of calcineurin inhibitors, should be monitored for urine output. Hematologic studies and serum chemistries should be checked routinely in the postoperative period and with any clinical changes. Immunosuppressive medications can be delivered via number of routes. Generally, medications requiring daily dosing should be delivered by mouth or via a subcutaneous or intramuscular injection to avoid repeated sedation. Medications that are dosed less frequently can also be given via an intravenous infusion. Fluids can easily be administered intravenously or subcutaneously while animals are sedated in the case of hypovolemia, and, in some centers, special cages allowing for the use of indwelling catheters and continuous infusions in conscious animals are available. Supplemental nutrition may also be given to anorexic or malnourished animals via an orogastric tube while sedated. Many medications used clinically, such as analgesics or antibiotics, can also be used in NHP; however, dose adjustments are often required. Animals receiving immunosuppression may be at increased risk of some infections, requiring prophylactic therapy in some instances. PCR-based assays for macaque homologs of CMV and EBV have been validated.

Small molecule-based immunosuppression

Most of the commonly used small molecule immunosuppressants have been found to have some success at prolonging graft survival, and in some cases tolerance, in large animal models. As new and more specifically targeted therapies are brought forward for testing, it is important to have an appreciation of what has been accomplished with small molecule immunosuppression.

Azathioprine and mycophenolate

Calne established the utility of 6-MP and azathioprine in transplantation using the dog model [53]. The translation of azathioprine to clinical use is a major milestone in the history of transplantation, and azathioprine would be the backbone of clinical immunosuppression strategies until the development of calcineurin inhibitors. Mycophenolate mofetil, which essentially replaced azathioprine in most clinical protocols, was also shown to be effective in canine models [149,150]. As part of most clinical immunosuppression protocols, mycophenolate is still widely used and studied as part of combination therapy in large animal models.

Calcineurin inhibitors

Calcineurin inhibitors have formed the backbone of most clinical immunosuppression protocols since the introduction of cyclosporine. This class of drugs has been studied extensively in all three animal models discussed in this chapter, and has been effective in each. Following on his success with azathioprine, Calne et al. were among the first to study cyclosporine in large animal models, publishing their results first in a canine kidney model [151] and later in a porcine cardiac model [152]. Tacrolimus was also studied extensively in dogs, with evidence of efficacy promoting its development. It is worth noting, however, that due to high toxicity in the dogs studied, additional studies in NHP were required to assure its safety for translation to humans [153]. Calcineurin inhibitors are capable of preventing liver or kidney rejection in dogs when appropriately dosed, although moderate rejection is often present when not used in combination with another agent [151,153–157]. Pigs are capable of tolerating supraclinical doses of calcineurin inhibitors without overt toxicity, allowing for the development of tolerance towards kidney or liver grafts [85,158–162]. Cyclosporine has also been able to induce tolerance in a partially MHC-matched rhesus macaque model [163]. Calcineurin inhibitors remain a commonly used immunosuppressant in large animal models and frequently serves in combination therapy or as a control against which new agents can be tested.

mTOR inhibitors

The use of sirolimus in dog models has been limited to combination therapy, typically with calcineurin inhibitors, due to gastrointestinal toxicity at relatively low doses [164]. In pigs, sirolimus has been much more successful, extending graft survival to 60 days [165,166]. However, tolerance has not been achieved with sirolimus in swine models. Sirolimus monotherapy has been shown to extend renal graft survival to 20–30 days in primates with relatively few side-effects [167,168]. In both studies, serum trough levels were determined to ensure adequate drug delivery. The combination of sirolimus with tacrolimus has been shown to be synergistic [169], with few animals continuing to have graft survival after the termination of immunosuppression [170]. However, the addition of daclizumab induction therapy to a combination of tacrolimus and sirolimus has been found to have significant intestinal toxicity [171]. Sirolimus has also recently been shown to have positive effects on the suppressive activity of T regulatory cells [172] and is now being used in combination with cellular therapy with Tregs [173] or as a primer during ex vivo expansion of Tregs as the cells are prepared for use as a cell-based therapy [172]. Everolimus, a second mTOR inhibitor, is much less frequently used in large animal models. It has shown efficacy in combination with cyclosporine in a NHP lung transplant model [122] as well as with basiliximab and FTY720 in a NHP islet model [174].

FTY720

FTY720 has been found to prolong renal allograft survival either alone or synergistically with calcineurin inhibitors in both macaque [175] and canine models [176]. The effect of FTY720 on peripheral lymphocytes appears to be consistent, with both models showing a significant reduction in circulation lymphocytes. Notably, in a canine liver model FTY720 was more effective at lower doses [177]. Although the reason for this is unclear, the phenomenon appears to be species and organ specific. This study also confirmed the synergistic effects of combining FTY720 with a calcineurin inhibitor, although over-suppression leading to infection was seen with the combination of FTY720 with tacrolimus.

Sotrastaurin

The selective protein kinase C inhibitor, sotrastaurin, has been shown to prolong graft survival in a NHP renal transplant model [178]. Sotrastaurin was also found to be synergistic with a host of other immunosuppressants, including cyclosporine, everolimus, and FTY720 [178,179]. The synergistic benefits of sotrastaurin were seen even at doses below what was necessary to prolong graft survival when using sotrastaurin alone.

Tofacitinib

Tofacitinib (CP-690550) is an inhibitor of Janus kinase 3 (JAK3), which takes part in the downstream signaling pathways from a number of cytokine receptors. Naturally occurring loss-of-function mutations in the JAK3 protein result in autosomal SCID. Treatment of cynomolgus renal transplant recipients with tofacitinib prolonged graft survival to a mean of 46 days. Consistent with multiple cytokine blockade, significant decreases in circulating NK and T cells were observed [180].

PG490-88

PG490-88 is the prodrug of PG490 (triptolide), the active ingredient in an immunosuppressive Chinese herb, *Tripterygium wilfordii* Hook F. Treatment with PG490-88 alone, or in combination with tacrolimus, has been shown to prolong renal allograft survival in both dogs and cynomolgus macaques [181,182].

Costimulation

Costimulation blockade as a method of immunosuppression, and possibly tolerance induction, is based on work from the 1970s in which it was recognized that a second signal was required in addition to antigen recognition for an optimal immune response [183,184]. Further work since that time has led to the generally accepted view that multiple ancillary signals exist, which allow for fine-tuned modulation of the immune response based on a variety of stimuli [185].

While costimulation-blockade-based strategies have been able to routinely induce tolerance in murine models [186–188], it has been challenging to replicate the results in larger, more outbred

models. This is likely due to one of two phenomena where costimulation appears to be less important for immune activation. First, a high precursor frequency of alloreactive immune cells is capable of overcoming costimulation blockade by sheer numbers [189]. It is apparent that antigen recognition in the absence of costimulatory signals generates some cellular response, albeit quite inefficiently [190]. In the case of high precursor frequency, the sheer number of reactive cells makes up for this inefficiency to produce a physiologically meaningful response [191]. Second, some cell populations appear to be less dependent on costimulatory signals for activation. Memory cells, in particular, appear to be less reliant on costimulation [192]. Thus, more experienced immune systems that may have populations of alloreactive memory cells due to prior sensitization or heterologous interactions are less dependent on costimulation for activation and response to antigen.

As more attention has been paid to the role of costimulation in the immune response, increasing numbers of receptor–ligand pairs have been identified with immunomodulatory effects [193]. Furthermore, as many of these molecules fall within families of receptors, including the immunoglobulin and TNF superfamilies as well as the integrin and TIM families, there is often substantial cross-talk between specific pairs. As the individual effects of a costimulatory pathway vary, and the expression of molecules change over the course of an immune response, the application of costimulation-based therapies to transplantation has become increasingly complex. Due to the highly specific affinities of many of the costimulation blockade agents being studied, the NHP has become the large animal model of choice for these experiments [104].

CD28-B7 blockade

The CD28-B7 interaction is, by far, the best characterized of the known costimulatory pathways. CD28 on the surface of T cells interacts with B7-1 (CD80) and B7-2 (CD86) to provide costimulatory signals leading to cell activation and production of IL-2, among other effects [194–196]. Alternatively, CTLA4 on the surface of activated T cells binds the same two ligands with increased affinity and transduces inhibitory signals to the T cell, essentially exerting a breaking effect on the activated T cell [197].

Blockade of the ligands for CD28 with monoclonal antibodies has been shown to prolong renal allograft survival in macaques. Three groups have reported success with monoclonal antibodies to CD80 and CD86, 1F1 and 3D1, respectively, in either their murine or humanized forms. Kirk et al. noted a modest prolongation of renal allograft survival in rhesus macaques with either antibody alone. When the antibodies were combined, a significant prolongation of survival was seen, although tolerance was not achieved. These antibodies failed to prevent formation of a donor-specific alloantibody response [198]. In an experiment performed by the same lab, combination of 1F1 and 3D1 with blockade of CD154 failed to provide a survival advantage over anti-CD154 monotherapy; however, alloantibody formation was delayed [199]. In a cynomolgus renal transplant model, Birsan et al. combined the humanized 1F1 and 3D1 antibodies with sirolimus. The study found a prolongation of graft survival with the combination therapy over either the antibodies or sirolimus alone, but, again, tolerance was not achieved [200]. The third study, by Hausen et al., combined the humanized antibodies with either cyclosporine or steroids. Neither combination antagonized the effect of the monoclonal antibodies, and the combination of CD80/86 blockade with cyclosporine significantly prolonged graft survival above either therapy alone [201]. Ossevoort et al. studied different murine clones against CD80 and CD86, B7-24 and 1G10, respectively. In a rhesus skin graft model, the combination of B7-24 and cyclosporine provided only a modest prolongation of graft survival [202]. In a rhesus renal transplant model, the antibodies were combined with either CD40 blockade or cyclosporine [203]. The combination of CD80 and CD86 blockade prolonged graft survival. The addition of CD40 blockade had little effect on graft survival compared to CD80/86 blockade alone; however, the antimouse response was somewhat diminished. Addition of cyclosporine A to the CD80/86 blockade provided graft survival comparable to cyclosporine alone. Despite these early positive results, the company owning the rights to 1F1 and 3D1 declined to develop them further for clinical use.

Another strategy for blockade of CD28 signaling is use of a soluble form of the CTLA4 receptor, the fusion protein CTLA4-Ig. CTLA4-Ig binds to both B7 ligands, and thus blocks activating signals through the CD28 pathway and suppressive signals throughout the CTLA4 pathway. After CTLA4-Ig was shown to be effective in several rodent models [188,204,205], it has been extensively studied in NHPs. Early studies of CTLA4-Ig showed only modest prolongation of graft survival in pancreatic islet [206], renal [106], and heart transplantation (when combined with anti-CD4) [207]. Continued interest in the CD28 pathway led to the rational development of belatacept which, while only differing from CTLA4-Ig by two amino acids, had a tenfold increase in its capacity to inhibit T-cell activation in vitro [208]. Belatacept was shown to be superior to CTLA4-Ig when used as monotherapy and exhibited significant prolongation of graft survival when combined with mycophenolate and steroids or basiliximab [208]. The same group would later show efficacy of belatacept maintenance therapy when combined with sirolimus and basiliximab/anti-CD154 induction therapy [146]. Lo et al. and Lowe et al. have also shown the combination of belatacept and sirolimus to prolong kidney and islet survival, respectively, and identified this regimen as promising for clinical translation [168,209]. The success of belatacept in NHP models led to human clinical trials and its subsequent FDA approval in June 2011.

Blockade of CD28 signaling via molecules directed at B7-1 and B7-2 has the potential drawback of simultaneous blockade of co-inhibitory signals via CTLA4. Significant interest exists in development of specific blockade of CD28 that would leave CTLA4 signaling intact. A monoclonal antibody against CD28, TGN1412, was developed and found to have superagonistic qualities. Surprisingly, CD28 superagonists had been shown to improve autoimmune disease and prolong graft survival in rodent models through selective expansion of regulatory T cells [210]. A phase I clinical trial of TGN1412 met with disastrous results when all six volunteers who received the drug developed severe, life-threatening, systemic inflammatory responses [211]. The fallout from this trial led to significant and understandable concern regarding further development of anti-CD28 therapy. The National Institute for Biological Standards and Control in the UK, where the TGN1412 trial took place, produced new recommendations for experimental controls to more fully explore potential agonist or superagonist properties of antibodies [212,213]. Since the TGN1412 trial, two trials using anti-CD28 in primates have been conducted. The first utilized sc28AT, a monovalent fusion antibody. Poirier et al. showed that sc28AT in combination with tacrolimus or cyclosporine prolonged graft survival in baboon renal grafts or cynomolgus cardiac grafts, respectively [214]. The same group subsequently conducted a pharmacokinetic study in cynomolgus monkeys using FR104, a

pegylated monovalent Fab' antibody against CD28. While promising results have been shown in rodent graft-versus-host disease (GvHD) models, no transplantation experiments using FR104 in primates have yet been reported [215].

CD40-CD154 blockade

The interaction between CD40 and CD154 (CD40L) clearly plays an important role in the activation of naïve T cells [216,217]. Unlike the interactions between CD28 and B7, however, CD40-CD154 ligation likely does not play a direct role in the T-cell activation pathways. Rather, it plays a significant role in T cell-APC interaction: CD154 expressed on activated T helper cells binds with CD40 on the surface of antigen presenting cells, greatly increasing the antigen presentation and costimulatory potential of the APC and essentially licensing the APC to, in turn, activate cytotoxic $CD8^+$ effector T cells [218,219]. It also is critically involved in APC activation in response to platelet degranulation, and as such likely serves as an interface between innate and acquired immunity [220–222]. Thus, blockade of CD40-CD154 interaction may function more to interrupt activation of T cells through mollification of the initial presentation signals. This may explain why, like the experience with CTLA4-Ig, results have been more impressive in rodents than in large animals and humans [14].

In primates, monotherapy with the monoclonal antibody to CD154, hu5c8, has shown to be efficacious in multiple models including rhesus renal allografts [223,224], rhesus skin allografts [112], rhesus or baboon pancreatic islets [114,115], and, less so, rhesus heart allografts [225]. Serendipitously, hu5c8 was one of the first antibodies to be tested at the dose of 20 mg/kg rather than the historical standard of 1 mg/kg. It was later found that multiple cell types in the body express CD154, providing large quantities of available ligand to compete for binding, and in the case of platelets, possible initiation of graft rejection [221].

Hu5c8 is not the only antibody against CD154 found to have effect. The monoclonal antibody IDEC-131 has been used in NHP cardiac, skin, and renal transplant models. While the antibody had only modest effect in the cardiac model [121,226,227], efficacy was seen alone and in combination with sirolimus and DST in both the skin and renal models [228,229], even in the face of a predominately memory response [230]. Similarly, ABI793 was shown to have efficacy in both rhesus and cynomolgus renal transplant models [231,232]. Unfortunately, clinical development of anti-CD154 therapies have essentially been halted due to perceived concern regarding thromboembolic events associated with the blockade of CD154 on platelets [233].

The notable efficacy of CD154 blockade prompted continued investigation of the CD40-CD154 pathway, focusing instead on the CD40 molecule, which is not involved in hemostasis. Early rodent models met with success, leading to the rational development of Chi220, a chimeric antibody against CD40 with weak agonist properties [117]. An early study with Chi220 demonstrated moderate prolongation of median graft survival to 48.5 days from 7 days in a rhesus renal transplant model. Notably, the combination of Chi220 and CTLA4-Ig did not synergize to prolong graft survival beyond Chi220 alone in this study [234]. A subsequent study from the same group in an islet transplant model replaced CTLA4-Ig with the higher-affinity belatacept, and they reported a marked synergy with the two drugs [117]. Chi220 was found to temporarily deplete B cells in these two studies, although the 2005 report showed that B-cell depletion was not wholly responsible for the drugs effect by comparing it to the anti-CD20 agent, rituximab.

The clinical development of anti-CD40-based therapies may be hampered by their potential deleterious effects of B-cell depletion. Badell et al. described the effects of 3A8, a non-depleting monoclonal antibody directed against CD40 [119]. While maintaining its graft protective qualities in a rhesus islet transplant model, 3A8 was also found to be partially agonistic and failed to prevent alloantibody formation. Interestingly, 3A8 also failed to fully block engagement of soluble CD154, indicating that complete blockade of the CD40-CD154 interaction may not be necessary. In a separate report, the same group found the combination of 3A8 with CTLA4-Ig and sirolimus did prevent a humoral response [118]. The same combination of 3A8 with CTLA4-Ig and sirolimus was also found to allow for graft survival in a bone marrow chimerism model in rhesus monkeys [235].

A number of other anti-CD40 antibodies have been developed. 4D11, which partially depletes B cells, has been shown to prolong renal graft survival in cynomolgus monkeys [236,237]. 4D11 notably also suppressed germinal center formation in the spleen and lymph nodes, a phenomenon that had previously been noted with another, non-depleting anti-CD40 antibody, ch5D12 [238]. The chimeric antibody 2C10 was shown by Lowe et al. to bind to a different epitope than either Chi220 or 3A8 [120]. The antibody demonstrated a significant survival advantage in a rhesus islet transplant model when added to a base regimen of sirolimus and basiliximab.

Combined CD28-B7 and CD40-CD154 blockade

As seen above when discussing each costimulatory pathway individually, the combination of blockade of CD28-B7 and CD40-CD154 pathways has been studied in several settings. The initial study by Kirk et al. demonstrated a synergy between hu5c8 and CTLA4-Ig [106]. However, subsequent optimization of the blockade of these two pathways eliminated the survival advantage seen with combined therapy, although a retained benefit in delayed alloantibody formation was seen [199]. Pearson et al. studied the combination of CTLA4-Ig with either CD40 blockade with Chi220 or CD154 blockade with H106 in a rhesus renal transplant model [234]. The addition of CTLA4-Ig did not translate to a median survival benefit with either antibody, although two animals receiving CTLA4-Ig and H106 had graft survival >100 days. However, as noted above, the replacement of CTLA4-Ig with belatacept in an islet model by Adams et al. did lead to a marked synergy when both pathways were blocked [117]. Haanstra et al. combined the CD40 antibody ch5D12 with CD86 blockade and found the addition of CD86 blockade did not prolong survival beyond CD40 blockade alone [239]. Finally, Ossevoort et al. combined blockade of CD80 and CD86 with CD40 blockade and failed to show a survival advantage for the combinations; however, B-cell suppression was reported [203]. In total, the data suggest that combination of CD28-B7 blockade with CD40-CD154 blockade may not provide improved overall graft survival, but positive synergy between the two strategies does exist, particularly in terms of the humoral response.

Other costimulatory and co-inhibitory pathways

A number of additional costimulatory and co-inhibitory molecules have been discovered to play a significant role in alloimmune responses and directing the functional differentiation of T cells [240], including OX40-OX40L, PD-1-PDL-1/2, CD27-CD70, ICOS, PD-1, and the TIM family of molecules. While many of these pathways are the subjects of intense research, most have not yet made it to the level of large animal testing for use in transplantation.

Clearly, there is plenty of opportunity for further development of these interactions for future clinical use.

Adhesion molecule blockade

A wide variety of cell surface molecules mediate the adhesive interaction between cells, and several of these molecules have been found to have particular importance in the function of the immune system. In addition to their role in cell trafficking, some adhesion molecules have been found to stabilize the immune synapse and provide costimulatory signals to immune cells. This section will review two prominent adhesion molecule pairs and their effect in transplantation experiments.

LFA-1

Perhaps the best studied of these adhesion molecules is the integrin LFA-1 and its primarily ligand, ICAM-1. The interaction between LFA-1 and ICAM-1 has been shown to be important in cellular arrest of leukocytes on vessel walls, transmigration across the endothelium, and homing to secondary lymphoid organs [241–243]. Furthermore, LFA-1 is an important component of the immune synapse, stabilizing the interaction between T cells and APCs [244], and has been shown to improve antigen presentation on B cells [245]. The interaction of LFA-1 with ICAM-1 has also been found to transmit costimulatory signals directly [246,247].

The importance of LFA-1 in several areas of the immune response led to significant interest in the potential for LFA-1-based immunosuppression. Early results in numerous rodent models were promising, prompting further development [247]. In monkey models, anti-LFA-1 therapy provided prolongation of graft survival in cynomolgus skin [110] and rhesus cardiac [248] models. Badell et al. used the anti-LFA-1 antibody TS-1/22 in a rhesus pancreatic islet transplant model and showed significant prolongation of graft survival when combined with sirolimus and basiliximab or belatacept [249].

Subsequent clinical development of LFA-1 blockade regimens has been challenging. One early study failed to show success in treating acute rejection with an anti-LFA-1 antibody [250]. However, a subsequent study did find that anti-LFA-1 therapy with odulimomab was effective at preventing acute rejection, with efficacy about that of antithymocyte globulin [251]. Later clinical studies focused on efalizumab, which had already received FDA approval for use in psoriasis. Studies in kidney [252] and islet [253] transplantation yielded promising early results; however, the drug was removed from the market by the manufacturer due to development of progressive multifocal leukoencephalopathy in four psoriasis patients. Although the results with LFA-1 blockade have been promising, concerns for patient safety will be paramount in the development of any future anti-LFA-1 based regimens, and it is likely more specific agents will be required to avoid the deleterious effects of LFA-1 blockade on protective immunity.

CD2-LFA3

The interaction of CD2 with its ligand LFA-3 strengthens the interaction between T cells and APCs, but also, like LFA-1 and ICAM-1, transduces important costimulatory signals [254]. Kaplon et al. developed a soluble form of LFA-3, termed LFA3TIP, which prolonged cardiac graft survival in baboons by approximately 8 days [255]. Another early pilot study utilizing a rat antiprimate CD2 antibody, LO-CD2b, revealed significant depletion of $CD2^+$ and a very modest prolongation of renal allograft survival in baboons [256]. After a similar antibody against human CD2, LO-CD2a, showed efficacy in the prevention and reversal of acute rejection in humans [257,258], a safety and pharmacokinetic study of a humanized form of this antibody, marketed as siplizumab, was reported, although no evaluation of efficacy of the humanized form was made [259]. Weaver et al. utilized the fusion protein, alefacept (LFA3-Ig), in a rhesus model of renal transplantation [167]. The addition of alefacept to a base regimen of CTLA4-Ig, sirolimus, and DST offered significant depletion of memory cells and prolongation of graft survival. However, a subsequent study by the same group revealed that replacement of CTLA4-Ig with the higher-affinity agent, belatacept, eliminated the therapeutic gain achieved with alefacept [168]. Further experiments will be needed to determine what, if any, role CD2 blockade may play in the future.

Other adhesion molecules

As we gain better understanding of the mechanisms of immune cell homing, adhesion, and migration, it is likely that molecules designed to exploit these mechanisms will be developed and brought forward for preclinical testing. One such potential pathway already in the pipeline is the integrin VLA-4, which when blocked reduces migration into the graft parenchyma [260]. Early work in rodents indicates a synergistic effect of VLA-4 and LFA-1 blockade [261] or costimulation blockade [262]. A humanized antibody against VLA-4, natalizumab, is already approved for use in multiple sclerosis, making it an ideal candidate for translation for transplantation.

Depletional strategies

As noted earlier in this chapter, there are two major barriers to the establishment of tolerance in large animal and human models: relatively high precursor frequency and sensitization, either through previous antigen exposure or heterologous immunity. It is no surprise then that lymphocyte depletion has been seen as a method to reduce or eliminate these barriers and is increasingly seen as an adjuvant in the development of tolerance regimens. However, attention must be paid to the relative depletion of regulatory versus detrimental cell populations. Depletion of the regulatory populations may have negative effects on the graft, as will be seen in the discussion below.

Thoracic duct drainage

Perhaps the most intuitive way to deplete lymphocytes is by simply removing them from the circulation. As the majority of lymphatic fluid returns to the circulation via the thoracic duct, this provides an ideal site to remove lymphocytes from the body. In 1962, Gowans et al. showed that thoracic duct drainage was both depleting and immunosuppressive in rats [263]. Subsequent work in a canine model of renal transplantation showed modest prolongation of graft survival [264]. Several clinical studies were undertaken with somewhat mixed results; however, it was later appreciated that the time course of preoperative drainage used in the rat models was insufficient for humans. Despite relatively quick depletion of the lymphocytes, the maximal immunosuppressive effect was not seen for at least 30 days [265]. The procedure never entirely caught on, and was later fully supplanted by less-invasive and more-convenient pharmacologic therapies. In 1996, a group led by Todo and Starzl revisited thoracic duct drainage via a chyloesophageal fistula in a

dog model of renal transplantation, showing a prolongation of survival from approximately 9 to 18 days [266]. The use of internal drainage had been previously described; however, insufficient drainage had been the norm, making the procedure unreliable. One proposed advantage of esophageal drainage, however, is the introduction of alloantigens in the lymph fluid to the GI tract and subsequent induction of "oral tolerance" [267]. A 1997 study by Kinukawa et al. failed to show any advantage with the addition of thoracic duct drainage to a regimen of cyclosporine and steroids [268]. As such, thoracic duct drainage is now primarily a topic of historical interest only.

Polyclonal depletion

Polyclonal deletion of lymphocytes using antilymphocyte globulins or sera was one of the first depletional strategies developed and tested in large animal models. In addition to providing antilymphocytic antibodies, these preparations also include antibodies directed against a variety of other cell surface molecules, notably adhesion molecules. As such, they may be of particular use in cases of significant ischemic injury, such as cadaveric donors, where activated endothelium provides a rich interface for leukocyte adhesion and migration [269].

Several antithymocyte globulin preparations have been developed and tested in large animals, including dogs, swine, and NHPs [270–274]. Generalizing results of these studies is challenging at best, as the polyclonal antibodies generated against T cells from one species are likely to have differing epitope spectra in other species, if they react at all. Regardless, the results of these studies showed some efficacy, but tolerance was not seen. The use of rabbit antithymocyte globulin (ATG) has been studied in NHP and shown to prolong graft survival to approximately 30 days [275], though the dose required is significantly larger than is used in humans, likely owing to decreased specificity of the preparation [276]. The addition of total lymphoid irradiation (TLI) to ATG is capable of further prolonging survival to about 100 days [277].

The failure of ATG to induce tolerance has led to its use primarily as an induction agent followed by some form of maintenance immunosuppression. Hirshberg et al. showed that rabbit ATG followed by sirolimus monotherapy prolonged islet allograft survival in NHPs; however, the survival was limited by sirolimus toxicity [278]. Liu et al. further developed this regimen with the addition of the B-cell depleting agent, rituximab, and showed further prolongation of islet survival [279]. Interestingly, Haanstra et al. showed that depletion with ATG shortened the time to rejection and increased alloantibody formation when combined with costimulation blockade, possibly due to an observed reduction in intragraft levels of the inhibitory molecule CTLA4 and regulatory marker FoxP3 [280]. Furthermore, Pearl et al. have shown that, following depletion with ATG, repopulating cells have an enriched memory phenotype [230] with potentially lower costimulation requirements.

It is important to note that polyclonal heterologous antibody preparations are, by definition, species-specific reagents; they are also highly variable with regard to their specificity. As such, their behavior in one species is unlikely to encompass the same breadth of effect in another, and it is unreasonable to anticipate that an agent raised against one species (for example RATG raised in rabbits against humans) will behave comparably when used in another species (e.g. rhesus). At present, there are no polyclonal agents that can be used in both in humans and in an animal model with similar effects; all require alterations of dose, result in variability in the spectrum of depletional and blocking effects, and have substantially altered duration of effect. As such, there is no scientifically valid large animal model for polyclonal agent use.

Monoclonal antibody preparations

The goal of monoclonal antibody-based depletion is to eliminate or coat reactive T cells and prevent them from carrying out their effector functions while minimizing the pan-immunosuppressive effects of less specific polyclonal depletion. Most preclinical large animal studies involving monoclonal antibodies are carried out in NHPs due to the need for highly conserved, cross-reactive epitopes on the target molecules. However, this is not exclusively the case. Watson et al. successfully developed monoclonal antibodies against canine CD4, CD8, and Thy-1 and showed they prolonged renal graft survival, particularly in combination [281].

The conjugation of CD3 and CD4 antibodies to idarubicin has allowed for the establishment of operational tolerance in half of kidney grafts when combined with TLI (itself a potent depletion therapy) in a baboon model [282]. Interestingly, when the conjugates were given for 2 weeks post-transplant rather than as a single pretransplant dose, no animals developed tolerance, potentially indicating a role for regulatory cells during this early post-transplant period. The use of the CD4 conjugate alone provided only modest prolongation of graft survival [283]. Additionally, previous studies with another non-depleting CD4 antibody, OKT4A, had shown only modest prolongation of graft survival [284–286], perhaps indicating the importance of depletion in the establishment of tolerance.

Broad depletion of CD45-positive cells is being tested as a conditioning strategy in hematopoietic transplantation and has shown some efficacy in dogs [287]. The selective depletion of CD45RB-positive cells has also been shown to be effective at prolonging solid organ graft survival in rodent models [288]. Chen et al. subsequently showed this strategy to be efficacious in a cynomolgus model of renal transplantation [289], with modest prolongation of survival as monotherapy as well as synergy with tacrolimus.

While the agents discussed thus far have focused on T-cell depletion primarily, depletion of B cells has also been shown to have positive effects in transplantation. The anti-CD20 monoclonal antibody, rituximab, has been found to promote graft survival in islet [279] and cardiac [290] NHP models when combined with other immunosuppressants. However, there is some concern regarding deleterious effects on protective immunity with rituximab, as a study of NHP renal transplantation failed to show a survival benefit when rituximab was added to a regimen of ATG, sirolimus, and donor bone marrow infusion, partially attributed to a high rate of SV40 infection in the animals treated [291].

It is worth noting that several of the monoclonal agents discussed earlier in this chapter in the context of costimulation and adhesion blockade may also exert some of their effect via depletion. Indeed, the anti-CD2 fusion protein, alefacept, and the anti-CD40 antibody, Chi220, both have some depleting effect [117,168]. Additionally, there are several depletion strategies being tested in rodents that have not yet transitioned to large animal models. The depletion based on the activation marker LAG-3 has shown promise in rats [292], and has been shown to prevent delayed-type hypersensitivity responses in baboons [293]. However, a pilot study of anti-LAG3 therapy using a different clone showed minimal effect in a rhesus renal transplant model (unpublished data).

Immunotoxin

Perhaps the most successful depletional agent in NHPs has been immunotoxin (IT), a fusion of a modified diphtheria toxin (CRM9) with the FN18 monoclonal antibody directed against primate CD3 [294,295]. Groups led by Knechtle and Thomas have independently shown pretransplant depletion with IT promotes tolerance in primate renal transplant models [107,296,297], with a modest increase in efficacy when paired with donor bone marrow infusion [297]. Thomas has also shown efficacy of IT in concordant islet xenotransplantation [298]. Furthermore, IT has also been shown capable of reversing rejection in a rhesus renal transplant model [299].

Perhaps surprisingly, treatment with IT at the time of transplant has been less effective in promoting tolerance. The treatment regimen prolongs graft survival and prevents cellular rejection; however, alloantibody-driven graft damage and rejection occur due to an intact antidonor IgG response [300]. This model has been pushed forward as a model of chronic allograft rejection due to similarities seen in the histology of primate grafts with clinical samples [301] and represents a rare, reproducible animal model of chronic rejection. Jonker et al. studied the effect of IT when given post-transplant and found a modest prolongation of survival that synergized with conventional immunosuppression such as cyclosporine and sirolimus [302]. This regimen was also notable for a high level of toxicity and infectious complications.

Concerns about the chemically linked FN18-CRM9 IT, particularly related to production yield and linkage heterogeneity, led to the development of a recombinant anti-CD3 immunotoxin [295,303,304]. Subsequently, Page et al. developed a model of chronic, antibody-mediated rejection in rhesus renal transplant recipients using the recombinant IT and tacrolimus [303]. Their model demonstrated development of de novo alloantibodies in 100% of animals treated with the regimen and represents a reproducible, modern model of antibody-mediated rejection.

Immunotoxin was also developed for use in porcine models [305]. However, significant neurotoxicity, not seen in the primate studies, limited the applicability of IT in the pig model [306]. The excellent results seen in the primate models prompted further development, and a new porcine immunotoxin utilizing a different construct was shown to lack neurotoxicity in swine while maintaining T-cell depletion, albeit not as efficiently as its historic counterpart [307].

The success of depletional strategies in large animal models has led to several human trials. Unfortunately, immunotoxin is not directly translatable to the clinic, owing to differences in the CD3 molecule between humans and primates. However, the anti-CD52 antibody, alemtuzumab, produces a similarly impressive depletion of T cells in humans and has been shown to prolong allograft survival [308,309], although tolerance has remained elusive [310].

Chimerism

Chimerism refers to the coexistence of genetically distinct donor and recipient cells within the recipient. This differs from mosaicism in that mosaicism refers to genetically different cell populations arising from a single zygote. While it can be said that all transplant recipients are chimeras due to the presence of the graft, the use of the term "chimerism" within transplantation almost exclusively refers to hematopoietic chimerism due to the unique effectiveness of these cells to influence the immune response. Chimerism-based strategies hope to extend the mechanisms of self-tolerance to the graft by introducing a replenishing source of donor APCs [311].

It can be said that the study of immune tolerance began with chimerism. In 1945, Owen described red cell chimerism in free-martin cattle. In this case, a placental vascular anastomosis in utero allows for the exchange of hematopoietic progenitors and development of life-long chimerism [312]. The group led by Medawar would subsequently show these cattle capable of accepting skin grafts from only their twin [313]. Continued research would reveal chimerism to be a potent strategy for tolerance induction in mice [2,314] and even capable of tolerance induction in humans [5,315–318].

Hematopoietic chimerism can be further classified by the relative contribution of donor cells to the population of mature, circulating cells. Full chimerism and microchimerism refer to the states of approximately 100% of circulating cells being of donor origin and $<1\%$ (i.e. detectable only by exquisitely sensitive techniques, such as PCR) of circulating cells of donor origin, respectively. Mixed chimerism refers to the intermediate state of detectable (i.e. $>1\%$) but incomplete (i.e. $<100\%$) of circulating cells originating from the donor. Infusion of hematopoietic stem cells, either from bone marrow or mobilized into the peripheral blood, into an unconditioned recipient leads to rapid rejection of the cells, failure to engraft, and resultant microchimerism, if any. However, conditioning of the recipient to allow for engraftment requires more intensively ablative regimens, sometimes with severe toxicity. Given the relative safety and efficacy of post-transplant immunosuppression, this has been a major barrier to widespread clinical translation of chimerism-based strategies, and significant effort has been placed into improving these regimens [311].

Microchimerism

The establishment of microchimerism by donor-specific unfractionated marrow infusions without preconditioning has been used in attempts to improve graft survival in a number of large animal and human studies [319–323]. However, it has been shown that likely all transplant recipients are microchimeric to some degree [324], and clearly not all recipients accept their grafts. The question has therefore been raised whether such chimerism in the presence of immunosuppression is biologically meaningful or whether it merely indicates that sufficient immunosuppression to maintain a transplanted organ is also sufficient to prevent rejection of some "microchimeric" cells [325]. Indeed, many studies have failed to show a benefit based solely on microchimerism alone [326–333]. It seems reasonable that the microchimeric state allows for presentation of donor antigen in secondary lymphoid organs, but at a level that is not tolerogenic in its own right. However, such antigen availability may have been of benefit when paired with other therapies, such as is seen when pairing costimulation blockade with donor-specific transfusion [334]. The studies of Thomas et al. [322]. provided evidence for the presence of veto cells as a subpopulation of marrow cells. These cells were shown to abrogate antidonor cytotoxic responses and represent one possible mechanism of peripheral tolerance induced by bone marrow infusion.

Full chimerism

Full chimerism is the goal of bone marrow transplantation for hematologic malignancy, where eradication of the cancerous cells is necessary. Such full chimerism is generally only achievable without problematic GvHD between HLA identical siblings. However, this full chimerism has been shown to carry with it

tolerance of subsequent kidney transplants from the same donors [315,335,336]. Additionally, it has been shown in large animal models, including miniature swine [337] and dogs [338,339], that full marrow replacement following lethal total body irradiation leads to acceptance of kidney grafts from donors that are MHC-identical to the original marrow donor. However, full chimerism does have some less desirable characteristics in the search for tolerance induction [314]. Compared to mixed chimerism, the achievement of full chimerism requires more intense conditioning and increases the risk of GvHD. Additionally, full chimeras often exhibit immune incompetence due to MHC disparity between positive-selecting cells in the thymus and peripheral APCs [340]. Thus, regimens designed to achieve full chimerism should be approached cautiously, especially when considering transplants across MHC barriers.

Mixed chimerism

It has been generally postulated that macrochimerism is necessary for the development of durable tolerance in animal models. Interestingly, rodent experimentation has demonstrated stable chimerism is required for durable central tolerance [341,342], while in larger animals and humans, only transient macrochimerism appears to be necessary [316,343,344]. Similarly, states of durable chimerism (although not of all hematopoietic lineages) have been established in NHPs without conferring tolerance on a renal allograft [345]. Thus, multilineage chimerism may be required for tolerance induction [346]. Nevertheless, these results point out that the fundamental relationship between chimerism and allograft tolerance remains incompletely understood.

Studies of mixed chimerism in the dog model have been led by Storb et al. His group has been able to establish mixed chimerism in their canine model using a regimen of sublethal total-body irradiation and a short course of CyA with or without mycophenolate mofetil [61,344,347,348]. These animals accepted kidney grafts from their donors [61,344,348]; however, some degree of tissue-specificity was observed, as not all animals subsequently accepted skin grafts from the same donor [61]. Storb and his colleagues were able to refine their method, showing that reduction of the total-body irradiation was possible by addition of CTLA4-Ig and DST [349] or by limiting the field to the lymphatic chains [350]. Together, these studies imply the value of conditioning irradiation lies in immunosuppression of the recipient and that the donor marrow is capable of creating its own physical space in the marrow cavity. Tillson et al. reported similar results [351]; however their study is notable in two ways: long-term survival of renal grafts was observed in both DLA-identical and DLA-haploidentical dogs, but skin grafts were only accepted in the DLA-identical pairs; secondly, animals receiving the conditioning regimen without the bone marrow infusion also accepted their kidney grafts, raising questions on whether or not chimerism was required for tolerance induction with that preparative regimen.

Mixed chimerism has also been successfully established in a miniature swine model using a combination of T-cell depletion with or without irradiation [87,352]. These animals subsequently accepted skin grafts from their donors, but not third parties. Interestingly, these animals were found to have a high risk of developing PTLD associated with a porcine gammaherpesvirus [353]. Further analysis showed that increasing degree of MHC mismatch and increased T-cell depletion were risk factors for development of PTLD in this model [354] and that the incidence of PTLD could be decreased substantially by including B-cell depletion in the preparative regimen [355]. Tolerance of kidney, heart and vascularized composite tissue allografts have all been achieved through mixed chimerism in miniature swine models [97,356,357].

The Boston group has utilized a similar regimen in cynomolgus macaques with successful establishment of transient mixed chimerism and acceptance of renal grafts following irradiation, bone marrow infusion, T-cell depletion, splenectomy at the time of transplant, and a short course of CyA post-transplant [99,100]. This regimen was also capable of preventing development of donor-specific antibodies in most of the animals tested [343], but it is worth noting that some animals did have antidonor activity on biopsies taken following the cessation of CyA therapy [99]. Similar to the porcine experiments, these studies also demonstrated development of PTLD, likely related to LCV [358]. Kawai et al. also studied this regimen in cardiac transplantation; however, full tolerance could not be established and grafts were ultimately lost to chronic cellular and humoral rejection [359]. The addition of CD154 blockade with 5C8 allowed for the omission of splenectomy from the protocol; however, long-term tolerance was not achieved uniformly as chronic rejection developed in some animals [360]. It is notable that the regimens developed by Kawai et al. were capable of inducing tolerance in most monkeys even across full MHC barriers without GvHD [99,100,360] and that these regimens have been the basis for the first successful human trial for tolerance induction through mixed chimerism in HLA mismatched kidney transplantation [5].

A mixed chimerism model has also been developed in rhesus macaques [361]. This regimen is based on busulfan rather than irradiation, and is followed by induction with basiliximab and continued immunosuppression with belatacept, sirolimus, and the anti-CD154 agent H106. This model is notable for its high levels and persistence of chimerism achieved (~80% lasting a median of 145 days). However, rejection of the donor marrow was found to be rapid following the cessation of immunosuppression [362], and viral infections occurred at a high rate following bone marrow transplant [361]. The same group sought to determine if CD40 blockade would provide the same benefit. A regimen consisting of busulfan, basiliximab, CTLA4-Ig, sirolimus, and the anti-CD40 agent 3A8 was found to promote engraftment and mixed chimerism. Similarly to the previous protocol, however, graft rejection and loss of chimerism followed discontinuation of the immunosuppressive drugs [235]. Neither of these models has been tested to determine their effect on the rejection of solid organ transplants following establishment of chimerism.

Tolerance based on induction of mixed chimerism is one of the few strategies that has been successfully translated from mice to large animals, and, as noted above, selectively in humans. However, the required conditioning regimens remain significantly more toxic than standard immunosuppressive therapies, so that this approach remains experimental at this point. Furthermore, safety concerns involving viral infection and PTLD that have been raised by the primate studies will also have to be considered. Despite these drawbacks, the strategy remains very promising and further research efforts into chimerism-based approaches to tolerance are definitely warranted.

Summary

In this chapter, we have reviewed the major large animal models for solid organ transplantation, discussing both the technical issues associated with working with these animals, and also a number of strategies to prolong graft survival with, in some cases,

establishment of long-lived tolerance of a graft. While a full discussion of all the available literature on the subject would be prohibitively long, we have focused on those approaches likely to provide meaningful advances in understanding of the immune response and improvements in clinical outcomes. Some of the therapies discussed have already been brought forward to clinical reality; others have been tested in humans with less impressive results. Clearly the reasons for differing outcomes are many, some of which we can account for, while we may not yet even be cognizant of others. Despite these issues, large animals remain the best models of the human immune response. Any ethical human trial must be predicated on at least some animal data, and large animal experiments provide the most relevant test bed for exploration of strategies to improve the outcomes for our patients.

Introduction

Our working definition of functional genomics comprises four general disciplines and their closely linked technologies: global gene expression profiling, tandem mass spectrometry proteomics, genetics, and epigenetics. However, we will only discuss the first discipline and applications of global gene expression profiling to transplantation research in this chapter. We use the term "functional" to communicate a focus on using these different genomic disciplines as a suite of tools to understand the biology of health and disease at a "molecular" level. The reader is no doubt aware that the continued proliferation of references to "-omics" and new fields like microbiomics and metabolomics are worthy of the name and their own chapters. But we also share the growing concerns in the field that the routine overuse of this term serves no valuable purpose.

In first principles, we organize our approach to functional genomics in biological terms (e.g. how complex systems like cells and tissues work at the molecular level). We think in terms of advancing from mechanistic knowledge of basic cell biology to understanding how a state of health transitions to disease at the cellular and organismal levels. The chapter is meant to complement Chapters 13, 14, and 15, which deal with the in vitro, small animal, and large animal model systems used in transplant research. This is a bottom-up approach. Applied to clinical medicine, we believe that functional genomics illuminates how diseases start, manifest, and progress. The course of any disease in an individual patient is actually determined by a combination of multiple factors, including genetics, environment, personal history, and our choices of therapy. For example, transplant rejection is triggered by an immune-mediated process with multiple balancing mechanisms but the outcome is impacted by the genetics of both recipient and donor, recipient age and immune history, the choice and timing of immunosuppressive therapies, the individual's genetically programmed and epigenetically conditioned responses to tissue injury, and the ability to heal or compensate. Therefore, by definition, bottom-up functional genomics creates a very complex view of biology and medicine. This is a challenge to a reductionist view where mechanisms of disease are defined by much clearer and simpler rules.

We believe functional genomic knowledge will contribute to creating the next generation of diagnostics and therapies. We also believe that personalized medicine will be part of our future and that it will be transformative, despite our concern that this future has been prematurely over-hyped. The rationale for this confidence is that the current sum total of all the biological information evolved by our ancestors is contained in the DNA of our genome. From this huge human knowledge base the information is constantly called upon, like a huge living search engine, to create, differentiate, maintain, protect, and heal. In our view, functional genomics applies to every step in this flow of genomic information, from reading the DNA, to splicing RNA, to translating and modifying the proteins, as well as the entire complex of regulatory and communication pathways controlling all these systems. When functional genomics matures as a fully integrated discipline and we can routinely follow the complete details of this information super-flow, there will be no place for the causes of disease to hide from our detection or our understanding. Whether we get there in our lifetimes is much less certain.

Functional genomics in practice

We will review the current technologies available for global gene expression profiling in transplantation. These are just tools and we will explain the basic principles of each. We will also discuss their limitations in the context of experimental designs and data interpretation. The reader can then ask what more they need to know to successfully apply any or all of these tools to whatever scientific or clinical challenge inspires them.

Gene expression profiling as a concept

Genomic information flow starts with the activation-dependent transcription of DNA into mRNA in the nucleus. This level of information flow is studied by gene expression profiling. The first product of gene transcription is called pre-mRNA, an RNA transcript that still contains all the introns and exons encoded in the DNA. A large multiprotein complex called the spliceosome is then assembled, which is comprised of over 100 different proteins that

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

are required to splice out the introns of the pre-mRNA [1,2]. Assembly of the spliceosome is regulated by sequence differences marking intron–exon junctions, by specific sequences in the exons, and by energy-dependent phosphorylation of various proteins in the complex. Essentially, all pre-mRNA transcripts require **splicing** into mRNA before export to the cytoplasm where protein can be made. One of the great mysteries at the present time is how cells determine the "when" and "where" of **alternative splicing** such that specific exons in the middle of a pre-mRNA transcript are included or removed from the mRNA under specific conditions [3]. We have shown that immune-mediated human T- and B-cell activation produced as much differential alternative splicing as up-regulated mRNA transcript expression [4]. We pointed out that most of the current approaches to measuring differential gene expression were completely ignoring the potential impact of this alternative splicing.

After splicing or alternative splicing at specific exon–intron junctions, the mature mRNA transcripts are exported in another energy-dependent manner to the cytoplasm for entry into the ribosomal machinery and protein translation. Translation is regulated at multiple steps, including entry and assembly of ribosomes, the delivery of amino acids for protein synthesis, and pathways that regulate mRNA transcript half-life such as the miRNAs bound to the RISC complex [5]. Importantly, protein synthesis is also regulated by the mTOR complexes that are the targets of the immunosuppressive drugs in the rapamycin class [6]. The entire process is remarkably complex. Thus, it is important to give a first reality check for the reader here: gene expression profiling of the mature mRNA produced by this process is very revealing but it is still only a limited view of the true information flow and the many regulated steps involved in cell activation. New methods are allowing us to add global profiling of alternative splicing and that is a great advance. But we all need to keep a firm grasp on what each piece of new knowledge contributes to our understanding of a profoundly complex process and avoid the temptation and the pressure to shape exaggerated hypotheses about the mechanistic significance.

The value of gene expression profiling starts whenever we want to compare one or more states (resting vs. activated, early vs. late) or phenotypes (rejecting vs. tolerant, viral infection vs. acute rejection) and study what genes are activated in individual cells or whole tissues to direct protein synthesis and influence function. Gene profiling done in a targeted fashion can be used to follow whole networks of molecules already known to be important, such as inflammation, apoptosis, cancer transformation, cell signaling, cell proliferation, and so on. A growing number of very good commercial, pathway-based sets of quantitative PCR assays are available for these purposes and should be considered as options. However, the rapidly falling costs of doing global gene expression profiling on microarrays or by deep RNA sequencing allows such comparisons of gene expression changes to be done without any bias to known networks of function. Global profiling allows for discovery and yet takes full advantage of everything known about functional pathways in the literature. Another common application of microarrays has been biomarker discovery [7,8]. Here the objective is to identify a signature of mRNA changes that consistently reflect a given state or patient phenotype (acute or chronic rejection, liver transplant regeneration vs. dysfunction) [9–12].

A decade of genomics literature in transplantation has already created many different sets of published gene expression profiles from mouse models to human patients. These data include biopsies of normal and rejecting kidneys, livers, hearts and lungs, profiles of many different immune and inflammatory cell types in tissue cultures, small animal models and patients, profiles of blood cell subsets (Treg, B cells, macrophages), and profiles of peripheral blood cells from operationally tolerant kidney and liver transplant patients. Therefore, a good start before getting into any gene profiling project is to check out what has already been done and deposited in the public domain databanks. For this purpose two good starting places are the Gene Expression Omnibus (GEO), the NIH National Library of Medicine gene expression database (http://www.ncbi.nlm.nih.gov/geo/), and the Array Express Archive maintained by the European Bioinformatics Institute (http://www.ebi.ac.uk/arrayexpress/). Another good data source is individual papers in the specific area of interest, as almost all journals now demand that gene expression data created by the research being described is provided to the reader in detailed supplemental tables unless already deposited in one of these public databases mentioned above. These datasets are powerful tools, especially when used correctly by skilled bioinformaticians, and they should be fully exploited.

A note of caution is also important. There are submission guidelines called MIAME (Minimum Information About a Microarray Experiment) that help standardize what terms are used to describe the experiment. However, there are no quality filters for datasets in these public domains. They vary dramatically in quality, technology platforms, methods, and by experimental designs in many critical details that are not described and rarely apparent from review of the MIAME metadata. The fact that they represent thousands, even millions, of data points does not mean that the rules of basic experimental design and rigorous laboratory conduct are suddenly suspended. Moreover, the same obligations on investigators remain for any conclusions reached by mining these datasets to validate claimed results with orthogonal approaches and validate mechanistic claims experimentally and under strictly controlled conditions. Thus, much of what is done and claimed using different bioinformatics tools to "mine" such databases is greatly exaggerated in our opinion. But in fairness, there are experts in the bioinformatics field that would strongly disagree with our view. They believe that they have changed the rules of experimental science with new statistical approaches designed to combine and mine these data troves successfully. Our view is that the tools alone cannot make the furniture for a carpenter but the proper use of tools is very useful. Time will sort these claims out but we would not recommend buying an expensive chair until you are sure that you are comfortable sitting on it.

Gene expression profiling by microarrays

Global gene expression profiling can readily be done with commercial microarrays (Table 16.1). Microarrays start by printing or

Table 16.1. Commercial microarrays

synthesizing in situ complementary DNA probes onto a physical surface like a glass or plastic slide [13,14]. Each individual spot on the array contains several million probes which are all identical and designed to be specific for one mRNA transcript. Thus, you can profile as many different RNA transcripts as you can make unique probes, identify and record the results of hybridization at separate spots. Current technologies can readily print probe spots for the entire human genome on the surface of a chip that can fit in the bottom of a 96-well microtiter plate. Similarly, putting the probes on the surfaces of beads can also create expression arrays (e.g. Illumina). The principles are essentially the same though the geometry and mechanics of the instruments are somewhat different. The results with all these technologies are highly reproducible as well as reliable.

To visualize and quantify mRNA expression the RNA transcripts from total RNA preparations of a given sample are most commonly reverse transcribed to generate the complementary cDNA. In most oligonucleotide arrays, in vitro transcription of the cDNA is employed to obtain biotin-labeled cRNA. These cRNA molecules are then hybridized to the oligonucleotide probes on the microarray. After hybridization, the microarray is stained with a fluorescent molecule that binds to biotin and is finally washed. After washing off unbound transcripts and then using UV light excitation, the amount of fluorescent signal released from each spot on the array is recorded, and this is proportional to the amount of labeled mRNA transcript for each gene present.

By providing the user a numerical, signal-based metric for relative gene expression, the differences in expression can now be normalized. We have used many normalization tools over the years but currently do all our normalization using the rank-based Quantile Normalization with RMA [15]. However, there is one additional step before proceeding to sample comparisons. We have found that microarrays have a tendency to amplify apparent differential expression changes for genes detected at very low signal levels. This is because at low signals the processes of normalization and subsequent ANOVA-based class comparisons (see next) tend to select out a class of data points with less technical signal variation and exaggerate the significance. If you have hundreds of arrays per group this is not an issue but very few studies reach such numbers to avoid this limitation. Therefore, typically in our laboratory we perform one additional signal filter step after normalization by removing any low normalized signals, which is usually below the normalized background signal intensity across all microarrays in a particular experiment. Though this is data dependent, the values are usually a log2 signal in the range of 5.64 to 6.64, which corresponds to a natural log10 scale signal of 50 to 100 using Affymetrix microarray data. However, while the principle remains the same, it is advised that the user determine the background threshold based on the array type used for the experiment before removing low-expressed genes as described above.

Next, we take all the results from the multiple individual samples in two or more different experimental groups (e.g. classes) and do **class comparisons**. For example, compare the profiles of biopsies taken from 50 different patients with acute rejection to 50 control transplants with excellent function. These gene differences by class of sample are called **differential expression**. The original data are delivered as an output file with a numerical value or signal for each gene that is expressed above the normalized background of the chip. Based on the direction of the class comparison chosen (e.g. rejection compared to controls), a positive change is designated as "up-regulated" and a negative change as "down-regulated." Differential expression is often referred to and expressed as a "fold-change" so that we can think in terms of a given gene being up- or down-regulated so many fold with rejection and so on.

The list of differentially expressed genes can then be mapped to functional biological pathways using different tools to gain insights into the mechanisms driving acute rejection in our example. The reader should just remember that these mapping tools are only as good as the current knowledge for a gene as there are clearly many things genes do that remain to be discovered. So just because one researcher looking at a gene's function in the brain of a mouse publishes that it is linked to signaling via a growth factor receptor doesn't mean that its function in an activated B cell is the same, though it is likely that it is a signaling factor of some sort. A new generation of mapping tools takes a very different approach. They find patterns of coordinate expression in complex data sets that suggest groups of genes function in some kind of associated network. There could be a dozen different discrete pathways defined by function contained within such a network but the point is to identify the fact that all the linked genes in the network, thus all the functional pathways, change in a predictable way with a given situation. So for example, acute rejection could cause signaling via the T-cell receptor and a costimulatory pathway that activates a number of cytokine genes that then up-regulate and signal through their cognate receptors and trigger cell proliferation inducing functional pathways and also inhibit apoptosis. These related events would all be represented in a single network using these new tools. Cytoscape is an excellent example of this new generation of network mapping tools and is available for anyone as open source software (http://www.cytoscape.org). It is too early to claim that you can go from gene expression data to such detailed understanding of linked functional pathways at this time but the use of such tools should be part of any discovery project.

Differential expression data can also be used to create biomarker signatures that might diagnose the presence of rejection in a biopsy or inform the user on some characteristic like severity or acuity. **Class prediction** refers to another set of tools that take the differentially expressed gene lists created with one set of samples to predict the classifications of a new set of samples chosen from different but similar subjects, for example acute rejection versus controls. This is how we validate such gene lists and how biomarkers for clinical diagnosis can be developed and the diagnostic results in terms of positive and negative predictive values (the balance between false positive and false negative classification of each sample in a cohort to the correct diagnosis like acute rejection) in Receiver Operating Curves (ROC). As already noted, having thousands of data points does not suspend the rules of experimental design. You still need to carefully design experiments with proper controls and appropriate numbers of samples in each group and then repeat and validate any results.

Experimental designs: power, replication, batching, and validations

Statistical power is always necessary to consider before trusting conclusions drawn from global expression profiling on microarrays. The tools now used for class comparisons and class predictions can provide lists of highly statistically significant gene candidates. But if there are not enough samples in the study set then the statistical power of these candidate gene calls can be very low and that is often not explained in publications focused on discovery. As a

general guide based on years of calculating statistical power for array-based experiments, we have found that 20 samples per group is sufficient for equal or greater than 85% power to detect fold-change differences of 1.5 or greater in gene expression experiments. Nonetheless, even with appropriate statistical power in the first round, you have to replicate the experiment at least a second time with an independent sample cohort of similar size in a clinical sample profiling design or a second series of biological replications of the same experimental design in the case of cell culture or animal model-based experiments.

However, there are alternative approaches to consider for specific objectives. For example, hypothesis generation in a well-defined experimental system can start with a small number of microarrays as a first discovery step; for example, six arrays per group is about right usually. You still have to replicate once to validate the results but you are still at only 12 arrays per group. Then, based on the confirmed list of high-value candidates, proceed to orthogonal mechanistic approaches to validate your results like knocking down a few key signal molecules that you are predicting are critical for the response and measuring downstream gene changes by qPCR or protein phosphorylation, or global impacts on cell proliferation or some other cell function assay.

Batching refers to the critically important step of how you group samples and prepare them for the actual profiling. Every time you have a different technician prepare the total RNA or any of the many steps in the labeling protocol, you can introduce a type of technical bias we call "batch effect." Every time you change the kit type or kit lot for labeling or buy a new set of arrays and every different day that the experiments are done, can add batch effects. So we take great pains to organize experiments so that each part is done by the same technician in the exact same way. We always randomize samples so that individual samples from different experimental groups and controls are mixed evenly across days, arrays, and reagents. We also include at least three replicates of mRNA pools on each day (e.g. activated T cells) that are treated exactly like all the other samples but where any data variability has to be introduced by the technical procedure. While there are statistical tools that can be used to remove batch effects in silica, these work in a manner that necessarily reduce the number of genes you can study as well as the dynamic ranges of the signals for comparisons thereby sacrificing potentially important biological detail. We strongly believe that good experimental design is the best way to minimize batch effects and emphasize the biological differences that are the whole point of the work.

Finally, we should comment on validation as this frequently comes up in the review of papers and grants. First, there is no point in technical replicates for the current generation of microarrays since their excellent inter- and intraplatform reproducibility has been well established [16] and these are now just a waste of money and effort. Biological replicates are what should be done. Second, there is really no point in demanding qPCR replication of significant differential gene expression results at this point if the work is done properly as discussed above. No one would demand that anyone do a microarray to confirm results produced by qPCR because we "trust" the results of qPCR as we should now "trust" the results of microarrays if they are done properly. And if microarray profiling is not done properly, then demanding qPCR is not enough to save the results. So if validation is necessary, then the best approach is orthogonal by a different approach and technology. For example, if the claim by microarrays is that a given signal pathway is critical to an experimental system, then knocking down or overexpressing the pathway, creating a reporter construct, demonstrating the downstream impacts, and so on would be of more value, especially in the mechanistic sense. If the conclusion relates to a clinical outcome like acute rejection then consulting the existing literature including animal models, and considering doing mass spectrometry proteomics on parallel clinical samples or testing a hypothesis in a cell-based or animal model of the clinical outcome, is warranted (e.g. T-cell activation or proteomic profiling of acute rejection biopsies).

Gene profiling by deep RNA sequencing (RNAseq)

The latest technology for gene expression profiling is deep RNA sequencing. These instruments function by detecting and reading out the sequences of mRNA or miRNA transcripts fixed by adaptors to the surfaces of slides, beads, or electronic sensors. The details of these technologies are complex and beyond the scope of the present chapter [17]. But the basic principle is massively parallel sequencing of the individual mRNA transcripts obtained from the target cells or tissues. Thus, instead of simply detecting the amount of a given mRNA sequence hybridized to a specific complementary probe on the microarrays, discussed above, deep RNA sequencing reads out the entire sequence of the captured transcript by adding one base at a time, cycle after cycle, and detecting that event as a signal generated by fluorescence or release of a charged molecule like hydrogen. The massive scale is accomplished by capturing millions of transcripts on the same surface and sequencing them all in parallel in every cycle.

The relative number of mRNA transcripts is determined based on the number of reads obtained for each mRNA in a pool of RNA where the determined sequence aligns or maps to that specific gene. This is very different from labeling the whole mRNA transcript at the start, hybridizing it to complementary oligonucleotide probes, and reading out the total amount of fluorescent signal detected at a given spot on a microarray. On the other hand, it is the nature of evolving technologies to be different. So the first question is whether there is any significant difference in the actual value of the data obtained by either technology. Once either technology accurately provides the numerical metrics for the relative number of mRNA transcripts in a pool of total RNA, the value in terms of understanding the biological significance of the transcriptional information revealed is the same. The fact that deep sequencing is the latest technology doesn't make it magic or impart magical value to your data. The key is to understand the limitations and the advantages and then use both these technologies strategically.

A common metric used to compare deep sequencing technologies is "read length" and it is literally the maximal length of sequence that a platform can read in a single string of reads (Table 16.2).

Table 16.2. Deep sequencing technologies

Next generation deep sequencing (short read)
Illumina HiSeq 2000
SOLiD 5500xi
Next generation deep sequencing (long read)
Roche 454 FLX
Pacific Biosciences
"Personalized" deep sequencing platforms
IonTorrent
Illumina MiSeq
Roche 454 Junior

The current "short read" instruments can read up to 250 bp but can also do this in both directions of the gene in the same run, called paired-end reading. The current "long read" instruments can read up to 750 bp, though several manufacturers claim they will hit 1000 bp reads, and much longer in the near future. While this all sounds good in the descriptive literature, the fact is that single direction reads of 50–100 bp long are completely sufficient for doing gene expression profiling by deep RNA sequencing. Longer reads and paired-end reads are not necessary and just increase costs. However, if your intention is to also profile alternative splicing of mRNA and identify differential exon usage, then paired-end 100–150 bp reads are highly desirable, if not necessary.

Nonetheless, most of the commercial hype regarding achieving greater and greater read lengths, and more and more sequencing throughput, is directed to DNA sequencing and genetics. The commercial competition is being the first to offer the complete sequencing of a human genome that meets a standard for accuracy which is "medical grade" for only $1000 or less, a cost point that is commonly assumed will suddenly usher in the promised era of personalized medicine. We look forward to this technological achievement and recognize that it will lower the threshold for clinical sequencing of whole genomes in various patient populations. More data in a new field is a good step. But simply having more data available, obtained at the rate of 3.5 billion bases for every human genome sequenced, does not equate with suddenly understanding the biological functions and implications for health and disease that successfully delivering true personalized medicine will require. Until these remarkably complex challenges to functional genomics are addressed and the information contained in the genomic code is understood in terms of biology, health, and disease, the claims of the transformative impact of simple sequencing success are just more hype.

Another key metric for deep RNA sequencing is "read depth." Data generated by deep sequencing of RNA reveals the number of reads detected for any given sequence by matching all the read results from a given run to the known sequence of the human genome. As a rough guide for successful RNAseq, we aim to hit about 75–80% successful alignment of all reads obtained to the human genome. The objective of RNAseq-based gene expression analysis is to simply detect the presence and quantify the relative number of specific mRNA transcripts in the total RNA pool. Thus, approximately 200 million reads in one Illumina HiSeq2000 lane with 80% alignment gives about 160 million reads of genomic sequence. If you started with an RNA library created by putting sequencing adaptors on only mRNA, you can count every read (e.g. 160 million) that maps to the coding sequence of the known human genes as individual events. It is generally agreed that a minimum of ten reads for any transcript is sufficient to have statistical confidence that the transcript is present. Thus, if you want to measure the relative expression of the same transcript or miRNA in two different samples, the difference in the number of reads detected between two conditions (e.g. resting vs. activated, control vs. rejection) is all that is necessary to detect and quantify differential gene expression.

However, if you also want to compare multiple different mRNA transcripts to each other in the same experiment, then you have to "normalize" the data first. Normalization is critical because every mRNA is a different length. Thus, the probability of finding 100 reads for a gene transcript that is 5000 bp long is significantly greater than finding 100 reads for an mRNA that is only 1000 bp long. Normalization of deep RNA sequencing data to individual gene lengths produces the term FPKM (Fragments Per Kilobase of exon per Million fragments Mapped) [18]. This is important to understand because that is the way you should be shown your final results if you want to go beyond simply identifying the presence of a given gene transcript and compare its changes to transcription of other genes that might create functional pathways or regulate your gene of interest.

In fact, once normalized gene detection values (FPKM) are established, all the standard tools for analyzing gene expression profiling on microarrays can use the deep RNA sequencing expression data interchangeably. This fact is critical in practical terms because the last decade has given us a very mature pipeline, with multiple validated tools for analyzing and graphically displaying global gene expression data obtained from microarrays without having to depend on bioinformatics experts to analyze your data. That these can also be used with the data generated by deep RNA sequencing is a great deal for all of us.

With that clear as a starting point, there are a number of things that deep RNA sequencing does now that are major advances over microarrays. In fact, these are opening up whole new areas for functional genomics research. For example, given the proven efficacy of multiplex barcoding to successfully sequence up to a dozen different samples in one lane of a flow cell, we now routinely do miRNA profiling by deep sequencing. The cost calculation and unbiased scope of the data is significantly better than any of the currently available commercial miRNA arrays. We are now taking advantage of deep miRNA sequencing to go further and profile both the mature miRNAs and the precursor miRNAs (pre-mIRs) in parallel. Thus, initially an miRNA gene is transcribed to create the primary miRNA (pri-mIR) in the nucleus and this transcript is spliced by Drosha and DGCR8 (e.g. Pasha) at a specific stem loop structure that these splicing proteins are evolved to recognize. The pre-miRs are then transported to the cytoplasm by an energy-dependent step in complex to another protein called Exportin 5. Once in the cytoplasm another RNA splicing complex is formed by DICER and Argonaut to create the mature miRNA and transport it to the target mRNA transcript. All of these steps are regulated but very little is known about any of it. Deep sequencing has created a novel opportunity to advance these studies. Another example is the crossover between RNA expression profiling and genetic variation studies. Because deep sequencing also reveals actual sequence, it can be used to discover the presence of genetic variations in coding transcripts (e.g. exon sequences). In this application the technology is orthogonal to genetic variation studies done by deep sequencing of DNA after exome capture (e.g. whole exome sequencing). However, the reader should note that the experimental designs including the depth of sequencing required and the analysis pipelines for this kind of variant detection are very different from those typically applied to gene expression profiling. Finally, another really fascinating new direction for the field is the analysis of long noncoding RNA (lncRNA). It is now clear from the exciting insights being generated by the ENCODE consortium (Encyclopedia Of DNA Elements; funded by the National Human Genome Research Institute of the NIH) that RNA is produced by many intronic, non-coding regions in the human genome as well as by transcription of certain genes where the antisense strand of DNA is also transcribed but does not code for known proteins [19]. The roles played by lncRNA and the rules for how lncRNA regulate gene expression and cell function in response to activation, stress, and other signals remain to be discovered.

Alternative splicing by deep RNA sequencing and current challenges

We believe that the study of alternative splicing is one of the next big discovery areas in transplantation biology because such splicing is a powerful creator of genomic diversity, changing the cell's proteome in dramatic ways [20]. Moreover, cell activation results in significant changes in the alternative splicing profile of cells that are independent of the changes in the levels of mRNA transcription measured by just expression profiling.

Our experience to date is that data obtained with paired-end read deep RNA sequencing is greatly superior to the data obtained with the latest generation of microarrays for alternative splicing. But, in our experience, alternative splicing requires paired-end reads, typically 100 × 100 in length, as well as greater depth of sequencing (e.g. less samples per lane) and a much more complex bioinformatic workflow to detect differential exon usage, all of which significantly increase the costs and time required to complete a run. Thus, cost-wise, it is currently more cost-effective to do alternative splicing profiling with the commercial microarray offered by Affymetrix (GeneChip Human Exon 1.0 ST Array) that has probes for every known exon in the current build of the human genome. The problem comes with deciding on the quality of the results generated. In our experience with both this array and deep sequencing, we found that up to 25% of the splicing events detected by the array could not be validated by sequencing. That still leaves 75% detected and these comparisons are complex enough, as discussed next, that it is important to keep a very open mind about both strategies at this time as used properly each has value. It is also important to remind the reader that microarrays are also evolving. Newer generations of splicing junction arrays have been promised by Affymetrix that have new probes custom designed, based on growing knowledge bases of alternative splicing and exon–intron junction boundaries, which might narrow or eliminate the advantage of paired-end RNA deep sequencing in the future. Thus, the reader should always consult with the local technical genomic technology experts for the most up-to-date information before making these technology and experimental design decisions.

But alternative splicing also presents two serious challenges at this time. First, it is difficult to detect differential exon usage because, unfortunately, the reality is not simple as a given gene having only one possible alternative form that coexists in some simple 50–50 mix. Most genes have multiple alternative transcripts (often six or more), they can exist at any level in a mix, and at any given time under any given condition there might be multiple alternative transcripts (i.e. isoforms) for each known gene profiled present together in the total RNA pool. And if you want to drive yourself even crazier, different cells in a pool of cells could have different sets of transcript isoforms for the same gene and that kind of detail is totally lost until we get to single-cell gene expression profiling (see later in the chapter). So the first point is that getting into alternative splicing requires a major commitment of technical effort and resources.

The second challenge of alternative splicing data is understanding what it means once you have detected it. A little background on the current state of functional genomics is informative and necessary here to explain this challenge properly. The field is now comfortable with the notion that if you properly normalize and detect significant differential expression of an mRNA transcript for a given protein coding gene that the protein is present. There are still some diehards that like to repeat the scientific canard that "there could be transcripts without proteins." The reality is that differences in detection technologies, depth of coverage, and dynamic ranges for current mRNA profiling and proteomic technologies explain why it is difficult to detect every known protein predicted by a global mRNA expression profile. In fact, when really deep proteomic coverage is done, it is possible to detect much of the cell's protein-coding transcriptome in protein [21]. So raising this concern over a transcript sounds critically scientific but it demands author's wasting precious resources and efforts doing parallel proteomics that ultimately are very superficial efforts (e.g. a Western blot or non-quantitative immunohistochemistry) and do little to advance the original insight. Honestly, if you have a documented coding mRNA transcript in a well-designed experiment that is validated by proper and conservative use of the latest generation of informatics tools for data analysis, there is protein.

However, the deal is completely different for alternative splicing. First, many alternative splicing events can lead to truncation of a transcript and prevent protein translation. But more importantly, there is just precious little information about what any given alternative splicing change does to a protein's function and almost nothing regarding its role in the complicated molecular pathways of a cell. For example, we can demonstrate conclusively that a given exon is spliced out of 25% of the transcripts in a particular cell population or tissue and observe that this exon contains an adaptor protein binding sequence or a tyrosine that is phosphorylated by activation. But at the current time, we can only guess at what these major structural changes mean to the cell's response in a given situation like immune activation of a memory CD4 T cell. So the second point is that discovering alternative splicing is only the first step and not particularly useful until we also understand what actually happens next in true functional and molecular terms. What is not in doubt, however, is that alternative splicing can create significant changes in a protein's function, location in the cell, ability to complex with other critical partners in a pathway, or recognition of cognate ligands and even regulate the half-life of the mRNA transcript. Figuring all this out for transplantation immunobiology and integrating these discoveries with existing knowledge is a remarkable scientific opportunity created by these new genomic technologies.

But it is instructive to add a note of caution too. These challenges for alternative splicing are a perfect example of one of the pitfalls in functional genomics research; whenever a new capability is realized by new technology there is a temptation to run out and just do a lot of profiles without taking into consideration the complexity of the endeavor in biological terms. However, with properly designed experiments and expectations, discovery profiling with new technology can be absolutely justified as a necessary first step; for example, to demonstrate the complex relationship between gene transcription and alternative splicing changes with T- and B-cell activation that we reported several years ago [4]. What is the point of gearing up to study alternative splicing in some comprehensive way without first using these new profiling technologies to establish at least the reasonable possibility that it is relevant to the biology we want to advance? But once such a proof of concept is established, the next series of experiments must be justified by the extent that they create new knowledge and in the case of alternative splicing that is no minor challenge. As long as we are clear about the objectives and relative value of any given set of experiments, deal properly with the limitations, and don't confuse using amazing new technology with magical knowledge, then this is how scientific work naturally evolves.

Comparison of microarrays to RNA deep sequencing

The obvious question at this point is which technology, deep sequencing or microarrays, should be used for gene expression profiling. The answer is "it depends."

The sensitivity for RNA deep sequencing is dependent on read depth. Thus, some experts originally concluded that with really deep sequencing many transcripts were identified that were never detected by microarrays. This was the beginning of the current view that microarrays are "on the way out" and that RNA deep sequencing revealed a whole new level of transcriptional activity. Ironically, this view also supported another incorrect view that RNA transcriptional profiling requires very deep sequencing depth so that these "hidden" transcripts can be detected and that deep depth is prohibitively expensive. The observation of low-level transcript detection by very deep RNA sequencing is absolutely true but the "devil" is hidden in the details. When you sequence well-characterized cell systems like cancer cell lines deeply enough it turns out that most of the low-level gene transcription detected may actually be only transcriptional noise and these often do not map to biologically significant pathways linked to the conditions being studied [22–24]. In fact, that is not surprising as we have known for many years that all genomic systems are "leaky" and that led us to the hypothesis of the "noisy transcriptome." We recently did extremely deep RNA sequencing on activated human T cells to demonstrate that much of this low-level transcription is indeed "noise" in functional terms and represents genes located in close proximity to highly transcribed genes and within their transcriptional insulator boundaries of the latter explaining the "leak" (manuscript submitted). We also demonstrated that most of these noisy transcripts are not detected by very deep proteomic coverage. Moreover, with the recent development of new directional sequencing methods, it was also realized that some of this low-level transcription is coming from antisense strands of coding genes. The putatively regulatory lncRNA transcripts discussed earlier are an example of what used to be thought was actual coding transcription. One practical impact of these insights is that very deep depth RNA sequencing coverage is not required for global gene expression profiling and suddenly the cost/value equation for arrays versus deep sequencing is changed dramatically.

At the present time, if your objective is to do simple global gene expression profiling, it actually matters very little whether you choose microarrays or deep RNA sequencing. This conclusion is based on a comparison study we recently completed for the NIH Clinical Trials in Organ Transplantation consortium (manuscript submitted). The details of the experimental workflows are very different but the resulting RNA profiling data is essentially the same. And contrary to the hype recently, deep RNA sequencing is not significantly more sensitive, more specific, or more reproducible than the latest generation of commercial microarrays. Of course, we cannot change the natural bias that a new technology with such potential must be magically powered or that being "cutting edge" for new grant applications demands the use of deep sequencing. But the simple truth is that the latest generation of commercial DNA microarrays is very powerful, easy to use, extremely cost effective, highly reproducible, can achieve fully automated throughputs of a 100 arrays in 2 days, and available to essentially every academic institution either locally in Cores or in commercial laboratories in the community as a service. Moreover, a cost comparison at Scripps of global RNA expression microarrays (Affymetrix ST 1.1^{ST} vs. deep RNA sequencing [Illumina HiSeq2000 with NuGEN library preparations and multiplexing]) reveals a per sample cost including labor of about $225 for microarrays and about $400/sample for deep sequencing.

On the other hand, it is also true that the depth of sequencing can be controlled during the design of a deep RNA sequencing experiment. Thus, it is possible to increase the effective sensitivity in order to detect transcripts that exist at very low copy number. This situation could be very important in profiling complex mixtures of cells, like a transplant biopsy, in which the effector cells under study represent only a very small fraction of the total cells being analyzed.

But, as we have discussed in detail above, once you want more than simple gene expression profiling, the situation is very different. Deep sequencing has huge advantages for the study of miRNAs, alternative splicing, genetic variations, lncRNA, and discovery of new RNA forms, as in ongoing projects in the ENCODE consortium. It is also not surprising that it is all evolving rapidly. Recently, a number of commercial automated instruments have been introduced that can produce the sequencing libraries for deep RNA sequencing and these have considerable promise to greatly lower the barriers, time, and labor costs. Another rapidly evolving area of technology for deep sequencing is represented by the IonTorrent instrument offered by Life Technologies, which uses a novel solid-state sequence detection protocol and can shorten the time of a sequencing run to less than a day from the current week required (http://www.iontorrent.com). And not to be out-competed, Illumina has introduced the latest version of TruSeq chemistry for sequencing on their MiSeq instruments, which accomplishes nearly equivalent shortening of the run time (http://www.illumina.com/systems/miseq.ilmn) and increases the read lengths to 250 bases (which can be run in a paired-end format to yield 500 bases of sequence per read). As one example of why this is important, such a significant increase in paired-end read coverage now allows sequencing of an entire VDJ region, and thus the ability to profile the recombinations in B-cell antibody production driven by antigen exposure after transplantation or blood transfusions.

Thus, before making a decision, you should consider the best options for your experimental questions with your functional genomics experts and the technology experts in your local Core Laboratory. A final thing to remember is that the coolest approach or technology is of no value unless you have access to technical expertise with real experience in performing these assays, designing experiments, and interpreting the results properly. Just buying instruments is not enough. Ultimately the considerations should be available expertise, workflow complexity, total costs, time and resources for experimental conduct, and resources available for data analysis.

Next-generation qPCR—digital and single-cell qPCR

As often happens during the rapid evolution of new technologies, new discoveries reveal new opportunities for older technologies to evolve and fill specific niches or requirements. In the case of microarrays and deep sequencing, the cycle of technology development has also turned back to create a new generation of quantitative PCR (qPCR) technologies. Thus, these new technologies should also be

part of the considerations for experimental design in mRNA transcription profiling. Profiling RNA transcripts using microarrays or deep sequencing has great utility for identifying relative changes in levels between different conditions or clinical states. And the obvious advantage is that they enable unbiased, global expression profiling and even discovery of new RNA forms by sequencing. But there are also several limitations to these technologies that can still be addressed better by qPCR.

First, arrays and sequencing are not strictly quantitative as qPCR can be, despite the claims that RNA deep sequencing is a form of "digital expression" data. If properly normalized, deep RNA sequencing data can give highly accurate comparisons of changes in a single transcript across many different conditions but more caution is necessary before assuming that comparisons of expression across thousands of genes is equally digital and precise. For example, we took a laboratory synthesized set of 400 miRNAs that were pooled at the same concentrations and used this as the "positive" control to benchmark a new multiplexing deep sequencing protocol we developed [25]. Instead of getting close to the same number of reads for all 400 miRNAs, as would be predicted for a "digital expression" technology, there was over a log difference in the number of reads obtained for each. We are still not certain what causes this surprising result.

Second, microarrays are based on capturing labeled mRNA by hybridization to complementary DNA or RNA probes and this is variable from sequence to sequence, creating data variability and the potential for selecting bad or low-performing probe sets. The good news is that RNA deep sequencing libraries are less subject to this limitation. On the other hand, RNASeq library preparation has multiple enzymatic and amplification steps that are vulnerable to sequence context-specific bias. Third, a qPCR can be done in less than an hour now, while most array-based and sequencing methods still require at least 1 or 2 days to complete and with much higher analysis costs. This makes qPCR a much more cost effective approach if you know the genes you wish to profile and this is particularly effective when applied to functional pathway-focused qPCR panels (e.g. Tregs, inflammation, apoptosis, NFκB signaling). Fourth, sensitivity for RNA transcript detection based on hybridization capture strategies on microarrays will always be significantly lower than sensitivity based on qPCR detection. This limitation is not an issue for deep RNA sequencing. However, if it is true that with deep enough sequencing that you can detect almost any transcript even if it has no biological function, one wonders how many times a study has depended on very high cycle PCR to detect transcripts as proof that a given pathway or gene was involved in some experimental event.

The first challenge in this new genomics era was to make qPCR technologies that could handle at least hundreds and even thousands of genes in a single run. One early example was qPCR instrumentation developed by Applied Biosystems to break the 96-well barrier and create 384-well qPCR plates (TaqMan Low Density Arrays; TLDA). These reactions could be done in as little as 1 microliter volumes to save significantly on reagent costs and time. We often use this technology to validate gene expression results obtained with microarrays for up to 100 gene candidates in a single run and more recently have tested it for validating alternative splicing results. However, the latest generation of ABI qPCR technology provides the OpenArray system that can generate over 30 000 data points in a single run and do up to a thousand genes easily.

The qPCR technology developed by Wafergen creates a chip that can run 5184 different qPCR reactions at once to enable profiling of a 1000 genes in quadruplicate. This technology is also done in nanoliter volumes, with significant potential for automation to high-throughput performance. Using a different platform but with similar objectives, Luminex has designed a strategy for high-throughput, multiplex, bead-based qPCR using their fluorescent bead technology. The advantage of this technology is that they claim they can multiplex up to 500 different qPCR assays in a single bead-filled well and easily run several hundred or more different clinical patient samples a day through their bead analysis instrument. The capabilities represented by these technologies will be critically important as the field of transcript profiling for biomarkers is translated into clinical diagnostics where cost, labor, and time become paramount. The reader should expect continued development in this area with new technologies and new companies.

Another new technology platform for qPCR, developed and implemented by Fluidigm as the BioMark system, takes advantage of microfluidics engineering to create a platform capable of doing 9216 qPCR reactions in nanoliter volumes in a single run with only several hours time. This system uses the ABI TaqMan technology for qPCR with nearly identical sensitivity and reproducibility. The first major advantage is the dramatic increase in the number of reactions done in a single run. In a standard configuration, the platform can do 96 different genes on 96 different samples (suitable for clinical biomarker profiling, for example) or 9216 genes on one sample or any combination of genes and samples possible with a 96×96 reaction well format. In fact, the microfluidic-engineered design creates the second major advantage, the exciting application of this new qPCR technology to do single-cell gene expression. This is enabled because the microfluidic chips in the BioMark instrument have multiple parallel sample sites that can be selectively piped to multiple reaction sites. Thus, using their 96×96 chip design, a researcher can profile 96 single cells for 96 genes that are measured on every individual cell in one run. This single-cell approach has started to reveal how diverse every different cell can be in a complex cell mixture. That is clearly critical for cancer cell mixtures where the behavior of a single malignant cell can change the entire outcome.

How single-cell profiling will inform the mechanisms of transplantation biology and immunology remains to be discovered. Thus, a key question is whether our biology is better represented by analysis of single cells or analysis of a whole population of cells in one big mixture. As already noted above, it is only when these technologies are available and investigators are willing to make the investments in time and work effort to develop these technologies for transplantation that we can even begin to ask these critical questions.

Non-PCR transcript detection and digital PCR

While we recognize the remarkable power and utility of PCR-based gene detection, PCR also has a number of limitations. First, the performance of PCR is significantly influenced by the target sequence just like the DNA hybridization approaches used for DNA microarrays and we suspect also the stepwise base pairing required for deep RNA sequencing. For every perfect PCR primer set, there are also sets that function less efficiently for the same target gene at target sequences just a few hundred bases in either direction or even when there are just a few base pair changes in

the sequence for the primer binding sites between two individuals due to inherited or acquired genetic differences. While we can almost always optimize PCR performance for a single reaction, the challenge is very different when we want to do hundreds or thousands of different PCR reactions at once and thus must do every reaction with the same reaction conditions. Second, one of the prices paid by PCR for high sensitivity is a higher degree of variation from reaction to reaction in the current detection technologies that are often accentuated by using log scales. This is why qPCR reactions are typically done in quadruplicates and the results used to create mean expression data. Third, the more cycles of PCR done, the greater the risk of differences in the underlying target sequences causing amplification biases. Thus, truly quantitative PCR-based approaches require parallel controls comprised of purified target sequences (typically cDNA clones of the gene) and serial dilutions of precisely determined concentrations for each gene. This need for gene-by-gene controls greatly complicates and limits the scope of any strategy to do absolutely quantitative, high-throughput, multigene qPCR profiling. In fact, streamlining of these challenges has not been created by any of the "next generation" qPCR platforms discussed above.

One solution to these limitations of PCR is offered by the Affymetrix Panomics Quantigene system where there is no PCR amplification required to detect as few as 200 total mRNA molecules in a single well. In this technology, gene-specific capture probes are first bound to the bottom of an assay well or to the surface of a Luminex bead. The sample is added to each well or to a mixture of many beads and hybridized to the capture probes overnight. In the next steps, a second set of probes binding the captured RNA is followed by branched chain DNA probes with many molecules of enzyme that when exposed to a soluble substrate creates the colorimetric or fluorometric quantifications. If it is not already obvious, this approach is essentially an ELISA assay using RNA probes instead of antibodies and it targets RNA transcripts instead of proteins. This technology is very useful for profiling several hundred genes in a single run, it is highly quantitative and can be implemented in both 96-well and Luminex bead formats. The one potential drawback for clinical diagnostic application is that it takes an overnight hybridization step and thus adds about a day in time to the current technologies used for qPCR. It is also presently not cost competitive with simple qPCR platforms.

Another solution to PCR amplification bias is a new generation of digital PCR technologies using emulsion PCR. In simple terms this involves creating tiny oil droplets and diluting the input total RNA target sample so that approximately one mRNA transcript is enclosed in each droplet. In effect, you have created a separate universe containing a single RNA target and can take the reaction to its maximum of 40 or more PCR cycles without any competition or any of the bias created by all the relative differences in efficiency between primer pairs for different gene sequences.

New technologies for digital PCR are using microfluidic engineering to create instruments capable of doing thousands of emulsion PCR reactions in a single run using microdroplets or a combination of droplets with tiny beads. For example, RainDance Technologies developed the RainDrop digital PCR system that can automate the creation of 10 million picoliter emulsion PCR droplets for eight different samples at a time and then detect the amplicons of 96 samples in a single run on a separate instrument. This platform is technically capable of using different fluorophores to do multiplexing so the platform could potentially allow profiling of several hundred genes in one sample or ten genes in multiple samples at once. Another emulsion-based PCR instrumentation is BioRad's QX100 Droplet Digital PCR, which has similar workflow capabilities to the RainDrop system though creates around 20 000 drops per sample. Statistically, BioRad maintains that 20 000 drops is more than enough to accurately produce digital data that captures the differential expression being interrogated and this is probably true for many situations. However, one potential advantage of the RainDrop system is that with so many drops to analyze, that optimization of the initial RNA input concentrations is not necessary and that might greatly improve the workflow.

It is too early to predict where digital PCR capability will fall in the current spectrum of using microarrays, RNA deep sequencing, and high-throughput quantitative PCR technologies. However, none of the other gene expression platforms are truly quantitative in their present forms. The key point is that if this new digital PCR technology fully delivers on its "digital" promise, then we will have the ability to absolutely quantify mRNA transcript numbers and their changes down to single cells with different experimental manipulations or disease states for thousands of genes in a single run. That is something to watch for with interest.

Technology and experimental designs

Ultimately, functional genomics and systems insights must be pursued and then validated with multiple technologies and the results from these multiple technologies can be integrated and conclusions tested mechanistically to achieve our objectives. But these technologies individually are complicated and all are evolving rapidly. The consequences are that the technology requires tremendous expertise to use properly. The first point for this section is that just giving a set of samples to a core laboratory with an order to run a particular technology and send back a spreadsheet of final results is simply not going to work. Scientists must be engaged enough to really understand the technology chosen and the data created, even if ultimately a set of technology experts and their core technicians still run the samples.

The fact that these genomic technology platforms are almost entirely driven, from instruments to kits, by the commercial life sciences companies adds yet another layer of hype, confusion, costs, and competition. If you read the advertisements, you can change your approach a dozen times a year and each time find "guarantees" of how wonderful the new data will be. But it is simply not true and these changes can dramatically undermine the value of your data, particularly if you need to compare experiments done in stages where data may be generated over a year or more. Thus, the second point is that when you create a strategy to address a scientific objective using functional genomics, you must commit to all the separate pieces of the experimental plan, not just the choice of the main instrument platform. The way the sample materials are collected, stored, purified, amplified, and labeled, even the manufacturers of the kits chosen are absolutely as critical to data integrity as the chip chosen. For example, we used to purify total RNA in a certain way that we all believed was necessary to "optimize" hybridization to DNA microarrays. We were very happy until one day we decided that we now wanted to also study miRNA and found out that using this technique was filtering away all the miRNA making our entire sample archive useless for this purpose!

Another point is that integrating data obtained by very different technologies requires integrating data obtained using very different

physical rules. For example, let us say we want to conclude something as basic as that when an RNA transcript was up-regulated that the up-regulated translation of a corresponding protein followed. The answer requires integrating hybridization-based DNA capture of a labeled RNA transcript on DNA microarray probes with ionization energy-mediated emission spectra created by mass spectrometry proteomics of peptides. Thus, we need specialists in bioinformatics to develop computational methods for successfully integrating the results from multiple technology platforms that can successfully find the intersections of very different kinds of data. What this means in practice is that real progress will take time, significant resources, and teams of scientists with the detailed domain knowledge to use these tools correctly. Frankly, all the technology has become the "900-pound gorilla" in the field. You can't ignore it; you have to deal with it. But it is definitely making an already remarkably complicated scientific challenge harder. Human nature is often to reject this kind of challenge and argue that the "gorilla" is not really important, "it is just a stupid animal" or technology is a distraction from "real science" or "I just hire professionals to run machines." This is not going to work for functional genomics any more than pretending that you just hire transplant surgeons to do the surgery. In the process of designing a strategy and interpreting the results, you must accept at least some "ownership" of the technologies you choose because they are complicated and changing constantly, and this is not a minor challenge.

Demonstrating the value proposition

If the complexity of functional genomics, both biology and technology, constitutes the first challenge, the second challenge is demonstrating the value proposition of the work. These compelling new views of biology beg the question of how functional genomics can be applied to change the practice of medicine. A powerful value proposition is that basic and translational scientists will be guided by functional genomics to the next generation of mechanistic insights into the biology of the cell or organism. These basic insights will come from many model systems as well as human subjects. Advancing a mechanistic understanding of biology in health and disease is critical and sufficient alone to justify the work. Good science is good medicine. But our ultimate success as a field will be judged in terms of the value proposition we create for patients, their families, the health care delivery system, and our Society. All our work is directly or indirectly funded by these expectations. There are many ways to deliver value from science but ultimately value must be delivered.

For example, let us say you decide that you are going to understand the molecular basis of chronic rejection mediated by B cells. We would all agree that this is a very worthy objective. Now consider the responsibility. No one starts off taking on such a huge task in one step. This is the kind of effort that rolls out in discrete stages, needs refinement, and is funded and published in stages. The facts that functional genomics is powerful, biology is complex, and the clinical challenge you choose is critical to medicine does not mean you can simply profile a bunch of biopsies or blood samples and have any useful answer or deliver any value proposition. In the design of any new functional genomics strategy, ask first what you expect to learn and how that work will contribute to a real calculation of value. Make this analysis with the help of experts in the technology or technologies you will use. Then you can design and power your studies to be successful.

Summary

We believe that functional genomics will drive discovery. To have value, this discovery must be informed by a pragmatic understanding of our clinical discipline of transplantation. If properly done, this will guide biomarker development in transplantation and both direct applications to practice and hypothesis-driven mechanistic studies about the nature of transplantation immunology, rejection, and tolerance. But we must stay firmly grounded in reality. The complexity of cell biology and immunology revealed by functional genomics today will require huge investments in research, the training of a new generation of clinical and basic investigators, and a reinvention of our current approach to experimental design before we really are the "masters of the universe."

Introduction

Organ transplantation has evolved into a successful standard therapy through progressive definition of the mechanisms of immune-mediated rejection and responsive development of therapeutic agents to counter alloimmunity. While all commonly used agents impair physiologic immune processes and are associated with off-target side-effects, they can be used successfully providing the practitioner has an understanding of their actions and can thus anticipate the adverse issues that may arise. Similarly, their adverse effects can be minimized through combination therapies that pair mechanistically complementary agents. This chapter will provide an overview of the mechanisms of action of the major immunosuppressants in common clinical use. It complements Chapters 98 and 101, which detail the clinical preparation specifically indicated or used off-label for transplantation, respectively. Pathways being exploited for agents still under investigation are covered in Chapter 18.

Steroids

Corticosteroids (CS), the product of the adrenal cortex, have broad immunosuppressive and anti-inflammatory effects, and were one of the first classes of drugs used to suppress immune responses [1]. Glucocorticoids (GC), representing both natural and synthetic steroids that activate gluconeogenesis, include prednisone and methylprednisolone, and are widely used as part of the immunosuppressive regimen to suppress transplant organ rejection. Despite their effectiveness in preventing acute rejection, they also lead to morbidity and probably mortality [2]. In particular, GC have various adverse effects on cardiovascular diseases, bone metabolism, and increased risk of infection [3]. As a result, starting in the late 1990s, GC doses have often been reduced, withdrawn, or discontinued in many induction and maintenance transplant immunosuppression protocols [4].

Structural and biochemical pathways

Prednisone is the most widely used GC and is metabolized in the liver, primarily to prednisolone, its major active metabolite. As shown in Figure 17.1, unbound steroids passively diffuse through the cell membrane into the cell, and corticosteroid-binding globulin (CBG)-bound steroid can also enter cells via receptor-mediated transport or endocytosis [1,5–7]. In the cytosol, steroids bind to and activate glucocorticoid receptors (GR), and then the receptor dimers interact with glucocorticoid response elements in various gene promoter sequences to regulate immune gene expression [1,5]. GC suppress multiple inflammatory pathways. They induce and activate annexin I, a molecule that interacts with and inhibits cytosolic phospholipase A2α, to block release of other proinflammatory molecules. GC also induce and activate MAPK phosphatase 1, and consequently inhibit the MAPK signal cascade-mediated inflammatory responses. GC directly interfere with NF-κB signal pathways to suppress expression of inflammatory cytokines, chemokines, cell adhesion molecules, complement factors, and other inflammatory mediators [5]. As a result, GC preferentially block proinflammatory Th1 and perhaps Th17 cytokines, promote Th2 cytokine production [8], and maintain or increase interleukin-10 (IL-10) production to benefit transplant graft survival [9,10].

Cellular targets

The mechanisms and cellular targets of GC are highly variable and remain incompletely understood. They induce apoptosis of T lymphocytes [11] and down regulate gene expression of cytokines and adhesion molecules in a variety of cell types as discussed above [12,13]. In addition to genomic actions (transactivation and transrepression) mediated by the cytosolic GR, GC also suppress immune responses by non-genomic mechanisms, including a direct interaction of the GR with cytosolic signaling molecules, the intercalation of glucocorticoids into the plasma membrane, and the activation of endothelial nitric oxide (NO) synthase [14–16]. GC anti-inflammatory properties include suppression of prostaglandin synthesis, stabilization of lysosomal membranes, reduction of histamine and bradykinin release, suppression of dendritic cell antigen presentation, and suppression of CD4 T-cell proliferation, trafficking, and activation [17,18].

Adaptive immunity

GC suppress antigen presentation by dendritic cells (DC), decrease circulating $CD4^+$ T cells, and suppress IL-1 production and lymphocyte activation [17,18]. Higher doses of GC inhibit B-cell

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

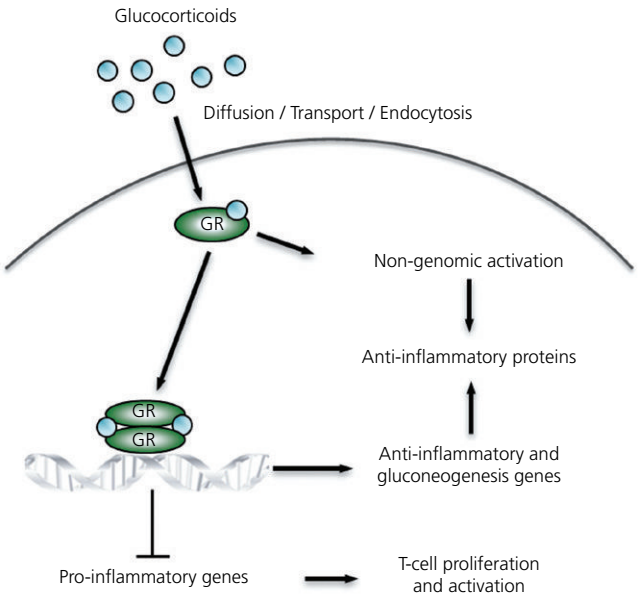

Figure 17.1. Mechanism of action of glucocorticoids. Unbound steroids passively diffuse through the cell membrane into the cell, and corticosteroid binding globulin (CBG)-bound steroids can also enter cells via receptor-mediated transport or endocytosis. In the cytosol, steroids bind to glucocorticoid receptors (GR), then the activated receptor dimer translocates into the nucleus, where it binds to glucocorticoid response elements (GRE) in the promoter sequence of the target genes, resulting in transactivation of gene expression. The activated receptor also interacts with specific transcription factors (such as AP-1 and NF-κB) and prevents the transcription of target genes. The net result is decreased proinflammatory cytokine production, lymphocyte proliferation, and changes in cellular trafficking.

production of immunoglobulins [19,20]. Thus, GC suppress diverse aspects of adaptive immunity.

Innate immunity

GC reduce neutrophil trafficking from blood vessels, and reduce their adherence to vascular endothelium and bactericidal activity [19]. GC limit chemotaxis, phagocytosis, and the release of cytokines such as TNF-α and IL-1 from macrophages and other antigen-presenting cells, and repress the expression of inflammatory mediators such as prostaglandins, leukotrienes, and platelet-activating factor [19]. Thus, GC also inhibit a vast and diverse array of innate immune mechanisms and effectors.

Infection

As noted above, GC suppress both adaptive and innate immunity, and thus are associated with an increased risk of infections. Acceleration of hepatitis C virus (HCV) infection is a major concern with GC [21]. Tapered GC usage and steroid-free regimens reduce the incidence of fibrosis related to HCV reinfection, cytomegalovirus (CMV) infection, and HCV recurrence [22–26].

Wound healing

Macrophages are essential for wound healing. GC inhibit circulating monocytes, the influx of macrophages, growth factor and cytokine production, and phagocytosis [27–30], all of which adversely affect wound healing. GC also diminish wound healing by delaying re-epithelialization, decreasing the fibroblast response, slowing capillary proliferation, and inhibiting collagen synthesis and wound maturation [27,29,31].

Table 17.1. Common complications of glucocorticoids

Organ/system	Complications
Endocrine and metabolic	Adrenal suppression, hyperglycemia, water retention, growth failure in children
Hematopoietic	Leukocytosis
Immune	Bacterial, fungal and viral infections, delayed wound healing, suppression of type IV hypersensitivity
Gastrointestinal	Gastric irritation, peptic ulcer
Cardiovascular	Hypertension, myocardial infarction, and cerebrovascular disease
Skin	Dermal thinning, skin fragility, ecchymosis, violaceous striae
Musculoskeletal	Osteoporosis, avascular necrosis, myopathy
Ophthalmic	Cataracts, glaucoma
CNS/psychiatric	Sleep disturbances, insomnia, euphoria, depression, mania, psychosis, obsessive behaviors, pseudotumor cerebri
Reproductive	Impotence, menstrual irregularity
Morphologic	Moon facies, dorsocervical hump, truncal obesity

Metabolism

GC are associated with many adverse effects (Table 17.1) related to their primary activity of inducing multiple processes related to gluconeogenesis. GC may lead to Cushingoid changes, hyperglycemia, decrease in bone density, avascular necrosis, cataracts, glaucoma, dermal thinning, skin fragility, ecchymosis, violaceous striae, hypertension, water retention, adrenal insufficiency, and secondary cardiovascular complications including myocardial infarction and cerebrovascular disease [20].

Calcineurin inhibitors

Introduction

Calcineurin inhibitors (CNIs) have been the mainstay of maintenance immunosuppression in transplant medicine since the introduction of cyclosporine A (CsA) [32–34]. CNIs work by suppressing activation of T cells and the transcription of cytokines by blocking the interaction of calcineurin with its substrate, the nuclear factor of activated T cells (NFAT) [35–37]. Clinically, CNIs are well tolerated; however, they may be associated with nephrotoxicity and islet toxicity [38–40]. Additionally, they have been associated with wound complications, particularly when used in combination with mTOR inhibitors [41]. For these reasons, many groups have recently focused on limiting the role for CNIs in the transplant population [42–44]. This section of the text will focus on the structure, function, and pharmacology of these frequently utilized drugs.

Structural and biochemical pathways

An understanding of calcineurin and its role in immunomodulation is a requisite for an understanding of CNIs. Calcineurin, a protein phosphatase, is calmodulin and calcium dependent [45,46]. It is a heterodimer that contains an active domain in addition to an autoinhibitory domain, and mutant calcineurins without this autoinhibitory domain are persistently active [45,46]. T cells are

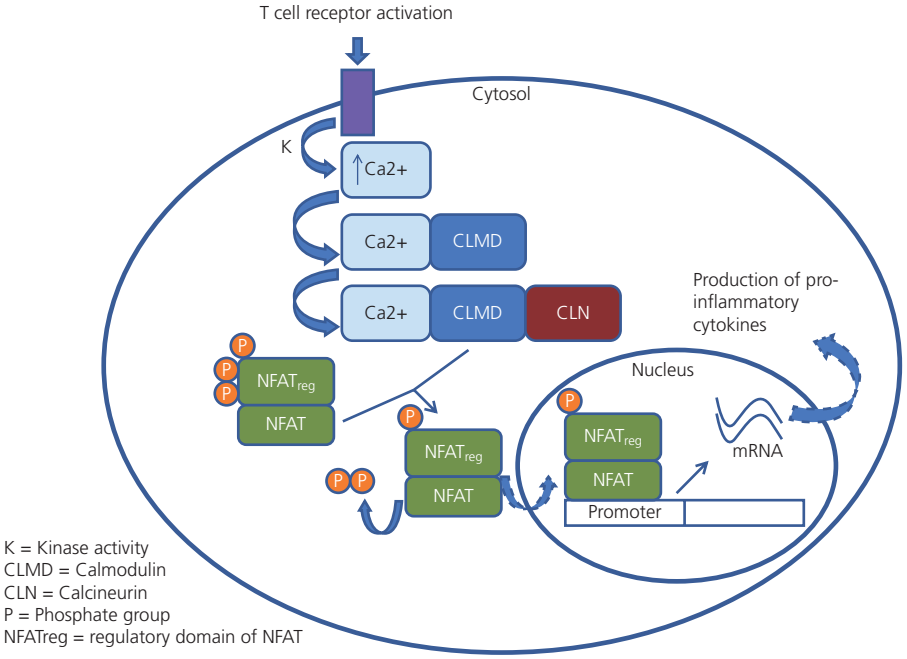

Figure 17.2. T cells are activated by cell surface receptors, leading to increases in intracellular levels of calcium. Calcium–calmodulin activates the phosphatase activity of calcineurin, which activates NFAT by cleaving PO_4 from the regulatory domain of nuclear factor of activated T cells (NFAT). NFAT is then translocated from the cytosol to the nucleus, where the dephosphorylated, and now nuclear, NFAT acts as a transcription factor for various immunologically important genes.

activated by cell surface receptors, leading to increases in intracellular levels of calcium. Calcium–calmodulin–calcineurin signaling then activates NFAT [47]. The NFAT family, which is comprised of at least five members, is a group of transcription factors that induce the genes encoding cytokines and chemokines associated with inflammation (Figure 17.2) [47,48]. Mice deficient in just two of these family members (NFAT1 and NFAT2) are essentially devoid of the ability to produce cytokines [48]. Calcium activates the phosphatase activity of calcineurin, which cleaves PO_4 from the regulatory domain of NFAT. This sets in motion a cascade of events during which a nuclear export signal binds Crm1 (also called nuclear export receptor), leading to the translocation of NFAT into the nucleus, wherein the dephosphorylated, and now nuclear, NFAT acts as a transcription factor for various immunologically important genes [48].

Tacrolimus (also called FK506) and CsA bind to different intracellular targets called immunophilins. Specifically, CsA binds cyclophilins and tacroimus binds FK-binding proteins (FKBPs) [35]. Despite these differences, both exert their immunosuppressive effect through inhibition of the calcineurin–calmodulin moiety by forming drug-dependent complexes [35,49].

Cellular targets

Most notably, CNIs act to suppress the proliferation and activation of T cells. This effect is exploited by transplant physicians trying to quell antidonor T-cell responses. CNIs, specifically tacrolimus, inhibit the ability of T-cell-dependent cytokine production, including IL-2, 4, 5, TNF-α and INF-γ, which are required signals for T-cell help and T-cell proliferation [50–52]. Interestingly, the CNI effect on T cells may be specific for the alloreactive population. Additionally, CNIs may potentiate T regulatory cell function, particularly in autoimmune skin disorders, although this point has been controversial [53–55]. CNIs affect both mature and immature T cells and are capable of inhibiting the development of not only $CD4^+$ but also $CD8^+$ single-positive lymphocytes from double-positive precursors during positive selection [56], likely enhancing their immunosuppressive efficacy.

The most obvious way in which CNIs affect B cells is through inhibition of T-cell help and immunoglobulin class switching [50,57]. Thus, CNI effects on B cells are largely indirect. In an in vitro system, in which either tacrolimus or CsA was co-cultured with T cells and B cells, immunoglobulin production was subsequently reduced. However, the same was not true when T cells were removed from the co-culture and B cells alone were co-cultured with tacrolimus and CsA. In the latter case, tacrolimus failed to suppress immunoglobulin production. CsA only modestly reduced immunoglobulin production [50]. Other reports suggest that CsA may indeed have direct effects on B cells. Cyclophilin B, an intracellular target of CsA, is involved in protein folding and may be inhibited by CsA [58]. In B cells, this inhibition leads to dose- and time-dependent decreases in IgG biosynthesis [59]. In the same study, CsA had no effect on transcription of IgG; rather, the reduction in biosynthesis was mediated by endoplasmic reticulum stress [59].

Neutrophil function is also affected by CNIs. These effects have been studied in parallel with angiotensin II in an in vitro model of vascular injury. Because angiotensin II up-regulates activity and synthesis of calcineurin, and is associated with neutrophil activation in the endothelium, investigators hypothesized that CsA might decrease neutrophil activation by inhibiting upstream

events. Experimentally, CsA decreased activation of angiotensin II-stimulated neutrophils by inhibiting both the MAPK and ERK pathways [60]. In the same system, CsA was shown to inhibit the translocation of Rac2, a molecular switch thought to lead to release of proinflammatory reactive oxygen species [61], from the cytosol of human neutrophils to the nucleus [62]. Impaired translocation was a downstream effect of inhibition of angiotensin II, a known stimulus of Rac2. Thus, CsA interferes with angiotensin II-stimulated neutrophils, a process which is critically dependent on translocation of Rac2 [60].

CNIs also reduce cytokine production, including INF-γ, from T cells. Because INF-γ is a powerful stimulus of macrophages, CNI downstream effects include the suppression of monocytes and macrophages. The direct effect that CNIs have on monocytes and macrophages may be limited [52]. In a rodent study of spontaneous ulcerative colitis, investigators noted that tacrolimus inhibited mucosal T-cell activation rather than mucosal monocyte and macrophage activation, and that macrophage activation was lessened by the addition of CNIs [52].

Effect on parenchymal cells

CNIs have well-known toxicity to endothelial cells [63,64], a pathology thought to underlie cardiac allograft vasculopathy. When bovine aortic endothelial cells were cultured with CsA, time- and dose-related cellular damage (and eventual cytolysis), characterized by increased levels of eluted lactate dehydrogenase, prostacyclin, and thromboxane [64], was observed. These deleterious effects of CsA on endothelial cells were likely due to alterations in nitric oxide (NO) and endothelin-1 (ET-1) regulation, which subsequently impair vascular vasodilatation. Interestingly, when investigators evaluated rapamycin, which is not known to lead to allograft vasculopathy, the same alterations in NO and/or ET-1 were not observed [65]. Because NO and ET-1 endothelial dysregulation led to the production of inflammatory cytokines, it is hypothesized that suppression of this system through the endothelial growth factor may abrogate calcineurin-related vasculopathy [66]. Indeed, in an in vitro model using human endothelial cells, investigators observed a significant decrement in CsA and tacrolimus-induced cell adhesion when cells were concomitantly cultured with endothelial growth factor 7, and thus concluded that targeting these pathways may be beneficial for cardiac transplant [66].

CNIs are known to be nephrotoxic [67,68]. CNIs have been shown to decrease both tubular and glomerular function [69], and that this decrease may be due to aquaporin gene down regulation and decreased protein expression [69,70]. In addition to their effects on urinary production and collection, both CsA and tacrolimus have been shown to be mitogenic for renal mesangial cells, likely through an extracellular-signal-regulated kinase pathway (ERK) [71]. Results have also implicated both endoplasmic reticulum stress and up-regulation of CD147, which is associated with renal fibrosis, in the development of CNI-induced nephrotoxicity [58].

It has long been reported that CNIs inhibit islet function [72]. CNI-related decreases in islet function are partially due to the involvement of calcineurin in insulin release [73]. When beta cells were cultured with tacrolimus and CsA at supratherapeutic levels both drugs led to a 48–69% decrease in basal insulin production in the steady state. In addition, tacrolimus was noted to have an acute effect at supratherapeutic levels, dropping insulin release by 61–87%. The diabetogenic effects of tacrolimus and CsA are due not only to calcineurin inhibition, but also to the islet-specific down-regulation of the transcription factor SREBP-1c, which is known to control beta cell function. In addition, both drugs are cytotoxic and lead to islet apoptosis [72].

Functional pathways of immunity (adaptive response, ischemia reperfusion injury, infection)

The ability of CNIs to inhibit T-cell activation, proliferation, and downstream activation of macrophages underlies the beneficial antirejection effects observed clinically, but portend potential morbidity manifested by inhibition of the adaptive and innate immune responses to pathogens. In toxicity studies comparing CsA with FK506, CsA was associated with a higher risk of overall infection, and the highest risk of opportunistic infection, in a dose-dependent manner [74]. Conversely, CNIs may have other immunologic effects, unrelated to transplantation, such as improvement in focal and global ischemia, as well as improvement in ischemia–reperfusion injury [75,76]. Improvements in ischemia are thought to be related to the ability of CNI to inhibit nitric oxide synthase [75], preventing oxidative stress, and subsequent prevention of DNA damage and lipid peroxidation [75]. Based on these and other data, a randomized controlled trial was performed in which pretransplant donor livers were perfused with tacrolimus at 20 ng/mL and compared with grafts perfused without tacrolimus [77]. Investigators found no difference in graft outcomes, but did observe decreases in ischemia–reperfusion injury at the molecular level [77].

Non-immune functions (metabolism, wounds/healing, tumors/proliferation)

CNIs have been associated with poor wound healing, neurotoxicity, nephrotoxicity, hypercholesterolemia, hypertriglyceridemia, and cholestasis [67,74,78]. With regard to wound healing, CsA is known reduce fibroblast-derived growth factors, specifically activin-β. CsA has little or no effect on fibroblast TGF-β or integrin-1, despite its other immunologic effects [79]. Post-transplantation hyperlipidemia (PTHL) is a well-described finding. While steroids have a well-known association with PTHL, the role that CNIs play is less clear [80]. Interestingly, CsA (but not tacrolimus) has been shown to increase total cholesterol as well as low-density lipoproteins (LDL), with a peak occurring 1 month following transplantation [81]. Interestingly, there was no concomitant increase in high-density lipoproteins (HDL) at the same time point [81]. Other groups that have observed similar results have shown that the improvement in lipid levels with tacrolimus over that of CsA may be due to alterations in LDL oxidation [82]. Neurologic complications are well documented after introduction of CNIs. These effects may be the result of: (1) binding of CNIs to intracellular substrates used for other physiologic processes, (2) vasoconstriction, (3) endothelin production, and/or (4) production of excessive reactive oxygen species [83].

Malignancy is also a risk of immunosuppression [84]. The most common malignancies following renal transplantation are skin cancer and non-Hodgkin's lymphoma [84]. Skin cancers affect approximately 7% of patients following kidney transplantation after 3 years; additionally, approximately 7% of patients also develop non-skin cancers, of which non-Hodgkin's lymphoma is the most common [84]. Interestingly, although tacrolimus is more efficacious in preventing rejection, it does not appear to lead more frequently to malignancies [85]. Although it is convenient to attribute the increased risk of malignancy following transplantation to

immunosuppression, some data also suggest that the rate of malignancy amongst kidney transplant waitlist patients is higher [86]. Additionally, the types of cancer that patients with end-stage renal disease (ESRD) develop is similar to the pattern observed in post-transplantation patients [86]. The neoplastic risk of ESRD may be a result of genotoxic uremic toxins and possibly increases in oxidative stress [87]. The malignant potential of CNIs may be related to regulation of the nuclear factor of kappa B cells (NF-κB), which is known to modulate growth factors and apoptotic mechanisms leading to cancer [88,89].

mTOR inhibitors

The profound effects of rapamycin on proliferation in a variety of cell types led to elucidation of the mammalian (or mechanistic) target of rapamycin (mTOR). mTOR is a serine/threonine protein kinase that acts as an integral component of two distinct signaling complexes (mTORC1 and mTORC2) involved in multiple pathways regulating cellular metabolism, activation, and proliferation [90–94]. Currently available inhibitors of mTOR (mTORi), including rapamycin (sirolimus) and everolimus, block mTOR activation, inclusion in the mTORC1 complex, and subsequent kinase activity, preventing the conversion from catabolic to anabolic metabolism [90,95]. In addition, there is evidence that mTORi are capable of blocking mTORC2 signaling in some settings, and that this blockade can further impact cell function [96]. Overall, current pharmacologic mTORi demonstrate broad suppression of cell proliferation, particularly proliferation induced by exposure to growth factors [90–94] (Figure 17.3).

While mTOR is a ubiquitous cellular signaling component, the significant increases in cellular metabolic demands associated with immunity results in a preferential reliance of immune cells on mTOR activation for immune cell survival and function. As a consequence, mTOR inhibitors exhibit significant immunosuppressive capabilities, particularly when combined with drugs targeted to alternate pathways of immunosuppression, such as mycophenolate mofetil [97,98]. However, recent studies have demonstrated that inhibition of mTOR can also result in enhanced production of inflammatory cytokines by cells of the innate immune system and enhanced adaptive immune memory. These contradictory results suggest that mTOR has multiple complex roles in immunity.

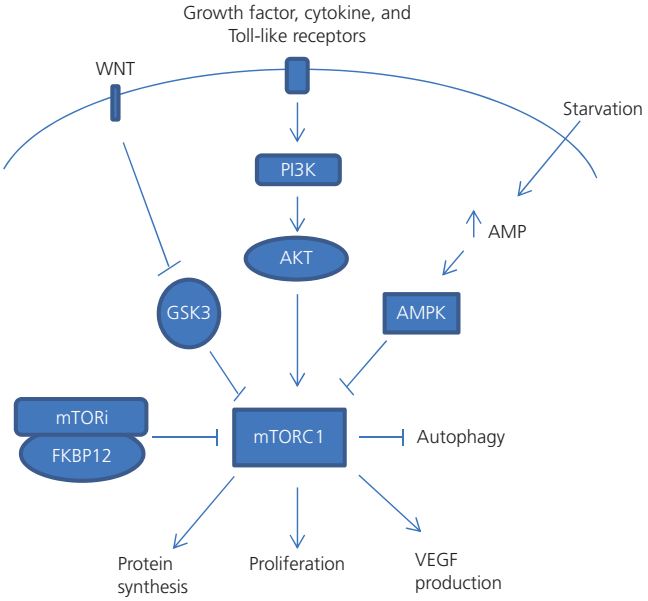

Figure 17.3. Activators and inhibitors of the mTOR signaling pathway. Activation of the mTORC1 signaling complex results in cell growth through enhanced protein synthesis and cellular proliferation and inhibition of autophagy. Simultaneously, mTORC1 induces production of other factors, including VEGF, that allow tissue remodeling and repair. Complexes of mTORi and the intracellular protein FKBP12 inhibit mTORC1 function. Endogenous regulators such as glycogen synthase kinase 3 (GSK-3) and adenosine monophosphate activated kinase (AMPK) can also block mTORC1 activity. Signaling through WNT receptors inhibits GSK3 activity while AMPK activity is only activated by increased AMP concentrations associated with energy depletion. Activation of mTORC1 can occur through AKT activation via phosphoinositide 3-kinase (PI3K) signaling activated by receptor recognition of growth factors, cytokines, and Toll-like receptor ligands (such as lipopolysaccharide).

Cellular targets

T cells are a major participant in graft rejection. The capacity of mTORi to decrease proliferation of T cells is well recognized and thought to play a vital role in mTORi-mediated immunosuppression. Inhibition of T-cell proliferation is associated with cell cycle arrest in the G1 phase and with a severe reduction in protein synthesis. In addition, antigenic stimulation of T cells in the presence of mTORi has been shown to result in hyporesponsiveness to subsequent stimulation, termed anergy [99,100]. Finally, new data suggest that mTORi can affect T-cell trafficking, mediating immunosuppression through sequestration of T cells within lymphoid tissue [101].

The mTORi-mediated induction of anergy is linked to an increase in the induction and/or survival of $FOXP3^+$ regulatory T cells (Tregs) [102–109]. There is evidence for a positive effect of mTORi on both de novo induction of FOXP3 expression and regulatory function in T cells, and preferential survival of established regulatory T-cell populations [102,107,110,111]. In the latter case, there are suggestions that Treg may utilize alternate signaling pathways for modulation of metabolism [110]. Overall, this suggests that mTORi change the balance of effector to suppressor T cells in favor of suppression.

Interestingly, mTORi treatment can also increase memory formation following antigen-specific stimulation of T cells. Memory enhancement has been shown clearly in multiple systems, and is thought to account for the enhanced accumulation of memory phenotype cells after induced lymphopenia in transplantation [109,112–115].

Like T cells, B lymphocytes appear to rely on mTOR signals for development and generation of effector functions. Interestingly, studies have demonstrated that both inhibition of mTOR signaling [116] and constitutive mTOR signaling [117] can negatively impact B-cell development and activity. These findings suggest that under normal circumstances, carefully controlled mTOR signaling is vital to B-cell function. However, many aspects of the mTORi–B-cell interaction in immunosuppression remain unexplored.

In addition to the significant role of mTOR in adaptive immunity, it also appears to play vital roles in inflammatory processes within innate immune cells. Inhibition of mTOR has been shown to decrease the number of circulating neutrophils and inhibit

neutrophil GM-CSF associated tissue migration [118]. For antigen-presenting cells such as DC and monocytes/ macrophages, the effects of mTOR inhibitors are complex. Studies that examined the effects of mTOR inhibition on antigen presentation by DC have suggested that mTOR activation is a necessary component of DC maturation and subsequent activation of T cells. DC treated with rapamycin demonstrated a reduced capacity to increase expression of costimulatory molecules in the presence of inflammatory signals normally associated with DC maturation, including GM-CSF, IL-1, and IL-4. This reduced capacity for DC maturation following mTORi treatment has been suggested to be involved in the production of Tregs.

In contrast, treatment with mTORi has also been shown to increase DC and monocyte production of inflammatory cytokines, including TNF-α, IL-6, IL-12, and IL-23, while blocking production of the anti-inflammatory cytokine IL-10 [119]. Further, mTORi treatment has been reported to inhibit the immunosuppressive effects of corticosteroids [120]. Thus, mTORi can have both anti- and proinflammatory effects on DCs and monocytes [121,122].

Finally, parenchymal cells are a vital component of inflammation and they are also modulated by treatment with mTORi [123–125]. Indeed, mTORi appears to strongly regulate the capacity of tissue cells to participate in inflammation with significant effects on tissue destruction, remodeling, and healing. Specifically, mTORi has been shown to decrease the responsiveness of fibroblasts to wound-associated growth factors, preventing cell replacement and wound closure [126,127]. This inhibition is accompanied by a reduction in VEGF production at the wound, with a concomitant loss in vascular tissue recovery [128].

Adaptive immunity

The effects of mTORi on individual components of the immune system outlined above predict the complex effects observed on adaptive immune responses. As previously mentioned, mTORi has significant immunosuppressive effects on lymphocyte-mediated graft rejection, while enhancing the development of CD8 T-cell memory [109,112–115]. This finding is true for both antigen-specific T-cell responses and memory phenotype T cells generated by homeostatic expansion [113], both of which can occur in a transplantation setting. Overall, it is clear that mTORi contributes to general immunosuppression and as such acts in conjunction with other immunosuppressants to increase susceptibility to infection, while also lowering the risk of infection with specific pathogens (see the infection section below).

Ischemia–reperfusion inflammatory responses

Several groups have demonstrated that mTOR signaling is critical for the protective effects of ischemic preconditioning and/or insulin on ischemia–reperfusion injury (IRI). As such, it might be expected that mTORi treatment could exacerbate IRI and enhance the inflammatory events associated with IRI. However, there is also some evidence to suggest that mTORi may act to inhibit IRI [129]. Further work will be required to determine the exact interplay between mTORi treatment and IRI.

Infection

Interestingly, the contributions of mTORi to development of CD8 T-cell memory appears to ameliorate transplant immunosuppression associated development of post-transplant lymphoproliferative disease (PTLD) [130,131] and cytomegalovirus infections [132]. Thus, while mTORi-mediated immunosuppression, like other immunosuppressive drugs, may play a role in allowing opportunistic infections, its inclusion in an immunosuppression regimen clearly decreases the susceptibility of the patient to specific pathogens.

Metabolism

As a vital component of cellular metabolism, it is not surprising that mTORi can have significant pathological effects on metabolism and homeostasis. Administration of sirolimus produces dose-dependent dyslipidemia, and can contribute to cardiovascular morbidity [133]. There is strong evidence that mTORi treatment increases the incidence of post-transplant diabetes [134,135]. Studies in preclinical models suggest that the diabetogenic effect of mTORi is mediated both through reduced insulin sensitivity and disruption of beta cell function and/or survival [135].

Wounds/healing

The powerful antiproliferative effects of mTORi are clearly seen in the wound healing process. Treatment with sirolimus increases surgical wound complications by interfering with several aspects of the healing process [125,136–139].

Tumors/proliferation

mTOR is a vital component in angiogenesis and growth factor-mediated proliferation. These functions appear to contribute to the association of mTORi with a significant decrease in tumor incidence associated with transplantation [140,141]. Further, there is evidence to suggest that mTORi-induced CD8 T-cell memory enhancement can result in immunological control of tumors in some settings. mTORi are now being investigated for use in the treatment of a variety of different tumor types.

Purine analogues

Purine analogues are chemicals mimicking the structure of essential building blocks of DNA and RNA. By impeding synthesis of DNA, RNA, and other nucleotides, as well as protein, they inhibit cell proliferation and immune responses. Azathioprine (AZA), and 6-mercaptopurine (6-MP) are purine analogues that are widely used as immunosuppressants and anti-inflammatory reagents for preventing organ transplant rejection. 6-MP and AZA were introduced clinically by Sir Roy Calne, the British pioneer in transplantation. Dr Thomas Starzl introduced the concept of using AZA plus steroids in transplantation. AZA is a prodrug of 6-MP with less toxicity, and after oral ingestion, AZA is metabolized into the active 6-MP. Other related compounds in the purine pathway are mycophenolate mofetil (MMF) and mycophenolic acid (MPA), with MPA being the active metabolite of MMF. Through inhibiting inosine monophosphate dehydrogenase (IMPDH), and thus repressing de novo synthesis of guanosine nucleotides [142], MMF inhibits cell proliferation. While other cell types can use the salvage pathway for guanosine nucleotide synthesis, lymphocytes depend on IMPDH for de novo synthesis, therefore MMF is a more specific and potent drug than AZA in suppressing purine synthesis. As a result, MMF has substituted AZA in many transplant centers in recent years.

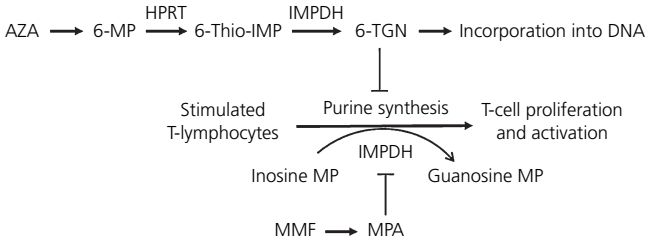

Figure 17.4. Mechanism of action of AZA, 6-MP, and MMF. AZA, Azathioprine; 6-MP, 6-mercaptopurine; HPRT, hypoxanthine phosphoribosyl transferase; 6-Thio-IMP, 6-thioinosine 5′-monophosphate; IMPDH, inosine monophosphate dehydrogenase; 6-TGN; 6-thioguanine nucleotide; MMF, mycophenolatemofetil; MPA, mycophenolic acid.

Structural and biochemical pathways

As shown in Figure 17.4, after AZA is absorbed, it is metabolized into its active form 6-MP, which is further metabolized into 6-thioguanine nucleotide (6-TGN) through 6-thioinosine 5′-monophosphate (6-Thio-IMP). 6-TGN can incorporate into DNA and RNA and act as an antagonist to the endogenous purines that are essential for the S phase of the cell cycle, and thus directly block cell proliferation. Studies of 6-MP in murine leukemia cells showed that cell death was consistent with a mechanism caused by DNA damage due to incorporation of 6-TGN into DNA. 6-TGN can also inhibit endogenous purine synthesis, alter the synthesis and function of RNA and DNA, and, as a result, prevent cellular and especially lymphocyte proliferation. For MMF, it is metabolized into its active form of MPA. MPA acts as a non-competitive inhibitor of inosine monophosphate dehydrogenase (IMPDH), consequently suppressing de novo synthesis of guanosine nucleotides [142] to specifically target lymphocyte proliferation (Figure 17.4).

Cellular targets

After transplantation, host immune cells will respond to alloantigen, proliferate, and mount immune responses to reject and destroy transplant organs. The main target for AZA and MMF is cell proliferation, thus preventing the clonal expansion of lymphocytes in the induction phase of the immune response, and suppressing both cellular and humoral immune responses. AZA/6-MP converts CD28 costimulation signals into apoptotic signals. Specifically, AZA/6-MP generated 6-thio-GTP binds to the GTP-binding protein Rac, thus blocking Rac1 activation, which prevents the activation of Rac1-regulated genes such as MEK, NF-κB, and Bcl-xl, and ultimately leads to a mitochondrial pathway of apoptosis. It has also reported that 6-TG blocks GTPase activation via blockade of Vav activity on Rac proteins, interfering with the interaction between T cells and antigen-presenting cells (APCs), and thus blocking immune activation [143].

The interactions between 6-MP and DC differentiation and activation were recently examined. It was shown that 6-MP inhibits DC differentiation from CD14 precursors and reduces LPS-induced CD83 expression [144]. Since CD83 is a marker of DC maturation and facilitates interaction between APCs and T cells, influences MHC class II turnover on the DC cell surface, and determines $CD8^+$ T-cell survival during immune responses [145–147], down-regulation of CD83 by 6-MP results in impaired allogeneic and antigen specific T-cell proliferation [144,148]. 6-MP reduces DC CCR7 expression, which is critical for lymph node homing. Together these reports all suggest that AZA suppresses immune responses also by modulating DC maturation and activation [144].

MMF exerts antiproliferative effects, especially on T lymphocytes by IMPDH. Two isoforms of IMPDH have been identified, and activated T lymphocytes strongly express type II, which has fivefold higher affinity than IMPDH I for MPA. MPA is able to increase apoptosis from 12% to 82–92% in cultured MOLT-4 cells [149], and accelerates the elimination of superantigen-reactive T cells by triggering apoptosis in both mice and humans [150,151]. MPA inhibits IMPDH and endogenous purine synthesis, depleting GTP, and consequently interfering with the transfer of mannose and fucose to lymphocyte glycoproteins [142], components of adhesion molecules for lymphocytes. MPA decreases attachment of human T lymphocytes to human endothelial cells, and treatment of both T cells and endothelial cells with MPA results in further decreases in adhesion, indicating that MPA affects immune responses through endothelial cells [152]. MMF significantly reduces ICAM-1 expression, LFA expression, and LFA^+ cell infiltration in various transplant and inflammation models [153–157], supporting a mechanism of MMF-mediated immune suppression through inhibition of adhesion molecule expression and immune cell migration.

MMF reduces CD40 and CD86 expression, and LPS-induced IL-12 production, leading to the decreased ability of murine DC to stimulate allogeneic T cells [158]. In human monocyte-derived DC cultures, MMF reduces the number of immature DC, induces apoptosis, down regulates costimulatory and adhesion molecules such as CD40, CD54, CD80, and CD86, lowers production of TNF-α, IL-10, IL-12, and IL-18, and inhibits stimulation of alloreactive T cells [159]. Together, these results indicate that MMF suppresses immune responses by affecting DC differentiation and activation.

MPA lowers GTP levels in monocytes [142], decreasing mannosylation of glycoproteins and monocyte attachment to endothelium [160,161]. Similar to the proapoptotic effects in lymphocytes, MMF induced apoptosis in THP-1 and U937 monocyte cell lines, and prevents glomerular macrophage infiltration in streptozotocin-induced diabetes [149,162]. Together, these results indicate that MMF can directly attenuate monocyte and macrophage responses.

Adaptive immunity

As noted above, purine analogues and related drugs directly inhibit lymphocyte proliferation, and therefore suppress induction phases of adaptive immunity via both humoral and cellular immune responses. These compounds also affect APCs, particularly a variety of DC functions, and thus interfere with interactions between lymphocytes and APCs, to suppress adaptive immune responses.

Innate immunity

AZA and MMF inhibit DC differentiation, adhesion molecule expression, maturation, and cytokine expression to suppress both innate and adaptive immune responses. In addition, MMF directly induces monocyte and macrophage apoptosis as well as inhibiting their migration and infiltration to allograft and inflammatory sites, further indicating their suppressive activities on innate immune responses.

Infection

The unique ability of MPA to specifically target T and B lymphocytes in transplant immunity [163,164] also increases the risk of infectious complications [165]. It has been reported that MMF leads to better allograft survival than AZA, but the rates of rehospitalization for infection was significant higher in patients who received MMF [166]. CMV infection is the most common infectious complication associated with MMF usage [167–169], and may be due to decreased levels of serum anti-CMV IgM in patients who received MMF compared to AZA [170,171]. BK virus infection has also been implicated in immune suppressive regimens that included MMF [172–174], as well as varicella and fungal infection [175,176]. On the other hand, there are reports showing possible antimicrobial activities of MMF, including against Dengue virus, hepatitis C virus, hepatitis B virus, pneumocystis, West Nile virus, and yellow fever virus [177].

Metabolism

Typical adverse effects of MMF for transplant patients are gastrointestinal symptoms, including diarrhea, nausea, vomiting, and abdominal cramps [178,179], possibly due to enterocyte toxicity and/or immunosuppression caused low-grade enteric infections [178,180]. MMF has also been associated with: hematologic side-effects including leucopenia, anemia, thrombocytopenia, and dysplasia [181–184]; genitourinary adverse effects including urgency, frequency, dysuria, and sterile pyuria; and other side-effects such as fever, myalgias, headache, and insomnia, as well as cardiovascular symptoms including peripheral edema and hypertension [180,185,186].

Monoclonal biologics

Biologic medicines are produced using biological processes involving recombinant DNA technology rather than being chemically synthesized. Biologics are designed to selectively target a key immune pathway without the side-effects associated with some of the pharmaceutical drugs [187,188]. This section will focus on monoclonal biologic therapies for prevention and treatment of transplant rejection. Kohler and Milstein won the Nobel Prize for their 1975 publication describing the creation of antibodies of predetermined specificity, now referred to as monoclonal antibodies [189]. Monoclonal antibodies have been instrumental in revolutionizing transplantation and cancer therapies and are key members of a class of drugs known as biologics or biologic medicines.

Basiliximab and daclizumab: anti-IL-2R antibodies

Structural and biochemical pathways

The receptor for IL-2, IL-2R, is comprised of three subunits: alpha, beta, and gamma, or CD25, CD122, and CD132, respectively [190]. Basiliximab (Simulect) and daclizumab (Zenapax) are both potent monoclonal antibodies directed at CD25 and are potent antagonists of IL-2. They are used to prevent transplant allograft rejection [191]. Basiliximab and the IL-2R have been studied and modeled. Basiliximab, a human–mouse chimeric antibody, and daclizumab, a humanized murine antibody, both bind the IL-2α chain (basiliximab specifically binds the IL-2Ra ectodomain), markedly limiting the immune response [190,191]. Daclizumab was withdrawn from the market in 2009 for financial reasons but figures prominently in the literature over the last 15 years. IL-2 is both a product of T cells and a signal involved in clonal T-cell expansion [192]. In addition, IL-2 signaling up-regulates expression of CD25 in a positive feedback loop that leads to rapid activation and proliferation of T cells [191]. In vivo, basiliximab decreases $CD25^+$ T cells for nearly 6 weeks [193]. Because $CD25^+$ is present on both activated $CD4^+$ cells in addition to suppressive Tregs, investigators hypothesized that this agent may compromise Treg-suppressive mechanisms [193]. In human patients, although numbers of $CD4^+/CD25^+/FoxP3^+$ cells decrease after the drug's administration, the number of $CD4^+/CD25^-/FoxP3^+$ cells has been shown to increase [193]. Authors of a study evaluating T-cell subsets after basiliximab therapy concluded that although the drug decreased Treg numbers, the decrease was not associated with functional consequences, and that the drug may not inhibit their tolerogenic potential [193]. Other groups have shown that basiliximab does not change the T effector cell to T regulatory cell ratios, in contrast to rabbit ATG which is thought to bolster Treg populations [194].

Rituximab: anti-CD20 antibody

Structural and biochemical pathways

CD20 (initially referred to as B1) is expressed on a large percentage of mature B cells, but not on early B-cell precursors or active antibody secreting cells and plasma cells [195,196]. Rituximab, a humanized chimeric anti-CD20 agent, was originally approved to treat relapsed indolent lymphoma [197,198]. Rituximab is now used to eliminate B cells to control the alloantibody response. Rituximab eliminates B cells through both complement-mediated cytotoxicity (CDC) and antibody-dependent cellular cytotoxicity (ADCC). Rituximab-induced ADCC is mediated by ligation of its Fc receptor [199]. For CDC, rituximab directly C1q binds, initiating the complement cascade [199]. Interestingly, steroid therapies such as dexamethasone have been shown to enhance CDC, but not ADCC [199]. Rituximab is also thought to be proapoptotic for B cells, likely due to down-regulation of IL-10 via the MAPK pathway [200]. Because plasma cells and highly mature antibody secreting cells express little or no CD20, the efficacy of rituximab in preventing or treating alloantibody responses and humoral rejection is likely very limited.

Alemtuzumab: anti-CD52 antibody

Structural and biochemical pathways

Alemtuzumab (Campath) is directed at CD52, a glycoprotein found on the surface of T cells, B cells, macrophages, monocytes, and NK cells. CD52 is not found on erythrocytes or hematopoietic stem cells [201]. The drug was originally approved to treat chronic lymphocytic leukemia, but was adopted by the transplant community as an induction therapy that causes widespread and rapid leukocyte depletion, which might lead to calcineurin inhibitor and steroid minimization, and a tolerogenic immunologic state [202,203]. In a multicenter trial alemtuzumab was associated with fewer episodes of acute rejection after 3 years, but had a worse malignancy profile [204]. Further, the drug yields more sustained lymphodepletion than other induction agents, such as equine antithymocyte globulin, so that it may take 1 to 2 years for patients to regain normal peripheral white blood cells counts and distribution of the various leukocyte subsets.

Muromonab: anti-CD3 antibody

Structural and biochemical pathways

Muromonab, also known as OKT-3, is a murine monoclonal IgG2a antibody [205]. The target of OKT-3 is CD3, a component of the

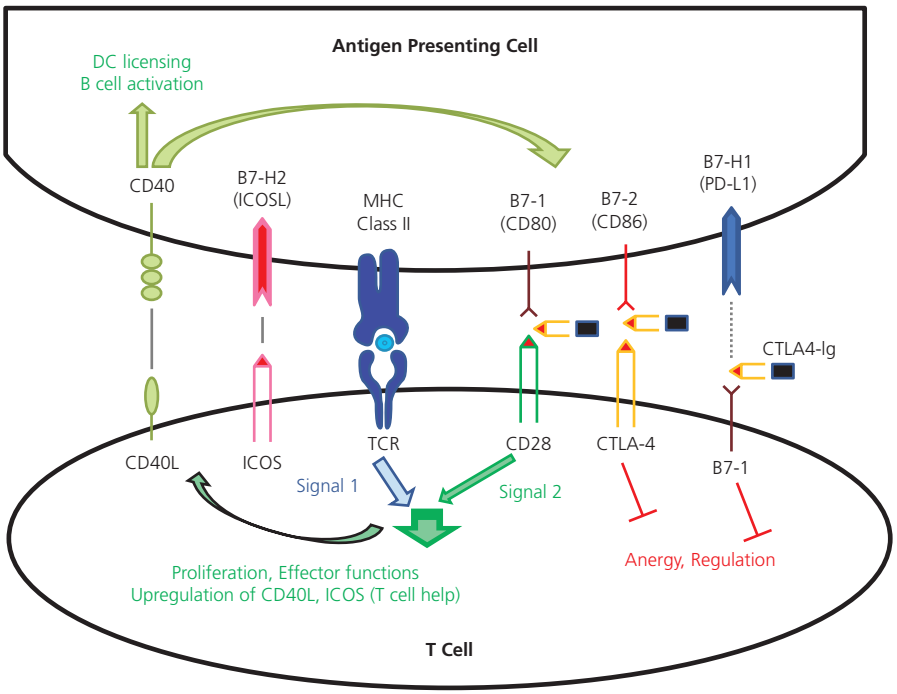

Figure 17.5. Mechanism of action of belatacept. The CD28-B7 counter-receptor group consists of two B7 ligands (CD80 and CD86) and two T-cell receptors (CD28 and CTLA-4). Both B7 ligands can bind to both CD28 and CTLA-4. If a T cell receives an antigen-specific T-cell receptor (TCR)-mediated signal (Signal 1), then B7-CD28 interactions generate a costimulatory signal (Signal 2) that promotes full T-cell activation, including up-regulation of additional costimulatory molecules like CD40L and ICOS, and reciprocal dendritic cell (DC) and B-cell activation (through T-cell help). In contrast, B7-CTLA-4 and B7-1-PD-L1 interactions appear to inhibit immune responses by inducing T-cell anergy or regulation. Belatacept is a recombinant fusion protein composed of the extracellular domain of CTLA-4 and the human IgG1 Fc domain. It binds to B7 ligands with a high affinity and thereby prevents interactions between B7 and other receptors. The end result is a status of immunosuppression with decreased T, B, and dendritic cell activation.

antigen specific T-cell receptor complexes, found on the surface of mature T cells as well as medullary thymocytes [205]. OKT-3 was the first monoclonal antibody ever approved for human use. It was removed from the market several years ago as it has been superseded by other agents, but remains an important basis in the historic transplant literature and our notions for current use of antibody reagents. Whereas other induction agents may act to reduce T-cell counts for days or weeks, CD3 counts begin to rise only 48 hours after administration of OKT-3 has ended [205]. Like rituximab, OKT-3 acts through CDC and ADCC, but it also exerts its effects via activation-induced cell death (AICD) and opsonization [206]. OKT-3 is also thought to modulate the T-cell receptor off the cell surface, such that it can no longer interact with APCs [206]. OKT-3 may also induce a long-lasting state of clonal anergy, simulating immunodeficiency [206]. As for many other antibody reagents, cross-linking of T-cell surface receptors can cause rapid and massive T-cell activation with release of cytokines, inducing clinically the cytokine storm characterized by fever, tachycardia, hypotension, vascular leak, and multiple end-organ dysfunction [207].

Belatacept

Concept and structure

Whereas biologic drugs used so far in transplantation are monoclonal antibodies, belatacept belongs to a new structural class of biologics: it represents a recombinant fusion protein corresponding to the soluble form of a receptor expressed at the surface of T-cells linked to an immunoglobulin frame [208]. Moreover, belatacept is the only biologic targeting a specific immune pathway (costimulation) currently used clinically.

Rejection of major histocompatibility complex (MHC)-disparate organ transplants is orchestrated and mediated by T lymphocytes. Costimulation can be defined as a second signal necessary for optimal T-cell activation delivered jointly to T cells along with a first signal mediated by engagement of the T-cell receptor (TCR) with the peptide–MHC complex on antigen presenting cells (APCs) (Figure 17.5). In vitro, signaling through the TCR alone (signal 1) in the absence of adequate costimulation (signal 2) fails to generate T-cell responses, and results in the induction of T-cell anergy or hyporesponsiveness [209,210]. These findings suggested a novel way to prevent pathogenic immune responses in autoimmunity and transplantation [187,211–213], an area that attracted much attention in the last decade. Many of the costimulatory molecules thought to be essential for T-cell activation have now been identified [214]. Costimulation blockade in various transplant models has now confirmed that costimulatory signals shape the outcome of an immune response and are potent immunomodulators of alloimmunity [215–222].

Elucidation of the now best-characterized costimulation receptor (CD28) in the 1990s led to the development of belatacept. Cytotoxic T lymphocyte antigen (CTLA)-4 is a structural homologue of

the T-cell costimulatory receptor CD28 that binds the same B7 ligands with a higher affinity. A recombinant fusion protein composed of the extracellular domain of CTLA-4 and the human IgG1 Fc domain (CTLA4-Ig) was designed to specifically bind B7 ligands and thus block CD28-B7 interactions. This blockade was shown to act as a potent immunosuppressive molecule in various animal models [213,215–220]. A first clinical formulation of CTLA4-Ig (abatacept) was developed with a mutated Fc domain for the treatment of rheumatoid arthritis and psoriasis. Belatacept (LEA29Y) was developed later as a second-generation higher affinity mutant for transplantation clinical trials [208]. In 2011, the US Food and Drug Administration (FDA) approved belatacept (Nulojix™) for the prevention of acute rejection in adult patients with a kidney transplant.

Cellular targets

The direct molecular targets of belatacept, B7-1 (CD80) and B7-2 (CD86), are weakly expressed by specific hematopoietic cells (DC, B cells, macrophages) and are up-regulated by signals that activate these cells to mature into antigen-presenting cells (APCs) (CD40, TLR agonists, inflammatory mediators). B7-1 and B7-2 represent the ligands for the costimulatory receptor CD28 constitutively expressed on essentially all murine and most human peripheral T cells.

The CD28/B7 pathway is pivotal for the activation of T cells [213]. The CD28 T-cell receptor provides a signal that synergizes with T-cell antigen receptor (TCR) stimulation in activating T cells to proliferate and secrete cytokines [223–225] (Figure 17.5). T-cell expansion is stimulated through increased transcription and mRNA stability of IL-2, and increased expression of the antiapoptotic protein Bcl-X_L. As a result, interruption of this pathway leads to an inhibition of T-cell proliferation and, under some circumstances, induces either antigen-specific hyporesponsiveness, anergy, or cell death [209,226]. CD28 signals also regulate T helper cell differentiation [227] and migration [228,229] through up-regulation of cytokines and chemokines. CD28 signals also enhance the expression of other costimulatory molecules like CD154 and ICOS, also involved in T-cell activation. Accordingly, CTLA4-Ig was shown to inhibit T-cell proliferation, activation, and differentiation in multiple in vitro and in vivo experimental models [230–233].

Different subsets of T cells exhibit varying degrees of susceptibility to CTLA4-Ig. For many years it was believed that memory T cells do not require CD28/B7-derived costimulation for recall responses [234], based on previous studies showing that memory CD4 T cells are fully activated by B7-deficient APC in vitro [235,236] and that $CD28^{-/-}$ mice are not impaired in the generation or recall of memory CD8 T-cell responses to a viral infection [237]. However, recent evidence has challenged this concept and shown that both $CD4^+$ and $CD8^+$ murine memory T cells require CD28 costimulation for maximal expansion and pathogen clearance [238–240], although some but not all T-cell functions are regulated by CD28/B7 interactions [241]. Clinical efficacy of CTLA4-Ig in treating rheumatoid arthritis [242] and psoriasis [243], diseases known to be driven by memory CD4 T cells [212], suggest that the CD28/B7 pathway may also regulate human memory CD4 T-cell-mediated responses. However, subpopulations of human and primate effector/ memory T cells that do not express CD28 have been described [244–249] and are therefore expected to be non-susceptible to CTLA4-Ig [250,251]. In addition, B7 blockade with CTLA4-Ig inhibits both positive (CD28/B7) and negative (CTLA-4/B7 and PD-L1/B7) immunomodulatory signals, which could result in a complex effect of CTLA4-Ig on effector and memory T-cell populations [234,252–258]. Besides naïve and memory T cells, CD28 and CTLA-4 receptors are also expressed by natural and induced/ adaptive Tregs [259], B7/CD28 costimulation is essential for the homeostasis of Tregs [260,261], and CTLA-4 regulates the potency of natural Tregs [262]. CTLA4-Ig can therefore alter the steady-state level and quality of Tregs [263–265], with potential implications regarding its effects on endogenous Tregs in patients receiving long-term therapy.

Although CD28 has been almost entirely characterized as a prototypic T lymphocyte receptor, it is also expressed on the surface of plasma cells (PCs) [266,267] but its expression is specifically repressed in B cells [268]. Therefore, whereas the effect of CTLA4-Ig on modulating humoral responses in various models [219,220,269] has been attributed to inhibition of helper T-cell costimulation and germinal center formation, a B-lineage-intrinsic role for CD28 in controlling the differentiation or function of plasma cells beyond germinal center formation is theoretically possible [268].

Treatment of macrophages with CTLA4-Ig in vitro was shown to down-regulate cytokine production [269,270] and in vivo CTLA4-Ig decreased macrophage-associated genes in rat renal allografts [219]. In addition, CTLA-4-Ig was shown to bind B7 molecules expressed on DC and activate a pathway of tryptophan catabolism resulting in the induction of indeolamine 2,3-dioxygenase (IDO), an intracellular enzyme that breaks down tryptophan and can lead to indirect inhibition of lymphocyte activation and T-cell death [271,272]. However, whether clinical versions of CTLA4-Ig (abatacept and belatacept) retain this intrinsic property despite a mutated Fc domain is unclear.

Adaptive immunity

As expected from its role in modulating T-cell activation and cognate reciprocal T-B and T-APC costimulatory signals, CTLA4-Ig/belatacept potently repress adaptive pathogenic immune responses in autoimmunity and transplantation [230–233].

Ischemia–reperfusion injury and inflammatory responses

Blockade of T-cell CD28-B7 costimulation with CTLA4-Ig significant decreased T-cell and macrophage infiltration and activation in a rat model of kidney IRI [273]. Moreover, B7-1 has been implicated in the regulation of inflammation in innate immunity in murine sepsis, a process mediated by macrophage/ neutrophil contact dependent on the B7-associated NF-κB repressor IRAK-M [274]. These findings raise the possibility of a direct effect of belatacept on innate immune responses.

Infection

As for other immunosuppressive therapies, belatacept is associated with an increased risk of opportunistic infections. In clinical trials of kidney transplantation, the overall incidence of infections in belatacept-treated patients was similar to that in the cyclosporine control group, with a predilection of tuberculosis and herpes infections with belatacept.

Metabolism

In a phase III multicenter clinical trial in renal transplantation, patients treated with belatacept exhibited fewer associated non-immune toxicities (nephrotoxicity, hyperlipidemia, cardiovascular

events) as compared to the control group, which received standard cyclosporine-based immunosuppression. In addition, patients who received belatacept had lower blood pressure levels compared to those on cyclosporine [275–277].

Tumors/proliferation

Similar to cyclosporine, belatacept is associated with an increased risk of tumors and malignancies due to the systemic immunosuppression. In addition, belatacept-treated patients have an increased risk for developing post-transplant lymphoproliferative disorder (PTLD), predominantly involving the central nervous system. Consequently, belatacept is contraindicated in transplant recipients who are Epstein–Barr virus (EBV) seronegative or with unknown EBV status. No direct inhibitory effect is expected on tumor proliferation, except if a specific tumor expresses B7.

Antithymocyte globulins

Antilymphocyte sera, particularly antithymocyte serum, have a long and successful history as transplant immunosuppressants [278–280]. Currently, two types of antithymocyte-γ globulin (ATG) products, produced in rabbits (rATG, clinically available as Thymoglobulin®) or horses (eATG, clinically available as ATGAM®) are utilized in both induction regimens and in treatment of acute graft rejection. Both ATG are purified polyclonal immunoglobulin mixtures containing mostly IgG isotype antibodies recovered from animals immunized with human thymocytes. Direct comparisons of rATG and eATG demonstrated increased efficacy of rATG in the induction and maintenance of lymphopenia and in preventing acute rejection of renal grafts [281].

Cellular targets

T lymphocytes are the major cellular target of ATG. The molecules recognized by ATG are extremely varied. ATG-targeted molecules include T-cell-specific targets, such as CD3, CD28, CD152, and the T-cell receptor, as well as molecules largely confined to T-cell populations, including CD2, CD4, CD8, and CD25, and more broadly expressed proteins such as CD11a, CD45, and HLA class I and II.

ATG recognition of T cells has multiple consequences [282–288]. Depletion of T cells is rapid and is thought to occur through several different mechanisms, including complement-mediated lysis [285], receptor-mediated apoptosis [282], and antibody-dependent cell-mediated cytotoxicity [287]. Further, ATG has been shown to negatively regulate T-cell proliferation through interaction with CD25 [289]. ATG has been also been shown to modulate T-cell trafficking, apparently as a result of specific binding to T-cell adhesion molecules or chemotactic receptors [283,290]. ATG has also been shown to enhance the development and/or accumulation of Tregs [291–294]. These cells in turn can negatively modulate effector T-cells function by a variety of mechanisms [295].

While T cells are the intended target for ATG, it is clear that other cells types are also modulated by ATG treatment. Both NK and B lymphocytes can be depleted by ATG [296,297]. NK cells that are not depleted demonstrate increases in activation markers and production of IFN-γ [298], but also demonstrate reduced capacity for antibody-dependent cell-mediated cytotoxicity [299].

In addition to its effects on lymphocytes, ATG also can modulate cells of the innate immune system, particularly DC and neutrophils. ATG treatment can result in brief activation of neutrophils followed by neutropenia [300]. In DC, ATG can block antigen uptake and maturation in response to inflammatory signals, and induce apoptosis [301].

Adaptive immunity

ATG can deplete $CD4^+$ and $CD8^+$ T cells, B cells, and plasma cells, and the DC that initiate adaptive immunity. Further, cells that survive exposure to ATG can still be functionally inhibited by antibody recognition of molecules involved in antigen presentation and recognition, B-cell help, trafficking, and effector function. These activities of ATG result in greatly diminished effector lymphocyte responses. Together these combined activities of ATG on leukocytes make it a profound inhibitor of adaptive immunity [278,279].

Ischemia–reperfusion inflammatory responses

There is some evidence to suggest that ATG inhibits IRI, presumably by inhibiting the trafficking and functional activity of innate immune cells involved in IRI responses [290]. Treatment with ATG in a primate model revealed significant reduction of endothelial adhesion molecules. This correlated with a reduction in expression of proinflammatory cytokines, suggesting that inhibition of leukocyte trafficking reduced inflammation associated with ischemia–reperfusion.

Infection

Treatment with ATG has been shown to increase susceptibility to opportunistic infections, particularly cytomegalovirus (CMV) [302–305]. However, other groups have reported that ATG treatment increased risk of CMV infection to the same extent as another method of induction, suggesting that it is general immunosuppression and not an inherent effect of ATG that drives increased risk [306]. Another study demonstrated that the increased CMV infection risk was abolished in the presence of CMV prophylactic treatments [307].

Metabolism

ATG treatment has not been associated with adverse metabolic effects, but rather has been utilized in corticosteroid reduction regimens aimed at preventing adverse metabolic complications [308,309].

Tumors/proliferation

Multiple studies have examined the effects of ATG on development of malignancy, particularly PTLD, with contradictory outcomes [310–312]. While the individual contribution of ATG to malignancy is unclear, it seems that the overall state of immunosuppression generated by combined immunosuppressants can increase the risk of malignancy [311]. Thus, ATG, like other drugs used in induction immunosuppression, can increase the rate of PTLD and other malignancies [310,311].

Intravenous immunoglobulin (IVIG)

Living donations have increased the availability of organs, but patients are increasingly found with existing sensitization to alloantigens, manifest by antibodies with broad specificity against HLA antigens (panel reactive alloantibodies). In addition, the role of alloantibodies developed de novo post-transplant in antibody-mediated rejection (AMR) has recently emerged as a major barrier to the success of kidney [313,314], as well as heart and pancreas,

transplantation [315]. Unfortunately, current immunosuppressive therapies do not efficiently target these antibody-mediated immune mechanisms. Intravenous immunoglobulin (IVIG) has demonstrated great clinical success in a number of antibody-mediated autoimmune diseases and chronic inflammatory disorders [316–318] and recently became part of the clinical armamentarium to desensitize transplant patients exposed to alloantigens prior to transplant, and to treat antibody-mediated rejection [319]. Although well documented, the efficacy of IVIG in this context is still controversial [320–322] and its mechanisms of action not well understood. IVIG has also been successfully used in the treatment of ABO-incompatible transplants [323]. Moreover, IVIG was widely used as therapeutic or prophylactic therapy for viral infections in bone marrow transplant patients before the development of cytomegalovirus-negative blood products and ganciclovir [324], and is still occasionally utilized against infections after bone marrow [325] or organ [326–328] transplantation.

Concept and structure

IVIG mostly (95%) contains the pooled immunoglobulin G (IgG) fraction extracted from the plasma of blood donors, with only trace amounts of immunoglobulin A (IgA) or immunoglobulin M (IgM). It is manufactured as a sterile, purified product. Despite its efficacy, the fact that IVIG is composed of the pooled IgG fractions from 5000 to 50 000 donors limits potential availability, increases cost, and each product (batch) is associated with its own characteristics that may affect tolerability and efficacy.

Although the use of IVIG has gained increasing popularity from the treatment of humoral immunodeficiencies to immunomodulation in autoimmune, inflammatory, and transplantation conditions, our understanding of its mechanisms of action are still incomplete [329–331]. Some of its mechanisms of action have been attributed to the presence of natural or anti-idiotypic antibodies [332,333]. IVIG directly binds to and "neutralizes" pathogens and various target cells and molecules, and blocks complement deposition. In addition to these antigen-binding or Fab-mediated mechanisms, recent evidence identified a key role for the Fc portion of immunoglobulins and the role of IVIG-mediated Fc multimerization in mediating immune modulation [334–337]. These Fab- and Fc-dependent mechanisms are probably not mutually exclusive and are likely variably involved in different pathologic conditions.

Cellular targets

IVIG can directly bind to various cell types by interacting with Fcγ receptors (FcγRs). Four different classes of FcγRs have been identified in mice (FcγRI, FcγRII, FcγRIII, FcγRIV) whereas orthologous proteins in humans and primate are divided into three large classes (FcγRI, FcγRII, FcγRIII) with additional variants within each family. Various hematopoietic cells, including monocytes, macrophages, DC, neutrophils, mast cells, NK, and NKT cells, express one or more FcγRs, but FcγRs are typically absent in T cells. Most FcγRs transmit activating signals involved in cellular immune functions such as phagocytosis and antibody-dependent cytotoxicity (ADCC). In contrast, FcγRIIB as the sole FcγR bearing an inhibitory ITIM motif, acts as a suppressor of cellular immune responses, and is associated with immune tolerance [338–340]. B cells only express FcγRIIB, and both their activation and survival [341,342] are modulated by FcγR signaling, findings consistent with the therapeutic effect of IVIG on humoral rejection. IVIG may also accelerate the clearance of pathologic IgG antibodies through binding to the neonatal Fc receptor (FcRn) on endothelial cells [343,344].

Adaptive immunity

Clinical use of IVIG targets the progression (B cells, plasma cells) and product (antibody) of humoral adaptive immune responses. Moreover, the presence of FcγR on various hematopoietic lineages as well as in subsets of Tregs [345] and suppressor cells suggest additional potential effects of IVIG in immune homeostasis [346] and tolerance.

Ischemia–reperfusion injury and inflammatory responses

Amplification of IRI and inflammation mediated by alloantibody is likely to be indirectly decreased by IVIG-based therapies. Additionally, direct effects of IVIG on FcγR-bearing innate cells are expected, based on anti-inflammatory properties of IVIG in other diseases [333].

Infection

IVIG was an established therapy for the treatment or prophylaxis of viral infections in bone marrow transplant patients [324], and is still occasionally administered against infections in bone marrow [325] and organ [326–328] transplantation. Desensitization with IVIG and rituximab did not increase the infection risk in kidney transplant patients [347]. However, the human origin of IVIG has potential unknown infectious risks.

Metabolism

A small but significant IVIG-related thrombosis rate was observed in patients treated for AMR, which was prevented by a slower rate of infusion combined with antiplatelet and anticoagulation [348]. Studies on IVIG in atherosclerosis suggest beneficial effects of IVIG on metabolism [349].

Tumors/proliferation

Natural antibodies found in IVIG preparations were shown to suppress tumor growth [350]. However, immune-modulation mediated by FcγR inhibitory signals may contribute to tumor development by supporting immunosuppression.

Summary

Modern transplantation remains dependent on numerous classes of immune modifying drugs, which can be group by general mechanism and structure into glucocorticoids, calcineurin inhibitors, mTOR inhibitors, purine analogues, and monoclonal and polyclonal protein biologics. Used cognizant of their effects and side-effects, these drugs have enabled the practice of transplantation. The reader will find reference to the clinical use of these drugs throughout this text, and is encouraged to consider the mechanisms described in this chapter when formulating clinical strategies to prevent and treat rejection.

CHAPTER 18

Future Pathways for Immune Manipulation

Allison B. Webber and Flavio Vincenti
Kidney Transplant Service, University of California, San Francisco, CA, USA

Introduction

Calcineurin inhibitor (CNI)-based regimens, while largely responsible for decreasing acute rejection rates and increasing graft survival at 1 year have failed to improve attrition rates beyond 1 year. Long-term renal allograft survival has remained unchanged since 1995 [1]. Furthermore, CNIs are associated with multiple systemic side-effects, including nephrotoxicity, as well as metabolic derangements, including hypertension, hyperlipidemia, and glucose intolerance. The metabolic derangements of CNIs likely contribute to the significant amount of cardiovascular disease seen in the transplant population, the leading cause of death with a functioning graft [2–6]. In addition, while effective at inhibiting acute T-cell mediated alloresponses, CNIs seem less effective, especially when used in minimization regimens, at targeting a chronic alloantibody response, now thought to play a significant role in late allograft loss [7–9]. This evidence suggesting the prominent role of alloantibodies and chronic humoral rejection in late allograft loss has sparked interest in the pursuit of novel B-cell therapeutic targets, including blockade of the CD40–CD154 costimulatory pathway with antibodies to CD40, as well as B-cell-activating factors (BAFF) and a proliferation-inducing ligand (APRIL), both tumor-necrosis factor family ligands which act as antiapoptotic factors critical for maturation of the B-cell lineage [10]. Still, T cells are thought to remain central to graft rejection. Landmark studies identifying that signal 1, delivered through the T cell receptor (TCR) interacting with antigen in the context of MHC, is insufficient to trigger productive T-cell responses, has spawned significant interest in costimulatory molecules. Costimulatory signals are now known to be responsible for signal 2, a signal required to drive survival, clonal expansion, and differentiation of activated T cells [11,12]. The best characterized costimulatory pathways under active investigation as therapeutic targets in transplantation thus far include the CD28/B7 and the CD40/CD154 pathways. LFA-1/ICAM and the CD2/LFA-3 pathways are also of interest in transplant immunology [13,14]. Monoclonal antibodies and fusion proteins developed specifically to target some of these pathways have shown promise in providing similar efficacy to CNI-based regimens in preventing rejection, with fewer side-effects. However, the complexity of costimulation, including the existence of negative costimulatory signals (i.e. CTLA-4) which inhibits T-cell activation, as well as the variable expression of these molecules both on different cell subsets and at different times points of immune activation, have made clinical trials with biologics challenging [15]. Finally, small molecules, including tofacitinib, a Janus kinase 2/3 inhibitor, have demonstrated efficacy in animal models in improving graft survival and Phase IIa and IIb clinical trials in humans have shown similar efficacy, albeit with more immunosuppressive-related complications including infections and post-transplantation lymphoproliferative disease (PTLD) [16,17].

This chapter will focus on prominent pathways currently being targeted in transplantation, including intracellular pathways, as well as B- and T-cell surface receptors and ligands. Emphasis will be given to the general mechanisms and novel targets that might be exploited for pharmacologic immune manipulation in the future. Ultimately, the goal of therapeutics in transplantation is to achieve a robust immunologic tolerance to the allograft while maintaining an intact immune system for surveillance of other antigens. This chapter will focus on therapeutics aimed at achieving this goal, and is complemented by Chapter 17, which focuses on those pathways exploited in common clinical practice.

Costimulatory pathways in transplantation

Costimulation pathways have long been viewed as important targets for the control of adaptive immune responses. While the recent approval of belatacept heralds the beginning of the therapeutic manipulation of costimulation pathways to combat rejection, it is generally held that their true promise has only begun to be realized, and that belatacept's use will be refined and followed by numerous other compounds. This section uses the development of belatacept as a launch point to outline how other costimulation pathways are likely to be explored in transplantation.

CD28/CTLA-4/B7 pathway

T cells play a central role in the initiation and regulation of the adaptive immune response and require two collaborative signals for activation [18]. Signal 1 is delivered through the T-cell receptor (TCR) interacting with the MHC and antigenic peptide complex on antigen-presenting cells (APC). Signal 2—the costimulatory signal—is provided by engagement of T-cell surface receptors with their ligands on the APC. In the absence of a concomitant signal 2, naïve T cells become anergic, precluding the development of an effector $CD4^+$ T-cell subset and clonal expansion of activated cytotoxic T cells (CD8 T cells). The best-characterized positive

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

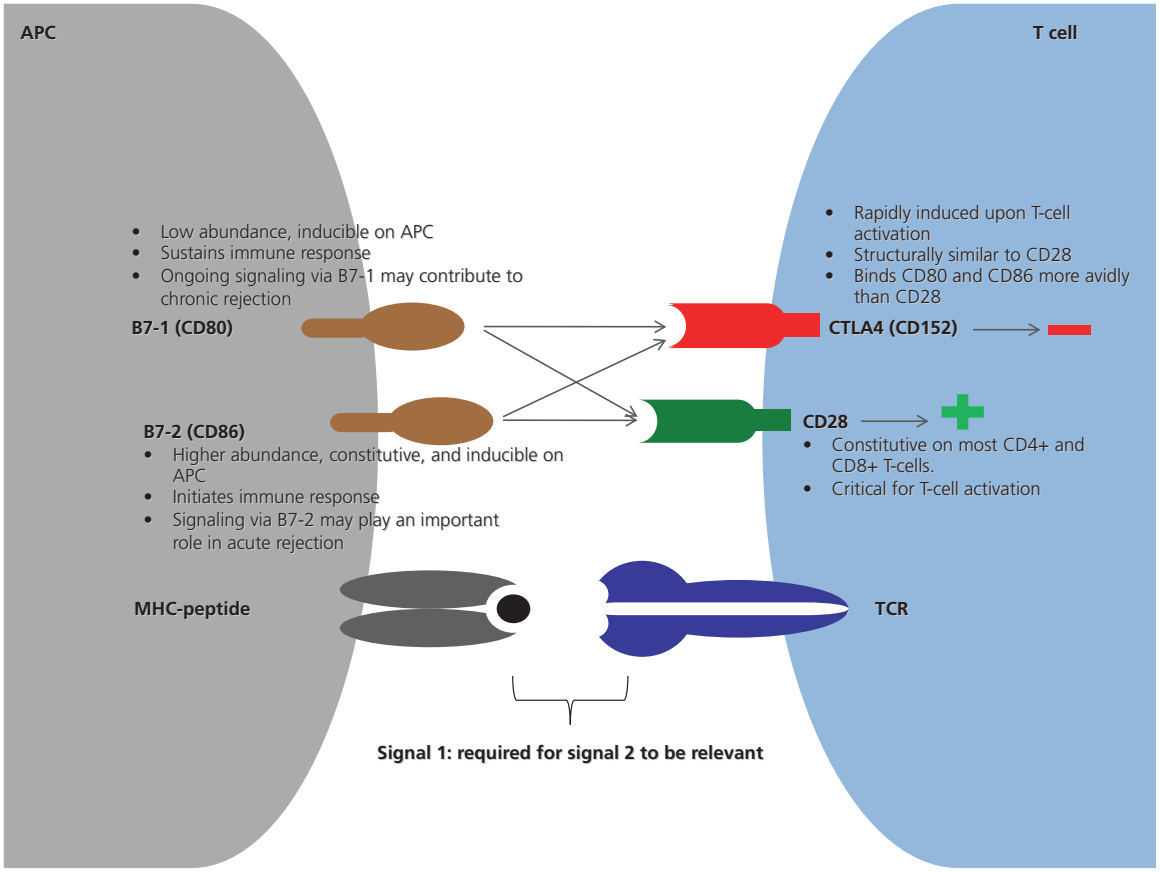

Figure 18.1. Signaling via B7-1/2 and CD28 plays a critical role in T-cell activation. Shown are the relationships between ligands B7-1 and B7-2, and their receptors CD28 and CTLA4. Note that engagement between the T-cell receptor (TCR) and MHC (signal 1) is required before the costimulatory signals are relevant. APC, antigen-presenting cell.

costimulatory pathway is the CD28/B7 pathway [13]. CD 28 is a homodimeric transmembrane protein constitutively expressed on all naïve $CD4^+$ and $CD8^+$ T cells [19] and has two known ligands, B7-1 (CD80), which is inducibly expressed, and B7-2 (CD86), which is constitutively expressed on the surface of APCs [19]. Engagement of CD28 by B7 ligands in the presence of TCR stimulation induces T-cell clonal expansion, cytokine production (including IL-2 and IFN-γ), and enhanced T-cell survival (Figure 18.1) [13,14]. Interestingly, as an example of the complexity of costimulatory signaling, activated T cells up-regulate cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4), a molecule that is structurally similar to CD28 but with higher affinity for ligands B7-1 and B7-2. CTLA-4 binding provides a negative costimulatory signal, down-regulating the T-cell response and providing a negative feedback loop. CTLA-4 is also critical for the function of $FoxP3^+$ T regulatory cells, cells instrumental in promoting tolerance [20,21].

Various biologics have been developed to target the CD28/CTLA-4/B7 pathway, most notably the recombinant fusion protein CTLA-4–Ig (abatacept), which consists of an extracellular domain of CTLA-4 and the Fc portion of IgG1. The development of CTLA-4–Ig was based on the known higher affinity/avidity of CTLA-4 for ligands B7-1 and B7-2 and its ability to bind B7-1 and B7-2 in lieu of CD28, thereby blocking positive costimulatory signals [22]. While in rodent transplant models CTLA-4–Ig prolonged allograft survival, this effect was not observed in non-human primates (NHP) [23,24]. This finding led to the discovery that CTLA-4–Ig's inhibition of B7-2 (CD86) is less potent than its inhibition of B7-1 (CD80) and its inhibition of the CD28/B7 pathway is therefore suboptimal for transplantation [22,25,26]. As a result, belatacept (previously referred to as LEA29Y), a second-generation CTLA-4–Ig fusion protein (with two amino acid substitutions in the binding sites) with higher affinity for B7-2, was developed and was found to prolong renal allograft survival in NHP when used in combination with mycophenolate mofetil and steroids (Figure 18.2) [27]. Additionally, belatacept inhibited the development of antidonor antibodies [27].

A Phase II multicenter clinical trial designed to demonstrate the non-inferiority of belatacept (using two dosing regimens) to cyclosporine (CsA) in preventing rejection revealed comparable rejection rates and higher glomerular filtration rate (GFR) and less chronic allograft nephropathy (CAN) in both belatacept groups at 1 year [28]. Given these encouraging results, two Phase III trials, "A Phase III Study of Belatacept-based Immunosuppression Regimens versus Cyclosporine in Renal Transplant Recipients" (BENEFIT) and "A Phase III Study of Belatacept Versus Cyclosporine in Kidney Transplants from Extended Criteria Donors" (BENEFIT-EXT), were designed to assess whether treatment with belatacept was equivalent or superior to cyclosporine with respect to acute rejection rates, GFR, and patient and graft survival at 1 year, in

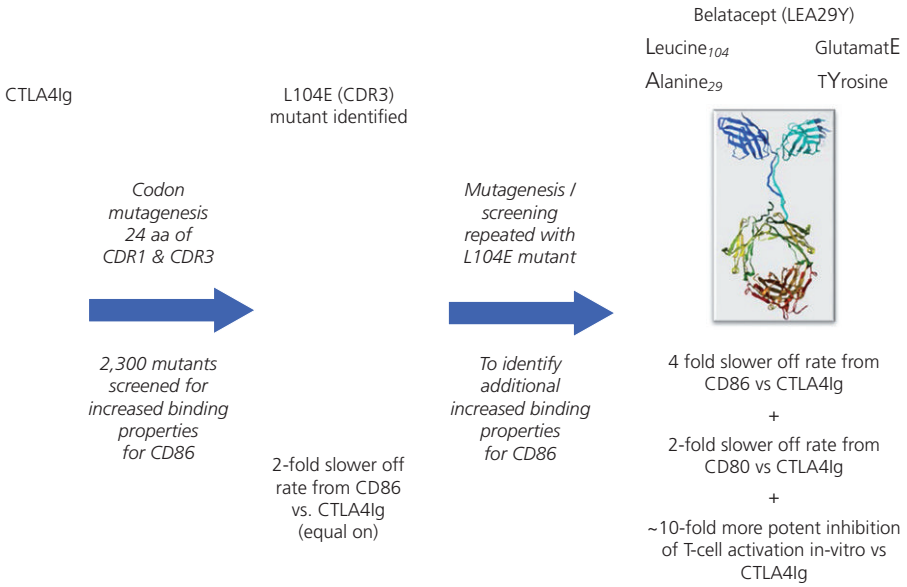

Figure 18.2. Belatacept (LEA29Y): rationally designed for transplantation.

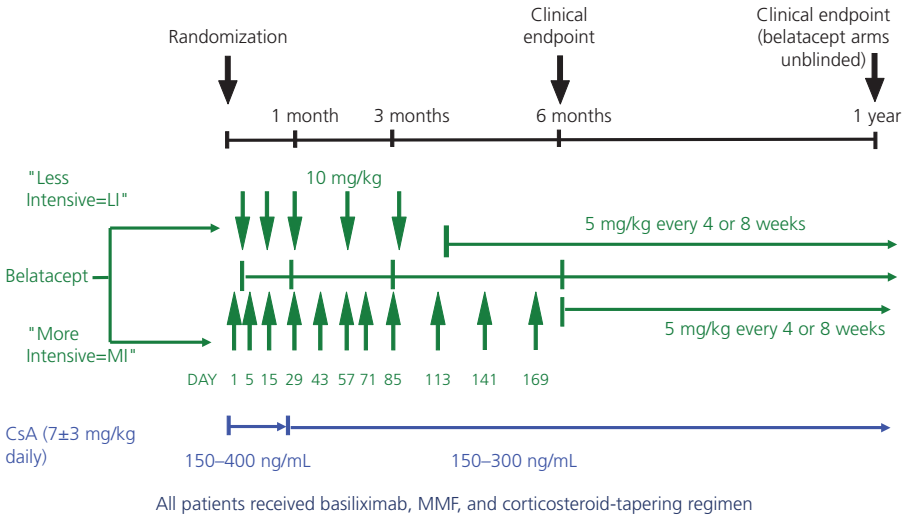

Figure 18.3. The immunosuppressive regimens used in the BENEFIT and BENEFIT-EXT trials.

recipients of living or standard deceased donor kidneys and extended criteria deceased donor kidneys, respectively [29,30]. Figure 18.3 depicts the treatment regimens employed in both studies. Results of the BENEFIT trial revealed equivalent patient/graft survival to cyclosporine at 1 year in both the more intensive (MI) and less intensive (LI) belatacept groups (95% MI; 97% LI; and 93% CsA) [29]. Renal function in both belatacept groups was superior to cyclosporine at 1 year (mean GFR 65 mL/min/1.73 m^2 MI; 63.4 mL/min/1.73 m^2 LI; 50.4 mL/min/1.73 m^2 cyclosporine, $P < 0.0001$ for MI and LI vs. CsA). Follow-up at 3 years showed that the difference in eGFR continued to widen between the belatacept and cyclosporine treated patients.

The presence of biopsy-proven CAN at 1 year protocol biopsies was lower in the belatacept groups compared to CSA (18% MI; 24% LI; 32% CSA). Further, cardiovascular outcomes, including blood pressure and lipids, were better in the belatacept groups (133/79 MI, *P* value vs. CsA 0.001; 131/79 LI, *P* value vs. CsA 0.0273; 139/82 CsA). The incidence of new-onset diabetes after transplantation (NODAT) was not statistically significant between the three groups.

Acute rejection rates, however, were higher in the belatacept groups (22% MI; 17% LI; 7% CsA) and more patients in the belatacept groups had Banff Grade IIB rejections compared to those in the cyclosporine group [29]. Further, an evaluation of safety endpoints, including malignancy and infections, revealed no difference between groups with respect to urinary tract infections, CMV infection, or BKV infection. Importantly, the incidence of PTLD at 1 year was 1, 2, and 1 patients in the MI, LI, and CsA groups, respectively; however, after month 12, two additional patients in the MI group developed CNS PTLD. Patients who developed PTLD had risk factors for its development, including serologic negativity for the Epstein–Barr virus (EBVIgG$^-$). In the BENEFIT-EXT trial, the incidence of PTLD was also increased in the belatacept groups (1 MI; 2 LI; 0 CsA at 12 months, then 2 MI; 3 LI; 0 CsA after month 12); 3/5 were negative for EBV IgG as well [30]. Otherwise, the findings of the BENEFIT-EXT trial were comparable to the BENEFIT trial, with the exception of equivalent rejection episodes between the three groups (17.9% MI; 17.7% LI; 14.1% CsA), equivalent incidence of CAN (45% MI; 46% LI; 52% CsA) and increased NODAT at 1 year in the cyclosporine group (2% MI; 7% LI; 11% CsA $P = 0.0308$ MI vs. CsA) [30]. The lower intensity regimen of belatacept, which had a better safety profile, was FDA approved as an antirejection therapy for EBV-positive patients in renal transplantation in June of 2011.

The histologic severity and increased incidence of rejection in the belatacept groups illustrates the complexity involved in costimulation blockade. Several hypotheses to explain this phenomenon include the notion that belatacept's blockade of B7-1 and B7-2 on APCs also inhibits the binding of CTLA-4, a known negative costimulatory signal as well as a molecule critical for the function of FOXP3$^+$ regulatory T cells [21,31]. Furthermore, memory T cells, a major hurdle to allograft tolerance, are less dependent on the CD28/B7-1/B7-2 for stimulation and have therefore been implicated as key mediators of costimulation blockade-resistant rejection [32–35].

A logical approach would be to develop a biologic that specifically targets CD28. This would theoretically allow for more CTLA-4/B7-1/B7-2 ligation and therefore promote allograft tolerance. Several attempts at humanized anti-CD28 monoclonal antibodies have failed [36,37]. One study investigating a superagonist, TGN1412, which promoted T regulatory cell expansion in preclinical studies, resulted in cytokine storm and multiorgan failure in six volunteers [37]. However, a chimeric human/primate monovalent fusion protein named Sc28AT, which competes with B7-1 and B72 for binding to CD28 and lacks superagonist activity, has been studied in non-human primates. In this study they found that monotherapy with Sc28AT significantly prolonged renal allograft survival and the combined administration of Sc28AT with tacrolimus further prolonged allograft survival [38]. In addition, there was an increase in peripheral CD4$^+$ T regulatory cells with Sc28AT and on renal allograft biopsies there was a predominance of FoxP3$^+$ CTLA-4$^+$ Tregs with a paucity of CD20$^+$ B cells, and reduced expression of inflammatory cytokines [38]. It is likely that clinical studies with Sc28AT, or related proteins, are forthcoming in the transplant population.

CD40/CD40L(CD154) pathway

Another costimulatory pathway of interest in transplantation is the CD40/CD154 pathway. CD40 is constitutively expressed on APCs, including B cells and dendritic cells (DCs), and, in an inflammatory milieu, its expression is up-regulated by endothelial cells and fibroblasts. Further, its own expression is up-regulated upon activation [39–41]. CD154, the only ligand identified for CD40, is expressed on activated T cells, NK cells, eosinophils, and platelets [42]. Binding of CD40 to CD154 promotes activation and maturation of dendritic cells, activates B cells, and promotes immunoglobulin class switching. Further, downstream signaling of CD40 increases DC expression of MHC complexes and costimulatory molecules (i.e. CD80 and CD86), and promotes the secretion of inflammatory cytokines including TNF and IL-12 (Figure 18.4) [41,43].

CD40's ligand, CD154, was the first target of monoclonal antibodies aimed at inhibiting the CD40–CD154 pathway. Targeting the ligand tends to be safer than targeting the receptor, since binding the receptor has the potential to promote agonistic signaling. In addition, in comparison to CD40, CD154 has more limited expression. Early trials of monoclonal antibodies targeting CD154 were encouraging in mouse and non-human primate models, mostly when used in combination with other therapies including CTLA-4–Ig, donor specific transfusion, and rapamycin [23,44–47]. In both Phase I trials using a humanized mAb to CD154 (Hu5C8) for lupus patients and kidney transplantation, as well as subsequent studies with non-human primates, an unexpectedly high rate of thromboembolic events occurred, now thought to be related to the expression of CD154 on platelets and the role of CD154 in clot stabilization [48,49]. Further development of Hu5C8 as well as other anti-CD154 antibodies has been suspended. However, if efforts to manipulate the Fc portion of anti-CD154 mAb to prevent its adhesion to platelets are successful, clinical trials will likely resume. In the interim, interest in blockade of this pathway has now shifted to the development of anti-CD40 monoclonal antibodies. A chimeric anti-CD40 mAb (Chi220) prolonged islet allograft survival in NHP in combination with belatacept and prolonged renal allograft survival in combination with anti-CD86 antibodies in another NHP model [23 45,50,51]. Other novel antibodies targeting CD40 in the pipeline are: OM11-62MF, fully human (Novartis, Basel, Switzerland) currently being studied in patients with rituximab-refractory lymphoma; PG102, deimmunized chimeric (PanGenetics, Utrecht, Netherlands), a recently terminated (due to poor recruitment) study in patients with psoriatic arthritis; and, finally, ASKP1240, a fully human antibody (Astellas Pharma, Deerfield, IL and the only antibody being tested in the transplant population. Following the safe completion of a Phase Ia trial in healthy volunteers, Astellas has completed a Phase Ib, randomized, double-blind, parallel-group placebo-controlled pharmacokinetic, pharmacodynamic safety and tolerability study using ASKP1240 in de novo kidney transplantation in centers across the United States (http://clinicaltrials.gov/ct2/show/NCT01279538) [52].

Memory T cells and Ox40–Ox40 L/LFA-3/CD2 pathways

Combined blockade of the CD28/B7 and CD40/CD154 pathways in an attempt to promote allograft tolerance and prolong allograft survival in experimental transplant models has shown success [23,45]. However, this combination is not always effective in preventing allograft rejection [53,54], and a new phenomenon, coined "costimulation blockade-resistant rejection" has emerged, with the effector memory T cell implicated as the main culprit. Effector memory T cells are less dependent on CD28 costimulation for activation [55,56] and, even in the absence of costimulation blockade, have been identified as a barrier to transplant tolerance [57–59]. While calcineurin inhibitors are effective at inhibiting the

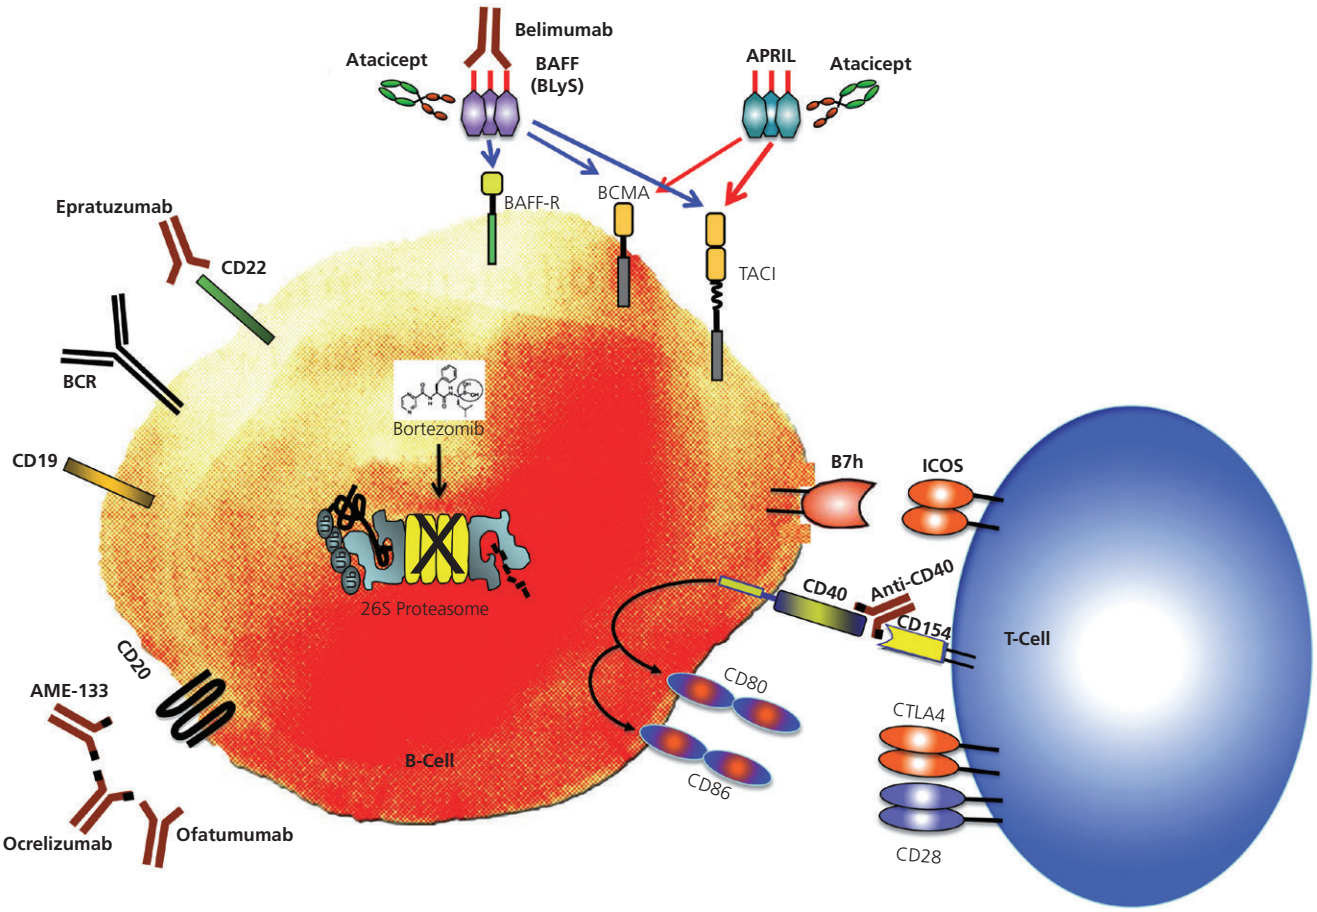

Figure 18.4. The CD40-CD40L (CD154) pathway. Reproduced from [52] Webber A, Hirose R, Vincenti F. Novel strategies in immunosuppression: issues in perspective. Transplantation 2011; 91:1057–1064, with permission from Wolters Kluwer Health.

de novo generation of $CD8^+$ memory T cells and the function of a pre-existing memory T cell repertoire, CNI-associated toxicities have prompted a search for alternatives [60].

OX40 (CD134) is expressed on activated T cells, and, when bound to its ligand (OX40L), which is expressed on dendritic cells, B cells, activated endothelial cells, and macrophages, promotes effector T-cell activation, as well as the humoral immune response through B-cell proliferation [61,62]. Conversely, OX40/OX40L ligation on T regulatory cells is an inhibitory (negative costimulatory) signal and results in the down-regulation of FoxP3 and therefore the loss of suppressor Treg cell function [63]. But perhaps most important is the OX40/OX40L role in $CD4^+$ memory T cell generation. OX40/OX40L interactions are imperative for the creation of a robust $CD4^+$ memory pool [64,65].

In a CD28/CD154 double-knockout mouse model to study skin allograft rejection, a vigorous rejection occurred largely dependent on OX40 costimulation [34]. In this study, neither treatment with mCTLA-4–Ig and anti-CD154 combined nor anti-OX40L alone prevented rejection in a wild-type mouse, but the mice treated with the combination of mCTLA-4–Ig, anti-CD154, and anti-OX40L experienced long-term skin allograft survival [34]. Similarly, long-term cardiac allograft survival was realized using a combination of CTLA-4–Ig and anti-OX40L in a rat heart transplant model [66]. The OX40/OX40L pathway is therefore a desirable target for future manipulation in solid organ transplantation.

While the OX40–OX40L costimulation pathway is vital for the proliferation and survival of $CD4^+$ memory T cells, the CD2–LFA-3 pathway is critical for $CD8^+$ effector memory T-cells function. CD2, a cell surface protein present on activated and memory T cells, acts as both an adhesion as well as a costimulatory molecule when bound to its ligand, LFA-3 (CD58). Alefacept (human LFA-3–IgG1 fusion protein, Amevive, Biogen, Cambridge, Mass) is a fusion protein FDA approved as an immunomodulatory therapy for psoriasis [67]. Interestingly, psoriatic plaques are characterized by infiltrating effector memory T cells and alefacept has been shown to preferentially reduce circulating effector memory T cells as well as effector memory T cells localized to psoriatic plaques in patients [68,69]. In response to the findings of increased acute rejection rates in patients treated with belatacept in the BENEFIT trial [29], a study aimed at better characterizing human effector memory T cells implicated in costimulation blockade resistant-rejection using flow cytometry was initiated. This study found that effector memory T cells, compared to other memory T-cell subsets, expressed the most CD2 [70]. Further, they found that alloresponsive $CD8^+CD2^{hi}CD28^-$ T cells produced the most cytokines and cytotoxic molecules (IFN-γ, TNF, and IL-2 granzyme B, CD107a) of all alloresponsive T-cell subsets, and that these cells are belatacept resistant. They theorized that these cells may have been responsible for the higher rejection rates seen in the BENEFIT trial [29]. The addition of alefacept in vitro inhibited belatacept-resistant

alloresponsive proliferating $CD8^+$ T cells [70]. The same group had previously demonstrated that, when used in combination with CTLA-4–Ig (abatacept) and sirolimus, alefacept significantly prolonged renal allograft survival in NHP [71].

Two trials were conducted (in the United States and Europe) comparing Alefacept administered initially i.v. and then subcutaneously for 3 months with a variety of tacrolimus-based regimens [72,73]. The alefacept-treated patients had either similar or higher rejection rates based on the tacrolimus dosing and the use of mycophenolate acid [72,73]. However, there were no safety signals and, as shown in the psoriasis studies, memory T cells in circulation were depleted. Astellas has decided to discontinue development of alefacept for renal transplantation. While an intriguing combination, a clinical trial combining CTLA-4–Ig and alefacept, previously shown to prolong allograft survival and deplete effector memory T cells in NHP [71], is unlikely to be performed.

LFA-1/ICAM pathway

Leukocyte function associated antigen-1 (LFA-1) is a beta integrin heterodimer and is composed of a unique alpha chain (CD11a) and a common beta chain (CD18) [74]. LFA-1 acts as a direct costimulatory molecule [75] but is also an integral component in stabilizing the immune interface between the TCR and MHC complex [76]. In addition, it is a cell adhesion molecule central to lymphocyte trafficking, primarily by interacting with intracellular adhesion molecule-1 (ICAM-1) [74,75]. It is expressed on T cells, B cells, and, like CD2, is more highly expressed on memory T cells [77,78].

Multiple studies using monoclonal antibodies to block the LFA-1/ICAM pathway in kidney transplantation have been performed [79–83]. Efalizumab is a humanized anti-LFA-1 monoclonal antibody, which had been FDA approved for the treatment of psoriasis [84–86]. A Phase I/II open-label multicenter trial using efalizumab in renal transplantation enrolled 38 patients and divided the patients into low-dose efalizumab (0.5 mg/kg) or high-dose efalizumab (2 mg/kg) at weekly subcutaneous doses in addition to maintenance therapy with either full-dose cyclosporine, mycophenolate mofetil, and steroids or half-dose cyclosporine, sirolimus, and prednisone [83]. While patient and allograft survival at 6 months were excellent, 8% of patients developed PTLD, albeit all of them treated with 2 mg/kg efalizumab and full-dose cyclosporine [83]. Eight patients with type 1 diabetes underwent islet cell transplantation and received induction with antithymocyte globulin followed by maintenance with efalizumab (0.5 mg/kg) plus sirolimus or mycophenolate. All patients achieved insulin independence and there were no reported adverse events related to efalizumab, and, interestingly, a marked increase in circulating $CD4^+$ $FoxP3^+$ T regulatory cells was demonstrated [87]. Similarly, another study using efalizumab for islet cell transplantation in diabetic patients showed that all patients treated with the efalizumab-based regimen achieved insulin-independence after a single islet cell infusion [88]. In April 2009, efalizumab was voluntarily withdrawn from the United States market due to safety concerns specifically related to progressive multifocal leukoencephalopathy (PML) seen in patients treated for psoriasis (www.fda.gov/Safety/MedWatch/default.htm). However, in light of the recent surge of interest in costimulation blockade-resistant rejection, a study, capitalizing on the known increased expression of LFA-1 on effector memory T cells, showed that TS-1/22, a mouse antihuman CD11a mAb, when combined with basiliximab and sirolimus or belatacept, prolonged pancreatic islet allograft survival in NHP [89]. Future clinical trials in transplantation will likely investigate the effect of combinations of biologics, targeting both costimulatory pathways integral to naïve T cell activation (i.e. with belatacept, anti-CD40) as well as pathways vital to the proliferation and activation of memory T cells (i.e. alefacept, anti-LFA-1, anti-OX40), and other pathways critical to the alloresponse, including complement and B-cell proliferation pathways. In a study using a mouse model of heart transplants, the combination of CTLA-4–Ig with a monoclonal antibody to the complement factor C5 (for both the donor and the recipient) showed significant prolongation of graft survival [90]. These combinations have shown great promise in experimental transplantation [34,70,71,90,91], but in human models may be limited by their potential for over-immunosuppression.

Future therapeutic targets of B cell and antibody-mediated injury

With recent data supporting the notion that chronic antidonor antibody mediated injury may be the primary pathology responsible for late allograft loss, therapeutic targets aimed at the B cell and plasma cell have been under active investigation in transplantation [7,8,92,93]. Current therapies used in desensitization protocols as well as for the treatment of acute and chronic antibody mediated rejection (AMR) include plasmaphersis, IVIG, and a chimeric anti-CD20 monoclonal antibody, rituximab [94–98]. Newer therapies with anecdotal success in AMR and desensitization include bortezomib and eculizumab. Bortezomib, a proteasome inhibitor, targets metabolically active, rapidly dividing cells by selectively inhibiting the 26s proteasome and inhibiting the transcriptional activator nuclear factor kappa B, thereby inducing apoptosis. It is FDA approved for the treatment of plasma cell dyscrasias, and by targeting the normal plasma cell in transplantation, has shown promise in reducing donor-specific antibodies and combating AMR in several case series, albeit limited by its neurotoxicity [99–104]. Eculizumab, a humanized anti-C5 antibody FDA approved for complement-associated diseases, including paroxysmal nocturnal hemoglobinuria and atypical hemolytic uremic syndrome (both recurrent and de novo post-transplant) [105–108], has been shown to decrease the incidence of AMR and transplant glomerulopathy in desensitization protocols [109] as well as improve outcomes in the treatment of AMR post-transplantation [110]. More agents targeting the complement cascade as a means to curtail complement-dependent alloantibody-mediated injury are likely to surface in the next few years; however, rigorous clinical trials will be required for bortezomib and eculizumab to better define their efficacy and safety.

It is important to note that B cells participate in the alloimmune response on many levels. They are clearly an integral component of antibody-mediated injury, but they are also effective antigen-presenting cells, and are thus crucial to the activation of T cells [111]. Thus agents targeting the B cell itself may become valuable therapies in promoting more enduring graft acceptance (Figure 18.5). New B-cell depleting antibodies in the biopharma pipeline include monoclonal anti-CD20 antibodies atumumab, ocrelizumab, veltuzumumab, and the B-cell depleting anti-CD22 antibody, epratuzumab, which is currently under investigation in a Phase IIb trial for lupus (www.clinicaltrials.gov) [112,113]. Belimumab and atacicept are novel B-cell therapeutics, mainly studied in the treatment of autoimmune diseases and blood-borne malignancies, with unique targets. Belimumab is a fully human monoclonal antibody that binds to and inhibits the action of soluble B-lymphocyte

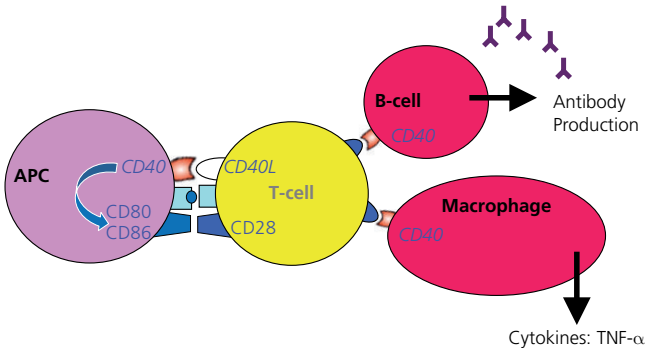

Figure 18.5. Novel B-cell targets.

stimulator (BLys, also known as B-cell activating factors BAFF). BLys is a tumor necrosis-factor family ligand that acts as a B-cell survival factor when bound to its receptors BAFF-R, B-cell maturation protein (BCMA), and the transmembrane activator and calcium modulator and cyclophilin ligand interactor (TACI) [10]. Belimumab has been efficacious in the treatment of systemic lupus erythematosus and has recently received FDA approval for this indication [113–115]. The University of Pennsylvania is investigating belimumab as a desensitizing agent for highly sensitized renal transplant recipients in a 1-year, Phase II study (www.clinicaltrials.gov).

Atacicept is a fusion protein composed of an extracellular domain of TACI, fused to the constant region of human IgG1. It interferes in the binding of a proliferation-inducing ligand (APRIL) to its targets BCMA and TACI, and thereby impedes B-cell stimulation and proliferation. Importantly, APRIL is required for later stages of B-cell differentiation and plasma cell survival [10]. A Phase II study of atacicept plus mycophenolate in patients with lupus nephritis was halted early due to an increase in infectious complications [113,116]. Further studies in lupus patients are ongoing. At present, there are no clinical studies investigating the role of atacicept in transplantation, but given its proven potency in reducing plasma cells and immunoglobulin levels, its future role in desensitization protocols and treatment of antibody-mediated rejection seems promising.

IL-6

The cytokine IL-6, traditionally considered a regulator of acute phase inflammatory responses, is emerging as a critical promoter of TH17 cells and inhibitor of T regulatory cells [117]. The relevance of the effects of IL-6 in autoimmune disease is well established both experimentally and clinically with the first anti-IL-6 therapy Tocilizumab (Genetech), a humanized anti-IL-6 receptor antibody, already approved for rheumatoid arthritis. The two other biologics targeting IL-6 are being developed for autoimmune disease by Bristol-Myers and Regeneron. Experimentally the effect of anti-IL-6 therapy in transplantation is most pronounced in combination with costimulatory blockade [118]. At present single center trials are underway with Tocilizumab at Cedar Sinai as a desensitization therapy to improve transplant rates (clinicaltrials.gov # NCT01594424) and at UCSF to treat inflammation and borderline rejection (clincialtrials.gov). If successful these efforts may be a catalyst for industry to consider extending their clinical development to organ transplantation.

Small molecules

JAK3/protein kinase C

Cytokine receptors that utilize the common gamma chain (i.e. receptors for T- and B-cell growth factors IL-2, 4,7, 9, 15, and 21) all require the cytoplasmic tyrosine kinase Janus kinase 3 (JAK3) for signaling. Cytokine signaling through JAK3 is critical for lymphocyte activation and differentiation and is the third and final signal (after MHC-TCR engagement and costimulation signals) necessary for T-cell activation [119,120]. In fact, illustrating its potent role in lymphocyte biology, mutations in the common gamma chain and/or JAK3 result in a severe combined immunodeficiency (SCID) phenotype [121]. JAK3's expression (as opposed to JAK1/2 expression) is predominantly limited to lymphocytes and natural killer cells, thereby making it a critical component of the alloimmune response and an appealing target to prevent allograft rejection [122]. The small molecule JAK3 inhibitor tofacitinib (originally named CP-690,550) has shown efficacy in the treatment of human autoimmune disorders [123,124] and interest in its role as an agent in transplantation followed, especially in light of its potential for selectively inhibiting T effector cell function while preserving the suppressive activity of $CD4^+$ $FOXP3^+$ T regulatory cells [125].

After successful use of tofacitinib in mice and NHP models of transplantation [126–129], a Phase I trial using JAK3 inhibition in renal allograft recipients was performed [130]. In this dose-escalation study, the co-administration of tofacitinib at different dosing regimens with mycophenolate mofetil in 28 stable renal transplant patients at least 12 months out from transplant revealed an acceptable safety and tolerability profile with doses ranging from 5 mg twice daily to 30 mg twice daily [130]. A Phase IIa, multicenter, randomized, open-label pilot study comparing two dosing regimens of tofacitinib (15 mg p.o. b.i.d. and 30 mg p.o. b.i.d.) compared with tacrolimus in de novo kidney transplant recipients induced with anti-IL2 receptor antibodies and maintained on MPA and steroids found the incidences of biopsy-proven acute rejection (BPAR) at 6 months to be 5.3% in the 15 mg twice daily group (CP15), 21.1% in the 30 mg twice daily group (CP30) and 4.8% in the tacrolimus group [16]. Estimated GFRs at 6 and 12 months were similar across all treatment groups but there was a higher incidence of BK virus nephropathy (20%) and CMV disease (21.1%) in the CP30 group compared to the tacrolimus group (0%). In terms of metabolic parameters, there was no difference in the incidence of NODAT; however, dyslipidemias were more common in the two groups treated with tofacitinib, with all cholesterol parameters increased by up to 34% and 44% in the CP15 versus CP30 groups respectively [16].

Data from the Phase IIb study has been published [131]. In this study, 322 de novo kidney transplant patients were randomized to one of three groups: tofacitinib (CP) dosing starting at 15 mg p.o. b.i.d. in groups 1 and 2, but the group 1 dose was reduced to 10 mg b.i.d. after month 6 and group 2 dose was reduced to 10 mg b.i.d. after month 3, versus cyclosporine [132,133]. All patients received induction with anti-IL2R antibodies and were maintained on mycophenoloic acid and steroids. Both tofacitinib groups demonstrated non-inferiority in 6 and 12 month biopsy-proven acute rejection rates, with statistically significantly higher estimated GFRs at 12 months (64.6 and 64.7 mL/min CP1 and CP2 versus 53.9 mL/min cyclosporine). The incidence of NODAT was reduced in both tofacitinib groups compared with cyclosporine; however, immunosuppressive–related complications, including infection (i.e. CMV) and malignancy, were higher in both tofacitinib

group. Alarmingly, five patients in the tofacitinib groups developed PTLD. No one in the cyclosporine arm developed PTLD [132,133]. Thus tofacitinib's role in transplantation is limited by the need to elucidate the optimal dosing regimen required to prevent rejection without precipitating adverse consequences from over-immunosuppression.

Protein kinase C

Finally, sotrastaurin, a novel small molecule targeting protein kinase C isoforms PKCθ and PKCα, represents yet another example of an agent studied in transplantation that targets calcineurin-independent pathways. Protein kinase C is central to antigen receptor signal transduction pathways in lymphocytes, and PKCθ and PKCα are isotypes crucial for IL-2 and IFN-γ production, respectively [134]. After showing prolonged renal allograft survival in murine and NHP models [135–138], and its utility and safety in the treatment of psoriasis patients in a proof-of-concept study [139], oral sotrastaurin was studied in a Phase II investigation evaluating its safety and efficacy in de novo renal transplant recipients [140]. In this study 216 patients were randomized to one of three groups: sotrastaurin 200 mg twice daily + tacrolimus standard exposure (SET), sotrastaurin 200 mg twice daily + tacrolimus reduced exposure (RET), versus control tacrolimus + MPA. Sotrastaurin recipients meeting conversion criteria were converted to a CNI-free regimen at month 3. All patients received induction therapy with anti-IL-2R antibodies and were maintained on steroids [140]. Prior to CNI withdrawal in the sotrastaurin groups, the primary efficacy endpoint (composite of BPAR, graft loss, and death) were equal amongst the groups; however, by the end of the study (after withdrawal of CNI in the sotrastaurin groups), the primary efficacy end point was reached in 7.8% of the control group, but 44.8% and 34.1% of patients randomized to the sotrastaurin + SET and sotrastaurin + RET, respectively. Conversely, the incidence of adverse events, including GI, cardiac, and infectious, were equal amongst the groups [140].

A more recent study randomizing de novo renal transplant patients to either a tacrolimus-based regimen or a sotrastaurin based regimen (at 300 mg twice daily dose) plus MPA and steroids (after anti-IL2R induction) had similar findings. Namely, despite improved eGFR in the sotrastaurin group at 3 months (59 ml/min vs. 49.5 mL/min), the primary efficacy endpoint (composite BPAR, graft loss, or death) was reached by statistically significantly more patients in the sotrastaurin arm than controls (25.7% vs. 2%, respectively), and the study was terminated early. Again, adverse events were similar between the two groups [141].

Summary

An editorial written by H. U. Meier-Kriesche and B. Kaplan entitled *The Search for CNI-Free Immunosuppression: No Free Lunch* aptly paraphrases the frustration involved in the ongoing search for novel targets in transplantation [142]. JAK3 inhibitors, while equally as efficacious at preventing allograft rejection as CNI's, do so at the expense of precipitating more adverse events. Conversely, PKC inhibitors, with similar incidences of infection and malignancies, fail to provide similar efficacy in endpoints including biopsy-proven acute rejection and allograft survival rates. Agents targeting costimulatory pathways appear remarkably efficacious against naïve immune responses, but less suited to control memory responses, leading to a combined phenotype of efficacy and adverse event that is largely dependent on the recipient's prior immune history. Nonetheless, it is clear that the future of transplantation and its quest for CNI-free immunosuppressive regimens is underway. Whether using combinations of novel biologics, optimizing the therapeutic window of small molecules, or some combination thereof will ultimately provide robust immunologic tolerance to the allograft while maintaining an intact immune system to other antigens, has yet to be elucidated.

SECTION 3

Organ Procurement

CHAPTER 19

Administration of Organ Procurement and Allocation

Jennifer M. Porter,[1] Lori E. Brigham,[2] and Susan Gunderson[3]

Introduction

Ethically sound and technically successful organ transplantation is logistically complex. It requires substantial attention to the best practices for identifying potential donors, obtaining donation authorization, determining donor medical suitability, coordinating the recovery and distribution of all donated organs, and maintaining methods for fiscal sustainability of the transplant process. Although historically, dedicated transplant clinicians based at the few centers with active transplant programs handled these functions, over the past four decades these needs have increasingly been codified in federal and state law and exercised by specific Organ Procurement Organizations (OPOs). This chapter examines the role of OPOs in organ recovery and allocation—how they are organized and operate, the legal and institutional framework within which they operate, and their integration into the general fabric of clinical transplantation. The chapter initially lays out the basis for OPOs, and the state and federal statutory frameworks governing their conduct of organ procurement and distribution. It then walks the reader through the process, noting the important interactions required to facilitate a successful organ placement.

This chapter focuses on the US' experience, and does so not as a matter of exclusivity, but rather to provide a means for a systematic survey of the numerous functions served by OPOs. The authors are cognizant of the fact that this is a prominent, but not exclusive, way to manage organ acquisition and distribution. The chapter closes with a brief discussion of the organizational models used in selected countries outside the US, with specific reference to the model originating from Spain and used in many countries outside the US. This section provides contrast and international perspective. An exhaustive account of all the practiced approaches is beyond the scope of this chapter.

What is an Organ Procurement Organization?

In the US, OPOs play "a crucial role in ensuring that an immensely valuable, but scarce resource—transplantable human organs—becomes available to seriously ill patients who are on a waiting list for an organ transplant" [1]. They are the entities designated by the federal government to be responsible for promoting organ donation, for identifying potential organ donors, and for recovering and distributing the recovered organs for transplantation into all patients who require them. OPOs are the stewards of the nation's donation process.

OPOs were created by the National Organ Transplant Act (NOTA), passed by the US Congress in 1984 [2]. The NOTA established a national system of OPOs to recover and distribute donated organs from deceased donors. The system and the OPOs exist today in substantially the same form as initially established by the NOTA. Additional discussions of national organization and regulation of transplant activities can be found in Chapter 128.

Each OPO is responsible for a defined geographic area, i.e. a "donation service area" (DSA). DSAs are not uniform. They vary in area, from approximately 3600 square miles to >866 000 square miles; in population numbers, from 1.3 million to 19.1 million people; in population diversity (ethnic, racial, urban, suburban, rural); and in number of hospitals served, from 12 to approximately 220 acute care hospitals in a single DSA. The country is divided into 58 DSAs, which are operated by 58 OPOs—hospitals or universities operate seven, and the others are serviced by independent entities E. Eidbo, Association of Organ Procurement Organizations, personal communication, February 19, 2013). The OPOs function as the foundation level of a national system of recovery and allocation that is coordinated through the Organ Procurement and Transplantation Network (OPTN).

The NOTA provided two sources of federal government funding: (1) Medicare reimbursement, under the authority of the Social Security Act (SSA), as the principal source of funding for kidney procurement, and (2) Health Resources and Service Administration (HRSA) grants for OPOs [3]. Participation in the Medicare reimbursement system requires that OPOs file cost reports, which are audited and adjusted by Medicare on a retrospective basis. In addition, Medicare regulates the amount that each OPO may charge a transplant hospital for a kidney [4].

OPOs are required to have arrangements to be paid for the acquisition of all organs. Payments from transplant centers for organ acquisition charges (OACs) are the single largest source of OPO funding. Each OPO develops its own OACs, based on its cost accounting data, which include direct acquisition expense

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

(including inpatient hospital services, physician services, laboratory testing, transportation, and other medical expenses), clinical staffing, information technology, administration, and the expenses related to mandated activities in community/public education and education for hospital and medical professionals.

Many OPOs also provide tissue donation services, including cornea donation, in their DSAs. In these tissue efforts, OPOs must comply with Food and Drug Administration (FDA) rules, in addition to Centers for Medicare and Medicaid Services (CMS) certification requirements for their organ procurement status.

The NOTA and the SSA place OPOs under the general supervision of the Secretary of Health and Human Services (HHS). They operate under regulations issued by the HHS CMS [5], and under the policies and procedures of the OPTN [6]. OPTN itself operates under the general supervision of the HHS Health Resources and Services Administration (HRSA) [7]. OPOs are subject to both federal and state law.

State law framework

Between 1967, when the world's first successful heart transplant was performed, and the passage of the NOTA in 1984, transplantation developed into an effective mainstream medical treatment. By 1978, the science was sufficiently defined that the federal government began reimbursing, through Medicare, the transplantation costs associated with end-stage renal disease. The need for transplantable organs of all types grew rapidly. Then, as now, the numbers of organs available for transplant greatly exceeded the numbers of desperately ill patients waiting for them.

Transplantation's emergence as an accepted therapy was facilitated by developments in state law that gave clear legal authority for the strides being made in science and medicine. The National Conference of Commissioners on Uniform State Laws (NCCUSL) [8] proposed two laws: the Uniform Anatomical Gift Act of 1968 (AGA) and the Uniform Determination of Death Act of 1981. When adopted into state law, these laws provided the legal foundation for the expanded availability of transplantation as a medical treatment. [The NCCUSL (now called the Uniform Law Commission) is a non-profit entity supported by the states. Through a broad-based collaborative process, it develops and recommends the adoption of uniform statutes on matters of national importance that by law are the responsibilities of the states. NCCUSL describes its function as bringing "clarity and stability to critical areas of state statutory law."] These state laws are the legal foundation on which OPOs, and numerous other aspects of transplantation, rely today.

The Uniform Determination of Death Act (UDDA)

The Uniform Determination of Death Act (UDDA) was issued by the NCCUSL in 1981 [9]. It recognized a new medical and scientific consensus that death could be determined based on neurologic criteria (brain death), in addition to the traditional cessation of circulatory function (discussed in detail in Chapters 21 and 22, respectively). This expert view had no precedent in the common law, which in the absence of specific precedent, acted as an impediment to organ recovery and transplantation. UDDA proposed that states enact a statute to permit death to be determined based on the cessation of neurologic function. UDDA was adopted by 38 states; but all states came to enact laws that recognized death by neurologic criteria. Based on this new clarity in the law, donors whose deaths were determined on neurologic criteria rapidly became the principal source of donated organs.

The Uniform Anatomical Gift Act of 1968 and its successors [10]

The AGA was introduced in 1968 to clarify uncertainties in common law that emerged with the new transplantation science. It was adopted rapidly in all 50 states and the District of Columbia.

It laid out, for the first time, a statutory right to give, receive, and use an anatomical gift from a deceased donor. The AGA recognized that individuals and their families had, effective at death, a right to donate organs, eyes, and tissues for transplantation, therapy, research, and education. It established some essential rules about who could recover anatomical gifts, to whom those gifts could be given, and how those gifts could be used. It gave immunity from legal liability to those who acted in good faith to comply with the AGA, thereby alleviating a significant concern for all participants in the developing donation and transplantation process [11].

NCCUSL emphasized the importance of the AGA in encouraging people to donate and in building a national legal foundation for organ donation and transplantation. It stated: "Both the common law and the present statutory picture is one of confusion, diversity and inadequacy . . . [T]he Act will provide a useful and uniform legal environment throughout the country for this new frontier of modern medicine" [12].

The AGA evolved through two major revisions in 1987 and 2006 that were made necessary by emerging federal law, by uncertainties left by prior AGA versions, and by the still developing science of transplantation. The 1987 revision, following federal law, clearly established the basic rule that it is unlawful to "sell, procure, transfer or facilitate the transfer for valuable consideration . . . of any part that could be the subject of an anatomical gift" (section 10) and specified that "valuable consideration" did not include "reasonable payments" for removing, processing, preserving, quality control, storage transportation, and implantation of a donated part. The Revised Uniform Anatomical Gift Act (RUAGA), issued by NCCUSL in 2006, brought state and federal law into harmony for the first time. It also restored the state law uniformity that the first AGA sought and that states (and NCCUSL) were unable to maintain in the face of developing medical science and changes in federal law.

The RUAGA expands and simplifies the methods by which individuals can make an anatomical gift; it now includes all the methods that recent experience has shown to be most helpful in encouraging donation, e.g. designation on a drivers permit, registration in a donor registry, having a healthcare agent, or any signed record, including a will or advance directive. It clarifies who has priority to make an anatomical gift. The AGA recognized the right of the individual to make an anatomical gift; however, OPOs, hospitals, families, doctors, other medical professionals, and the community at large routinely acceded to the wishes of bereaved family members—often at the expense of a decision made by the deceased individual. The RUAGA addressed this issue squarely. If a person has made a decision to donate, or to refuse to donate, the RUAGA bars everyone else from changing that decision [13]. The bar applies to everyone; however, because of their front-line role in the recovery process, OPOs have a primary responsibility for honoring the donor's wishes and ensuring that others do as well. The RUAGA is now the law in 46 states, and even where it is not, the law requires that the deceased individual's decision be respected.

Reflecting the donation and transplantation practices of the time, the 1968 AGA and its 1987 revision both permitted hospitals, surgeons, and physicians to receive donated organs and tissues

for transplantation and therapy. The 2006 RUAGA, however, authorized donation to a named person for transplantation and therapy if the named person is the recipient of the donation, or is an eye or tissue bank. All other donations for transplantation or therapy must be received by the appropriate procurement organization (i.e. eye, tissue, or organ). Donations for research and education can still be made to named institutions [14].

The RUAGA also spells out a list of OPO rights and duties. When a hospital refers a potential donor to the OPO (as required by federal law), the OPO must make a reasonable search of department of motor vehicles records and donor registries to see if the referred individual is registered as a donor, and must make a reasonable search for any other person authorized to make an anatomical gift. It authorizes the OPO to make any reasonably necessary examination, including an examination of all medical and dental records, to determine the medical suitability of a part that could be an anatomical gift, and further provides that while this examination is being conducted, "measures necessary to ensure the medical suitability of the part may not be withdrawn unless the hospital or procurement organization knows that the individual expressed a contrary intent." After the donor's death, the RUAGA authorizes the OPO, among others, to conduct any reasonable examination necessary to ensure the medical suitability of the body or part for its intended purpose [15].

When a patient dies in a hospital, state law determines, among other things, whether the patient is dead, and whether the patient or another person authorized by law made an anatomical gift that can be recovered if medically suitable.

Federal law framework

Prior to the NOTA in 1984, the US did not have an organized or coherent national response to the task of recovering and distributing organs. The system developed in an ad-hoc manner, responding to local and regional circumstances and the events of the time. The state laws described above were an outgrowth of this process. Organ procurement agencies (OPAs) began operating in the 1960s and their functions were a natural outgrowth of the expanding availability of transplantation. By 1984, approximately 90 OPAs operated in the US. Fifty were hospital based and 40 were separately incorporated legal entities serving multiple hospitals and regional areas [16].

The congressional hearings and public discussion that preceded passage of the NOTA focused attention on the persistent and growing gap between organ supply and the inability of the existing process to resolve the issue. A national response was seen as a necessary part of the answer, and the NOTA sought to address the shortage by creating a national system that would encourage donation and ensure recovered organs were distributed and used in an equitable manner [17].The NOTA established the basic institutional framework for organ recovery, distribution, and use in the US; it created a Task Force on Organ Transplantation that was charged with responsibility for conducting a broad ranging inquiry into organ donation and transplantation in the US, and with making recommendations on how the system could be improved (see Chapter 137).

Institutions and system created by the NOTA

Prohibition of the sale of organs

The Act declared it unlawful to "knowingly acquire, receive, or otherwise transfer any human organ for valuable consideration for use in human transplantation" [18].It also provided that: "valuable consideration" did not include "reasonable payments" associated with the "removal, transportation, implantation, processing, preservation, quality control, and storage of a human organ or the expenses of travel, housing, and lost wages incurred by the donor of a human organ in connection with the donation of the organ" [18].

Creation of OPOs

The Act organized a nationwide network of OPOs to take on functions previously exercised in an ad-hoc manner by the 90 OPAs. The NOTA prescribed the structure, governance, and responsibilities of these OPOs. It also required the OPO to have an advisory board to make recommendations to its regular board about all matters pertaining to organ procurement and allocation. To assure the independence of this advice, the NOTA prescribed that the members of this advisory body should represent all parties with an interest in organ recovery and procurement, e.g. transplant hospitals and surgeons, members of the public, donor families, hospital administrators, eye and tissue banks, and individuals with skill knowledge and experience in neurology and histocompatibility.

The NOTA required OPOs to be members of the newly formed OPTN, the entity created for the purpose of coordinating OPOs at the national level and operating a national list of people requiring transplants. The role of the OPTN is discussed more fully below.

The NOTA and subsequent amendments set in place a mechanism that mandated co-operation with all other participants in the donation process, e.g. donor hospitals, transplant hospitals, and tissue and eye banks, although it left it to the affected parties to work out the content of that co-operation. These requirements are incorporated, in expanded form, in federal regulations administered by CMS [19].

Creation of the OPTN

The OPTN was established to: develop and maintain a computerized organ transplant waiting list, now called UNET; to facilitate organ matching and placement; to develop consensus-based policies and procedures for organ recovery, allocation, and transportation; to collect and manage scientific data on the organ transplantation process; to provide data to the government and others, including the Scientific Registry of Transplant Recipients (SRTR; see Chapter 133 for additional detail regarding this registry), for use in the effort to improve solid organ allocation and transplantation; and to provide professional and public education about donation and transplantation, the activities of the OPTN, and the critical need for donation [20] (see Chapter 137).

The OPTN is operated by a private, non-profit contractor, the United Network for Organ Sharing (UNOS). The UNOS operates and maintains UNET on behalf of the OPTN. UNET is the computer system used to receive donor and recipient information and facilitate organ allocation and distribution. Transplant hospitals are responsible for placing data on the UNET waitlist program, and keeping current the name and pertinent medical information of patients in need of transplants. UNET maintains different lists for different organ systems. OPOs use the DonorNet module of UNET to enter similar information for donors. They then use this program to match the donor with possible recipients listed on the UNET waitlist program.

OPOs are required to be members of the OPTN. The OPTN requires its members to comply with its policies and procedures

[21]. The HHS requires OPOs to comply with the OPTN "rules and requirements," which are OPTN pronouncements that the HHS has determined should have the force of law [22]. Like CMS, the OPTN also measures the effectiveness of OPO performance.

Creation of the SRTR

The SRTR was established by the NOTA to be a repository of accurate information about all organ transplants performed in the US [23]. OPOs among others are required to submit specified information to it on a regular basis [24]. The data collected in the registry support ongoing evaluations of the status of solid organ transplantation in the US.

The SRTR also designs and implements scientific studies using the accumulated data to better understand the performance of the US donation and transplantation system. It disseminates its information and analyses to the transplant community (transplant programs, OPOs, policy makers, transplant professionals, transplant recipients, organ donors and donor families, and the general public). It also gives qualified researchers access to data to assist their independent efforts to study various aspects of solid organ transplantation.

The US organ transplantation system employs evidence-based allocation policy development through collaborative efforts between the OPOs, transplant community, the SRTR, and the OPTN. Policy making is the OPTN's responsibility; the SRTR, however, plays an important role by performing data analyses to provide policy makers with the information necessary to make informed decisions.

SRTR is administered for the HHS by the Chronic Disease Research Group of the Minneapolis Medical Research Foundation [25].

NOTA requires OPOs to be effective

Since the inception of the national system, one goal has remained constant: that of closing the gap between available organs and the people awaiting transplantation. In 1984, the NOTA envisaged that participants in the donation and transplantation process would make continuous efforts to improve their performance. Changes in the law after that time have aimed to strengthen that initial and perpetually relevant idea.

The Organ Procurement Organization Certification Act of 2000, P.L. 106-505 [26], required CMS to develop and apply standards to measure OPO performance. The Act was designed to rectify uncertainties created by the performance measurements then in use. In 2006, CMS issued new performance standards in response to this legislation [27]. These regulations specified that OPOs (other than those in non-contiguous states) must meet all three of the following outcome measures to retain their certification to operate as an OPO [27]:

- The OPO's donation rate of eligible donors as a percentage of eligible deaths must be no more than 1.5 standard deviations below the mean national donation rate of eligible donors, averaged over the 4 years of the OPO's recertification cycle. Both the numerator and denominator of an individual OPO's donation rate ratio are adjusted by adding 1 for each donation after cardiac death and for each donor over the age of 70 years.
- The observed donation rate is not significantly lower than the expected rate for 18 or more months of the 36 months of data used for recertification purposes.
- At least two of the three following yield measures are no more than 1 standard deviation below the national mean, averaged over the 4 years of the recertification cycle:
  - the number of organs transplanted per standard criteria donor, including pancreata used for islet cell transplantation;
  - the number of organs transplanted per expanded criteria donor, including pancreata used for islet cell transplantation; and
  - the number of organs used for research per donor, including pancreata used for islet cell research.

Failure to meet all outcome measures resulted in automatic decertification. Within the OPO community, these outcome measures were criticized for failing to provide any useful insight into OPO performance. OPOs requested CMS to revise the regulation. In July 2013, CMS acknowledged OPO concerns and proposed several regulatory revisions [28]. In particular, CMS determined that an OPO would retain its certification if it satisfied two, instead of three, of the outcome measures. Despite continuing OPO concerns about the validity and utility of the outcome measures that were articulated again during the rulemaking proceeding, the proposed rule became final in December 2013 [29].

CMS performance evaluation

At this time (January 2014), the 2006 regulation, as amended in December 2013 to require compliance with two of the three outcome measures, is the standard by which OPO performance is measured. OPOs are required to comply with that regulation in order to be certified by CMS to operate as an OPO.

CMS contemplates that an OPO that fails to meet these outcome measures will lose its certification to operate as an OPO. Once an OPO is decertified, its DSAs could then be taken over by any other entity that submits an application to CMS and is approved as meeting the requirements to be an OPO [30].

As noted above, OPOs are also required by law to comply with OPTN policies and procedures and rules and requirements. The OPTN uses a different methodology to determine whether an OPO is effective at its job.

OPTN performance evaluation

The OPTN uses a performance methodology developed by the SRTR using a set of statistical models and based on actual donor information collected in the registry. These models take into account various donor characteristics that are not under the control of the OPOs, in an attempt to risk adjust for differences in the types of donors managed by each OPO. A separate risk adjustment model is used for each of six organs: heart, intestine, kidney, liver, lung, and pancreas. The models were based on donors from whom at least one organ was recovered for the purpose of transplant (not necessarily transplanted), and "yield" is defined as an organ that was eventually transplanted. Expected yields are given for kidneys, lungs, hearts, livers, pancreata, and intestines. For hearts, livers, pancreata, lungs, and intestines, the expected yield will range from 0 to 1. For example, if the expected liver yield is 0.7, one would expect a similar donor to yield a transplanted liver seven out of 10 times. The lung yield is modeled as the probability of yielding at least one lung for transplant; therefore, expected lung yield ranges from 0 to 1 rather than 0 to 2. For kidneys, the expected yield will range from 0 to 2. The total expected organ yield is then calculated as the sum of the organ-specific expected yields and ranges from 0 to 7. On an organ-specific basis, the models predict

how many organs would have been expected to be recovered and transplanted based on the national experience for donors with similar characteristics.

In July 2012, the OPTN adopted SRTR's expected organ yield methodology to monitor OPO performance. The performance requirement is contained in the OPTN Bylaw, Appendix B (Membership Requirements for Organ Procurement Organizations), at Section B.2 [31]. This section also specifies that the OPTN Membership and Professional Standards Committee (MPSC) will evaluate all OPOs to determine if the difference in observed and expected organ yield can be explained by some unique aspect of the DSA or OPO in question.

The MPSC is required to review all OPOs whose observed organ yield rates fall below the expected rates by more than a specified threshold. The absolute value of the relevant parameters in the formula may be different for different organs. It is anticipated that the values will be reviewed and modified periodically, as the OPTN Board agrees.

The initial criteria used to identify a lower than expected organ yield, for all organs as well as each organ type, are:

- >10 fewer observed organs per 100 donors than expected yield (Observed per 100 donors – Expected per 100 donors $=< -10$);
- a ratio of observed-to-expected yield of <0.90;
- a two-sided P value of <0.05.

An MPSC review is triggered when an OPO meets all three criteria. If an OPO's organ yield rate cannot be explained by donor mix or some other unique clinical aspect of the OPO or DSA in question, the OPO member, in co-operation with the MPSC, is required to implement a performance improvement plan. Failure to do so is a violation of OPTN obligations.

Participants in the organ donation and transplantation process have engaged in voluntary efforts, outside the formal legal and regulatory framework, to improve performance by identifying "best practices," and by using evaluation methods that more accurately reflect the effectiveness of OPO efforts. The most far-reaching and potentially transformative of these efforts was the Organ Donation Breakthrough Collaborative (ODBC or Collaborative).

Organ Donation Breakthrough Collaborative

The ODBC started in 2003 as an initiative of the Secretary of HHS conducted under the auspices of the HRSA's Healthcare Systems Bureau (HSB), Division of Transplantation (DoT). Its aim was to dramatically increase the availability of transplantable organs and provide best practices for organ recovery and placement. The HRSA worked in partnership with the Institute for Healthcare Improvement (IHI), Quality Reality Checks, Inc. (QRC) and teams of OPOs and their hospital and transplant center partners from across the country to create change that could lead to breakthrough transformations in the system for organ donation.

The initial focus of the effort was national in scope and aimed to improve organ donation conversion rates (the conversion rate is the ratio of the number of actual donations occurring at the hospital as compared to the number of eligible donors) in hospitals with more than eight eligible donors annually. The methodology used was built on the Model for Improvement, a nationally recognized and highly effective method of performance improvement used by the IHI.

During the first two cycles of the ODBC conducted in 2003–2005, the HRSA and an expert faculty, comprised of healthcare professionals from high performing organizations across the country, helped each participating organization try to achieve goals, set by HRSA, to:

- notify OPOs of all deaths or imminent deaths in a timely manner;
- increase the donation authorization rates in participating hospitals by 30%;
- increase the donor conversion rates to 75% or greater;
- notify OPOs of all pending decisions to withdraw mechanical support from patients with non-survivable conditions;
- increase to 100% the number of families who receive organ donation counseling from a trained and effective donation request team;
- respond to all death notifications in <90 min.

The goal of the ODBC was to identify best practices and create systems based on those practices that would assure, within each DSA nationwide, accurate and timely donor referral, screening, consent, organ recovery, and placement.

In 2006, during the fourth cycle of the ODBC, the HRSA introduced "organs transplanted per donor" (OTPD) as another way to assess OPO, transplant program, and donor hospital performance. The OTPD is the ratio of the number of all organs transplanted to the number of actual organ donors. The HRSA established goal is to achieve an average OTPD rate in excess of 3.75 organs transplanted from each donor.

In 2007, the ODBC pushed its national learning strategy to the regional level to provide a local, more accessible platform for ongoing improvement efforts and to complement the ongoing national learning sessions. The purpose was to sustain cross-DSA learning opportunities in pursuit of national performance goals; to make cross-DSA learning opportunities accessible to more OPOs, and hospital and transplant center representatives; and to create local and regional ODBC leadership opportunities that would enhance individual professional development. This strategy proved only minimally successful and was discontinued as a major point of focus in 2012. A broader approach involving all partners in every DSA seems to be the most effective means of implementing best practice and evaluating outcomes.

The HRSA established outcomes goals for each DSA are:

- 75% conversion rate;
- 10% of all donors to be donation after circulatory death (DCD) donors;
- 3.75 OTPD;
- 20% increase in volume of deceased donor organs transplanted.

The ODBC produced breakthrough increases in both organ donation and transplantation. To ensure that this progress continues, the work of the ODBC has been institutionalized in the "Donation and Transplantation Community of Practice (DTCP)," a grouping that includes all the various disciplines and professionals involved in the donation and transplantation process nationwide. The DTCP is organized and coordinated by the Organ Donation and Transplantation Alliance (the "Alliance") with funding provided by an HRSA grant. The Alliance is a 501(c)(3) non-profit, independent organization incorporated in 2006 for the purpose of ensuring a continued national commitment to increasing organ availability and eliminating deaths on transplant waitlists. The Alliance provides a permanent structure for seeking lasting cultural change within the organizations and individuals whose cultural and institutional behavior impact organ donation and transplantation. The Alliance performs this task by continuing specific activities focused on meeting and achieving the national organ donation and transplantation goals established by the HRSA. The Alliance, in

partnership with the HRSA, oversees and organizes meetings, subject-focused task forces, and learning opportunities for the DCTP. Experience with the DTCP and the OBDC shows that the goal of 35 000 organs transplanted per year will be achieved only by creating a donation and transplantation system open to learning and systematically engaged in monitoring, assessing, and improving its own performance [32].

How does the system work?: step-by-step from recovery through allocation

The overarching theme of this section is that the system works best when all participants, be they individuals (doctors, nurses, hospital executives and administrators, and OPO staff) or institutions, understand the importance of organ donation, subscribe to organ donation and recovery as a mission in its own right and not just an afterthought, know their roles in the process in advance, and co-operate to implement the shared mission. At each step, co-operation and timely communication and coordination between all the parties involved are essential. For a more detailed discussion about effective donation approaches, see [33,34].

The organ donation and recovery process applies only to those deaths that occur in hospitals. Some 2.46 million people died in the US during 2010. [35,36]. Of those who die each year, approximately 30% (or 738 000) die in hospital. The deaths most likely to be suitable for donation are those that occur in the hospital emergency department (ED) or intensive care unit (ICU). Living donations have emerged as a significant source of donated organs. The OPTN has adopted some policies and procedures applicable to such donations [35], but the system described here addresses only donation after death.

Notice to OPO of all deaths or imminent deaths

The hospital and the OPO are required by law to ensure that every family is informed of its organ donation options [37], and to ensure that this right is not compromised, they are required to have an agreement to notify the OPO of every death or imminent death in the hospital. The OPO is required to co-operate with the hospital and the hospital's chosen eye and tissue banks to ensure that tissue banks and eye banks receive timely notice of possible eye and tissue donors [38]. Hospitals may elect to make separate referral calls to the tissue and eye banks. Most often, however, the hospital makes only one call to the OPO or the OPO's referral call center. The OPO then coordinates with the eye and tissue banks, or in still other instances, performs the eye and tissue recoveries under agreement with the hospital or with the tissue and eye banks. These regulatory obligations seek to ensure that the maximum number of eyes and tissues are recovered, as well as the maximum number of organs. They also seek to ensure a coordinated approach to families, so that families are not subject to the distress of multiple donation requests from different organizations.

Since the adoption of the UDDA and other state laws recognizing brain death, most donors have donated after cessation of neurologic function—so-called DND donors. More recently, improvements in medical science have resulted in increased attention again being paid to DCD (also known as circulatory death). All OPOs are required to have a policy on DCD recoveries whether or not it performs them [39]. If an OPO does perform DCD recoveries, its agreements with hospitals are required to address DCD recoveries, although the law does not require that hospitals engage in such recoveries [40]. Currently, most OPOs do perform DCD recoveries.

Table 19.1. Imminent death clinical triggers for hospital referral calls used by Washington Regional Transplant Community (WRTC)

Hospital shall notify WRTC of:

1 Every ventilated patient who meets one or more of the following criteria:
- Glasgow coma score of 5 or less without continuous sedation
- Brain death testing being considered or pursued
- Patient being made do not resuscitate (DNR) or family considering comfort care measures
- Life-sustaining therapy is to be withheld
- Family initiates a conversation about donation

Note: these triggers are in addition to required notification for non-ventilated patient deaths

2 Every patient death, within 1 h of death

Reproduced with permission of WRTC.

A patient who has serious, irrecoverable neurologic injury, but has not clinically progressed to neurologic death, is a candidate for DCD recovery. The decision to withdraw life-sustaining medical treatment will have been made by advance medical directive or a legal surrogate. When the medical intervention (the ventilator) is stopped, and circulatory and respiratory functions cease, the patient is then declared dead following a defined period of asystole, ventricular fibrillation, or pulseless electrical activity. To be a viable organ donor, the patient must be declared dead within a limited time frame following the removal of the ventilator. The time limits may vary by OPO protocol, but generally all are within a period of 60–90 min. The recovery of organs then is carried out rapidly to ensure organ viability.

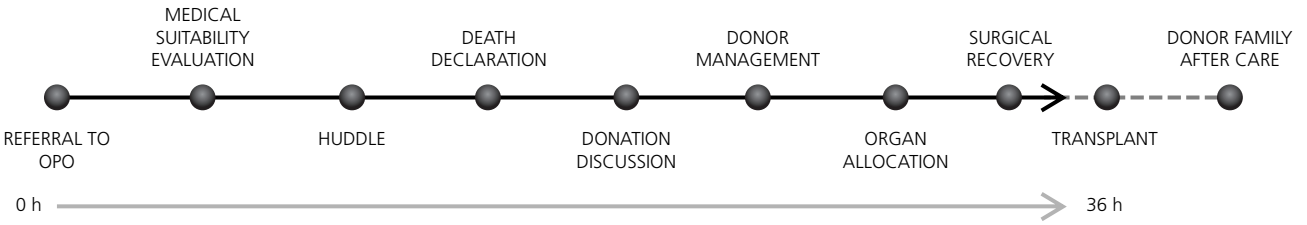
Clinical triggers for the referral call

The OPO and the hospital agree in advance on the clinical criteria that trigger the referral call. There is currently no single set of standard clinical triggers that all OPOs and hospitals use. The particular triggers used may depend on the preferences and capabilities of the OPO, and the hospital concerned, e.g. some hospitals do not perform DCD recoveries. Table 19.1 shows an illustrative set of the clinical triggers used by one OPO within its DSA.

In general, a referral made >1 h after a death occurs is untimely. Early notification of imminent death is the best practice. The clinical triggers define when death is considered "imminent." They intend that the hospital will not remove ventilator support or make any treatment decisions that foreclose the possibility of donation until the OPO has been notified. This will help to ensure that the OPO has adequate opportunity to perform its statutory responsibility to identify potential donors and ensure that every family knows of the option to donate.

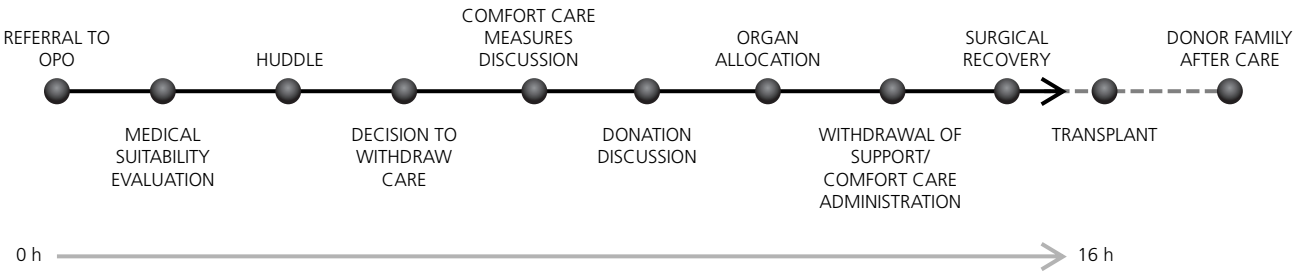
Donor identification and evaluation

The OPO is open 24/7 to receive these referral calls and to begin the process of identifying potential donors. Figures 19.1 and 19.2 illustrate the donor identification, recovery, and allocation timelines with respect to DND and DCD donors that are initiated by the referral call made on the death or imminent death of each and every one of the individuals who dies in hospital. Upon receipt of the call, the OPO has the legal right to review the patient's medical record and at this point, begins to perform its initial screening to determine the medical suitability of the potential donor. This initial screening may be performed over the phone or by OPO staff on site at the hospital.



REFERRAL TO OPO	➢	30–45 min obtaining referral information; 1–1.5 h arrival of OPO at hospital
MEDICAL SUITABILITY EVALUATION	➢	30 min chart review to determine medical suitability
HUDDLE	➢	5 min (may take 15 min–1.5 h to get all parties available for huddle)
DEATH DECLARATION	➢	4–24 h for brain death determination (may take several additional hours if brain death is not definitively diagnosed and additional testing is required)
DONATION DISCUSSION	➢	1–3 h for donation discussion with family/LNOK (includes 1–2 h discussion with family/LNOK for review of past medical/social history)
DONOR MANAGEMENT	➢	8–10 h for serologies and preliminary tissue typing results; 2–12 h awaiting special procedures (echocardiogram, bronchoscopy, special labs, etc.)
ORGAN ALLOCATION	➢	5 h (liver, kidney) and 24 h (thoracic) for organ-specific allocation to primary recipients and required back-up recipients
SURGICAL RECOVERY	➢	4–8 h for surgical recovery of organs (delay in OR availability may increase ICU time)
DONOR FAMILY AFTER CARE	➢	2-year program, including grief seminars, widowhood support group, donor family retreat, annual donor family gathering, facilitate communication between donor families and recipients

Figure 19.1. Optimal timeline for do not resuscitate (DND) donor identification, recovery, and allocation process initiated at the death or imminent death of all persons who die in hospital. Timeline used by Washington Regional Transplant Community (WRTC). (Reproduced with permission of WRTC.) OPO, Organ Procurement Organization; LNOK, legal next of kin; OR, operating room; ICU, intensive care unit.



REFERRAL TO OPO	➢	30–45 min obtaining referral information; 1–1.5 h arrival of OPO at hospital
MEDICAL SUITABILITY EVALUATION	➢	30 min chart review to determine medical suitability
HUDDLE	➢	5 min (may take 15 min–1.5 h to get all parties available for huddle
DONATION DISCUSSION	➢	1–3 h for donation discussion with family/LNOK (includes 1–2 h discussion with family/LNOK for review of past medical/social history)
ORGAN ALLOCATION	➢	2–12 h organ specific allocation to primary recipients and required back-up recipients
SURGICAL RECOVERY	➢	2–4 h surgical recovery of organs (delay in OR availability may increase ICU time)
DONOR FAMILY AFTER CARE	➢	2 year program, including grief seminars, widowhood support group, donor family retreat, annual donor family gathering, facilitate communication between donor families and recipients

Figure 19.2. Optimal timeline for donation after circulatory death (DCD) donor identification, recovery, and allocation process initiated at the death or imminent death of all persons who die in hospital. Timeline used by Washington Regional Transplant Community (WRTC). (Reproduced with permission of WRTC.) OPO, Organ Procurement Organization; LNOK, legal next of kin; OR, operating room; ICU, intensive care unit.

The OPO also proceeds to check state Department of Motor Vehicle (DMV) records and donor registries to determine if the patient has made an anatomical gift.

Role of the family in making an anatomical gift and obtaining authorization

If the patient is registered with the DMV or a donor registry as a donor (or has made any other document of gift), no other permission is required for the donation to be effective, and the OPO, hospital, physicians, and the donor family are required to uphold the patient's decision. If the patient is not a donor, federal law requires that every family be offered the option to donate or to decline. The OPO is responsible for locating a reasonably available decision maker, usually the patient's next-of-kin, to whom the request to donate must be made. An approach to the family, whether made for authorization or to inform the family of the patient's own decision, is made only after consultation between the OPO and hospital staff, and is conducted by staff who are trained in making such approaches. Federal law requires the approach to be made with discretion and sensitivity to the circumstances, views, and beliefs of the potential donor family. Federal law as well details the types of information required to be provided to the family [41].

Based on studies and experience, it has been the practice to approach the family about donation after it is informed of, and had time to accept, the patient's terminal prognosis. More recently, this premise has been re-examined. New evidence indicates that families are more likely to respond favorably to a donation request when the request is seamlessly integrated into an end-of-life care process that respects the grief of family members, and that communicates with them openly and often about dying and appropriate end-of-life care options [42]. The newfound importance of DCD donors as a source of available organs has increased the importance of addressing end-of-life care in a holistic way that continues after the recovery has been performed (Figures 19.1 and 19.2).

DCD recoveries are extremely time sensitive and optimally require that some prerecovery treatment be administered to the donor to facilitate the donation. Regardless of whether the patient made a donation decision or left that decision to surrogates, the administration of any prerecovery treatment requires assistance from the family before death is declared [43]. OPOs and hospitals are examining how best to make this approach so that families do not lose the option to donate by not knowing about this until organ viability is compromised and donation for transplantation is no longer an option.

Death declaration

The patient's physician declares death in accordance with state law. The OPO confirms that the declaration of death satisfies the requirements of the law. To protect the integrity of the donation process and to assuage the concern of donors and their families that the need for organs may dictate end-of-life decision-making, state and federal laws prohibit the patient's physician and the physician who determined the patient's death from taking any part in the recovery or transplantation process. Once death is declared, or the family agrees, as in the case of the DCD recovery discussed above, the OPO proceeds with the remaining tests and examinations necessary to determine whether the potential donor is medically suitable to be a donor. Federal regulation and OPTN policies and procedures spell out tests that are required, who must perform the tests and in what time frame, and the information about the potential donor that must be gathered, e.g. the medical and behavioral history (risk assessment). The OPO is responsible for donor evaluation and management [44].

Organ allocation

All organs from a deceased donor are required to be recovered and distributed through the national system created by the NOTA. All patients who require a transplant must be listed on the national waitlist. No patient can receive a deceased donor organ outside this process, except in the rare possibility, permitted by the RUAGA, of a donor designating a specific individual to receive the donation and the named individual is a match.

When the OPO determines that an individual is medically suitable to be a donor and authorization for donation is confirmed, the OPO enters the donor's information, including at a minimum, blood type and tissue type, in the OPTN's national organ allocation program, DonorNet, so that the computer algorithms appropriate to the particular organ can be run to identify potential recipients [45]. The computer match run yields a list, or lists, of potential recipients in rank order, depending on the organs available and based on screening criteria provided by the particular transplant center. The OPO then offers the available organ(s) to the transplant center or centers that listed the potential recipient(s). The transplant center has 1 h to accept or express interest in the offer. The OPO is primarily responsible for making the organ offer; the transplant center, however, has ultimate responsibility for deciding in any particular instance whether an offered organ is transplanted into a patient. The OPTN encourages the OPO to make back-up offers to ensure against possible organ wastage.

Recovery

The OPO is responsible for coordinating the recovery, a task that includes making arrangements with the donor hospital for access to the operating room and the necessary staff support, arranging for the recovery teams, and subsequently for packaging and arranging to transport the organs to their intended destinations. Organ recovery may be performed by any physician or technician qualified to perform it. The OPO is required to maintain credentialing records on all physicians or other practitioners who regularly recover organs within the OPO's DSA. It also is required to ensure anyone who performs a recovery in its donor hospitals, including members of recovery teams from outside the DSA, is qualified and trained. The OPO medical director, who is required to be a physician, is responsible for implementing the OPO's protocols on donor evaluation and management and organ recovery and placement. The medical director is as well responsible by law for supervising the clinical management of potential donors, and for assistance in managing a donor case when the surgeon on-call is not available [46].

Record keeping

The OPO is responsible as well for obtaining and maintaining records of recovery activities in its DSA, including obtaining out of DSA recovery teams records pertaining to the organs recovered by those teams. The records kept by the OPOs are used by the OPTN (as discussed above) for OPO evaluation purposes and by SRTR for research purposes.

Quality assurance obligations

In 1984, the NOTA required OPOs to perform annual evaluations of their own effectiveness in acquiring all available organs. Since then, in response to the chronic shortage of donated deceased donor organs, these requirements have become considerably more specific. CMS regulations require the OPO to have a formal "data driven" quality assessment and performance improvement program. The program must cover all areas of OPO activity and the OPO must act on and monitor any identified deficiencies. At least monthly, the OPO must conduct death record reviews in the hospitals from which it receives referrals to identify missed or mishandled donation possibilities. CMS also requires the OPO to have written policies and procedures for identifying and correcting any adverse events that occur in the course of its work [47].

The Association of Organ Procurement Organizations (AOPO) has developed a peer-reviewed accreditation program that requires accredited OPOs to implement organizational and ethical standards that in many respects are more detailed and rigorous than those required by CMS. Fifty-three of the nation's 58 OPOs are accredited by AOPO and another three are in the process of becoming accredited. AOPO conducts accreditation reviews every 3 years. The OPO's ability to meet AOPO and CMS quality standards is a principal focus of these reviews.

These programs provide the means by which OPOs can gain a detailed understanding of their own operations, which is an essential prerequisite for the required self-improvement efforts that have marked US efforts to close the gap between the organs needed for transplant and those available.

In addition to these explicit quality assurance activities, the OPOs are subject to regular audits conducted by CMS and the OPTN as part of their oversight responsibility. A survey team from the OPTN/UNOS conducts ongoing and periodic reviews and evaluations of each member OPO for compliance with OPTN rules and policies. OPOs are surveyed every 3 years by the OPTN. The OPTN will also conduct special reviews of an OPO if there is reason to believe that the OPO may not be in compliance with these rules and policies, or may be acting in a manner that jeopardizes patient safety.

International organ donation models

All donation activities operate under some form of national authority for donation and transplantation. A solid legal framework that provides the authority for donation, defines an organizational structure, establishes policies for organ allocation, and prescribes a financing model is critical to the procurement system.

The organizational structure and staffing of organ procurement functions vary globally with each nation responding to its unique challenges, resources, and political and legal frameworks. While there is no accepted international model, most donation systems across Europe generally follow either the independent OPO-based model of the US or the frequently referenced Spanish model [48].

OPOs as independent non-profit companies are organized to serve a defined geographic area and operate outside of donor hospitals or transplant centers. In contrast, the Spanish model utilizes organ procurement personnel who are located within the donor hospital (Figure 19.3). Referred to as "transplant procurement management (TPM) coordinators", the inhospital staff are hospital employees who carry a part-time dedication to organ procurement. Most transplant coordinators are ICU doctors or anesthesiologists who are responsible for identification and evaluation of donors, donor management, and family authorization. Registered nurses also serve in this role. Each hospital has dedicated staff and the transplant coordinators typically do not travel to donor hospitals outside of their home institution. Onsite familiarity with potential donor patients, through a dual role of treating physician and procurement professional, allows close monitoring of potential donations, but requires clear separation of duties.

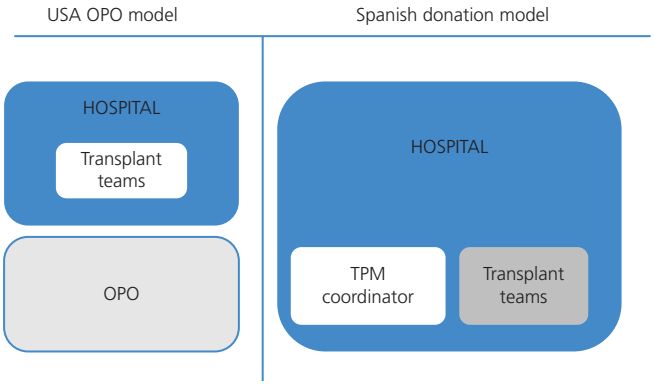


Figure 19.3. Contrast between the US and Spanish organizational models. Spain utilizes organ procurement personnel located within the donor hospital. (Reproduced from Vidal MM, et al. Transplant Coordination Manual, 2001; Transplant Procurement Management – TPM: A transplant coordination model to procure donors for transplantation, by permission of TPM – Les Heures, Universitat de Barcelona.) OPO, Organ Procurement Organization; TPM, transplant procurement management.

While OPOs in many cases have implemented inhouse donor coordinators, this is significantly different from the Spanish transplant coordinator model. OPO inhouse coordinators are employed by the OPO, and do not have shared accountability for patient care and donation. The professional profile is also markedly different, with most OPO coordinators having clinical backgrounds in nursing, respiratory therapy, or a related field. In contrast, in Spain and several other European countries, physician model is primarily used.

Many countries have adopted key components of both the US and the Spanish model, including the utilization of hospital-based, part-time transplant coordinators. Some countries, such as Germany, have created a national organ procurement system, the DSO, which is based on the OPO structure of centralized oversight and independent/regional organ procurement teams. Changes over time tend to incorporate elements of both models, with the German DSO, for example, introducing a pilot hospital-based donor program [49].

Responsibility for organ allocation and distribution also varies significantly between countries. Eurotransplant, a non-profit organization, is responsible for organ allocation and distribution for seven European nations. Other countries such as Switzerland have centralized organ-sharing offices located outside of the OPO activities [50]; and in some cases the local organ procurement team is responsible for determining organ allocation.

With perhaps the exception of Eurotransplant centers, organ allocation policies are much less complex than those adopted by UNOS/OPTN.

While there is significant variability in structure, authority, and operating scope of donation programs across Europe, all programs remain focused on the shared goal of providing organs for transplantation. The professionalization of procurement organizations and sharing of international best practices will lead to global improvements in donation.

Summary

The US organ procurement and allocation system operates on a nationwide basis with the goal of making the best and most equitable use of a scarce resource, donated deceased donor organs. The system was started in response to the shortage of transplantable donated organs and it continues to be driven by that persistent scarcity.

OPOs are the most visible public face of donation in the US. They are responsible, each within their geographic service area, for educating the public about organ donation; for persuading members of the public to use driver license and donor registries to become organ donors; and for interacting with the families of all potential donors who die in hospital, to obtain family authorization for donation if necessary and to provide them with information if not, but in any event to provide them with bereavement support.

Within the hospital setting, the OPO is responsible for determining whether a potential donor is medically suitable to donate. It manages the deceased donor until the recovery takes place, and arranges all aspects of the organ recovery, including coordinating and overseeing the medical teams that perform the actual work of removing the organs from the deceased donor. It locates potential recipients through UNET, extends offers to the transplant center that listed the potential recipient, and, upon acceptance of an offer, arranges transport to the pertinent transplant center for transplant into the listed patient.

OPOs are regulated by CMS and the OPTN, and are subject to audit inspections by both to review all aspects of their operations, and their performance in identifying donors and recovering organs is subject to measurement and frequent review. Most OPOs are also accredited by the AOPO and subject to its standards and audit requirements. The OPOs are held accountable for their performance and are responsible for identifying and implementing improvements.

The gap between the number of organs available and those needed for transplant, which impelled the passage of the NOTA in 1984, has not been closed. The number of organs available in any given DSA is a function of population size and location (e.g. rural, urban, or suburban), as well as other demographic characteristics, such as age, race, ethnicity, religion, and incidence of public health issues (HIV, hypertension, diabetes, heart disease). The organ donation and transplantation community and its regulators have focused considerable time and effort on identifying and understanding the societal impediments to donation, and the cultural and structural obstacles to organ donation and transplantation that exist within the community itself. To the extent that these factors are within the control of OPOs and hospitals to influence, they can be best addressed by closer co-operation and coordination between all the institutions and individuals involved in the donation and transplantation process. The ultimate effectiveness of the system depends on all the parties, the hospitals, doctors, nurses, administrators, and their OPO counterparts, working together over the long haul to make organ donation a valued societal priority.

Introduction

Organ transplantation remains the only life-saving option for an increasing number of patients with a variety of medical conditions that lead to failure of vital organs and death. Advances in the transplantation process and the prevention and management of post-transplant complications have resulted in markedly decreased morbidity and mortality in recipients of transplanted organs. This has increased the spectrum of disease states where transplantation is considered an appropriate treatment. This in turn has led to an increase in demand for organs for transplantation with resultant increases in the number of patients waiting for life-saving organs.

The opportunity for organ donation occurs either as a voluntary gift from a living donor or at the time of declaration of death in the appropriate setting, i.e. deceased organ donation. Living donation is discussed specifically for kidney and liver transplantation in Chapters 23 and 24, respectively. In the situation where deceased organ donation is possible, the event of death must occur in such a way that the transplantable organs do not suffer significant injury. Deceased donors of organs are declared dead either by neurological criteria (DNC; formerly called "brain dead donors"), donation after circulatory determination of death [DCDD; formerly called donation after cardiac death (DCD)], or non-heart beating donors (NHBD). Additional specifics regarding DCDD donation can be found in Chapter 22.

DNC donors represent the majority of donors utilized in the US and Europe, and provide the largest potential pool of organs annually for transplantation. DCD accounts for ~12% of the annual deceased donors in the US, with fewer organs transplanted per donor. According to recent data from the Organ Procurement and Transplantation Network (OPTN), the transplantation needs are far from being met. At the end of 2010 there were more than 120 000 patients awaiting organ transplantation, and only 22 000 patients receiving a transplant, with 11 000 patients dying on the waiting list or becoming too ill to be transplanted in 2010 [1]. Therefore, despite a steady increase of patients in need of organ transplantation, the number of organs available for transplantation has increased minimally, while the imbalance between organ availability and need continues to widen.

Over the past decade concerted efforts to make more Americans aware of the critical need for organs for donation led to modest increases in donation, with the numbers of organ donors annually increasing from ~5000 per year to ~8000 per year; however, this has plateaued over the last 5 years. In addition, attempts to increase organ utilization per donor have not significantly changed the average number of organs transplanted from each donor, which remains at around three organs per donor. This is due in part to the changing characteristics of donors that represent higher risk for organ failure, such as older age, diabetes, overweight, hypertension, and causes of death that represent concomitant medical conditions. Thus, a major challenge is how to maximize the number of organs available for transplantation by impacting the numbers of viable organs recovered and successfully transplanted from each donor, while improving the post-transplantation functionality of each organ to maximally benefit each recipient.

There is little in the way of published science on the medical management of the organ donor and what is available is often "best practice" approaches, small observational studies, or retrospective reviews. In most situations, donor management decisions post declaration of death is the responsibility of the Organ Procurement Organization (OPO) for the region in which the donor is located. There has been a recent trend of OPOs to involve intensive care physicians to assist in the management of the deceased donor, which may arguably present some of the most challenging physiological issues they may face. This practice has met with some success [2].

The critical care management of the deceased organ donor can at its simplest be broken into two phases: one prior to pronouncement, the pre-OPO management; and one after declaration of death occurs (OPO management). However, it is much more complex as optimal management represents a continuum, all based on accepted critical care principles. Initially, care of the critically ill intensive care unit (ICU) patient includes supporting cardiac output and maintaining oxygen delivery, essential to improving the potential for survival from the devastating injuries/illnesses that threaten recovery. Additionally, if the patient succumbs to the underlying process and fulfills neurological criteria for brain death, this hemodynamic support increases the likelihood of successful donation of organs should the patient go on to become an organ donor.

The timely recognition of the ICU patient who cannot survive their devastating illness or traumatic process, and subsequent continued support of their cardiopulmonary system, is essential to minimize the insults that may potentially compromise function and

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

use of organs. During the course of the ICU management team care of the critically ill patient, when likelihood of futility of care is increasing, it is imperative that the individual's wishes about end-of-life care are clarified. In the situation where progression to death by neurological criteria is imminent, intentions regarding organ donation should be determined – in the case of first person consent this may be made known through donor registries or through other legal documents, or if this information is absent, the next of kin should be approached regarding willingness to pursue donation of their family member. Family refusal to donate remains a significant impediment to organ donation. Studies have shown that this can be minimized with appropriate interactions between the ICU team and the family that facilitate understanding and communication with the family throughout the patient's ICU stay.

The correct recognition and timely declaration of death by neurological criteria is also critical. Delay in diagnosis or non-recognition of evolving death by neurological criteria is another concern that puts organ donation at risk. However, educating healthcare professionals about clinical features and diagnosis of brain death can minimize this.

Even after the diagnosis of DNC, loss of a potential donor can occur in spite of implementation of OPO management protocols. Organ donors unfortunately show such heterogeneity in their clinical presentations that care of these patients is challenging for the healthcare professionals. DNC triggers numerous physiological changes associated with hemodynamic instability and end-organ damage. Up to 25% of potential donors are lost due to clinical deterioration after the development of DNC [3]. Therefore, appropriate management of potential donors is essential to prevent organ damage and loss [4,5]. With increasing understanding of the physiology of DNC and the ability to mitigate the potential physiological changes with appropriate critical care management strategies, significant increases in the number of transplantable organs as well as improved post-transplantation organ function in the recipient may be achieved [6]. Physiological changes begin with the herniation process and, if left untreated, may lead to rapid deterioration and cardiovascular collapse [7]. These changes are associated with profound dysregulation of hormones, massive cytokine release, and numerous electrolyte abnormalities, which may be blunted, moderated, or even reversed with a number of management interventions. Significant efforts have been made to maintain or improve organ function following DNC and have successfully increased the number of donors for those who need transplantation [3,6,8].

In this sense, a standardized approach with a focus on multiorgan resuscitation with maintenance or improvement of oxygen delivery (DO_2) to transplantable organs would be a useful tool in guiding a systematic and comprehensive approach to overall donor management. This philosophy necessitates an aggressive approach to interventions in the donors, from the declaration of brain death until the operating room and completion of the organ retrieval and preservation processes.

Diagnosis of brain death

Diagnosis of death by neurological criteria

Declaration of death by neurological criteria is a clinical diagnosis made following a devastating neurological injury leading to a comatose state confirmed by serial neurological examinations showing persistent loss of all reflex activities mediated by both brain and brainstem activity [9,10]. The final event in the progression to brain death is the development of catastrophic intracranial pressure (ICP) elevation, leading to loss of brainstem function due to ischemia, infarction, hemorrhage, or herniation. A variety of brain pathology is known to cause elevations of ICP. In the early process of evolving brain death, a rapid expansion of supratentorial lesion or progressive brain edema causes a loss of upper brain function, resulting typically in decreased level of consciousness. Further progression of brain injury causes transtentorial herniation with infratentorial compartment compression.

Brain death is defined as a clinical condition characterized by the total and irreversible loss of function of the whole brain, including the cerebral cortex and brainstem, as set out in the published guidelines in adult patients, first in 1981 [11] with recent updates [12]. Key is that brain death is a clinical diagnosis. It can be made without confirmatory testing if one can establish the etiology, eliminate reversible causes of coma, and conduct a full neurological examination including an apnea test. The diagnosis requires demonstration of the absence of both cortical and brainstem activity as well as the irreversibility of this state. In neurological examinations, the diagnosis of brain death requires documentation of coma or unresponsiveness, loss of brainstem reflexes, and apnea. Prior to initiating testing for DNC, it is necessary to exclude reversible medical conditions that can confuse the clinical assessment including:

- severe imbalance of electrolyte, acid base, and endocrine function;
- drug intoxication and poisoning;
- use of sedatives or neuromuscular blockades;
- hypotension [may suppress electroencephalography (EEG) activity]; and
- hypothermia (core temperature $<36\,^{\circ}C$, pediatric revision requires $>35\,^{\circ}C$).

Once the absence of these exclusions is confirmed, testing of brainstem reflexes is performed with cranial nerve examinations. In DNC, patients show fixed and midpoint or dilated pupils with no response to light, no corneal reflex, no oculocephalic reflex (Doll's eye phenomenon), no oculovestibular reflex (tonic deviation of eyes toward cold stimulus), no gag reflex or cough to tracheal suctioning, and absence of facial muscle movement to noxious stimuli (spinally mediated reflexes with peripheral stimulation may be noted) [12]. Once the absence of brainstem reflexes has been confirmed, apnea testing is then conducted to verify the loss of brainstem function. Certain conditions must be met before an apnea test is performed to avoid cardiac dysrhythmias and systemic hypotension that may occur during the test. These are the prerequisites to performance of the apnea testing:

- normotension;
- normothermia;
- euvolemia;
- eucapnea; and
- absence of hypoxemia.

The procedure for apnea or hypercapnea testing is shown in Table 20.1. The apnea test is confirmed to be unresponsive by the absence of any signs of respiratory effort; a $Paco_2$ of >60 mmHg; or >20 mmHg above baseline for chronic CO_2 retainers. Because apnea testing can induce further clinical deterioration, such as hypotension, severe cardiac arrhythmias, and elevated ICP, it should be performed last in the clinical assessment of brain death. When apnea testing is inconclusive or cannot be done safely, ancillary tests should be considered [9,12].

In the clinical determination of brain death, serial observations further confirm the irreversibility of brain damage. A repeat evaluation of cardinal findings in brain death is recommended. Most

Table 20.1. Apnea test

1. Pre-oxygenate with 100% oxygen for 10–15 min with SaO_2 >95%
2. Reduce ventilator rate to allow for normal PCO_2 (40–45 range) prior to beginning the apnea test:
   - If the patient has chronic CO_2 retention, then the goal is pH 7.35–7.40 prior to beginning the apnea test
3. Obtain initial arterial blood gas (ABG)
4. Remove from ventilator – place on either t-piece with flow by oxygen or with small non-occluding tubing (either cut cannula or feeding tube) with O_2 at 4–6 L flow:
   - Leaving the patient on the mechanical ventilator may result in autocycling of the vent, which may be confused with patient respiratory effort
5. Remove any warming blanket or obstructing material, so chest rise may be observed, and monitor for any signs of respiratory effort
6. Continue to monitor as long as patient remains hemodynamically stable (<20% decrease in blood pressure or heart rate), and O_2 saturations remain >90%. At the 10-min mark, draw a blood gas and replace patient on mechanical ventilator at settings prior to apnea testing while awaiting results of ABG. If at any point these criteria are not met, immediately draw ABG and replace patient on prior ventilator settings while awaiting the results
7. If the $PaCO_2$ rises to >60 Torr and by >20 Torr above baseline without respiratory effort, then this is considered a failed hypercapnea test and is consistent with declared dead by neurological criteria (DNC)
8. If the $PaCO_2$ failed to incrementally rise and the patient was hemodynamically stable at the time the gas was drawn, the test may be repeated. The baseline ABG should be reattained, the test should be redone for an incrementally longer period of time, at least 12 min, and the ABG should be repeated. (repeat steps 6–8 but for 12 min or longer if the patient is hemodynamically stable). If the test is inconclusive and cannot be done due to patient instability, then an ancillary test should be performed to aid in determination of DNC

experts recommend an arbitrary interval of 6 h between initial and repeat observations for clinical determination of brain death in adults.

Special consideration for declaration of brain death in infants and children

The guidelines for the determination of brain death in infants and children were initially published in 1987 [13], with a recent update on the subject [14]. In this update, a few significant changes from the prior recommendations for pediatric determination of DNC have been made.

The clinical exam remains the cornerstone of diagnosis, with waiting periods between serial exams; however, the age ranges have been changed [14].

1. Infants over the age of 37 weeks' gestation to 30 days of life may be evaluated for DNC if they are >24 h old and more than 24 h after receiving cardiopulmonary resuscitation. For this age range the recommendation is that two complete neurological examinations, by two separate physicians, occurring at least 24 h apart and both consistent with DNC be required prior to declaration of death.
2. For pediatric patients aged 31 days to 18 years the time interval is decreased to 12 h, but other stipulations are unchanged.
3. The use of confirmatory testing for instances where the complete examination cannot be completed or to decrease the waiting period.

Ancillary testing for determination of brain death

Ancillary testing for brain death is not mandatory in most situations, but it is necessary for declaring brain death in patients in whom the results of specific components of clinical testing cannot be reliably evaluated (Table 20.2). Choice of testing depends on the discretion of physicians who perform brain death diagnosis. Neurophysiological technology and neurodiagnostic testing are the gold standards for confirmatory testing.

Table 20.2. Clinical conditions that need confirmatory testing to determine brain death

- Coma of undetermined etiology
- Incomplete brainstem reflex testing
- Incomplete apnea testing
- Toxic drug levels
- Children younger than 1 year old
- Required by institutional policy

Cerebral angiography

Selective four-vessel angiography is a neurodiagnostic test performed by a neuroradiologist. An angiographic finding consistent with brain death is absent cerebral blood flow above the entry of the carotid bifurcation or circle of Willis, where the external carotid circulation is patent. From a technical standpoint, the contrast medium should be injected under high pressure in both anterior and posterior circulations. However, the presence of cerebral perfusion does not mean that brain death has not occurred [10].

Electroencephalography

EEG can be used to determine brain death. In patients with brain death, EEG should demonstrate a lack of reactivity to intense somatosensory or audiovisual stimuli over a period of 30 min [9,15]. It should be noted that EEG findings are affected by high barbiturate dosing [16].

Transcranial Doppler ultrasonography

Transcranial Doppler ultrasonography may show abnormalities such as: absent diastolic or reverberating flow; systolic flow only or diastolic reversal flow; and small systolic peaks in early systole. Blood flow velocities may be influenced by marked changes in $PaCO_2$, hematocrit, and cardiac output [17]. A complete absence of flow may not be a reliable finding owing to inadequate transcranial windows for insonation. Ten per cent of patients may not have temporal insonation windows.

Cerebral scintigraphy

Cerebral scintigraphy (technetium nuclear medicine scan) is another alternative to determine brain death. In brain death, the scintigraphy shows no uptake of the radioisotope (hollow skull phenomenon). The isotope should be injected within 30 min after its reconstitution and a static images should be obtained at several time points; immediately, between 30 and 60 min later, and at 2 h.

Somatosensory and brainstem auditory evoked potential

This can be performed at the bedside with a portable instrument that provides bilateral stimulation of median nerves. In patients with brain death, no responses are observed to tests for somatosensory and brainstem auditory evoked potentials. Both types of tests are less sensitive that the other confirmatory tests.

Physiology of brain death

Severe brain injury or disease induces primary damage to the brain that causes secondary cerebral ischemia. As this catastrophic injury progresses to brain death, a cascade of extensive, progressive, and

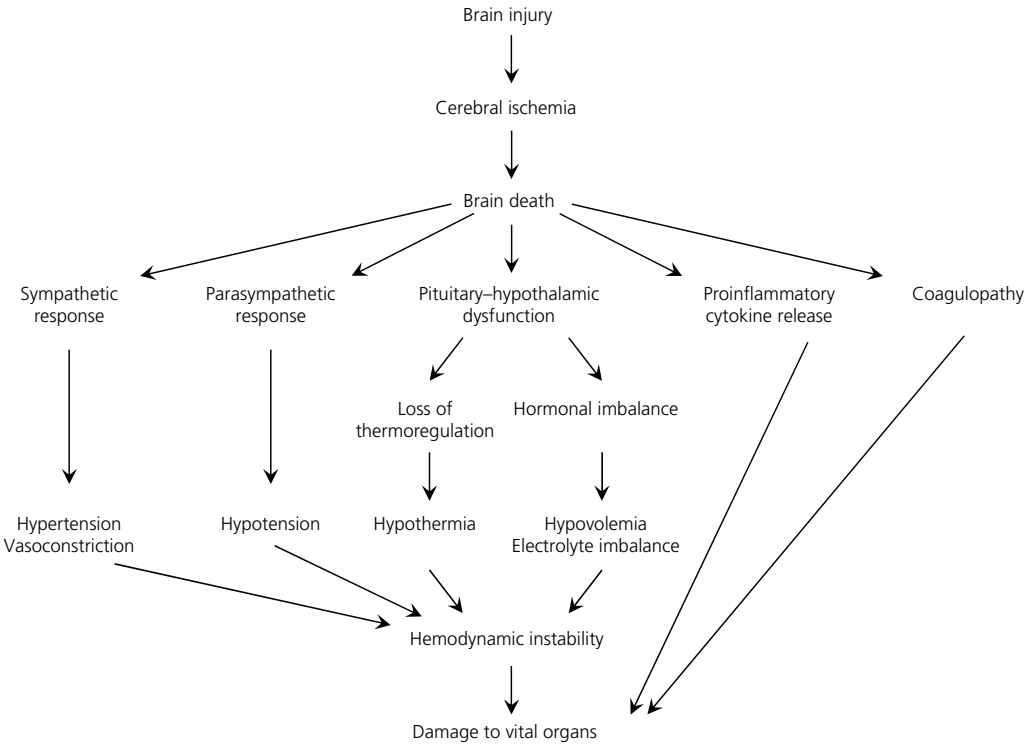

Figure 20.1. Pathways by which brain death evokes organ injury.

Table 20.3. Progressive cerebrospinal ischemia

Brain structures damaged	Physiological correlations
Cerebrum	↓ heart rate, ↓ cardiac output, ↓ blood pressure
Pons	↓ heart rate, ↑ blood pressure, irregular breathing
Medulla	↑ heart rate, ↑ blood pressure, impaired thermoregulation
Spinal cord	↓ heart rate, ↓ cardiac output, ↓ blood pressure

irreversible changes is activated, leading to a variety of physiological changes, including sympathetic and parasympathetic responses, pituitary–hypothalamic dysfunction, proinflammatory cytokine release, and coagulopathy. These changes have been shown to result in a variety of complications that may jeopardize vital organ function (Figure 20.1). Not all these changes are seen in every potential donor, but the incidence and severity of the complications depend upon the etiology and time course of brain death. The risk of complications increases with time after the onset of brain death. These complications are directly and indirectly associated with significant alterations in vital organ function.

Physiological changes related to brain anatomy

The development of brain death is accompanied with coning of the brain structures in a predictable rostrocaudal pattern (Table 20.3). When the cerebrum is involved, vagal activation occurs, leading to suppression of cardiovascular systems. This typically coincides with destruction of the hypothalamus and the pituitary gland, causing subsequent temperature and hormonal dysregulation. Pontine ischemia is associated with Cushing's reflex leading to mixed vagal and sympathetic outflow [18]. Medullary ischemia occurs in the early phase of brainstem death and is characterized by sympathetic or autonomic storm [19]. Ischemia of vagal and cardiomotor nuclei results in unopposed catecholamine surge. This causes intense systemic and coronary artery vasoconstriction, tachycardia, hypertension, and further elevation of ICP. This hypersympathetic state can lead to systemic organ and tissue ischemia. Elevated systemic vascular resistance (SVR) and pulmonary vascular resistance (PVR) result in increased pulmonary capillary bed pressure and endothelial damage. Ischemia to the respiratory center in the lower medulla results in apnea. When brainstem ischemia is completely developed, a progressive loss of spinal sympathetic pathways and total sympathetic denervation can occur. Global loss of sympathetic vascular tone and profound reduction in SVR leads to cardiovascular collapse [20]. Due to the combination of the loss of sympathetic activation and vasopressin deficiency caused by pituitary ischemia, a majority of potential donors fails to maintain hemodynamic stability [4]. Furthermore, ischemia of the pituitary and hypothalamic regulatory system can induce the loss of various homeostatic control mechanisms.

Cardiovascular changes

Brain death is associated with profound physiological changes that result in cardiovascular instability and widespread organ damage [4,5]. As previously described, the hemodynamic instability after brain death occurs in two serial phases. The first phase results from the physiological sequelae of mobilization of catecholamine stores. In an animal study, brainstem death causes marked increases in circulating dopamine, epinephrine, and norepinephrine levels, by 800%, 700%, and 100%, respectively [21]. Similar phenomena have also described in human donors who experience brain death [22]. This sympathetic storm causes intense vasoconstriction leading to profound hypertension and tachycardia. Although this causes a

secondary increase in myocardial oxygen demand, there is no increase in myocardial oxygen supply because the catecholamine storm also induces coronary vasoconstriction. This imbalance of oxygen demand and supply may induce early cardiac dysfunction and may cause direct injury to the myocardium in brain dead donors [23]. Myocardial damage in brain death is characterized by myocytolysis, subendocardial hemorrhage, edema, and interstitial inflammatory changes [19]. Contraction band necrosis, one of the common pathological changes in myocardial injury, is observed in 90% of patients following brain death [24]. The catecholamine storm may induce significant increases in intracellular calcium, resulting in impaired adenosine triphosphate (ATP) production and increased free radical formation, which cause further tissue damage. A significant rise in systemic vascular resistance increases afterload and results in acute cardiac failure in potential donors. Acute pulmonary edema may develop because of raised hydrostatic pressure and increased capillary permeability [25–27].

The initial phase of sympathetic outflow is followed by autonomic collapse with the loss of sympathetic tone and significant reduction of systemic vascular resistance associated with depletion of catecholamine stores rather than cardiac damage. Clinically, this is characterized by profound hypotension and bradycardia [3,18]. The uncontrolled vasodilation accelerates heat loss and hypothermia. The loss of vascular tone results in marked functional hypovolemia due to tremendous increase in vascular capacity and fluid volume shifts. Acute electrocardiographic abnormalities are common in brain death, including atrial and ventricular arrhythmias, conduction abnormalities, and changes in ST segment further compromising hemodynamic status.

Aggressive treatments for brain edema such as diuretics and mannitol cause further volume depletion and exacerbate hemodynamic instability. Insensible fluid loss due to diabetes insipidus also contributes to hemodynamic instability. Volume loss due to diabetes insipidus can exceed 2 L/h, leading to rapid total body water depletion. Close monitoring of urine output is crucial to assess hemodynamics of potential donors.

Pulmonary changes

Pulmonary dysfunction is common after severe brain injury [28]. Subsequent brain death is frequently complicated by pneumonia, aspiration, and neurogenic pulmonary edema. In trauma patients, pulmonary contusion and pneumothorax are common and result in severe respiratory dysfunction. The catecholamine release related to brain death also causes direct cellular injury to the lungs [5]. Severe vasoconstriction induces increased pressure in the pulmonary capillary bed and endothelial damage. Inflammatory response causes directly an increase in pulmonary capillary permeability. Volume overload after fluid resuscitation increases the risk of pulmonary edema. Patients who receive blood transfusions are also at risk for transplant related acute lung injury (TRALI). These changes make successful organ procurement challenging and negatively affect transplant outcomes [4,29].

Endocrine changes

With the onset of brain death, a number of endocrine changes occurs and may precipitate metabolic and hemodynamic instability [27]. Brain death disrupts the hypothalamic–pituitary axis, leading to serum hormone depletion. Dysfunction of hypothalamic and pituitary systems induces loss of thermoregulation, leading to either hyperthermia or hypothermia. Posterior pituitary function is commonly lost, resulting in low or undetectable levels of vasopressin in up to 90% of brain death organ donors [21,30]. This commonly causes central diabetes insipidus, which is clinically characterized by polyuria, leading to severe hypovolemia, hyperosmolality, and hypernatremia.

With dysfunction of the anterior pituitary gland, TSH, triiodothyroxine (T3), thyroxine (T4), adrenocorticotropic hormone (ACTH), and growth hormone (GH) are commonly depleted. Consequent hypothyroidism and adrenal insufficiency may lead to loss of the mitochondrial ability to regenerate ATP, resulting in functional organ instability [31]. Reduced levels of thyroid hormones may therefore contribute to deterioration in cardiac function and general organ perfusion in some donors. Rapid decline in free T3 is seen in brain death due to impaired thyroid stimulating hormone (TSH) secretion and peripheral conversion from T4 to T3 [31]. The lack of T3 results in a shift to anaerobic metabolism and acidosis.

Significant decrease in cortisol levels may occur after brain death, resulting in impaired stress response. In association with T3 depletion, this change may negatively affect the cardiovascular system. The decrease in cortisol levels may be associated with a decreased release of adrenocorticotropic hormone (ACTH) from the anterior pituitary gland [21]. Exogenous corticosteroids contribute to stabilization of organ function.

Hyperglycemia is a common endocrine imbalance. Decrease in intracellular glucose concentration is common and results in a cellular energy deficit, which is unfavorable to aerobic metabolism and induces acidosis. Steroid administration and increased catecholamine levels may further adversely affect hyperglycemia. High-dose insulin infusion is often required to prevent the development of a hyperosmolar state, a severe osmotic diuresis, and profound hypovolemia.

Inflammatory responses

Brain death is associated with various systemic inflammatory responses. Increased levels of inflammatory cytokines are associated with poor outcomes after organ transplantation [32–35]. This response is mutually related to activation of the immune, coagulation, and complement systems [36,37]. Brain death is known to trigger the production of various cytokines such as tumor necrosis factor (TNF), interleukin (IL)-1, and IL-6. The mechanisms of cytokine production in brain death are not fully understood, but there several pathways are reported. Ischemic brain tissue is known to release inflammatory cytokines into the systemic circulation [38]. Brain death initiates an inflammatory state, which may up-regulate adhesion molecule expression on damaged endothelial cells, resulting in adherence of recipient T lymphocytes and macrophages and further inflammatory cytokine release upon graft reperfusion after organ transplantation [35]. The inflammatory response is maintained or amplified by the physiological changes related to brain death [34,39]. This affects all vital organs and is associated with significant organ damage in the donor, and subsequent poor function and increased risk of graft loss in the recipient with elevated levels of proinflammatory cytokines and up-regulation of receptors in target organs.

Coagulopathy

Abnormalities in coagulation are commonly seen in brain death. Because of the pathophysiological changes, brain death is associated with an increased risk of disseminated intravascular coagulation (DIC) [40]. There are two main explanations for the etiology: first, release of thromboplastin, fibrinogen, and tissue plasminogen from damaged brain tissue; and second, dilution of circulating

clotting factors due to large volume fluid resuscitation [3,41]. Because hypothermia exacerbates coagulopathy, management includes the use of warmed intravenous fluids, warming blankets, and heating inspired gases in order to maintain normothermic body core temperature. It has been controversial whether disseminated intravascular coagulation (DIC) in the donor compromises donor organ viability. Theoretically, DIC may adversely affect the graft quality due to the deposition of fibrin and microthrombi in the graft organ, and many transplant centers consider the presence of microthrombi a relative contraindication to organ donation. In contrast, other studies have shown that both thoracic and abdominal organs from such donors can be transplanted without compromising recipient outcomes [21,42,43].

Management for organ donation

Before the diagnosis of brain death, all medical efforts are directed at caring for the critically injured patient, maintaining adequate cardiac output to support all vital functions, including preserving potential residual brain function and maximizing any reversible injuries. Once futility of care is determined and declaration of death by neurological criteria is imminent, the focus of care is switched to maintaining and optimizing organ function to allow for the opportunity for organ donation.

Once the declaration of death is confirmed and consent for organ donation is confirmed, unnecessary delays should be avoided because the risk of organ dysfunction progressively increases with time. If the physiological changes related to brain death are untreated or under-treated, donors may deteriorate and undergo cardiac arrest within a relatively short time frame. Appreciating the importance of donor management and coordination for timely procurement has to be shared institutionally and individually. Donor management requires a multidisciplinary collaborative approach between the OPO and clinical care team. Organ donors should be monitored in an ICU setting to provide vigilant care. Close hemodynamic monitoring and aggressive resuscitation are essential to optimize organ quality and maximize potential for organs to be recovered for transplantation [6]. The application of a standardized donor management has significantly increased the number of organs transplanted without compromising post-transplant outcomes [6,44].

Achieving and maintaining stability in the donor enhances the opportunity to maximize organ function, resulting in increased placement and retrieval rates. Organs that appear unusable at the time of declaration of DNC may have functional improvement with aggressive donor management and thus become transplantable. Although in the past, the duration of time from declaration of brain death to recovery of organs for transplantation had been seen as an adverse factor for the outcome of transplanted organs [45]; more recent evidence suggests a period of good donor management can moderate this effect and, indeed, lead to improved outcomes [46,47]. In contrast, failure to maintain stability of the donor is associated with high rates of donor loss, fewer transplantable organs, and impaired organ function after transplantation.

UNOS Critical Pathway for the Organ Donor

Since the early era of transplantation, it was known that failure to restore normal physiology led to deterioration and cardiac arrest in potential organ donors. Goals were therefore set and standard critical care protocols were applied, with the intent to achieve better organ quality for transplantation. However, up to 25% of potential donors lost adequate perfusion to their vital organs, making them unsuitable for donation [7].

In addition to intensive medical care, OPO personnel have to obtain or confirm consent for organ donation as well as provide emotional support to the donor family. In response to these challenges, a guideline aiming to enhance donor management has developed by the UNOS [48]. This guideline, "Critical Pathway for the Organ Donor," facilitates management and delivery of quality care, which has been widely used and found to have beneficial effects in increasing the number of organs available for transplantation [6]. This pathway is designed to provide the information necessary to evaluate the functional status of donor organs, including heart, lungs, liver, kidneys, and pancreas, and to determine the management steps necessary to improve and optimize the performance of each organ. This also promotes communication between professional medical staff in the care of organ donors.

Elements of the Critical Pathway

The Critical Pathway has five distinct but partially overlapping phases. Each phase has subsections that may be used by professional medical staffs caring for organ donors as a guide to conduct thorough evaluation and management.

Phase I (Referral)

When a patient with a severe brain injury is identified as a potential organ donor, critical care staff should initiate the Critical Pathway. This initial step establishes contact between the hospital and the local OPO, and initiates referral before the potential organ donor becomes brain dead. Unless this step is initiated, the likelihood for organ donation will be diminished. In this phase, the organ procurement coordinator (OPC) performs a quick assessment of the potential donor to determine suitability for organ donation.

Phase II (Declaration of brain death and acquisition of consent)

Once the potential donor is confirmed brain dead, the patient's choice about organ donation is evaluated through the statewide/local donor registry (usually through the motor vehicle registry or on the driver's license) and the family is provided with this information or, if no first person consent is found, the family is approached about the option of organ donation. If the patient is not on the donor registry and the family is approached prematurely or by inexperienced requestors, they may opt against donation because of the difficulty of the situation. Therefore, the family should be offered the option of donation only after they have been given enough time to understand that death of their loved one has occurred [49,50]. If the family decline donation, the pathway is terminated at this phase and postmortem care should be initiated. If the patient is on a first person consent donor registry or the family consent to donation, donor management becomes a priority. First person consent supersedes a family declining the option of donation in many states and OPOs in the US.

Phase III (Donor evaluation)

After consent for organ donation is obtained or confirmed through a donor registry, donor evaluation and management protocols are initiated. The OPC obtains all the necessary history and the results of diagnostic tests. The cause of death, length of hospital stay before the development of brain death, estimated or witnessed down time (duration of cardiopulmonary arrest), and duration of cardiopulmonary resuscitation, thoracic or abdominal trauma, and vital signs are crucial pieces of information. Past

medical history needs to be obtained, including the history of hypertension, diabetes, coronary artery disease, pulmonary disease, liver disease, kidney disease, malignancy, infection, and history of blood clot. If old medical charts or a donor's primary care physician is available, more useful information can be collected. Surgical history is important information for procurement surgeons. History of smoking and alcohol abuse should be obtained as well. If the donor has a history of having been incarcerated, having used intravenous drugs or having multiple sexual partners, the potential donor may be considered to be high risk for transmission of human immunodeficiency virus (HIV) and hepatitis viruses. A thorough physical examination is also important to rule out any findings that may affect the donation process, including presence of tattoos, needle track marks, or suspicious lesions or masses. Laboratory tests include complete blood count, serum chemistries including liver function tests (LFTs), arterial blood gases, coagulation profile, infectious disease serology testing, and tissue typing for cross-match are performed. Cultures of blood, urine, and sputum for bacteria and fungi are sent to the labs to screen for infection. In addition to a chest X-ray, electrocardiography (ECG), echocardiography, and arterial blood gas, indications for cardiac catheterization and bronchoscopy will need to be determined with thoracic transplant teams. Completing these tests in a timely fashion is important to promote expeditious organ placement and recovery.

Phase IV (Donor management)

At the same time that the donor is being evaluated, optimal management also needs to be started to achieve hemodynamic stability, adequate oxygenation, and optimal fluid and electrolyte balance. Placement of an arterial line and a central venous line are necessary for aggressive respiratory and hemodynamic monitoring, and management of the cardiopulmonary status of the donor. Occasionally, minimally invasive hemodynamic monitoring or pulmonary artery catheters are considered helpful as well. The duration of this phase of care will depend on the status of the donor going into this phase of care, the stability of the donor, and discussion of potential organs thought to be viable for transplantation in each donor. The current trend is for longer donor management times of up to 48–72 h to maximize improvement in organ function prior to transplantation.

Phase V (Organ recovery)

After potential recipients are identified, the donor is transferred to the operating room where the organs are recovered. The clinical focus is shifted from donor management to organ preservation. All organ recovery teams should resolve potentially conflicting priorities prior to the recovery procedure.

Crystal City Meeting

Recognition of the donation crisis by the federal government led to a consensus meeting in March 2001 in Crystal City, VA, USA to develop initial acceptable guidelines that would improve the recovery and transplantation of organs from deceased donors. Five work groups were assembled that focused upon maximizing the use of hearts, lungs, livers, and kidneys, and increased use of organs from deceased donors with a history of malignancy or positive serology testing for hepatitis C or B virus. At this meeting the multidisciplinary teams outlined some management options and made treatment recommendations to improve utility of their individual organs or organs from the higher risk donors described above.

Table 20.4. Critical pathway for the organ donor (UNOS)

1. Early echocardiogram for all donors:
   - Insert pulmonary artery catheter to monitor patient management (particularly important in patients with an ejection fraction (EF) of <45% or on high-dose inotropes)
2. Fluid and electrolytes:
   - Maintain Na^+ <150 mEq/L
   - Maintain K^+ >4.0 mEq/L
   - Correct acidosis with sodium bicarbonate and mild-to-moderate hyperventilation (P_{CO_2} 30–35 mmHg)
3. Ventilation:
   - Maintain tidal volume 10–15 mL/kg
   - Keep peak airway pressure <30 mmHg
   - Maintain mild respiratory alkalosis (P_{CO_2} 30–35 mmHg)
4. Hormonal resuscitation:
   - Triiodothyronine
   - Arginine
   - Vasopressin
   - Methylprednisolone
   - Insulin

The heart work group made a recommendation to improve the evaluation and utilization of potential cardiac donors [41,51]. According to its recommendations, a new donor management algorithm was incorporated into the UNOS Critical Pathway (Table 20.4). After conventional management to adjust volume status, acid–base balance, oxygenation, anemia, and doses of inotropic agents, an echocardiogram is performed to assess ejection fraction and rule out structural abnormalities. If the ejection fraction is <45%, hormonal resuscitation is initiated, aiming to stabilize and improve cardiac function:

- T3: 4-μg bolus followed by 3 μg/h continuous infusion;
- arginine vasopressin: 1 U bolus followed by 0.5–4.0 U/h drip (titrate to an SVR of 800–1200 dyn·s/cm^5);
- methylprednisolone: 15-mg/kg bolus (repeat every 24 h as needed); and
- use of an insulin drip: at a minimum rate of 1 U/h, titrate blood glucose to 120–180 mg/dL.

A pulmonary artery catheter is also placed to allow for aggressive monitoring and management of the cardiopulmonary status. This is initiated simultaneously with hormonal resuscitation and continued for a minimum of 2 h. Adjustment of fluids, inotropic agents, and vasopressors every 15 min should be based on serial hemodynamic measurements to minimize the use of α-agonists to meet the following target criteria: mean arterial pressure >60 mmHg; central venous pressure 4–12 mmHg; pulmonary capillary wedge pressure 8–12 mmHg, SVR 800–1200 dyn·s/cm^5[5]; cardiac index >2.4 L/min/m^2 [2]; and dopamine or dobutamine 10 μg/kg/min. The use of hormonal replacement has been recommended as an integral component of donor management [4,6,41,51]. The hormonal replacement abrogates certain physiological changes related to brain death, resulting in cardiovascular stabilization and better organ perfusion. This effect has been associated with a 22.5% increase in organs transplanted per donor [6].

Fluid and electrolyte management

There are specific problems associated with the frequent development of central diabetes insipidus, which should be suspected if a patient develops inappropriate diuresis with rising plasma sodium and osmolality. Diabetes insipidus needs to be aggressively treated because it is closely linked with hemodynamic instability in organ donors [52]. Hypotonic intravenous fluid may be required to restore normal sodium levels but in the face of untreated diabetes insipidus

is rarely successful. Thus, euvolemia, normonatremia, and normal osmolality require a multipronged approach to correcting the underlying pathology (pituitary failure) and replacing volume deficits with free water. The use of large volumes of D5W may cause secondary elevation of blood glucose levels, which should also be treated with insulin, preferably as an insulin drip. Hypernatremia has been associated in some studies with poor organ function after transplantation [53], but it may in fact be a marker of poor overall donor management. A recent study showed, however, that hypernatremia in brain dead donors did not affect transplanted organ quality or graft survival [53].

Donor management is commonly complicated due to conflicting priorities of different specialties that have a different perception of optimal intravascular fluid balance amongst and within thoracic and abdominal organ teams. Generally, lung surgeons and pancreas transplant surgeons prefer to minimize intravenous fluid to minimize lung and pancreas edema. By restricting fluid administration, edema or congestion of these organs are thought to be minimized. In contrast, optimal fluid management for hearts and kidneys is diametrically opposite. By aggressively hydrating donors, kidneys are well perfused to maintain brisk urine output and cardiac output can be optimized. Because multiple recovery teams work concurrently in organ management and subsequent multiorgan recoveries, the importance of communication between different teams and OPO coordinators must be emphasized.

Inflammatory responses

Administration of methylprednisolone to the donor in an attempt to reduce inflammation has been shown to be beneficial in randomized studies of lung and liver transplants, and is commonly given as soon as a plan for donation is confirmed [54–56]. In a recent observational evaluation of organ donors, higher IL-6 levels were correlated with worsening subsequent organ outcomes in recipients [36]. In addition, the same group performed a recent pilot study to explore the feasibility of using a hemoadsorption device to remove inflammatory cytokines in brain dead donors [57]. This device was able to achieve modest reduction in plasma cytokine levels; however, no data are available on clinical transplant outcomes.

Coagulation

Coagulopathy may be related to donor pathology or release of activating substances from the injured brain. Treatment is required if there is active bleeding and correction of a markedly abnormal coagulation profile should be considered before a retrieval procedure. Point-of-care coagulation testing, including thromboelastography, may aid treatment decisions. Transfusion should be considered if necessary as for any ICU patient, except if TRALI develops.

Intraoperative management during organ recovery

A multiorgan donation operation generally involves a laparotomy extended by sternotomy, even if thoracic organs are not to be retrieved. As with any major body cavity surgery, there is potential for significant blood loss and hypothermia. Marked cardiovascular instability can occur during organ retrieval and vasoactive drug infusions are likely to be in progress. The goal of perioperative organ donor management is to maintain stability during the organ recovery period to allow unhurried removal of optimized organs. Surgical safety checks (appropriately modified) should be carried out.

Intraoperative active warming should be continued, as the duration of retrieval may be extended if there are any delays. Intravenous fluids should be warmed and blood and blood products should be immediately available if required. Cardiovascular changes mediated by spinal reflexes may be induced as a result of surgical manipulation and may require treatment with vasoactive drugs. Since brainstem death has occurred, the administration of anesthesia is unnecessary. Some retrieval teams administer volatile anesthetic drugs during retrieval for the control of hypertension as they may have beneficial preconditioning effects on retrieved organs, although there is no evidence for this. Coordination of drug administration, particularly heparin, is important. Retrieval teams should be skilled in abdominal and thoracic perfusion techniques.

Assessment of donor quality

With the disparity between the need for organs for life-saving transplants and the limited numbers of organ donors, the general premise that most OPOs have adopted in evaluating a potential organ donor is an "every organ every time approach." The goal is to make available to transplant surgeons and their patients all possible organs for transplantation from all individuals who choose to give this gift. Unfortunately, not all organs from individuals who desire to help others by being organ donors at the time of their death are in fact suitable.

It is the responsibility of the OPO to review the available information on each potential donor to assess each potential donor's quality and determine which organs from each specific donor are potentially transplantable. The OPO begins with a thorough review of the potential donors past medical and social history. Assessment of donor quality is generally based on donor age, size [especially body mass index (BMI)], general medical history, organ specific medical history, smoking history, with attention to malignancies, infections, and high risk behaviors, including substance abuse [alcohol or drugs (intravenous, inhalational, oral, etc.)], multiple sexual partners, incarceration, etc. The cause of death, length of hospitalization, hemodynamic status (blood pressure, heart rate, inotropic support), pulmonary function, hepatic function, urine output, glucose level, and acid–base balance are also important in the analysis of donor quality. Increasing age, high BMI, history of co-morbidities, prolonged ischemic time, and hemodynamic instability have all been known to increase the risk of organ dysfunction and poor survival after transplantation.

It is important to remember that the only current absolute contraindication for organ donation in the US at this time is a proven diagnosis of HIV in a potential donor. This is currently federal law, but is being re-evaluated in light of a recent article published from South Africa showing that HIV-positive donors may donate to HIV-positive recipients with success of these organs post transplantation [58]. Other potential contraindications to donation are disseminated malignancies, ongoing treatment of cancers, non-identified causes of meningoencephalitis, and severe multiorgan dysfunction. Nevertheless, these should be evaluated on a case-by-case basis and should not result in automatic turndown as potential donors.

Next, the OPO will evaluate the circumstances of the cause of death of each donor and again assess the potential impact of the catastrophic event leading to death. One consideration is anoxia time and whether cardiopulmonary resuscitation (CPR) was performed, as well as the duration of the CPR until return of

spontaneous circulation. Also important is functionality of the organ systems between the time of catastrophic injury and the deterioration and pronouncement of death by neurological criteria. Any respiratory, cardiovascular, renal, hepatic, and pancreatic dysfunction may negatively impact potential for recovery and transplantation of organs. One mechanism of tracking these variables and evaluating the impact of the ICU management predeath is to utilize "donor management goals (DMGs)." DMGs are agreed parameters that are used to direct the management of an organ donor. These parameters vary by program/OPO/region, but all are based on targeting normal physiological endpoints in terms of cardiopulmonary function while minimizing additional support (fewer inotropic agents), maintaining normal or near-normal chemistries and pH, and evaluating adequate perfusion of end organs. These DMGs have been evaluated and meeting more of these DMGs appears to correlate with increased numbers of organs recovered and transplanted from donors [59,60]. A proposed usage of the DMGs is the establishment of a uniform objective DMG list for all organ donors to allow study of the variations in management to achieve the physiological parameters outlined in the DMGs, as well as to determine superior management outcomes. Another proposal is to evaluate DMGs at varying times through the donor management time period and serially assess the percentage of DMGs completed. There is some evidence that if the donor meets a high percentage of the DMGs prior to the OPO management of the donor, the potential for more organs transplanted per donor will be increased. This may be used as a guide for pre-OPO management strategies prior to OPO involvement. Accurate and detailed accounts of problems during the donor management period, the period after DNC is determined, and prior to recovery of organs for transplantation should be chronicled, as there are a host of potential problems that may be identified during this management period of the potential donor.

Once all the information has been gathered and collated, and any issues identified, these are made available electronically to the transplant centers for evaluation and review for suitable recipients among those listed by their center through the OPTN computer network. Each specific center has developed its own independent criteria by which recipient suitability is evaluated and determined. Ultimately, it is the transplant surgeon and their patient who must make the final decision based on the combination of the condition of the recipient and the anticipated donor organ quality. Included in the donor organ quality assessment is the potential risk(s) of the donor based on the information available and the anticipated cold ischemic time that lead to a final determination of acceptance of each organ for transplantation. The assessment of organ suitability from the perspective of the recipient surgeon can be found in Chapter 53.

Heart

As previously discussed, there are a multitude of factors affecting the potential quality of the donated heart. Most transplant programs have a maximum donor age criteria of between 60 and 65 years, with some room for exception with extremely fit donors above this age range. Other exclusion factors include prior cardiac pathology, prior heart surgeries, and suspicion of primary cardiac etiology behind the acute event that resulted in the donor's death (myocardial infarction, primary arrhythmia, myocarditis, cardiomyopathy, etc.). If the catastrophic event caused the donor to lose spontaneous circulation, then the amount of time without perfusion is a significant concern, as well as the time of CPR and time to return of spontaneous circulation. The usage of inotropic or vasopressor agents and the dosages needed to maintain hemodynamic stability during the predonor care and following declaration may affect the heart transplant potential.

We have previously commented on the physiological changes that are associated with death by neurological criteria; these may lead to temporary or permanent cardiac dysfunction, cardiac arrhythmias, and/or decreased myocardial DO_2. Assessment of the potential for heart donation hinges upon donor management through the catecholamine storm, subsequent hemodynamic collapse, and until normal physiological cardiac output (CO)/cardiac index (CI) with normal SVR can be established. If the donor can be supported through this cascade without compromising heart function, the post-traumatized heart may be reassessed to determine the likelihood of successful transplantation. Based on data previously quoted, current practice is for most OPOs to institute thyroid replacement therapy in all potential heart donors, as well as in many donors who are not potential heart donors, to stabilize the hemodynamics and allow the reduction or weaning of inotrope infusions. Decisions as to T3 or T4 replacement, the dosing of each, and whether delivery is intermittent or continuous are based on expert opinion and local practice. As with most aspects of organ donor management, little randomized data exist. Our practice locally is to initiate levothyroxine (synthetic T4) as a continuous infusion, beginning at 10 μg/h and titrating to a maximum of 30 μg/h as long as the hemodynamic effect is tolerated without adverse effects – the most common being tachycardia and hypertension. In addition, routine doses of corticosteroids are given and continued until organs are recovered. Again, objective data are limited and best practices vary as to specific medication choice, i.e. glucocorticoid and/or mineralocorticoid, doses used, and continuous versus intermittent infusion.

In the evaluation of the heart for transplant potential it was common practice to obtain an echocardiogram at the time of initiation of OPO management; this practice has shifted to postponing echo evaluation until after weaning catecholamine infusions to a minimum and preferably completely. In addition to assessing adequate functionality, commonly by ejection fraction, ventricular wall thickness and motion dynamics must demonstrate near-normal function. In older donors, a cardiac catheterization is often necessary to determine if coronary artery disease renders the heart unsuitable or if it can be utilized after back table coronary artery bypass grafting.

The use of pulmonary artery catheters has declined in donor management, as it has in general ICU management, due to the lack of demonstrable benefit, recognition of risks associated with insertion and maintaining the catheter, and the lack of qualified personnel and equipment in most hospitals. It has been replaced by minimally invasive hemodynamic monitors that for the most part utilize pulse contour to measure either stroke volume variability or pulse pressure variability as a marker of hemodynamic status. Some OPOs have utilized tracheal Doppler flow probes with success in guiding their donor management.

Lungs

Available data on lung acceptability for transplantation focus primarily on the PaO_2-to-FiO_2 (P/F) ratio being >300–350 on minimal mechanical ventilator support. As with the heart, factors affecting lung transplantability include age (<60 years old), historical information, cause of death, treatment of the donor in the pre-OPO phase, and treatment during the OPO phase. When the catastrophic

event was traumatic or associated with CPR and vomiting, concerns include the extent of the contusion injury, development of pneumothoraces, and the possibility of aspiration of gastric contents, all of which impact lung transplantation potential. In a donor with a history of moderate-to-severe asthma, pulmonary artery hypertension, or emphysema, transplantation of the lungs is unlikely. A smoking history of more than 20 pack years or history of marijuana use for a significant period of time decreases the potential of lung donation as well.

The duration of intubation and extent of mechanical ventilation, as well as placement of a tracheostomy tube due to long-term mechanical ventilation needs, are other risk factors for non-transplantation as they introduce the possibility of infection and ventilator-induced injury, e.g. barotrauma. The cascade of catecholamines, hormones, and mediators released during the herniation process may cause direct cellular injury to the lung tissue. Increased transthoracic pressures cause pulmonary capillary bed and endothelial injury, resulting in an acute respiratory distress syndrome (ARDS) event that leads to increased lung dysfunction and ongoing inflammatory cascade. With cessation of neurological function, loss of spontaneous respirations, loss of cough, and loss of spontaneous movement occur, all of which result in mucus plugging, atelectasis, and derecruitment of alveoli. Additionally, "neurogenic pulmonary edema" develops, leading to further water accumulation in the lungs and further worsening of the gas exchange. Also, the need for aggressive fluid resuscitation to support hemodynamics and renal function during the phase of vascular collapse, will worsen lung water status.

Early chest X-ray is helpful in identifying potential issues in the lungs, both easily and without having to move the patient. Initiation of chest physiotherapy – with the vest or bed – and albuterol to enhance mucociliary clearance are helpful in reversing some mucus plugging. N-acetylcysteine may assist as a mucolytic agent as well. The use of systemic corticosteroid treatment has also been shown to improve lung function, along with better assessment and control of donor volume status to accomplish an isovolemic state.

Alveolar recruitment strategies with the mechanical ventilator include the San Antonio Lung Transplant (SALT) protocol [61], a low tidal volume (TV), high positive end-expiratory pressure (PEEP) recruitment approach, and an alternative approach using a severely inverted inspiratory-to-expiratory (I:E) pressure ratio controlled ventilation – BiVent or APRV-like modes [62]. Recalling that the neurologically deceased donor produces little CO_2 and so needs decreased minute ventilation, there is little downside to this approach. Both strategies of donor management have been shown to increase the likelihood of successful recruitment and subsequent lung recovery and transplantation (Lebovitz et al., personal communication). An argument may be made in most donor management cases for early bronchoscopy, but this is particularly true in cases of excessive mucus plugging or aspiration of gastric contents to relieve the obstruction and improve the VQ matching, leading to improved P/F ratio.

While chest X-ray is a good initial screen to look at lung fields, computed tomography (CT) scan of the lungs may assist in the case of a smoker with no past history of emphysema to rule out the likelihood of this condition in the early OPO donor management phase. If evidence of emphysematous changes are noted, the lungs are not suitable for transplantation and a less aggressive ventilation strategy may be utilized.

All donors need be thought of as potential lung donors. Addressing the numerous factors described above is among the highest priorities for the OPO early in the immediate post-OPO management phase, as it focuses the goals of management on improving the DO_2 and the pulmonary dynamics, while minimizing the potential for barotrauma and oxygen toxicity and improving the fluid status of the lungs and the patient. Support of DO_2 is essential to maintain viability of all transplantable organs. If the P/F ratio can be raised above the 350 range with a low peak ventilator pressures and a PEEP of 5 cmH_2O, and if the chest X-ray is cleared with little concern for an ongoing pneumonic process at the end of the OPO donor management phase, the likelihood of successful lung recovery and transplantation is high.

New on the horizon is a process for recovering lungs that do not appear to be able to be transplanted and supporting these lungs with an ex-vivo apparatus that allows them to be reconditioned. This apparatus has been used and studies published that demonstrate that marginal lungs (i.e. that would not have previously been used for transplantation) can be recovered, reconditioned, and transplanted. [63]. The Food and Drug Administration (FDA) is currently engaging some US transplantation programs in the evaluation of these product/processes for use in the US.

Liver

The liver is one of the organs most resilient to a lack of adequate DO_2 in the donor. In addition, the age of the donor is less of a factor for post-transplantation functionality. Nevertheless, there are a number of unique issues to be evaluated when liver transplant potential is being considered. BMI of the donor is an important factor to take into account. Donors with BMIs of >30 are more likely to have significantly fatty livers, which some surgeons will not consider for transplantation. Other factors include alcohol ingestion history – duration and quantity. A long history of alcohol abuse results in a fibrotic and dysfunctional liver that is not transplantable. The presence or absence of viral hepatitis in the donor is also significant in the assessment of donor liver quality. The presence of past indicators of hepatitis B infection or evidence of active hepatitis C serologies makes it more challenging to identify the correct recipient for such a liver transplant. Additional testing may be indicated if it is uncertain if there is an active infection or if the serologies are explained by prior immunization and other factors. It is critical therefore, to have the necessary knowledge to interpret the results of serological testing in order to place these livers into the most appropriate recipient. Occasionally, it is helpful to perform a bedside needle biopsy of the liver of a donor who has a number of risk factors for poor liver transplant potential.

The issue of elevated serum sodium in the donor leading to poor outcome of these livers post transplantation is controversial. While the literature is divided, and a recent study from Indiana appears to debunk this myth [53], the elevation of sodium in fact reflects that the volume status of the donor is inadequate, which may be a major factor in determining liver function post transplantation.

Kidneys

Kidneys are the organs in by far the highest demand for transplantation in the US and around the world. However, age and other fairly common underlying medical diseases may limit their desirability as donor kidneys.

When a patient is treated in the ICU for catastrophic brain injury with hyperosmolar therapy, fluid limitation, and vasoconstrictors, in order to decrease intracranial pressures and support cerebral perfusion pressure, the result may be inadequate perfusion of the renal parenchyma. As the patient continues to deteriorate

neurologically, these treatments are further pushed, worsening potential injury to other vital organs. Once care is determined to be futile and the patient is evaluated for DNC, these treatments may or may not be stopped by the primary care team prior to consent for donation and the OPO orders beginning. After DNC is declared, during the pre- and post-donor management periods, the kidneys are at significant risk for developing worsening acute tubular necrosis. This is due to the rapid fluid shifting and the variability in CO/CI of potential donors as the catecholamine surge and subsequent hemodynamic collapse occurs. Additionally, the loss of the hypothalamic/pituitary access, resulting in development of diabetes insipidus, may additionally cause severe intravascular volume depletion and exacerbate hemodynamic instability.

Organ donors are at risk for renal failure from the prehospital events they suffered (e.g. trauma, hypotension, toxins such as ingestion of ethylene glycol), hospital events (e.g. sepsis, nephrotoxic agents such as intravenous pyelogram dye or antibiotics), or the treatment regimen they underwent (e.g. fluid restriction). Catastrophic events such as crush injury, drug overdoses (especially cocaine, heroin, amphetamines, and PCP), seizures, severe hypoxia, and trauma, can lead to rhabdomyolysis causing renal injury from myoglobin deposition. Donors are at risk for multiorgan system failure with DIC and microthrombi formation in the kidneys as well. Procedures requiring intravenous contrast in deceased donors like cardiac catheterization may cause "contrast-induced nephropathy."

Thus, aggressive adjunctive therapies directed at maintaining isovolemia, enhancing urine output, and providing protection from toxic effects might have some utility. In a recent study, kidneys from donors receiving low dose dopamine during the OPO management phase had improved renal function post transplantation in recipients [64].

The serum BUN, creatinine, and hourly urine output are monitored to give the best indication of the likelihood of kidney donation by a deceased donor. In addition, renal biopsies and ex-vivo pumping – shown to improve renal function post transplantation – can be helpful adjuncts in determining suitability for donation and success after transplantation.

Pancreas and intestines

Both the pancreata and intestines in a potential donor are extremely fragile organs and many stressors in the potential donor can lead to untransplantability of these organs. They are particularly susceptible to hypoxic ischemic insults with autolysis, sloughing of their mucosal lining, and ischemia.

The best indicators of potential for transplantation of the pancreas are a normal amylase, lipase, and hemoglobin $A1_c$. More data need to be gathered to determine if there are indicators for the intestines that are helpful in predicting likely successful transplantation of these organs.

Infectious disease risks

Inherent in transplantation is the potential for transmission of disease from the donor to the recipient. This can be the result either of a pre-existing disease process in the donor or an acute process associated with the current hospital illness/injury. Steps need to be taken in evaluation of the potential donor, treatment of the donor during the acute hospital phase and including the donor management phase, and the post-transplantation treatment of the transplant recipient. Detailed discussions of donor-derived infections are found in Chapter 92.

Evaluation

Initial evaluation of the donor per the current UNOS Policy 2.2.4.1 requires non-hemodiluted donor serological testing for HIV 1 and 2, HepBsAg and HepBcAb, Hep C, cytomegalovirus (CMV), Epstein-Barr virus (EBV), Venereal Disease Research Laboratory (VDRL) or rapid plasma reagin (RPR), as well as acute bacterial cultures of blood, urine, and for lung donation, bronchoscopy/sputum Gram stain and culture. As previously discussed, positive serology testing for HIV currently disqualifies a potential donor in the US. Other positive findings from these screening tests may influence the potential transplantation of specific organs from seropositive donors or influence the post-transplantation treatment of the recipient of these organs.

Nucleic acid testing

There is recent controversy amongst experts in donation/transplantation regarding additional testing using the Nucleic Acid Test Systems (NAT) to screen potential donors for HIV, hepatitis C, and hepatitis B viruses. This newer technology allows for small amounts of DNA/RNA to be detected by a process of massive copying of the gene fragments. The advantage of NAT testing is that the "window period" – the period between infection of an individual and time to detection – may be shortened by NAT testing.

Proponents of NAT testing of all potential donors (as is currently done in the blood banking industry) state that mandatory NAT testing may allow for detection of positive individuals prior to serological conversion, thus further decreasing the likelihood of unanticipated transmission. In addition, a survey of organ procurement organization clinical directors suggested that the incorporation of NAT testing for Hep C and HIV may improve "high-risk donor" organ utilization [65].

This decrease in the "window period" is different for each of the viruses tested. For HIV, standard serology testing will give a positive result 17–22 days following infection; enhanced serology (combined antibody–antigen) testing decreases this to 7–16 days, with NAT decreasing it to 5–6 days. For Hep B, standard serology testing can give a positive result in 35–44 days following infection; no enhanced testing is available, but NAT decreases this time to 20–22 days. Most significantly, the average window for Hep C can be reduced from ~70 days for standard serology testing, to 40–50 days with enhanced serology testing, and to 3–5 days when NAT is used [66–72].

Opponents remain concerned about the potential adverse effect of NAT in terms of lost donors and organs available to transplant due to false-positive testing, which is known to occur with inexperienced/infrequent use of this testing, and inability to obtain testing results prior to transplantation (time limitations on testing sites/travel of serum to sites, etc.) [73]. A recent expert consensus conference concluded that, "there is insufficient evidence to recommend universal prospective screening of organ donors for HIV, HCV and HBV using current NAT platforms." Further study of viral screening modalities may reduce disease transmission risk without excessive donor loss [74]. Since the publication of these recommendations, the Centers for Disease Control and Prevention (CDC) has distributed and is continuing to revise new guidelines for testing of all prospective organ donors, both living and deceased. Recently, the public comment period on its proposed revised guidelines generated a significant outcry from the transplant community and the recommendation to have all parties meet further to balance the opposing viewpoints. This revision may have impact on testing of donors in the future.

Antibiotic use in donors

The use of antibiotics in donors depends on a number of conditions and situations, but should adhere to standard medical and surgical guidelines. Traditionally, relatively young, trauma victims are rarely chronically ill and usually devoid of infectious risk complications – prophylaxis is often accomplished with the use of a first-generation cephalosporin. However, donors with more complex medical conditions and underlying co-morbidities, or those who have been hospitalized for a long period of time, may have acquired antibiotic-resistant organisms, including methicillin-resistant *Staphylococcus aureus* (MRSA), and have other risk factors for infection associated with hospital care of the critically ill patient. The OPO must decide if antibiotics are needed or helpful in the ongoing management of these patients as potential donors. Antibiotics with known specificity should be targeted based on site-specific cultures, e.g. cerebrospinal fluid, respiratory, urinary, blood, or catheter sites. In many donors, the approach of using broad-spectrum antibiotic coverage during the OPO management phase reflects the short time available for preparing for donation. One concern is the use of antibiotics that may cause acute organ dysfunction and decrease the likelihood of successful transplantation of organs. Recent publications have commented on the potential of acute renal dysfunction/failure in critically ill patients treated with piperacillin–tazobactam. Another concern is that this acute respiratory failure may be worsened with co-incidental usage of vancomycin [75]. In general, unless there are specific organisms that require more toxic antibiotics, a fourth-generation cephalosporin with extended Gram-negative coverage is recommended. If Gram-positive cocci thought to be staphlococci species are identified in the donor process, vancomycin may be added with close monitoring of renal function and vancomycin serum concentrations in the event of any identified issues. Conversion to a less toxic antibiotic should be accomplished as soon as sensitivities are obtained.

Summary

There is a critical shortage of organs available for life-saving transplantation, and the numbers of deceased donors have remained static for the last 5 years. The responsibility to maximize the numbers of organs available for transplantation is shared by the hospital team that has cared for the patient prior to declaration of DNC (physicians, nurses, respiratory therapists, etc.) and the OPO team (requestors, bedside management professionals, etc.). Protocol management of critically ill patients who transition to potential donors aids in the ability to reach target goals and to normalize physiological functions, and thereby to increase the likelihood of successful donation and subsequent transplantation.

Introduction

To date, brain dead donors represent the largest source of organs utilized for transplantation. During the last decade, organs procured from brain dead donors have increased each year in the US, peaking at approximately 28 000 organs in 2007. Since then, however, numbers for brain dead donors have slightly declined. At the same time, an increasing availability of organs from donors after circulatory death has been observed; more than 10% of all available organs are currently procured from donors after circulatory death [1,2].

Brain death criteria were established by a committee at Harvard Medical School in the late 1960s and define an irreversible loss of brain and brainstem activity caused by extensive and irreversible central nervous system damage subsequent to trauma, hemorrhage, or infarction [3]. Clinical criteria defining brain death include coma with cerebral unresponsiveness, apnea, absence of brainstem reflexes, and persistence of these conditions for 6–24 h. Although confirmatory tests are not mandatory, additional testing, such as electroencephalography, transcranial Doppler sonography, somatosensory and brainstem auditory evoked potentials, cerebral blood flow and magnetic resonance imaging studies, may be necessary to determine the diagnosis. The presence of sedative drugs, hypothermia, shock, or other potentially reversible conditions that may depress brain function must be excluded prior to confirming the diagnosis [4].

Brain death leads to considerable systemic changes, including the so-called autonomic storm, arterial hypo- and hypertension, massive coagulopathy, and abnormalities in electrolyte balance [5]. This chapter details the technical methods for organ procurement from brain dead donors, with particular attention to the consequences of brain death for these techniques. Organ procurement is a surgical procedure that proceeds in the face of, at times, catastrophic instability, necessitating speed and precision in its conduct. A general understanding of the decedent's abnormal physiology is important to allow the surgeon to assess the conduct of the case and coordinate compensatory plans with the procurement team. Specific details regarding the management of brain dead donors prior to procurement are given in Chapter 20 and the techniques specific to the procurement of organs from non-heart beating donors after circulatory death are featured in Chapter 22.

Profound effect of brain death on the cardiovascular system

The profound increase in intracranial pressure linked to brain death causes ischemia from the cerebrum to the spinal cord (Figure 21.1). This results in herniation of the medulla oblongata, followed by vagal motor neuron ischemia, culminating in systemic hypertension and tachycardia. The observed peripheral ischemia is a consequence of a sympathetic overload causing increased vascular resistance and subsequent hypertension [6].

Despite an increased coronary blood flow, cardiac perfusion remains poor, leading to global myocardial ischemia and subsequent structural changes, such as interstitial hemorrhage, diffusely scattered subendocardial necrosis, and mononuclear cell infiltration. Following brain death, the "catecholamine storm" remodels the myocardium structurally in ways similar to the changes observed after the administration of high doses of catecholamines [7,8].

Large animal experiments have shown that a cardiac sympathectomy can limit local catecholamine effects and structural remodeling subsequent to brain death. The magnitude of the cerebral insult and the level of intracranial pressure is often proportional to the extent of released catecholamines [9].

Following the initial hypertensive period, peripheral vascular resistance declines, leading to hypotension mainly due to spinal cord ischemia. Cardiac and peripheral organ hypoperfusion are the consequence of a combined effect of hypotension, vasodilatation, hypovolemia, impaired vascular autoregulation, and compromised microcirculation subsequent to impaired endothelial-dependent vasodilatation [8,10].

Judicious management of donor cardiac output, peripheral vascular resistance, and perfusion pressure determine the quality of organs from brain dead donors. Fluid resuscitation, inotropic support, and hormonal substitution are usually used for stabilization. Coagulopathy following brain death leads to fibrin deposition

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

and organ damage due to free hemoglobin. Strategies pre-empting the consequences of those events include aggressive fluid replacement, hormonal replacement with the administration of platelets, clotting factors, and early organ procurement. Whether delayed procurement and stabilization of the donor help to ameliorate some of the neurohumoral consequences of brain death remains controversial [5] (Figure 21.1).

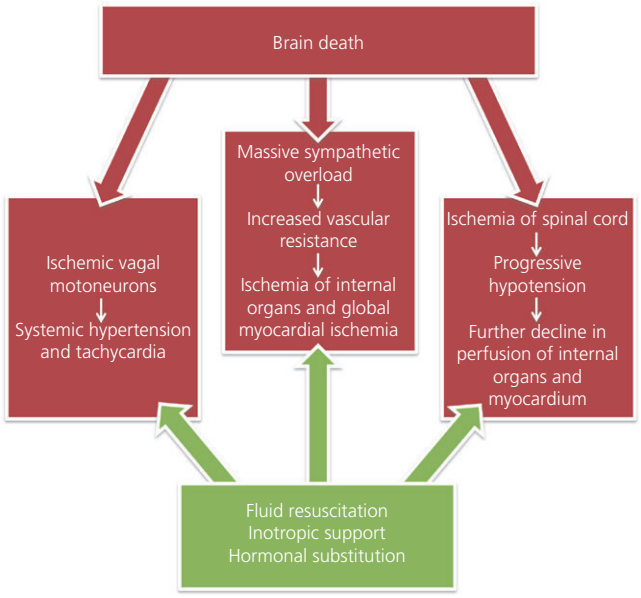

Figure 21.1. Sequelae of brain death on the cardiovascular system and possible treatment strategies.

Endocrine changes as a consequence of brain death (Figure 21.2)

The autonomic storm following brain death leads to a dramatic increase in plasma catecholamine levels. Moreover, brain death is associated with the so-called anterior and posterior pituitary failure, leading to dysfunction of the hypothalamic–pituitary axis. In animal models, brain death is linked to a dramatic decrease in plasma levels of thyroid hormones, cortisone, and insulin. Although some clinical reports have described comparable findings, most authors describe normal levels of cortisone and insulin following brain death [11,12].

In the presence of varying degrees of necrosis, hemorrhage, and edema of the pituitary gland, thyroid stimulating hormone (TSH), adrenocorticotropic hormone (ACTH), and human growth hormone (hGH) are mostly within normal limits. However, subnormal concentrations of thyroid hormones have been observed and substitution of T4 has been shown to prevent hemodynamic and metabolic alterations [13,14].

The posterior pituitary function is impaired in almost all patients after brain death, resulting in diabetes insipidus with subsequent hypovolemia and massive electrolyte imbalances. Lack of vasopressin aggravates the peripheral vasodilatation, which is furthermore promoted by an impaired thermal regulation linked to brain death [15].

Morphological changes in donor organs after brain death

Brain death has profound effects on organ morphology and functional properties, influencing not only immediate graft function but also long-term graft outcome. Systemic and local inflammatory consequences following brain death have been explored extensively.

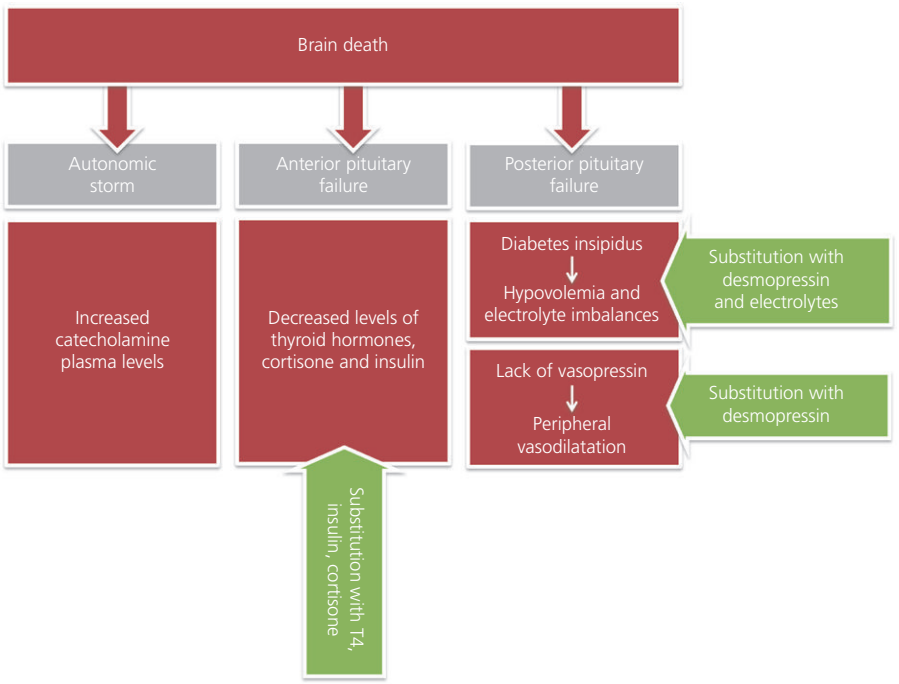

Figure 21.2. Neurohumoral impact of brain death and therapeutic options.

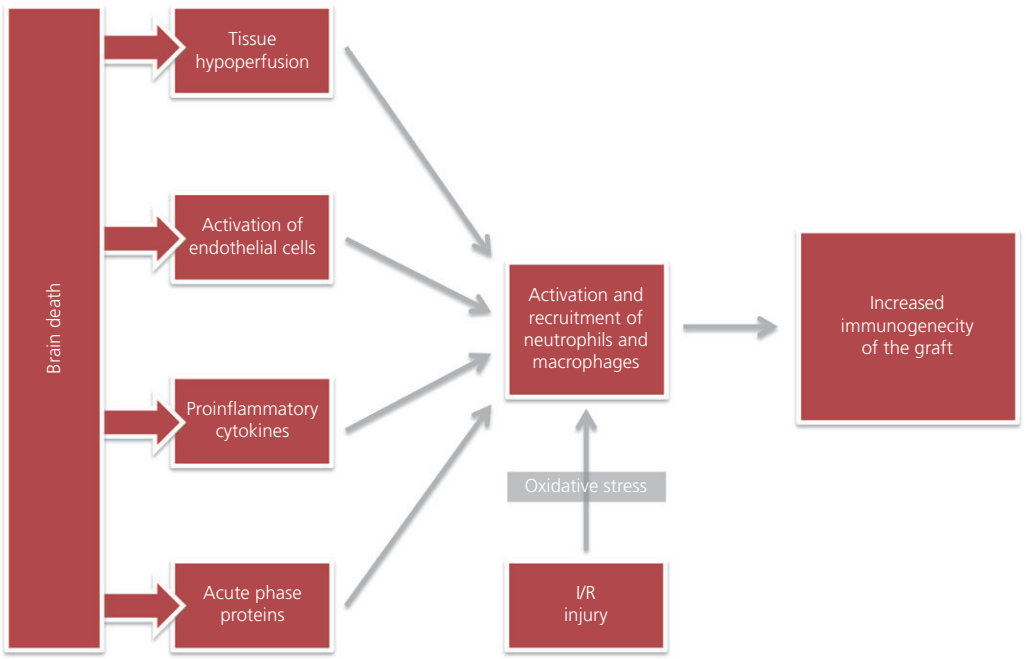

Figure 21.3. Pathophysiology of increased graft immunogenicity following brain death. I/R, ischemia/reperfusion.

Of note, most of those studies have thus far been descriptive and basic mechanisms remain unclear.

It has been shown that the explosive increase in intracranial pressure is linked to an increase in proinflammatory cytokines (TNF-α, IFN-γ, IL-6), chemokines, and adhesion molecules (ICAM, VCAM, LFA-1). Increased cellular infiltrates were found in kidneys and hearts after brain death, potentially augmenting the immunogenicity of donor organs and leading to an intensified alloimmune response. Putative modes of actions include (Figure 21.3):

1 a direct release of inflammatory cytokines from the ischemic brain and brainstem after brain death;
2 a secondary release from circulating lymphocytes and macrophages as a consequence of the catecholamine storm;
3 endothelial cell activation;
4 a bacterial translocation as a consequence of gut ischemia [5,16].

As the sympathetic storm following brain death reduces coronary perfusion, structural changes are comparable to those observed after cardiac ischemia. Moreover, norepinephrine is released from sympathetic nerve endings located in the epicardium. The combination of local and systemic effects causes an imbalance between oxygen supply and consumption. As a consequence, a predominantly anaerobic metabolism is observed, resulting in an accumulation of lactate within the myocardium. Morphological hallmarks of hearts from deceased donors include subendocardial necrosis and petechial hemorrhage with loss of desmin and interstitial mononuclear cell infiltration. However, these changes occur even in well-perfused hearts and as a thoracic sympathectomy is protective, local effects of catecholamine seem to be critical [17].

Following the onset of brain death and subsequent to hemodynamic imbalances, kidney perfusion is compromised. Impaired perfusion and proinflammatory changes are the major cause of kidney damage seen in grafts from brain-dead donors. Typical histomorphological changes in kidneys from brain-dead donors prior to organ procurement include a degeneration of the proximal tubular lining, endothelial proliferation, periglomerulitis, leukocyte infiltration, and interstitial collagen depositions. Moreover, brain death leads to an alteration of kidney viability as the sodium-to-potassium ratio is dramatically reduced in kidneys from brain-dead donors [18,19].

Reports on the effects of brain death on the liver are limited. The liver seems to be less affected by brain death, potentially related to the organ's relative resistance to compromised perfusion. Morphological characteristics include central and periportal fibrosis, diffuse cell necrosis, fatty metamorphosis, and mononuclear cell infiltrates. Clinically, donor treatment with steroids has been shown to reduce proinflammatory cytokines in the liver, thus improving graft function [6,20].

The lung is especially vulnerable to damage subsequent to brain death, resulting in structural injuries and pulmonary edema. Direct toxic effects of catecholamines, elevated left atrial pressure, systemic hypertension, pulmonary vasoconstriction, and pulmonary endothelial damage all ultimately lead to an increased permeability of pulmonary capillaries. Moreover, volume overload subsequent to volume resuscitation may increase the risk for pulmonary edema compromising gas exchange [21].

Technical considerations of organ procurement in heart beating donors

General preparation and positioning of the donor

Prior to the procurement procedure, the responsible surgeon needs to verify that the donor's blood group has been determined, compatibility with the recipient's blood group has been confirmed, the donor's history has been reviewed, and the brain death protocol has been completed.

Successful organ recovery requires close coordination between all surgical teams participating in the organ procurement process. The primary donor surgeon should introduce the procurement team to the operating room staff and briefly review the steps of the procedure with all participating teams so that recovery can

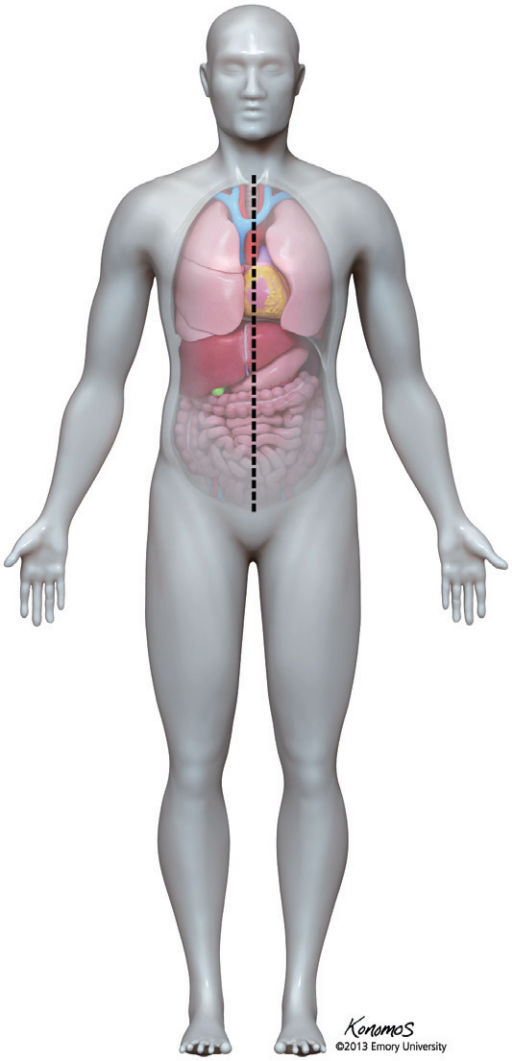

Figure 21.4. The opening exposure for a multivisceral organ procurement procedure.

proceed in a synchronized and expeditious manner. Cardiothoracic organs (heart and lung) are removed first as they are the most susceptible to I/R injury, followed by small bowel, liver, pancreas, and kidneys. The liver and pancreas are recovered en bloc or, alternatively, they may be procured separately. The donor is positioned supine with both arms by the side. Hair is shaved, the surgical site is prepped, and the donor is covered with sterile drapes. For best access, a long midline incision from the suprasternal notch to the pubic bone is made even if thoracic organs are not going to be retrieved [22,23]. Figure 21.4 shows the initial exposure. Diathermy should be used for all of the following steps. Proper hemostasis is particularly important as brain death is linked to a systemic peripheral vasodilatation and compromised hemostasis [24].

After performing a median sternotomy with a sternal saw and achieving hemostasis with bone wax in addition to diathermy, a self-retaining thoracic retractor is inserted. The large Belfour abdominal retractor with teeth can be inserted following the separation of the ligamentum teres hepatis and the falciform ligament. The diaphragm to the left and right of the pericardium should be incised to reduce tension. The pericardium should be divided in coordination with the cardiothoracic team from the apex to the innominate vein. Subsequently, the pericardium will be fixated suprasternally in every corner.

All abdominal and thoracic organs are then examined thoroughly for apparent pathologies. If no evidence for potential contraindications to organ procurement is found and ABO and tissue compatibility have been confirmed, the recipient's center should be informed that the implant procedure may be initiated [25].

Abdominal organs

General considerations

There are two distinct techniques for the procurement of abdominal organs. First, the "rapid perfusion technique with dissection in the cold," which reduces operating time and is recommended for hemodynamically unstable donors and when procuring organs from circulatory death donors (DCD) [26]. In this approach, the abdominal aorta is isolated and cannulated, with no further dissection until core cooling of the organs is achieved in situ. The aim is to minimize organ ischemia by rapid aortic cannulation, exsanguination, and cold perfusion. Following administration of 30 000 IU of heparin, expeditious access to the abdominal cavity is obtained by sharp dissection using a knife and making a midline incision from the xiphoid to the pubis. The Belfour retractor is placed and the retroperitoneal aorta just above the bifurcation is exposed. The aorta or common iliac artery and inferior vena cava (IVC) are cannulated and the flush is initiated. For rapid exsanguination, the suprahepatic vena cava is divided inferior to the right atrium. The pericardium is then opened and the descending thoracic aorta is cross-clamped. Ice and slush are packed around the liver and kidney, which may require further mobilization of the colon so that the kidneys are adequately cooled. Subsequent dissection is carried out after completion of cold perfusion [26]. This procedure is diagramed and discussed in detail in the Chapter 22.

Second, in the standard "warm dissection technique" an anatomical dissection is performed prior to cannulation and perfusion. Some evidence suggests that this technique is associated with more parenchymal and vascular damage due to vasospasm, potentially leading to inferior initial graft function [27]. A recovery period of 30–60 min after dissection might be able to reverse some of these adverse effects. Dissection in the cold on the other hand might be complicated by a more challenging anatomy.

There are many different approaches to the donor operation. Some surgeons prefer to perform all their procurements using the rapid technique. Others use varying degrees of "cold" and "warm" dissection. Irrespective of the technique, multiorgan procurement should be performed meticulously such that all organs can be removed without being compromised. The basic principles of the donor operation include dissection of the great vessels of the chest and abdomen, isolation of the aorta in preparation for cross-clamping, perfusion and core cooling in situ, and rapid recovery to prevent ischemia.

Preparatory steps and cannulation

The peritoneal attachments of the distal ileum and cecum are divided and the retroperitoneal space is exposed with the mobilization of the right hemicolon. Next, the duodenum is mobilized through a Kocher's maneuver and the infrahepatic IVC and abdominal aorta are exposed down to the aortic bifurcation and

the common iliac arteries. At this point, some surgeons prefer to isolate the superior mesenteric artery (SMA) at the root of the small bowel mesentery, and place a vessel loop around it. This is used to control the amount of aortic flush coursing through the pancreas to 1–2 L. The inferior mesenteric artery (IMA) may be ligated and divided at this stage, taking care not to injure any accessory renal arteries [28]. In 1–3% of individuals, lower pole renal arteries can arise from the common iliac artery [29]. The common iliac artery has to be cannulated distally to insure the perfusion of accessory distal renal arteries in these cases. To insure a successful vascular reconstruction, especially in pediatric or split liver transplantations, the IMA should be preserved. In case of severe arteriosclerosis or aneurysms of the distal aorta, the thoracic aorta can be cannulated for perfusion.

The liver is mobilized by dividing the round ligament between heavy silk or Vicryl sutures. Subsequently, the attachments of the falciform, left triangular, and gastrohepatic ligaments are released. Prior to proceeding with the dissection of the gastrohepatic ligament, the presence of an accessory/replaced left hepatic artery originating from the left gastric artery should be explored. This anatomical variation is present in 15–23% of donors and should be carefully preserved [30].

The common bile duct is visualized just above the duodenum and the presence of a replaced right hepatic artery can be palpated posterior to the liver hilum. This anatomical variation is found in 10% of donors. The hepatoduodenal ligament is dissected next, and the common bile duct is exposed, proceeding from lateral to medial by staying as distal and close to the duodenum as possible. The distal bile duct is ligated with 2-0 silk or Vicryl and divided.

The gallbladder is either removed from its bed after dividing the cystic duct between 3-0 Vicryl or Silk sutures, or incised and flushed with saline until the affluent from the divided common bile duct is clear. This step prevents autolysis of the bile duct epithelium during cold preservation [31].

The supraceliac aorta is then dissected in preparation for cross-clamping. This is done by incising the preaortic fascia, retracting the esophagus to the left, and separating the diaphragmatic fibers of the right crus. The supraceliac aorta is encircled and an umbilical tape is placed around it.

Heparin (30 000 IU or 300 IU/kg) is administered at least 3 min prior to cannulation. While waiting for the thoracic team, abdominal organs should be protected with wet abdominal gauzes.

The abdominal aorta is cannulated by tying the distal umbilical tape at the level of the bifurcation of the common iliac arteries. The second tape is then lifted up and the abdominal aorta is incised while occluding the proximal aorta. The perfusion cannula is inserted and the assistant secures the umbilical tape around the cannula. The tip of the cannula should be positioned below the origin of the renal arteries. A second cannula for the portal flush can now be placed [32].

The superior mesenteric vein (SMV) may be used for the portal flush as long as the venotomy is made well away from the margin of the pancreas. Alternatively, the inferior mesenteric vein (IMV) is dissected and isolated at the mesenteric root of the transverse colon and cannulated for the portal flush. Care should be taken not to push the cannula too far, thus preventing injury to the splenic vein.

The surgeon should inform the entire team that preliminary dissection and cannulation has been completed, indicating that it should prepare for cold perfusion and organ removal.

Perfusion

The supraceliac aorta is cross-clamped with a long, straight aortic clamp at the same time as the surgeon transects the vena cava or the right atrium and exsanguinates the abdominal organs into the abdomen or right thoracic cavity. The aortic and portal cannulas are opened to begin perfusion and the organs are packed with slush and ice. Topical cooling of all abdominal organs using ice and cold saline should be applied immediately following perfusion. Pockets are created in the retroperitoneum and the lesser sac to allow for adequate cooling of all organs.

Removal of liver and pancreas

Once the effluent emerging from the transected IVC is clear, the surgeon begins the process of removing the abdominal organs. The pericardium and diaphragm are incised bilaterally: on the left, extending to the esophagus, and on the right, extending posterior the right lobe of the liver, adrenal gland, and IVC. This allows the liver to fall back into the chest. Always keep the liver covered with slush and ice. Figure 21.5a,b details the anatomy relevant to the procurement of the liver and pancreas.

The gastroduodenal artery is identified at the superior border of the duodenum and followed proximally to the common hepatic artery. Once the origin of the common hepatic artery from the celiac artery is identified, the gastroduodenal artery can be ligated. Dissecting proximally on the common hepatic artery will lead to the splenic artery, which is isolated and divided close to its origin from the celiac artery. The splenic artery should not be dissected into pancreatic tissue as this may injure the dorsal pancreatic branch.

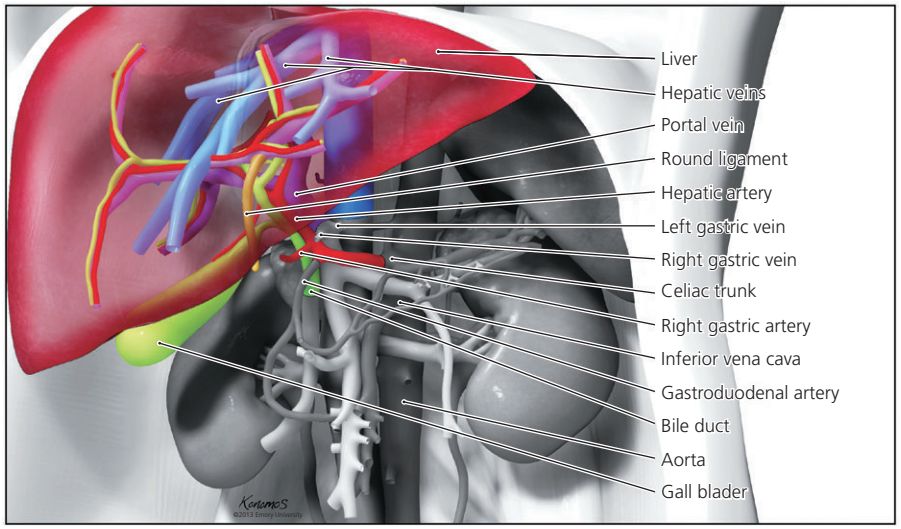
Using sharp dissection along the greater curvature of the stomach, the short gastric vessels are divided up to the diaphragmatic hiatus. The proximal duodenum is stapled just distal to the pylorus and staple lines are thoroughly disinfected. Stomach and duodenum are flushed with betadine and an antifungal solution via the nasogastric tube prior to cross-clamping.

If an accessory hepatic artery has been ruled out, the left gastric artery is divided and transected. All splenic attachments are then divided and the spleen is mobilized completely. The proximal jejunum distal to the ligament of Treitz is stapled, divided, and disinfected; next, the splenocolic ligament is divided while lifting up the tail of the pancreas, with the spleen used as a handle. The dorsal side of the pancreas is dissected using the same technique.

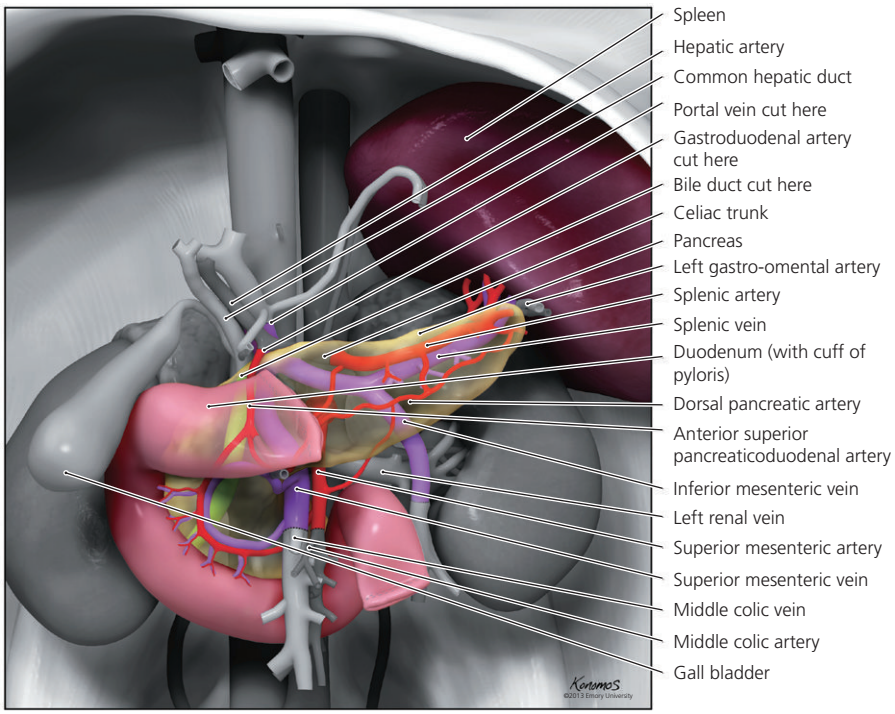
The root of the small bowel mesentery is exposed. The SMA and SMV can then be individually ligated, or stapled and divided, taking care to keep the mesenteric staple line well away from the head of the pancreas and the uncinate process to avoid injury to the inferior pancreaticoduodenal arcade.

The portal vein is divided at the level of the coronary vein, ensuring sufficient venous length for both, liver and pancreas. If the pancreas is not being procured the portal vein should be divided at the splenic confluence.

The SMA is then excised with an aortic patch under direct vision, ensuring the identification of the orifices of the renal arteries, which are usually located just below the origin of the SMA. The infrahepatic IVC is now divided just above the renal veins. To release liver and pancreas en bloc, the right and left paravertebral muscle layers (including the right and left adrenal glands) are divided. The SMA is then excised with the proximal aorta and the celiac trunk. Stiff neural tissue around the celiac trunk might complicate this step. If a replaced right hepatic artery is present, the SMA should be divided distal to the origin of the replaced artery. In rare



(A)



(B)

Figure 21.5. Anatomical relationships of importance for (A) liver procurement and (B) pancreas procurement. The procured anatomy is shown in color.

circumstances the accessory hepatic artery will traverse the substance of the pancreas, in which case the organ may not be utilized [33].

Nephrectomy

The kidneys may be removed en bloc or individually. After removal of the liver and pancreas, the colon and duodenum are mobilized and retracted up into the upper abdomen. The ureters are identified, dissected with sufficient periureteral tissue to insure blood supply and divided as distally as possible. The IVC is divided just above the bifurcation of the common iliac veins, and the aorta is transected at the level of the aortic cannulation. The kidneys are then removed en bloc by incising the prevertebral fascia and mobilizing the kidneys from lateral to medial with Gerota's fascia, using sharp dissection [25]. Kidneys from donors younger than 5 years should always be procured en bloc with a complete abdominal aorta and inferior caval vein.

The pertinent anatomical relationships to kidney procurement are shown in Figure 21.6.

Back table preparation of the kidney

The left renal vein is divided with a cuff of the IVC and the right kidney is preserved with a complete vena cava. The aorta is incised between the paired lumbar arteries, and after visualizing of the

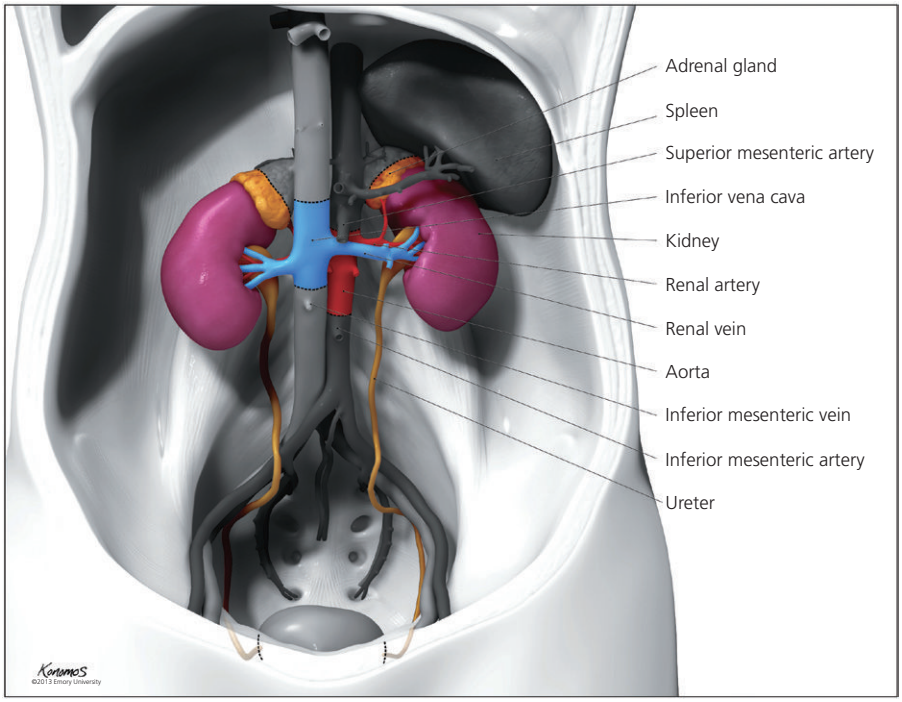


Figure 21.6. Anatomical details of importance in procurement and preparation of the right and left kidneys. The procured anatomy is shown in color.

orifices of the renal arteries from within, the anterior portion of the aorta is divided and the kidneys can be separated. Further preparation of the ureter should not be performed as this might compromise the ureter's blood supply. Placing a hemostat on the tip of the ureter to facilitate its identification throughout the dissection is commonly practiced; however, the ureter should remain cooled and not draped outside the preservation solution for prolonged periods of time.

Removal of iliac arteries and veins

Common, external, and interior iliac arteries and veins should always be procured and need to be sent with the pancreas and/or liver. The iliac bifurcation should be dissected gently to avoid traction injuries. Procurement of the internal iliac artery should include second-degree branches. In case of severe arteriosclerosis, the brachiocephalic trunks should also be procured.

Small intestine

Following the midline sternolaparotomy, the small intestine is thoroughly inspected for apparent pathologies, such as congestion and hematoma, edema, adhesions, petechial hemorrhages, angiodysplasias, or signs of contusion and peritonitis. The motility of the small bowel should be evaluated. The small bowel is wrapped in a moist abdominal pad. Selective gut decontamination with antibiotics (amphotericin B/gentamicin, and polymyxin E) via the nasogastric tube is instituted at the time of procurement.

The abdominal aorta and IVC are exposed from the bifurcation cephalad to the SMA following the mobilization of the right hemicolon and a Kocher's maneuver (see Chapter 62 for illustrations of the procurement technique and details of intestinal procurement). The distal duodenum and the ligament of Treitz are then mobilized. The IMA and IMV are divided and the SMA is exposed with a vessel loop. The distal abdominal aorta and distal IVC are encircled with two 0-Vicryl or Silk sutures. The greater omentum is now divided and the left colon is mobilized and the colic vessels are identified. Antegrade decompression of the intestine is controversial and has become widely discouraged [22].

A complete colectomy is performed after stapler transection of the terminal ileum close to the ileocecal valve. The cecum and right colon are mobilized, preserving the ileal branches of the ileocolic artery. The colon is mobilized further by dividing the middle colic, left colic, and inferior mesenteric arteries. The sigmoid colon is stapled and transected to allow a complete exposure of the mesenteric root. After a left-sided medial visceral rotation (the so-called Mattox maneuver), the tail of the pancreas and the spleen are mobilized as described in detail earlier. The mesenteric root of the proximal jejunum is now divided and the jejunum is divided with a stapler 1–2 inches distal to the ligament of Treitz. The SMA and SMV are exposed by transverse dissection of the mesenteric root distal to the level of the middle colic artery and vein [34]. Critical is the preservation of the SMA–portal vein axis.

An early branching of the SMA requires close attention if the pancreas and small intestine are procured simultaneously. En-bloc removal with back table preparation should be preferred in these cases. The inferior pancreaticoduodenal artery (IPA), which originates just proximal to the origin of the middle colic artery, should be preserved with the pancreas. Injury to the IPA will devascularize the head and parts of the uncinate process of the pancreas as the superior pancreatciduodenal artery (SPA) is sacrificed while removing the liver.

The anterior side of the mesenteric root is marked with a suture prior to stapler transection of the duodenum directly distal to the pylorus. The left gastric artery can then be ligated and the short gastric vessels to the spleen are transected. The abdominal aorta is tied off distal to the diaphragm, and heparin is administered as detailed earlier. The abdominal aorta is cross-clamped and the

perfusion is initiated. The small intestine is the first abdominal organ to be procured after perfusion. The subpancreatic portions of the SMA and SMV are ligated afterwards to prevent backflow of blood into the pancreas graft.

Multivisceral procurement

Following the medial visceral rotation and mobilization of pancreas and spleen, the left liver lobe is mobilized up to the left hepatic vein. The lesser omentum is divided while paying attention to potential left hepatic arteries. The gastrolineal ligament is divided and the distal esophagus is exposed. The cardia can then be transected with a stapler. Next, the abdominal aorta is exposed distal to the diaphragm and clamped or ligated following the application of heparin. Cannulation and perfusion as detailed above follow. Abdominal organs (liver, pancreas, small intestine, stomach, and colon) can then be removed en bloc [35]. Additional detail regarding multivisceral procurement and transplantation can be found in Chapter 74.

Thoracic organs

General preparation

Following a midline thoracolaparotomy as detailed above, the pericardium is opened and fixed to the suprasternal skin. The ascending aorta (up to the aortic arch) and the pulmonary artery are exposed subsequently.

The superior vena cava (SVC) and IVC are exposed and two heavy silk ligatures are positioned around the SVC cephalad to the azygos vein. Sharp dissection of the Sondergaard (Waterston) interatrial groove is then performed to facilitate the differentiation of cardiac and pulmonary left atrial cuffs. After separating the aorta and pulmonary artery, a pearl string suture is placed on the anterior mid-portion of the ascending aorta for the insertion of the perfusion cannula. The perfusion cannula can then be inserted into the ascending aorta after heparin (30 000 IU) has been administered for a minimum of 3 min. A cannulation suture is placed in the distal main pulmonary artery using a similar procedure.

If deemed necessary by the lung team, prostaglandins can be administered intravenously at this point. Prostaglandin E_1 is a strong vasodilator and has been shown in some studies to reduce ischemia/reperfusion injury of the lungs. A shift to anti-inflammatory cytokines might partially be responsible for this effect [36].

The relevant anatomy is displayed in Figure 21.7a,b.

The SVC is then ligated twice after all central venous lines have been removed. In coordination with the abdominal team, the ascending aorta is then cross-clamped as distally as possible to increase the amount of graft tissue. The clamped IVC is incised. If only the heart is to be removed, either the left or right upper pulmonary vein is incised; if both the heart and lung are to be

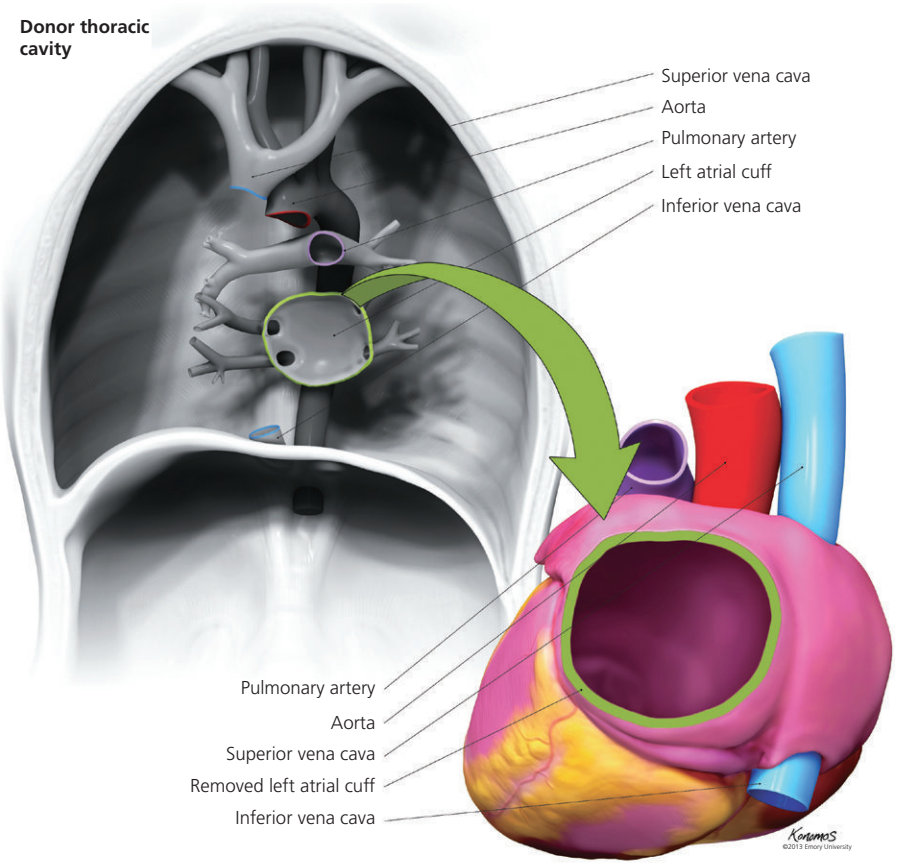

Figure 21.7. The anatomical relationships of importance in (A) heart (before lungs are also procured) and (B) lung procurement (after heart has already been procured). The procured anatomy is shown in color.

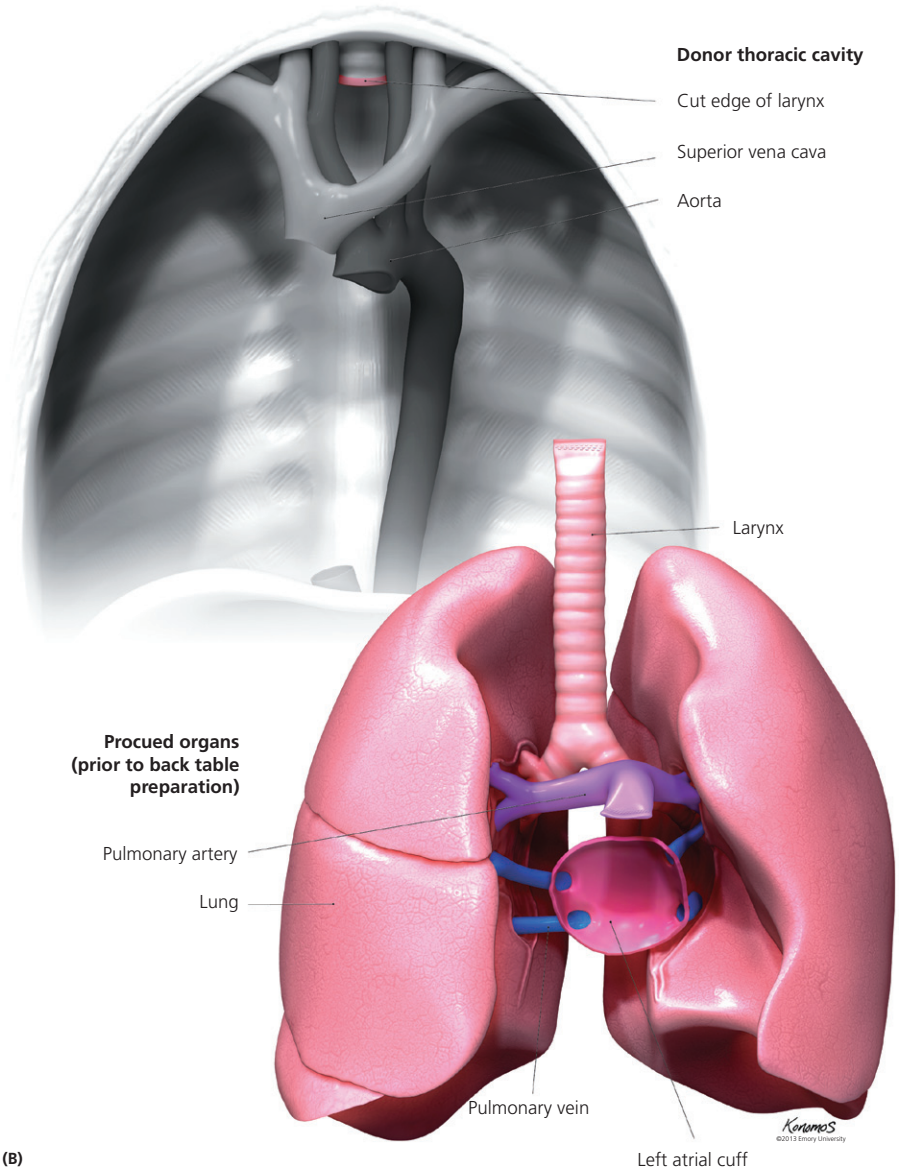

Figure 21.7. (*Continued*)

procured, the left atrial appendage is incised. The main trunk of the pulmonary artery is incised if the lung is to be perfused in a retrograde fashion.

A single flush preservation is started after letting the heart beat empty. The abdominal perfusion can be started in parallel. The pulmonary perfusate is administered through the pulmonary arteries at gravity pressure while the cardioplegic solution is infused at a pressure of 80 mmHg. Local cooling with ice-cold water is started immediately.

An improvement of external cooling of the lungs can be achieved with ice saline slush placed into both pleural spaces through a small reduction of the ventilatory tidal volume. In turn, cardiac cooling is facilitated by the administration of cold saline solution through the pericardium. Pulmoplegia requires approximately 5 L of cold Perfadex® lung preservation solution, while cardioplegia requires a minimum of 1 L of cold crystalloid cardioplegic solution. If both cardioplegia and pulmoplegia are to be administered, cardioplegic solution should be continuously infused for the duration of pulmoplegia. Aortic root pressure and absence of ventricular distension must be continually monitored during infusion of cardioplegic solution. Rapid termination of contractile and electrical activities are hallmarks of adequate cardioplegia. A continuing electrical activity can be related to an unknown coronary artery disease or left ventricular hypertrophy. More and longer cardioplegia should be used in this case. During pulmoplegia, the perfusate must be uniformly distributed throughout both lungs and free flow of gradually clearing solution from the left atrial vent site should be carefully monitored.

Following cardioplegia, the perfusion cannula is removed and the pearl string suture is closed. The incision of the posterior pericardium between the SVC and ascending aorta allows dissection of the trachea above the carina. The anterior, lateral, and medial surfaces of the trachea can be cleared to enable faster tracheal access during the lung excision.

Heart removal

The IVC and SVC are divided between ligatures. If the heart alone is to be procured, the pulmonary veins are also divided between ligatures. If both the heart and lung are to be removed, a transverse incision is made into the left atrium, leaving a sufficiently large cuff of the left atrium around the pulmonary veins. The incision is started at the midpoint between the left inferior pulmonary vein and the coronary sinus, and extended towards the base of the left atrial appendage and towards the inferior edge of the IVC on the right. The left atrium can then be released from the posterior mediastinum by separating it from the posterior pericardium.

The SVC and azygos vein are transected immediately below the supra-azygos and SVC ligature. The innominate and left carotid arteries are separated. The aorta and pulmonary artery should be divided as distally as possible. The heart can then be removed and a final inspection should follow on the back table. Additional detail and illustrations can be found in Chapter 58.

Lung removal

Prior to the beginning of the procurement procedure, a bronchoscopy should be performed to examine the lung for inflammation, edema, lacerations, and amount and consistence of the sputum. A sputum sample should be obtained and a bronchial lavage can be performed. In addition, the arterial blood gas data and chest X-ray should be reviewed.

The ventilator should be disconnected temporarily prior to sternotomy to avoid damage to the lungs during inflation.

Following a midline sternotomy, access to both pleural spaces is gained without cauterization to prevent injury to the lungs. The lungs are then palpated and examined thoroughly, which requires both lungs to be elevated. Parameters and pathologies of interest include size and appearance, adhesions, atelectasis, consolidation, air leakage, bullae or edematous swelling, and palpation for any lesions. Anomalies that can compromise the transplant procedure or organ function following transplant should be immediately reported to the recipient's implant team along with the anticipated cross-clamp time. Additional detail and illustrations can be found in Chapter 70.

The lungs should continue to be ventilated even after the heart has been explanted.

The main pulmonary artery is dissected away from the ascending aorta and the SVC is separated from the right pulmonary artery. After cannulation, all central venous lines are removed and ventilation continues. The SVC is ligated and the IVC is incised right above the diaphragm.

The left atrial appendage is opened to decompress the left ventricle. If the heart is not going to be procured, the left atrium is incised. The ascending aorta is then cross-clamped and perfused with a cardioplegic solution. After a left ventricular distension has been ruled out, the pulmonary perfusion can be initiated. Topical cooling should start immediately and strong suction is used to remove any effluent from the perfusion solution.

After cardio- and pulmo-plegia, both cannulas are removed, the ventilator is disconnected, and the pleura opened widely on both sides. The anterior part of the pericardium is removed along the phrenic nerve anterior to the pulmonary hilum. The posterior part of the pericardium is then excised transversely. The inferior pulmonary ligament on the left side is transected and the left lung is exposed and mobilized to the right. The descending aorta can now be transected below the origin of the left subclavian artery after dissecting upwards close to the esophagus. This step is repeated for the right lung where the dissection is extended up to the level of the azygos vein.

All neck vessels away from the trachea are then divided. Both lungs are gently massaged and manually inflated up to a continuous 30 cmH_2O pressure until all atelectatic tissue is fully expanded. Inflation is then held at a mid-ventilatory level and the trachea is stapled as far cephalad as possible after removal of the endotracheal tube. Two more stapler lines are placed prior to dividing the trachea between the two proximal lines. All remaining mediastinal connections are divided and the double lung block is removed from the thoracic cavity [37,38].

Back table preparation of the lungs

The explanted lungs are re-inspected for all the aforementioned apparent pathologies. Retrograde flushing of the pulmonary arteries by inserting urinary catheters into the pulmonary veins should be performed in order to remove any thromboembolic material and to insure uniform distribution of the preservation solution to both lungs.

Further dissection of the left and right bronchi should be avoided to insure proper vascularization. Only if the left and right lungs are to be transplanted separately, both bronchi should be divided with an additional stapler line at the level of the carina.

Heart and lung en-bloc removal

Pleura and pericardium are excised up to the pulmonary hilum. The SVC, IVC, and aorta are then divided, leaving as much vessel length for the heart graft as possible.

The trachea is then divided between three stapler lines as described above. To remove the heart and lung en bloc, the connective tissue above the esophagus, aorta, azygos vein, and the inferior pulmonary ligament are divided [39].

Organ packing

Following removal from the field, organs are placed into a sterile bag with perfusion solution at 4 °C. This bag is placed into a bag filled with sterile, ice-cold Ringer's lactate or saline and a third empty bag is placed around these two bags, which is then carefully labeled and placed into a transport box with crushed ice. Kidneys, single lungs, and split livers are stored separately and unambiguous labels are attached to the third bag. Vessels are placed into a separate bag with perfusion solution. Blood specimens and segments of the spleen (or, if absent, lymph nodes) are placed in the box with cold Ringer's lactate or saline. Any relevant information about the explanted organ or donor should be updated and included or attached to the transport box. The implant team should then be informed that the organ procurement procedure has been completed.

Care of the donor after procurement

Upon completion of the organ procurement procedure, all foreign materials and fluids are removed and all wounds are closed carefully with watertight sutures before wound dressing is applied. Care should be taken that no derivations are visible before the corpus is transferred in a respectful manner.

Summary

Organ procurement is a technically demanding procedure performed under conditions of temporal pressure and at times

marked hemodynamic instability. The procedure is typically conducted in an operating room with which the surgeon is unfamiliar, at times of night that are taxing, and with other surgical colleagues with whom the surgeon has not operated before. The procedure thus requires exceptional knowledge regarding the entirety of thoracic and abdominal anatomy and specific understanding of the anticipatable consequences of brain death. Operative planning should be intentionally facilitated prior to incision and potential conflicts resolved prior to conduct of the case. Understanding of the donor procurement is the first step to a successful transplant for numerous recipients, and also an opportunity to highlight the transplant field to guest hospitals. It is without doubt an exceptionally important part of the transplant field, and indeed serves as the foundation for success in every deceased donor transplant.

CHAPTER 22

Techniques for Organ Procurement after Circulatory Death

Chandrasekar Santhanakrishnan[1] and Anthony M. D'Alessandro[2]

Introduction

Prior to the adoption of brain death criteria in 1968, most cases of organ donation were primarily of the non-heart beating donor category [1]. The concept of brain death as an endpoint definition of death was advanced largely through the efforts of an ad-hoc committee on the topic from Harvard University, and the general acceptance of this principle has precipitated the current state in which most organ donation in western countries is either from brain dead donors or living donors. In both of these circumstances, organ procurement proceeds while tissue perfusion continues. In the early 1990s, with the persistent shortage of organs and continuing wait-list deaths, there was a renewed interest in donation after circulatory death (DCD), that is the removal of organs from individuals whose death is commensurate with cardiopulmonary arrest, and as such, is accompanied by progressive warm ischemia. This chapter will review the techniques for procurement of organs from DCD donors. Specific treatment of organ procurement from brain dead donors or living kidney or liver donors, can be found in Chapters 21, 23, and 24, respectively.

Definitions

DCD donors are patients who have suffered catastrophic and irreversible neurological injury, but do not meet criteria for brain death; or whose circumstances of death preclude formal brain death declaration. Death is determined by loss of cardiopulmonary function and classified according to the Maastricht criteria [2]:

Category 1 – dead on arrival to the hospital
Category 2 – death following resuscitation
Category 3 – death following planned withdrawal of life support
Category 4 – cardiac arrest while brain dead

DCD can be divided in to two categories: controlled and uncontrolled. In an uncontrolled setting, patients usually have sustained cardiopulmonary arrest prior to arrival at the hospital, and arrive without cardiorespiratory function either with or without intervening attempts at cardiopulmonary resuscitation. In selected centers, and under the guidance of established protocols, some patients who have been declared dead in the field by cardiorespiratory criteria are placed on cardiopulmonary bypass to maintain some degree of perfusion to the organs, typically excluding cerebrovascular reperfusion [3]. In the controlled setting, patients undergo withdrawal of care in an intensive care unit (ICU) or operating room (OR) setting. Death is declared by virtue of witnessed cardiopulmonary arrest, and organ procurement proceeds thereafter. Our experience is drawn largely from the controlled setting. Nevertheless, the technical details of procurement are similar in both settings, and driven by the need for expedient organ procurement, perfusion with preservation solution, and cooling.

Outcomes

The critical issue in DCD donation has been that of warm ischemia affecting the organs as a result of circulatory dysfunction, arrest, and rapid perfusion and cooling at the time of recovery. This impacts organ viability and graft function. However, there is mounting evidence that brain death might have its own deleterious effect on the quality of organs (see Chapter 21). Organs recovered from a DCD donor might not be subjected to this same inflammatory cascade [4]. A more complete discussion regarding the outcomes of DCD donor organs relative to other categories of donor organs is found in Chapter 65.

The results are more encouraging for DCD kidneys than livers. Studies by Weber et al. have shown that, despite the high rate of early graft dysfunction in DCD kidneys, the long-term graft and patient survivals are equivalent to those for brain dead donor-derived kidneys [5]. Graft survival for DCD donors was noted to be 78% at 10 years; compared to 76% for brain dead donor-derived kidneys.

Another study by Rudich et al. compared 708 DCD organ recipients with 97 990 brain dead recipients in the US between 1993 and 2000 [6]. DCD kidney recipients had a higher delayed graft function rate (42.4%) compared with recipients who received organs from a brain dead donor (23.3%). However, the rate of allograft survival was similar at the end of 6 years (73.2% for DCD, 72.5% for brain dead).

The results for liver transplantation from DCD donors have been inferior to those obtained for kidneys. Nonetheless, DCD donors serve an important role in narrowing the gap between demand and supply of livers for transplant, particularly when the individualized risk–benefit assessment is specifically considered and found to be favorable. Abt et al. reviewed the results obtained from the UNOS database [7]. They compared livers procured from 144 DCD donors with those from 26 856 brain dead donors. The 1-year graft survival rate was lower in the DCD group (80% vs. 85%). The DCD

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

recipients also had a higher rate of retransplantation compared to the brain dead group (14% vs. 8%).

Foley et al. also reported a higher rate of vascular and biliary complications in livers obtained from DCD donors [8]. The rate of biliary strictures was higher in the DCD group at the end of 1 year (33% vs. 10%). However, the incidence of hepatic artery thrombosis and primary non-function was the same in both the groups. This study also found that the graft and patient survivals were worse in the DCD group in comparison with the brain dead group. A subset analysis of the DCD group revealed better results with DCD donors under 40 years of age compared to donors over 40 years. Three-year graft survival for livers from DCD donors under 40 years was better than that from the over 40-year-old DCD donor group (65% vs. 45%), although this was not statistically significant. The same was true for patient survival rates at 3 years.

Results from pancreas transplantation using DCD donors have been acceptable, although likely subject to significant selection bias. Qureshi et al. compared patients who received pancreata from DCD donors with those receiving them from brain dead donors between 2008 and 2011 in the UK [9]. They noted no difference in graft thrombosis rates or any difference in hemoglobin $A1_c$ levels at 1 year between the groups. The pancreas graft survival rates were also not significantly different.

A larger study done by Bellingham et al. at the University of Wisconsin had similar results [10]. They compared patients from 1993 to 2008. The pancreas graft and patient survival rates at 1, 3, and 10 years were similar between the DCD and brain dead groups. In addition, there were no differences in perioperative complications like thrombosis, enzyme leak, and abscess formation between the groups.

Preoperative phase

Potential donors are identified after referral to the organ procurement organization (OPO). These patients have had catastrophic brain injury but have not met brain death criteria. Such have patients have been determined to have no significant opportunity for meaningful recovery. It has to be made clear that the transplant team has no involvement in these medical decisions. Also, the patient who is a potential candidate for a DCD is not legally dead or a donor until he/she has been declared dead after cardiac arrest.

Utility of the University of Wisconsin DCD Tool

Crucial to a successful DCD recovery is the ability to predict if clinical death will occur within 2 h of the withdrawal of support. The University of Wisconsin has developed a tool to assess a potential DCD donor and predict if the patient will expire within a set time, thus making him/her a DCD donor (Table 22.1)[11]. A score is calculated based on the following: patient's age, body mass index (BMI), O_2 saturation, method of intubation, level of spontaneous respiration, and pressor requirements. If the score is high, there is a higher likelihood that the patient will expire in the appropriate time period after withdrawal of support. Other models exist, but no prospective comparison between the models has validated one or another as clearly superior.

Table 22.1. The University of Wisconsin criteria for predicting asystole following withdrawal of life support (evaluation tool for donation after death)

Criteria	Assigned points	Patient score
Spontaneous respirations after 10 min		
Rate > 12	1	
Rate < 12	3	
TV > 200 mL	1	
TV < 200 mL	3	
NIF > 20	1	
NIF < 20	3	
No spontaneous respirations	9	
Body mass index		
25	1	
25–29	2	
> 30	3	
Vasopressors		
No vasopressors	1	
Single vasopressor	2	
Multiple vasopressors	3	
Patient age		
0-30	1	
31–50	2	
51 +	3	
Intubation		
Endotracheal tube	3	
Tracheostomy	1	
Oxygenation after 10 min		
O_2 saturation > 90%	1	
O_2 saturation 80–89%	2	
O_2 saturation < 79%	3	
Final score		
Date of extubation time of extubation		
Date of expiration time of expiration		
Total time		
TV = tidal volume; NIF = negative inspiratory force.		
Scoring		
8–12 – High risk for continuing to breathe after extubation;		
13–18 – Moderate risk for continuing to breathe after extubation;		
19–24 – Low risk for continuing to breathe after extubation.

Consents

Organ donation is only discussed after the family, in consultation with the primary treatment team, has made a decision to withdraw support. Once the patient is deemed to be a donor, detailed consents are obtained from the next of kin or their legal surrogate. Consent may be obtained for procedures to be performed prior to death, such as the placement of femoral artery and vein catheters, and the administration of agents such as heparin, phentolamine, amphotericin B, mucomyst, vitamin E, and prednisone (Anderson M, personal communication)

The family is also assured that organ donation would not occur until the patient has expired and been declared dead by a physician who is caring for the patient and who is independent of the transplant team. The family is also told of the possibility of the patient not expiring within a set amount of time, usually 2 h, and that this would preclude the patient from being an organ donor. If this were to happen, the patient would be taken back to the ICU where he/she would expire without organ donation. There is variation in practice regarding the duration of this waiting period, depending on the specific OPO protocol, the hemodynamic status of the donor, and whether the donor is a potential liver donor, among other factors. Importantly, these regional variations are critically important to maintaining the integrity of the DCD process. As such, members of a procurement team must be cognizant and respectful of the specific guidelines governing procurement in their current setting.

Premortem administration of pharmacological agents

As discussed above, the OPO may obtain specific consents from a patient's family for administration of medications prior to

withdrawal of support. These medications may minimize the ischemia/reperfusion injury and have the potential to improve organ function after implantation. There is some evidence to indicate that premortem treatment may have a protective effect on the vascular endothelium and thus have a beneficial effect on the transplanted organ [12].

Heparin is administered prior to withdrawal of support to reduce the risk of thrombi in the recovered organ. There is a theoretical risk that heparin might hasten death, but evidence for this is lacking. Phentolamine may be infused prior to withdrawal to prevent vasospasm and facilitate an adequate organ flush. This agent may cause a transient drop in blood pressure; however, this is not believed to promote the progression to circulatory death. Regardless, the overriding principle is that the transplant team cannot interfere with the progression to death and doubt in this regard should be resolved so as to eliminate any concern from the family or participating members of the donor's care team.

Surgical technique

The goal of a DCD recovery is the rapid procurement of organs to minimize warm ischemia, using a technique that insures that the organs are not injured and are usable for transplantation. Clear communication between the surgical recovery team and the donor hospital OR team is crucial.

Different methods of rapid procurement have been described previously in the literature. We will describe the recovery method used at the University of Wisconsin [13].

A DCD recovery in the OR is preferred. This minimizes time lost in transporting the patient to the OR and prepping the patient for recovery after he/she has been declared dead. The patient's family members are given the opportunity to be with the donor prior to and after withdrawal of support.

All maneuvers actuating the withdrawal of life support from the patient are performed entirely at the discretion of the physician responsible for the care of the patient. The surgical recovery team is in no manner involved in these decisions. As mentioned before, prior to withdrawal of support, and in the setting of consent from the family and care team, we administer 30 000 IU of heparin, 10–20 mg of phentolamine, and 12.5–25 g of mannitol. Consent for medication administration, femoral artery/vein cutdown, and possible cannulation prior to withdrawal will have been obtained from the family. Sedatives, local anesthetics, or narcotics are used at the discretion of the primary care team, but are not to be administered by the transplant team or given in such a way as to promote progression to cardiorespiratory arrest.

Once the patient has been brought to the OR, he/she is prepped and draped from chin to the proximal thigh. We expose the femoral artery and vein and prepare it for cannulation prior to withdrawal of support (Figure 22.1). This cutdown is performed using local anesthesia. During this time, it is important to recognize the potential DCD donor is a patient who is still alive. The 18–20-Fr cannulas are kept ready for cannulation, which is usually done after the patient has been declared dead and the mandatory 5-min waiting period has elapsed. The chilled preservation solution is also kept ready, with the tubing primed for rapid infusion.

Once the premortem interventions as described above are performed, members of the surgical recovery leave the OR. A member of the OPO is usually present in the operating room during the withdrawal process. He/she records hemodynamic measurements every minute after withdrawal of support, along with times of declaration of death, the 5-min waiting period, when the recovery was begun, and the times when the organs were flushed. These data are crucial for the transplant team to decide if the organs can be used for transplant.

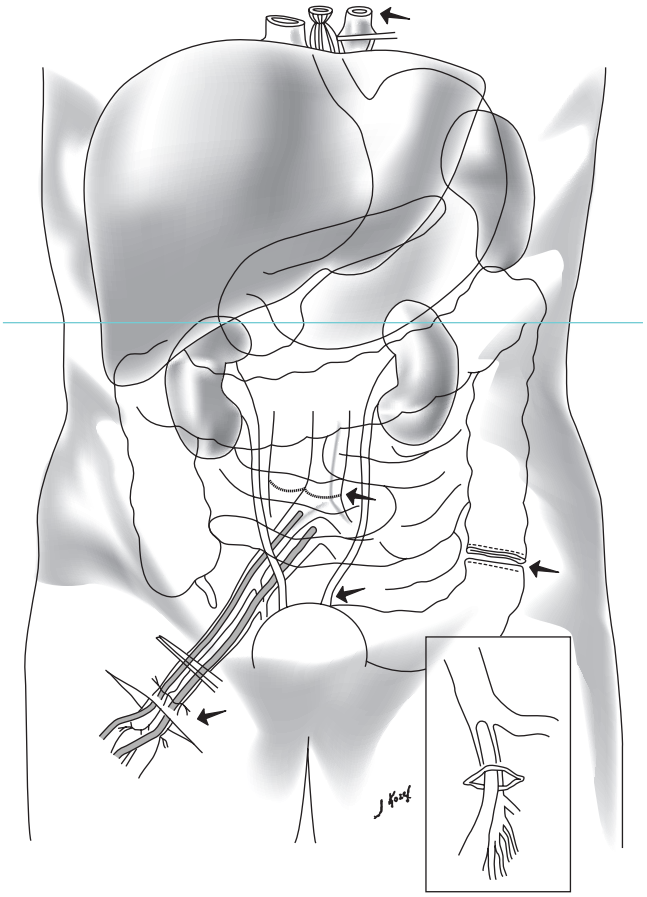

Figure 22.1. Technique of rapid en-bloc removal of all intra-abdominal organs. Arrows indicate major steps and insert depicts ex-vivo superior mesenteric/portal vein flush out. (Redrawn from D'Alessandro et al. [13], with permission from Wolters Kluwer Health)

The patient's primary treatment team withdraws support. This team monitors the patient and notes the time of cessation of cardiorespiratory function. Once the donor is declared dead by the physician, we wait for an additional 5 min to elapse prior to beginning the procurement and infusing the preservation solution. The 5-min waiting period is per the Institute of Medicine guidelines published in 1997 [14]. The issue of the waiting period to assure irreversible death has been under debate. The waiting period is to assure that there is no autoresuscitation after cardiorespiratory arrest has occurred. DeVita et al. reviewed published case reports on 108 patients from 1912 to 1970 who had expired while their vital signs were monitored [15]. They did not find any evidence of autoresuscitation 65 s after cardiopulmonary arrest was noted. The Society of Critical Care Medicine has thus endorsed a 2-min waiting period [16]. Thus, the debate in this area continues. As there is no evidence that an additional 3 min alters outcome, erring on the longer time is prudent.

After the waiting period has elapsed, the surgical recovery team returns to the OR. The femoral artery is cannulated with a preselected cannula. The cannula is inserted to approximately the

aortoiliac junction. A rapid flush with cold preservation solution is begun. Concurrently, a median sternotomy is performed and the abdomen is opened sharply from the xiphoid to the pubic symphysis. The pericardium is opened and the right atrium is incised. This serves as a vent to the flush solution. The femoral vein can also be incised to serve as a vent while the chest and abdomen are being opened. The thoracic aorta is then identified and clamped. This insures that the abdominal organs get the majority of the cold flush. Two to 3 L of preservation solution are infused. The abdomen is filled with ice.

Once the flush is complete and the effluent is clear, retrieval of the abdominal organs en bloc proceeds. The esophagus is divided using a GIA stapler in the chest. A large clamp is placed on the thoracic aorta; this serves as a useful retraction tool. Dissection starts at the level of the right atrium and all retroperitoneal attachments are sharply divided along with the diaphragm. Care is taken to remain anterior to the vertebral bodies and posterior to the aorta and the vena cava. This dissection plane is carried down to the aortic bifurcation.

The organs then are placed in their anatomical position. The lateral attachments of the left and right colon are taken down. The ureters are identified and divided close to the bladder. Dissection is carried to a level just above the aortic bifurcation. Hemostats are placed on the ureters to help with their easy identification. The distal aorta and cava are divided just cephalad to the bifurcation. The sigmoid colon is then identified and divided using a GIA stapler. Any remaining retroperitoneal attachments are divided. The abdominal viscera is then removed en bloc and placed in a large basin with ice. The usual operative time for this portion of the procedure is less than 15–20 min.

Once the organs have been removed en bloc, either the inferior mesenteric vein or a branch of the superior mesenteric vein is identified and cannulated. One liter of preservation solution is flushed through the portal system. The common bile duct is also identified and divided close to the duodenum. The biliary system is flushed with 50 mL of preservation solution. The gall bladder is also opened and its contents emptied. This is also flushed with cold normal saline.

The posterior wall of the aorta is opened longitudinally. The celiac, superior mesenteric artery (SMA), and renal artery orifices are identified. The celiac and SMA arteries are each flushed with 500 mL of preservation solution. The right and left renal arteries are also flushed with 500 mL of preservation solution. The organs en bloc are then stored in preservation solution at 4 °C and transported to the transplant center for further back table dissection. As an alternative, the organs may be divided in the donor operating room for transport to multiple transplant centers.

Prior to completion of the donor operation, the iliac veins and arteries are procured for possible vascular reconstructions. The choice of preservation solutions remains a matter of debate, as does the choice of static versus pulsatile perfusion of the organs, particularly the kidneys, after procurement. Further discussion of these points can be found in Chapters 25 and 26.

Casavilla et al. from the Pittsburgh group have described a "super-rapid" technique (Figures 22.2 and 22.3) [17]. In this technique, the abdomen is opened from the xiphoid to the pubic symphysis. The distal aorta is identified and is cannulated. Perfusion of the organs with cold preservation solution is started. The chest is then opened via a median sternotomy. The thoracic aorta is then cross-clamped and the vena cava is opened to vent. The inferior mesenteric vein is then cannulated to perfuse the

portal system. Once the organs have been flushed and cooled adequately, a hepatectomy is performed. This is followed by en-bloc nephrectomies.

Reich has described a similar recovery procedure to the "super-rapid" technique mentioned above [18]. He describes in detail how a hepatectomy is performed in situ in the cold and cautions against spending time procuring the pancreas after weighing the risk of injuring a possible replaced or accessory right hepatic artery. In such cases, the liver is procured along with the head of the pancreas. An alternative, the author suggests, is procuring the liver and pancreas en bloc. Once the liver is removed, bilateral nephrectomies are then performed.

Summary

The gap between the number of patients on the waiting list and the number of organs available for transplant is not decreasing. In fact, one may argue that the demand is increasing with supply still lagging. DCD donors present an acceptable source of organs and add to the number of organs available for transplant. Results have shown that the kidneys and pancreata from DCD donors do well in the long term in properly selected circumstances. The results for livers from DCD donors show a higher rate of complications, but nonetheless are acceptable in terms of patient and graft survival when the individual risk–benefit balance for the recipient is properly assessed.

The operative strategy for DCD procurement is somewhat different from that for a brain dead donor. Emphasis is on a safe, expeditious recovery once the patient has been declared dead, without inflicting injury to the organs being procured. The techniques described above should serve as a guide to achieving this.

Acknowledgments

We would like to thank Janet Fox in assisting with the research for this chapter. Also, we would like to acknowledge Michael Anderson, UW OPO, in providing documents pertaining to DCD recoveries/protocols.

CHAPTER 23

Techniques for Living Donor Kidney Procurement

Andrew B. Adams, Ashtar Chami, and Kenneth A. Newell
Emory Transplant Center, Emory University School of Medicine, Atlanta, GA, USA

Introduction

Living donor kidney transplantation is now widely recognized as the most effective treatment for patients with renal failure. Compared to dialysis, it provides excellent function and improved quality of life. Compared to deceased donor transplantation, it provides a reduced risk of delayed graft function, improved long-term function, lower rates of rejection, and increased flexibility in preparing recipients for transplantation. However, as living donor transplantation places a healthy person at risk, the proper use of this modality has remained a matter of some debate since its introduction in 1954. The pressures impelling greater use of living donor kidneys are many and include growing waitlists for deceased donor kidneys, increasing degrees of sensitization amongst potential recipients, and worsening co-morbid conditions of recipients. This is juxtaposed against a generally aging population of potential donors with increasing co-morbid conditions of their own, making the risk of the procedure, particularly when considering long-term kidney function, more concerning. Thus, proper patient selection and operative technique is paramount in the conduct of a living donor transplant to provide a quality organ for an appropriate recipient, while providing safe passage of the donor through a major operative procedure from which he/she has no potential for physical gain. This chapter will cover the evolution of living donor kidney transplantation, examining patient selection, the technical aspects of the donor nephrectomy, and issues likely to influence its outcome. Additional discussion of the ethical aspects of living donation can be found in Chapter 138.

History and current status of living kidney donation

On December 23, 1954, a team lead by Dr. Joseph Murray transplanted a kidney from the then 23-year-old Ronald Herrick into his identical twin brother, Richard. The success of this procedure was a watershed event in the development of both kidney transplantation and living organ donation. Ronald Herrick's selfless gift provided his brother with 8 years of quality life; an event beyond reasonable expectation for patients with end-stage renal disease before the advent of chronic dialysis. Ronald Herrick went on to live a rich and complete life prior to his death at the age of 79 [1].

From this remarkable beginning, kidney transplantation and living organ donation have grown steadily in terms of both the number of procedures performed and their success. Since 1998 there has been a total of 112 012 living kidney donors in the US [2]. During this time period the number of living kidney donor transplants expanded steadily from approximately 2000 to on average >6000 per year. While the factors fueling this growth remain uncertain, it seems likely growing public awareness of the benefits of living donor renal transplantation, new surgical techniques, and changing donor demographics were each important. The demonstration that kidney transplantation confers a significant survival benefit for patients with end-stage renal disease (ESRD) relative to dialysis, together with the knowledge that the short- and long-term survival of kidneys from living donors was vastly superior to that of kidneys from deceased donors, certainly contributed to the growth of living kidney transplantation (also see Chapter 103 for an in-depth discussion of long-term kidney transplant outcomes). Steadily increasing waiting periods for renal transplantation (from 1276 days for unsensitized patients listed in 1999–2000 to 1382 for patients listed in 2003–2004) have encouraged patients with ESRD and their relatives and friends to increasingly consider living donation as an alternative to the transplantation with organs from deceased donors. During this time it was also reported that renal transplantation prior to the institution of dialysis (pre-emptive renal transplantation) was associated with improved graft survival [3]. For the majority of patients with developing kidney failure, living donor renal transplantation represents the only opportunity to undergo a pre-emptive transplant. The introduction of minimally invasive procedures to perform nephrectomies in living kidney donors, while not significantly changing the risks of the surgical procedure, have been shown to reduce postoperative pain and expedite the recovery of the donor, and thus almost certainly have contributed to increased numbers of living kidney donors. This may be particularly germane for the increasing number of donors who are not closely related to their recipient. In this vein it should be noted that much of the growth of living kidney donation has been associated with changes in donor demographics. The most striking trend in this regard is the increase in unrelated and distantly related directed donors, as well as spouse/partner donors observed between 1998 and 2008 [2,4]. This increase has been partially offset by a modest decline in related living kidney

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

donors. There is also a trend toward an increase in the age of living kidney donors.

Despite these positive trends in living kidney donation, it is concerning that after peaking at 6647 in 2004, the number of living donors declined each year to 5968 in 2008. After increasing again in 2009 and 2010 (6387 and 6278, respectively), the number of living donors fell again to 5770 in 2011. As the factors driving the increase in the number of living donors in the 1990s and early 2000s are poorly understood, so too are the factors responsible for the decline in the number of living kidney donors in the mid to late 2000s a matter of speculation. Some have speculated that this may be related to the decline in the US economy during this time and the consequent lesser ability of potential donors to cover the costs associated with living kidney donation. Others have reasoned that the increasing age of the population with ESRD listed for kidney transplantation may be associated with more limited numbers of potential living kidney donors. A less speculative factor that has been associated with significantly decreased rates of living donor transplants in children is the Share 35 rule. This initiative prioritizes kidneys from deceased organ donors younger than 35 years of age to patients listed for transplantation prior to their 18th birthday in all cases aside from zero HLA mismatches, allocation of the kidney with life-saving, non-renal organs, or highly sensitized patients. While the Share 35 rule had the intended effect of decreasing the waiting time of children for kidneys from deceased organ donors, it had the unintended consequence of reducing the number of living donor kidney transplants performed in children. Finally, geographic and program-specific differences in the practice of living kidney transplantation may influence the availability of living kidney donation. Generally speaking, rates of living donor kidney transplantation are highest in New England and the north central US, and lowest in the south-east [4]. Finally, it has been reported that the use of medically complex living kidney donors varies widely by program, with the largest programs having a significantly higher proportion of living donors categorized as medically complex [defined as donors with a reduced glomerular filtration rate (GFR), obesity, or hypertension] [5]. It seems highly likely that there are similar differences in the willingness of programs to accept technically or surgically complex donors. The use of medically and surgically complex donors is a controversial area that merits careful study. However, greater dissemination of data and broader consensus about the acceptable medical and surgical criteria for living kidney donation have the potential to increase the access of patients with ESRD to living donor kidney transplantation.

Several other initiatives to increase access to living donor kidney transplantation are being implemented or considered. Approximately one-third of all potential living donor pairs are ABO incompatible. This combined with the high frequency of sensitized recipients waiting for a kidney transplant results in many recipients with medically suitable donors being unable to undergo living donor renal transplantation using standard approaches. Two strategies specifically aimed at increasing the opportunity of highly sensitized patients to undergo living donor kidney transplantation are desensitization and paired donor exchange programs [6]. Critical advances facilitating each of these approaches include the introduction of solid phase assays to detect anti-HLA antibodies (also see Chapter 36) and the potential to more effectively treat antibody-mediated rejection using agents such as the proteasome inhibitor bortezomib or eculizumab, an antibody targeting the complement protein C5 (covered in more depth in Chapter 99) [7]. Desensitization is most easily applied in the setting of living donation and directly addresses the pre-existing antibodies specific for blood group antigens or HLA molecules. The two most common desensitization protocols make use of high-dose intravenous immunoglobulin G (IVIG) alone or low-dose IVIG in combination with plasmapheresis. Rituximab, an anti-CD20 monoclonal antibody, has been added to each of these regimens in an attempt to deplete the B cells responsible for producing the donor-directed antibodies, thereby increasing the effectiveness of each therapy. There are now numerous studies demonstrating that desensitization using either method results in acceptable short-term patient and graft survival. However, the observed rate of acute cellular and antibody-mediated rejection is higher than that observed in recipients without evidence of donor-directed humoral immunity. Furthermore, emerging data suggest that long-term outcomes following desensitization may be inferior to those observed in transplants between individuals without pre-existing donor-specific immunity.

As detailed in Chapter 27, an alternative approach, kidney paired donation (KPD), avoids the deleterious effects associated with immunologic memory by exchanging donor kidneys between the originally intended, immunologically incompatible pairs such that each recipient receives a kidney from an immunologically compatible donor who originally intended to donate to a different recipient [8,9]. The exchange between the incompatible donor and recipient pairs is organized such as to ensure that each recipient with an incompatible donor receives an immunologically more suitable kidney, ideally resulting in a negative cross-match. While making the medical management of the recipient substantially easier and almost certainly improving graft function and long-term survival, the implementation of KPD is mathematically and organizationally complex. Although individual programs have reported remarkable successes [10], the large number of incompatible pairs necessary to optimize KPD has lead to the creation of regional and national KPD programs such as the National Kidney Registry, the Alliance for Paired Donation, and a pilot KPD program operated by the Organ Procurement and Transplantation Network (OPTN) and administered by the United Network for Organ Sharing (UNOS). The introduction of altruistic, non-directed living donors into KPD programs has allowed the creation of transplant chains that have exceeded 30 donor–recipient pairs. Despite the appeal of KPD, mathematical modeling based on large KPD programs suggests that highly sensitized recipients and O recipients with A donors will be relatively disadvantaged. As experience with KPD has increased, it has become increasingly apparent that no single approach is optimal for all groups of patients. As the risk of rejection has been shown to be associated with the strength of the donor-specific antibodies (DSA), desensitization offers the potential for timely transplantation with good outcomes of recipients who have relatively weak DSA. For recipients who are not broadly sensitized but have strong DSA, KPD can provide the realistic option of receiving a living donor kidney without an increased risk of immune-mediated injury. For those patients who are both broadly sensitized and have numerous high-strength anti-HLA antibodies, a hybrid approach using KPD to identify the best potential donor in terms of known DSA together with desensitization to minimize the risk imposed by low-strength DSA may offer the best approach.

An additional initiative under consideration is some form of donor compensation aimed at offsetting at least partially the financial barriers and health risks associated with living kidney

donation. The results of surveys indicating donors' concerns about the potential negative impact of kidney donation on their health and financial status suggest that these concerns are significant barriers to living kidney donation and lend support to careful consideration of limited compensation of living organ donors. However, the National Organ Transplant Act of 1984 (NOTA, see Chapter 19) has been viewed as precluding any form of compensation to living donors. The NOTA makes it illegal to buy or sell organs and further stipulates that it is a crime "for any person to knowingly acquire, receive, or otherwise transfer any human organ for valuable consideration for use in human transplantation." The realization that living kidney donors incur significant personal expenses in terms of travel, lost wages, and potentially future medical risk and expenses has lead some to suggest providing limited compensation to living donors in terms of health and life insurance, as well as a small amount of cash to offset the indirect costs related to kidney donation [11,12]. It is of note that although the Amsterdam Consensus Conference explicitly states opposition to compensating living donors, it does mandate lifetime health insurance, a form of compensation, be provided to living donors [13]. Of all the major industrialized nations, only the US has failed to meet this expectation. Thus, while legal, ethical, and emotional concerns persist, a growing group expresses support for consideration of a limited and regulated system of compensation to offset the financial costs and risks assumed by living kidney donors.

Evaluation, selection, and post-donation follow-up of living kidney donors

Evaluation of the potential living donor begins with a conversation aimed at obtaining basic medical information to determine the potential donor's general health status and to begin the process of educating him/her about the potential risks, both operative and long-term, associated with living kidney donation. It is important to emphasize that the process of obtaining "informed consent" is not an isolated event, but rather a means of initiating an ongoing dialogue that continues and evolves throughout the evaluation and donation process. Consistent with this approach, obtaining informed consent is not the responsibility of any single member of the living donor team, but instead is a process requiring the participation and input of multiple team members, including but not limited to the nephrologist, surgeon, living donor advocate, social worker, and a mental health expert. An important component of the informed consent dialogue is being certain that the potential donor understands that the evaluation/donation process is entirely voluntary and that he/she may terminate the process at any point independent of a specific medical reason. In this event, the transplant team generally assumes responsibility for this decision by indicating that the potential donor was found not to be a suitable candidate for kidney donation, rather than informing the intended recipient that the donor had changed his/her mind about proceeding. In addition to providing potential kidney donors with information related to the possible surgical and long-term medical risks resulting from kidney , it is necessary to inform the individuals being evaluated for living kidney donation about the risks of the evaluation process itself. To those not intimately involved in the process of living kidney donation, the risks of the evaluation process may not be intuitively obvious. However, in addition to the potential risks of medical procedures that constitute the evaluation, such as allergic reactions to the contrast agents used for abdominal imaging, the information obtained in the course of the evaluation itself may be harmful or unwanted. Examples include the discovery of infections or malignancies unknown to the potential donor that may impact his/her established relationships, employment, and future access to healthcare insurance. In some cases these conditions may require that health agencies be informed of the finding. It is also possible that these findings could have significant financial implications for the potential donor. Alternatively, the early diagnosis of these conditions at a time when they may be more amenable to treatment may be seen as a benefit to the potential donor. Another potentially harmful consequence of the evaluation process is related to the results of HLA typing that may demonstrate that believed family relationships are incorrect [14]. For these reasons, it is common practice in living donor kidney transplantation to obtain separate consents for the evaluation process and the surgical procedure. In order for the donor and recipient to determine the balance of the potential risks and benefits of living kidney donation and transplantation it is important that they be provided with both national outcome data and the data of the individual transplant center. As far as possible, this should include a discussion of unique donor or recipient factors that could be expected to modify the outcomes predicted by these data.

The specific goals of the evaluation process are to examine all aspects of the potential donor's medical and psychosocial health in order to determine any conditions that may increase the risk of kidney donation. A complete psychosocial evaluation by a psychiatrist, psychologist, or social worker with experience in transplantation is mandated by the bylaws of the UNOS and the OPTN. The psychosocial assessment of living kidney donors focuses on determining whether the individual has adequate social support systems and financial resources to safely proceed with living kidney donation, as well as assessing the donor for psychiatric diseases and behavioral disorders. Information impacting this assessment includes determining the patient's employment and insurance status, as well as the status of interpersonal relationships with their spouse, family, and close friends. The psychosocial evaluation also assesses the patient's ability to understand the potential short- and long-term consequences of living kidney donation and his/her ability to make an independent, informed decision. The final component of the psychosocial evaluation is an assessment of current or past drug or substance abuse.

Central components of the medical examination include the history and physical examination, with a special focus on a family history of kidney diseases, laboratory testing to include determination of the immunological compatibility with the intended recipient and the presence of transmissible infectious diseases, abdominal imaging to define the renal anatomy, and the results of age-appropriate health screening [15]. The medical evaluation is usually structured to facilitate the early detection of medical conditions that would preclude living kidney donation, thereby minimizing the cost of the evaluation as well as the time spent evaluating unsuitable donors, which in turn allows new donors to be identified and more rapidly evaluated. The components of a standard living kidney donor evaluation are listed in Table 23.1.

The medical evaluation usually begins with a focused medical history aimed at determining if the donor has a history of kidney disease (including proteinuria, renal calculi, frequent urinary tract infections, or chronic use of nephrotoxic drugs such as non-steroidal anti-inflammatory drugs), cardiovascular or cerebrovascular disease, hypertension (including eclampsia or pre-eclampsia),

Table 23.1. Components of a standard living kidney donor evaluation

Studies that may be performed prior to visiting the transplant center
1 Initial interview
2 Completion of a detailed health questionnaire by the donor
3 Informed consent provided by donor to be evaluated as a potential living kidney donor
4 Donor ABO typing
5 Cross-match performed
6 HLA typing of the donor may be done at this time
7 24-h urine collection to quantify renal function and assess for proteinuria
8 At least three random blood pressures provided
9 Other testing as indicated by the history:
  (a) 24-h blood pressure monitoring study
  (b) 2-h oral glucose tolerance test ± a HbA1c
  (c) Metabolic work-up for donors with a history of renal stones
Studies performed during a visit to the transplant center
10 Detailed history and physical examinations by transplant nephrologists and surgeons to include at least three sets of complete vital signs
11 Detailed interviews by the independent living donor advocate and a mental health expert
12 Laboratory studies to include:
  (a) Complete blood count with platelet count and differential
  (b) Electrolytes
  (c) Comprehensive metabolic panel to include fasting serum glucose and measurement of transaminases
  (d) Fasting lipid profile
  (e) Coagulation studies to include the prothrombin time (PT), international normalized ratio (INR), and partial thromboplastin time (PTT)
  (f) Urinalysis and culture
  (g) Pregnancy test if indicated
  (h) Prostate-specific antigen (recommendations based on donor age and family history)
  (i) Serologies for HIV, hepatitis B and C
  (j) rapid plasma reagin (RPR)
  (k) Testing for tuberculosis – TB skin testing or Quantiferon – TB Gold
  (l) Testing for strongyloides, *Trypanosoma cruizi*, and West Nile virus for donors from endemic areas
  (m) Electrocardiogram (ECG)
  (n) Chest X-ray
  (o) Abdominal imaging using CTA or MRA
  (p) Echocardiography and cardiac stress testing as indicated
  (q) Pulmonary function studies and CT scanning of the chest as indicated
Additional studies to be reviewed by the living donor evaluation committee
13 Results of age appropriate cancer screening
  (a) Gynecologic examination with PAP smear
  (b) Colonoscopy
  (c) Mammogram

diabetes mellitus (including gestational diabetes), autoimmune disease, chronic infections, or bleeding/thrombotic/embolic disorders. Individuals without apparent contraindications to organ donation then undergo testing to assess their immunologic compatibility with the intended recipient. This includes determination of the donor's ABO group (and comparison with that of the recipient), a cross-match to determine the presence and, if present, to quantify the amount of donor-directed anti-HLA antibodies, and in some settings HLA typing. HLA typing early in the evaluation process is most common in the setting of multiple, potential donors; it may be deferred until near the end of the process with single donors to avoid the expense in the fraction of individuals who are determined not to be eligible kidney donors. At this stage incompatible donor–recipient pairs wishing to proceed may be offered the option of paired donor exchange programs, desensitization, or a combination of the two approaches as an alternative to identifying other donors or waiting for a kidney from a deceased organ donor. Compatible donors may then proceed with a 24-h urine collection to assess both renal function (creatinine clearance) and proteinuria. The medical history may dictate additional studies, such as an oral glucose tolerance or hemoglobin A1c (HbA1c) in individuals at increased risk of diabetes, a 24-h blood pressure study in those at increased risk of hypertension, and a urine collection to assess the risk of stone formation in individuals with a history of renal calculi. Routine laboratory studies, including a complete blood count, a comprehensive metabolic profile, a lipid profile, a urinalysis, coagulation studies, hepatitis and HIV serologies, a rapid plasma reagin (RPR) test for syphilis, and testing for tuberculosis (TB skin testing or an interferon-γ release assay (e.g. Quaniferon®–TB Gold), and a urine culture, may also be attained at this time. Additional testing for strongyloides, *Trypanosoma cruzi*, and West Nile virus is indicated for potential donors from endemic areas (see Chapter 92 for additional consideration of donor-derived infections). The potential donor should also provide a series of blood pressure values at random times.

Individuals whose test results are compatible with living kidney donation may then present to the transplant center to undergo further diagnostic studies and imaging, which at a minimum would include an electrocardiography (ECG), chest X-ray, abdominal imaging, and completion of any of the laboratory testing described above that were previously deferred. Individuals over the age of 50 years or those over 40 years with risk factors for coronary artery disease, such as a history of tobacco use, hypertension controlled by a single agent, an abnormal ECG, or a strong family history of early coronary disease, should undergo cardiac stress testing. Potential donors found to have a murmur should undergo echocardiography. Donors with a history of syncope, dizziness, or palpitations should undergo both an echocardiogram and Holter monitoring. Potential donors with a sustained history of cigarette smoking or an abnormal chest X-ray may require pulmonary function testing or a chest computed tomography (CT) for further evaluation. Based on their gender, age, and family history, potential donors should also undergo screening for cervical, breast, prostate, colon, and skin cancer in accordance with the American Cancer Society recommendations.

Abdominal imaging is a critical component of the evaluation of potential living kidney donors. It is usually preformed later in the course of the evaluation to minimize cost and avoid exposing potential donors who are deemed not to be candidates for other reasons to radiation and contrast agents. The one exception to this approach may be the early use of ultrasound to screen potential donors with a family history of polycystic kidney disease to exclude those with obvious renal cysts from further evaluation. The choice of the imaging modality used has evolved with the introduction of new technologies and the improvement of existing approaches to abdominal imaging. Angiography, once the mainstay of imaging for living donors, is now rarely if ever used due to its inherent risks and its limited potential to detect incidental findings involving organs other than the kidneys that may influence the decision about an individual's candidacy for living kidney donation. Computed tomography angiography (CTA) and magnetic resonance angiography (MRA) are each widely used for imaging the abdominal organs of potential living donors. Both define the vascular anatomy of the kidneys with a high degree of accuracy and are similarly effective for assessing other abdominal organs and tissues for anatomic or pathologic entities that may influence an individual's suitability to be a living kidney donor. CTA has the disadvantage of exposing potential donors to ionizing radiation and iodinated contrast agents that may provoke an ana-

phylactic reaction in susceptible individuals. These concerns are mitigated to some extent by improvement in scanning protocols that reduce radiation exposure as well as the introduction of safer contrast agents. One advantage of CTA compared to MRA is its ability to detect small-to-moderate sized renal and ureteral calculi not visualized by MRA. Aside from avoiding exposure to radiation and iodinated contrast agents, evolving MRA protocols may allow for the quantification of renal perfusion and function. Given the current capabilities of CTA and MRA, the choice between the two modalities for imaging potential living kidney donors likely depends on institutional considerations, including the available equipment and the necessary interpretive expertise. Radioisotope renography using agents such as ^{99m}Tc-DTPA or ^{99m}Tc-labeled MAG3 also allow for assessment of renal perfusion and function. As the capabilities of cross-sectional imaging modalities have improved, nuclear medicine renograms are used less frequently, but still may contribute useful information in the setting of significant size discrepancies that may suggest differences in the functional contributions of the right and left kidneys.

Review of the results of the living kidney donor evaluation by a multidisciplinary evaluation committee is a critical component of the evaluation process. The composition of this evaluation panel varies by institution, but should generally include a nephrologist, surgeon, living donor coordinator, an independent living donor advocate, social worker and/or mental health expert with knowledge about kidney transplantation and donation. The members of this group should be independent of the team evaluating potential renal transplant recipients in order to objectively assess the risks to the donor without being biased by considering the potential benefits to the recipient. Although criteria vary somewhat by program, commonly accepted exclusion criteria for living donation are shown in Table 23.2. The areas of special focus during the committee's deliberations are described below [16].

Table 23.2. Potential contraindications to living kidney donation

- Age <18 years or a mental or psychiatric condition that impairs the prospective donor's ability to assess the potential risk or make an autonomous decision
- Established diabetes mellitus or impaired glucose tolerance
- Hypertension
  - Requiring multiple agents or high doses of single agents for control
  - With evidence of end-organ injury
  - In populations at increased risk for kidney damage
- Cancer current or treated but at significant risk for recurrence, excluding non-pigmented skin cancers that have been adequately treated
- Communicable infectious diseases such as HIV, hepatitis B, hepatitis C, West Nile virus, and Chagas disease
- Evidence of renal disease, including a reduced creatinine clearance, proteinuria, or hematuria
- Documented risk for inherited renal diseases
- Multiple or recurrent renal calculi of a metabolic condition that predisposes to the recurrence of renal calculi
- Renal abnormalities, including significant discrepancy in the kidney sizes or anomalies of the renal vasculature that predispose the recipient or donor to increased technical complications
- Coronary or peripheral vascular disease
- Significant valvular heart disease
- Autoimmune diseases such as rheumatoid arthritis, Crohn's disease, or ulcerative colitis
- Chronic lung disease
- Morbid obesity or obesity with co-morbid conditions
- History of major thrombotic or hemorrhagic events
- History of substance abuse without completion of an appropriate rehabilitation program

Donor age

Results of a survey reported in 2007 showed a trend towards the acceptance of older individuals as living kidney donors [15]. Of the 132 centers surveyed in the US, approximately 21% excluded living donor candidates over 65 years of age, while 60% of the programs had no set upper age limit. Simultaneously, transplant programs are more closely scrutinizing younger donors. An age of younger than 18 years is considered a contraindication to living kidney donation by virtually all programs and donors aged 18 years–21 are more closely evaluated, particularly with respect to their maturity and motivation to donate. This more cautious approach is motivated by their relatively longer expected survival, concerns about the rate of decline in renal function with increasing age, and the obligation to be certain that their decision to donate is made autonomously. The living donor advocate's role is central to this process.

Hypertension

While hypertension was previously considered an absolute contraindication to living kidney donation, programs are increasingly considering and evaluating potential living donors who may have risk factors for the development of hypertension or may even have been diagnosed with mild, well-treated hypertension. Studies have demonstrated that a significant percentage of individuals classified as hypertensive based on measurements of blood pressure performed in the clinic are found to be normotensive based on 24-h ambulatory blood pressure monitoring studies [17]. For the purpose of classifying living donor candidates an average blood pressure of >135/85 mmHg is considered diagnostic of hypertension. Regarding those accurately diagnosed as having hypertension, an increasing number of programs now consider individuals achieving good blood pressure control with a relatively low dose of a single antihypertensive agent (or more rarely two agents) as appropriate candidates for living kidney donation, assuming the absence of end-organ injury such as left ventricular hypertrophy, retinopathy, or proteinuria. Hypertensive individuals with risk factors for cardiovascular disease, such as hypercholesterolemia, obesity, smoking, and a strong family history of coronary artery disease, would also be excluded from living donation. The trend toward accepting selected individuals with well-controlled hypertension as living kidney donors is based on reports that with short-to-intermediate term follow-up, living donors with mild-to-moderate essential hypertension and normal renal function did not experience worse outcomes with respect to blood pressure, proteinuria, or renal function when compared to non-hypertensive donors [18,19]. Frequent exclusion criteria for potential donors with mild, well-controlled hypertension include relatively younger donors (age <45–50 years), African–American donors, and those donating to more distantly related/non-related recipients under the assumption that they will derive a lesser psychological/emotional benefit. Those donors with pre-existing hypertension who meet the selection criteria for living kidney donation should be informed of the relatively incomplete safety data related to the short-term follow-up of hypertensive donors to date, and be encouraged to make the appropriate lifestyle modifications, including adhering to an appropriate diet, engaging in moderate exercise, and committing to routine, scheduled medical care.

Diabetes

Overt diabetes, defined by the American Diabetes Association as a fasting plasma glucose of >126 mg/dL, a plasma glucose level of

>200 mg/dL 2 h after a 75-g oral glucose challenge, or a HbA1c of >6.5, is a contraindication to living kidney donation. Similarly, impaired glucose tolerance also precludes donation at most centers due to its association with an increased risk of developing diabetes in the future. Impaired glucose tolerance is defined as a fasting plasma glucose between 100 and 126 mg/dL, a glucose between 140 and 200 mg/dL in a 2-h oral glucose tolerance test, or an HbA1c ranging from 5.7 and 6.5. While a normal fasting glucose value is sufficient to exclude diabetes and impaired glucose tolerance in most donors, individuals with a past medical history of impaired glucose tolerance, gestational diabetes, delivery of a child with a birth weight of >9 lb, first-degree relatives with diabetes, African–Americans, and individuals with a body mass index (BMI) of >27 kg/m^2 should all undergo a 2-h oral glucose tolerance test to more accurately assess their future risk of diabetes. In addition to a glucose tolerance test, measurement of their HbA1c may provide useful information in assessing potential donors with risk factors for diabetes mellitus who do not meet the diagnostic criteria for diabetes or impaired glucose tolerance. In addition, individuals with multiple risk factors for the metabolic syndrome, including high blood pressure, triglyceride levels of >150 mg/dL, high-density lipoprotein levels of <40 mg/dL for a man and <50 mg/dL for a woman, should undergo screening for glucose intolerance. Individuals at risk of developing diabetes mellitus but not meeting the criteria for impaired glucose tolerance may proceed with donation given an appropriate understanding of the future risks and counseling related to the need for lifestyle modifications. Weight loss may significantly improve glucose homeostasis and metabolic parameters, although concerns about the donor's ability to maintain the lifestyle associated with these changes must be carefully assessed.

Obesity

Some evidence suggests that obese and morbidly obese living donors are at increased risk for renal dysfunction following kidney donation [20]. They are definitely more likely to have proteinuria, hypertension, and hypercholesterolemia; each of which increases their life-time risk of cardiovascular disease. In fact, irrespective of kidney donation, obese individuals have decreased survival relative to those with normal weights. Although a point of contention, in consideration of these risks, many programs impose an upper limit on the BMI of living donors. The value most widely used among centers imposing size limits is a BMI of 35 kg/m^2, although a small number of centers restrict living donation candidacy to individuals with a BMI of <30 kg/m^2. One intermediate approach is to allow individuals with a BMI of up to 35 kg/m^2 to proceed with donation in the absence of other conditions related to obesity, while those with borderline hypertension, borderline glucose intolerance, hypercholesterolemia, and ongoing use of cigarettes are required to attain a BMI of ≤30 kg/m^2.

Assessment of donors for underlying renal diseases

Renal function is perhaps the best single predictor of kidney health and renal diseases. Determination of an individual's creatinine clearance (CrCl) is the most widely used measure of renal function. The use of formulas to estimate CrCl may provide some insights that help in deciding which potential living kidney donors to evaluate, but are not sufficiently accurate to serve as the sole means of assessing renal function in prospective living kidney donors. When equations are used, the CKD-epi equation is preferred as it provides a more accurate estimate of CrCls in the normal range as compared to the MDRD of Cockrault–Gault equations. A 24-h urine collection is the most widely used method to measure the CrCl of prospective kidney donors. However, this relatively simple test is subject to numerous errors, including over- and under-collection, that make its results variable and <100% reliable. Another approach is to use radioisotopes or iodinated tracers to directly measure the CrCl. Although conceptually more accurate in that the test is directly supervised, many centers do not use this methodology due to its logistic complexities. Regardless of the method used to determine a potential donor's level of renal function, a threshold value for CrCl must be selected. Historically, many programs selected a value of 80 mL/min as the threshold. With the definition of the stages of chronic kidney disease (CKD), many programs adopted the threshold of 90 mL/min, which defines stage II CKD. Regardless of the value chosen, the measure of renal function should be normalized for donor size by expressing it as the value per 1.73 m^2. An increasingly common approach is to define acceptable thresholds as being within 2 standard deviations of the normal value for the potential donor's age and sex, thereby taking into account the effect of these variables on renal function.

Significant proteinuria and hematuria each are strong indicators of serious underlying glomerular pathology and renal disease. Proteinuria can be quantified by determining the amount of protein present in a 24-h urine collection or by measuring the albumin-to-creatinine ratio on a spot urine sample. Values of >250–300 mg/24 h or >30 mg/g, respectively, are generally considered indicative of possible significant underlying pathology and would exclude donation in the absence of known benign causes such as postural proteinuria. Reasons for falsely elevated measurement of proteinuria based on a 24h urine collection include intensive exercise immediately prior to the collection period and over-collections, which can be estimated based on the amount of excreted creatinine (15–20 mg/kg for women and 20–25 mg/kg for men). Like proteinuria, hematuria can be indicative of serious underlying renal diseases. The definition of microscopic hematuria varies somewhat by transplant program, but typically is defined as five or more red blood cells (RBCs) per high power field. The first step in evaluating hematuria is to obtain an accurate history. In females who are menstruating or men or women who have been exercising intensively, collection of a repeat urine sample in the absence of the potentially confounding event is indicated. Urinary tract infections and renal stones can be excluded as the cause of microscopic hematuria by obtaining a urine culture and CT scan of the abdomen and pelvis. If these diagnostic studies fail to reveal the cause of the hematuria and it persists, urine cytology and cystoscopy are indicated. If these studies are not informative, individuals who remain interested in kidney donation should undergo kidney biopsy to exclude intrinsic kidney disorders as the cause of the hematuria. In the absence of a documented benign cause such as thin basement membrane disease of mild severity, potential donors with persistent hematuria should be counseled against living kidney donation.

Screening for hereditary renal diseases

For potential living donors with a significant family history of renal disease, genetic testing and a kidney biopsy in addition to abdominal imaging studies may be necessary to assess their future risk of developing kidney disease. Examples of renal diseases with signifi-

cant genetic components include adult polycystic kidney disease (ADPKD), systemic lupus erythematosus (SLE), thin basement membrane disease (TBM), Alport's syndrome, and IgA nephropathy. ADPKD is the fourth leading cause of renal failure in the US and is the most commonly inherited renal disease. Loci related to ADPKD include mutations on chromosome 16 (*PKD1* locus, 85% of affected patients) and chromosome 4 (*PKD2* locus, 15% of affected patients). Patients with the *PKD2* mutation may present later in life. Individuals 30 years of age or older who do not have renal cysts as determined by high-resolution, cross-sectional abdominal imaging can be considered free from the risk of developing ADPKD. Potential donors younger than 30 years old require genetic testing to determine whether they are at risk for ADPKD in the future. SLE may occur in approximately 12% or more of individuals with an affected first-degree relative. The evaluation of living donors with a family member affected by SLE should include studies to detect the presence of antinuclear antibodies, antiphospholipid antibodies, and measurement of complement levels. Persons thought to be at risk for developing SLE based on these studies should be excluded from donation. Familial kidney diseases that present with hematuria include TBM disease, Alport's syndrome, and IgA nephropathy. TBM generally has an autosomal dominant pattern of inheritance. First-degree relatives of affected individuals should be screened for hematuria as well as hypercalciuria and hyperuricosuria. Individuals who do not have severe thinning of their basement membranes on renal biopsy, do not have proteinuria or hypertension, and do not have concurrent IgA nephropathy or Alport's syndrome may proceed with kidney donation, although the potential donor should be counseled that the long-term risk of renal disease in this setting is not known with absolute certainty. Alport's syndrome has different modes of inheritance with most being X-linked. Components of Alport's syndrome include sensorineural hearing loss, ocular findings such as lenticonus, cataracts and retinal lesions, hematuria, and hypertension. Males aged 20 years or older found not to have any of these conditions can proceed to donation. Female siblings of affected individuals with normal urinary results may also proceed to donation.

Renal calculi

Results of a recent survey indicate that 77% of the responding programs allowed individuals with a history of kidney stones to be considered for living kidney donation [21]. Patients with a history of documented kidney stones should undergo a metabolic evaluation to determine whether there is a metabolic condition, such as hypercalciuria, hypocitraturia, hyperuricemia, hyperoxaluria, or metabolic acidosis, that places them at increased risk for stone formation in the future. Most programs exclude potential donors with a metabolic cause for kidney stone formation that cannot be corrected and those who have formed multiple stones or developed their first renal stone at a young age, as these individuals are at increased risk for recurrence.

The final component of the living kidney donation process is an attempt to ensure that living donors are instructed about the need for maintaining a healthy lifestyle. This discussion should address a healthy diet, moderate exercise, and routine age-appropriate medical care. At a minimum, this should include routine measurements of blood pressure and laboratory studies, including a serum creatinine, urinalysis, fasting blood glucose, and fasting lipid profile.

Operative technique

Living organ donation is one of the few procedures that surgeons perform where the intent is not to improve the condition of the patient undergoing the procedure; instead, it actually places his/her health at risk for the benefit of another individual. While there are tangible and intangible benefits as a result of the donor evaluation process, the majority of the risk associated with donation is related to the operative procedure. Given the dictum of medicine is "primum non nocere" or "first, do no harm," it particularly behooves the surgeon to understand and ultimately optimize the operative techniques employed.

As mentioned above, the evaluation process for living donation can be quite complex. While the medical and psychosocial metrics are extremely important and may contribute to predicting long-term success, it is the donor's fitness for surgery and anatomic considerations that are paramount in the surgical preoperative assessment.

While the preparatory medical evaluation has previously been discussed, including specific populations warranting additional testing, there are also anatomic considerations that must be taken into account regardless of the specific surgical technique that is employed. The use of preoperative abdominal imaging in this day and age is considered mandatory. The choice of technology, either CT or magnetic resonance imaging, is primarily determined by the expertise present at one's institution. We prefer CT imaging with three-dimensional reconstructions, which impart superb depictions of both arterial and venous anatomy (Figure 23.1). While most early experiences with minimally invasive donor nephrectomy considered vascular anomalies such as multiple renal arteries or circumaortic renal veins to be a contraindication to donation, this is not the case in the current era. Currently, most centers will proceed with nephrectomy with two or even three renal arteries or when there are complex venous aberrations [22]. Preoperative imaging, both CT and MRI, has been shown to accurately predict eventual operative findings and provide critical information to the donor surgeon [23]. In addition to providing clarity to both arterial and venous anatomy, preoperative imaging can provide excellent definition of the renal parenchyma as well as relay information about the collecting system and ureter with delayed sequences during excretion of filtered contrast. Lastly, but of paramount importance, abdominal imaging can alert the surgeon to any occult intra-abdominal pathology that might prevent donation.

Once it has been determined that there are no medical, psychological, or anatomic contraindications to donation, the surgeon can proceed with finalizing an individualized operative plan. Current techniques of living donor nephrectomy vary among centers and have significantly evolved over time as newer strategies have been introduced. We will discuss the traditional "open" operative technique as well as the more recently described minimally invasive approaches to safely remove the donor kidney without jeopardizing patient safety or donor organ quality.

Open donor nephrectomy

When Ronald Herrick stepped forward to donate his kidney to his twin brother over 50 years ago, Joseph Murray and his surgical team procured the kidney via an "open" donor nephrectomy. Similar to other traditional operative procedures of the day, there was no thought of minimizing the invasiveness of the procedure. Open donor nephrectomy is a well-established procedure to safely procure a kidney from a transplant donor. The patient is positioned with the right or left flank elevated and exposed (depending on

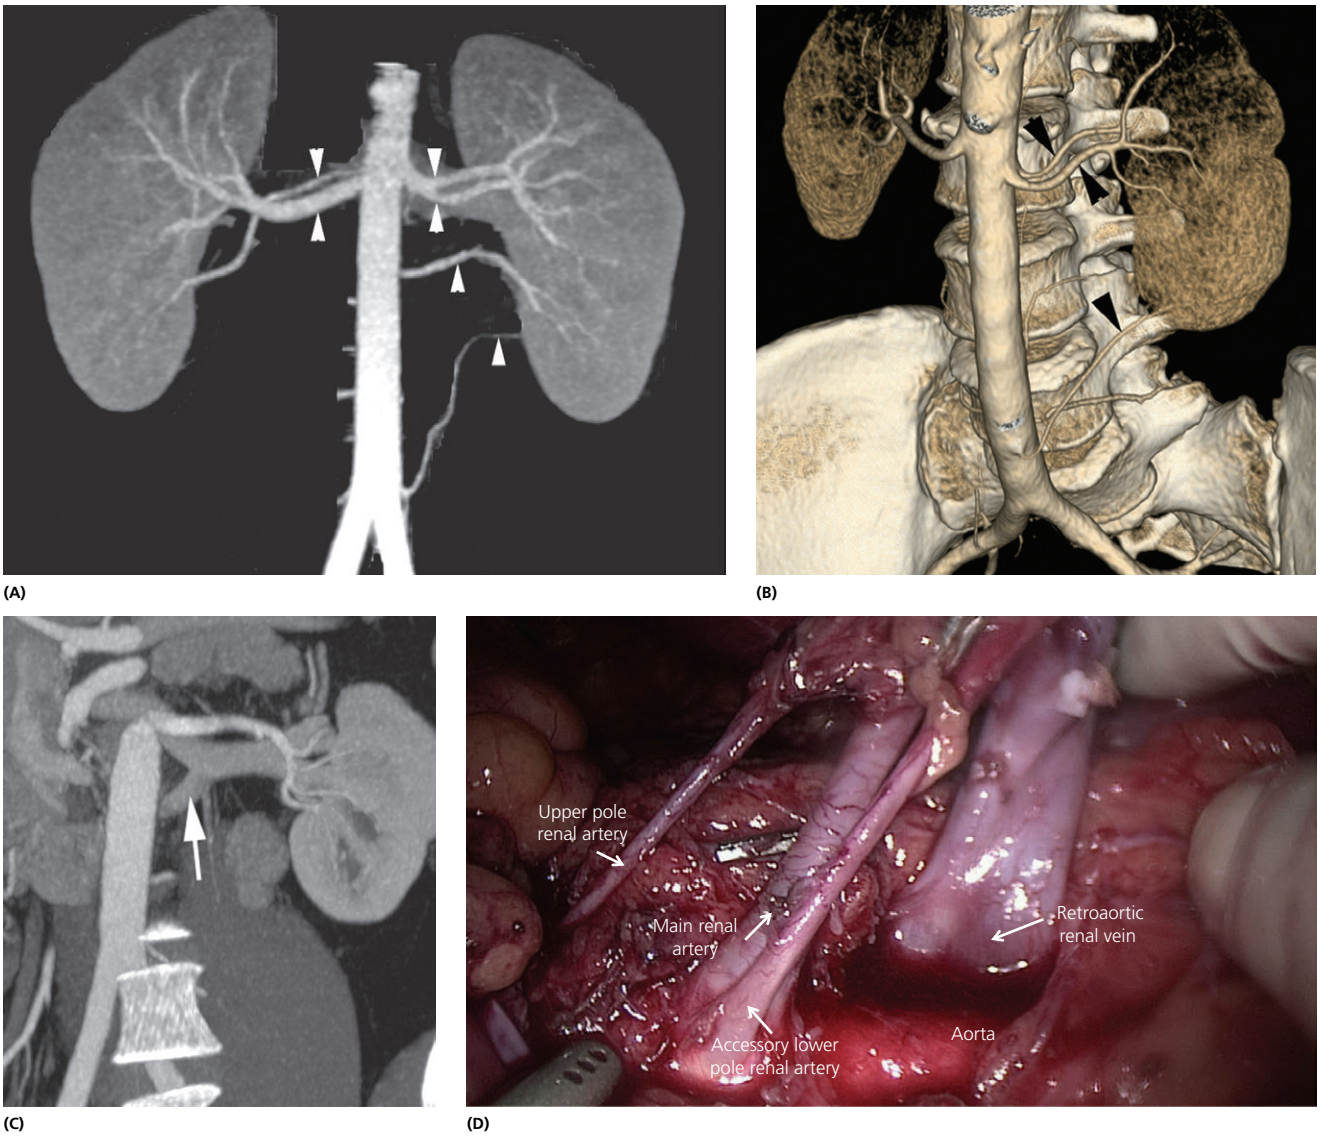

Figure 23.1. Reconstruction of abdominal computed tomography (CT) scans demonstrating aberrant anatomy. (A) The renal arterial anatomy for a potential donor with two right and four left renal arteries (each arrowhead marks a separate artery). Of note, the smaller right renal artery originates cephalad to the main renal artery but supplies the low pole of the kidney. On the left there is a small lower pole renal artery arising at the level of the aortic bifurcation. This arterial anatomy may increase the risks of technical complications with use of either the right or left kidney. (B) A donor with three left renal arteries, including a small artery supplying the lower pole that originates near the aortic bifurcation (each arrowhead marks a separate artery). Of note, there is a single right renal artery making the right kidney potentially more suitable for donation and transplantation. (C) CT reconstruction from a donor with a circumaortic left renal vein (the arrow marks the retroaortic component of the circumaortic vein). (D) An intraoperative picture of three renal arteries and a retroaortic renal vein. While it is important for the surgeon to be aware of this aberrant anatomy prior to surgery, this finding does not significantly increase the risks of technical complications or impact the choice of which kidney to use.

which kidney is to be removed). The incision begins at the tip of the 12th rib and curves anteriorly in the direction of the umbilicus until reaching the lateral border of the rectus sheath. The surgeon then continues to divide the muscular layers of the abdominal wall—external and internal oblique muscles as well as the transversalis. If needed, the latissimus dorsi muscle is divided and retracted posteriorly. Occasionally, a portion of the 12th rib may need to be removed for exposure. Deep to the muscular layers, the peritoneum is identified and pushed medially to expose the retroperitoneal space. The ureter is identified emanating from the lower pole of the kidney and coursing along the anterior surface of the psoas muscle. It is carefully mobilized down to the pelvis with a generous packet of periureteral tissue to ensure adequate blood supply. A vessel loop or umbilical tape may be passed around the mobilized ureter to aid with gentle retraction. Gerota's fascia is then incised and the kidney is separated from the surrounding perinephric fat. The renal vein is then identified and mobilized medially towards the inferior vena cava (IVC). When harvesting a left kidney, the vein is freed to the point where it crosses the aorta. The adrenal vein must be divided on the superior aspect, while the gonadal and one or more lumbar

veins must be identified and divided on the inferior aspect. The shorter right renal vein does not usually have any connecting branches and needs to be mobilized to the point where it enters the IVC. The renal artery is skeletonized near its origin from the aorta after lifting the kidney and reflecting it anteriorly. If the surgeon prefers, a dose of systemic heparin may be given at this time. The ureter is then ligated distally and transected. The renal artery and then vein are clamped and divided, leaving a sufficient cuff of donor vessel to allow for adequate ligation. The donor kidney is removed from the field and handed to the waiting recipient surgeon. The donor renal artery is carefully cannulated and a cold perfusate is used to flush the organ in preparation for its implantation. The wound is then closed in layers with an absorbable suture and the patient is awoken from anesthesia and returned to the recovery room.

The early postoperative care of donors is very similar to that of anyone undergoing a major intra-abdominal procedure. Volume status, electrolytes, as well as urine output are closely monitored. Pain and other postoperative symptoms such as nausea should be adequately addressed. Donors should be closely observed for any potential surgical complications, including postoperative bleeding, bowel injury, or wound infections. They should be encouraged to ambulate early to minimize the risk of pulmonary complications or deep venous thrombosis. The usual hospital stay is 3–5 days, with resumption of employment within 4 weeks if strenuous physical activity is not required.

Much like for other traditional operative techniques, open donor nephrectomy is associated with a longer hospital stay, prolonged postoperative pain, poorer cosmesis, and slower convalescence when compared to newer less invasive techniques [24]. As in the field of general surgery as a whole, in the past 20 years there has been a persistent drive to develop minimally invasive techniques in transplantation as well. Even more so than for open cholecystectomy or traditional appendectomy, in the current era open donor nephrectomy is a procedure that has mostly been relegated to the textbooks and reserved only for unique circumstances.

Laparoscopic donor nephrectomy

While laparoscopy had been employed for simple gynecologic procedures for many years, it was not until the development of the computer chip color camera that the indications of laparoscopy expanded to include more complex procedures. The early 1990s ushered in the era of laparoscopy for general surgery with the introduction of laparoscopic cholecystectomy and appendectomy. With the eventual success and acceptance of these procedures, the indications for laparoscopic surgery expanded to include solid organs. The first laparoscopic nephrectomy was performed in 1991 [25]. Reports thereafter demonstrated that the new, minimally invasive technique for nephrectomy resulted in less postoperative pain, shorter hospital stays, and diminished recovery periods when compared with open donor nephrectomy. Within a short period of time, the technique for laparoscopic donor nephrectomy was developed. First described in a large animal model, the initial experience in humans was detailed closely thereafter in 1995 by Ratner et al. [26]. Since that time, several variations in the technique have arisen. These include hand-assisted, full laparoscopic, lap retroperitoneal, hand-assisted lap retroperitoneal, robotic-assisted, and laparoendoscopic single site donor nephrectomy. While there are several minimally invasive approaches to donor nephrectomy, the full laparoscopic and the hand-assisted laparoscopic approaches are currently the most widely employed. Ultimately, the technique chosen depends on the individual patient and the surgeon's expertise and preference. We will describe in detail the hand-assisted laparoscopic approach for a left-sided kidney since that is what we favor at our own institution.

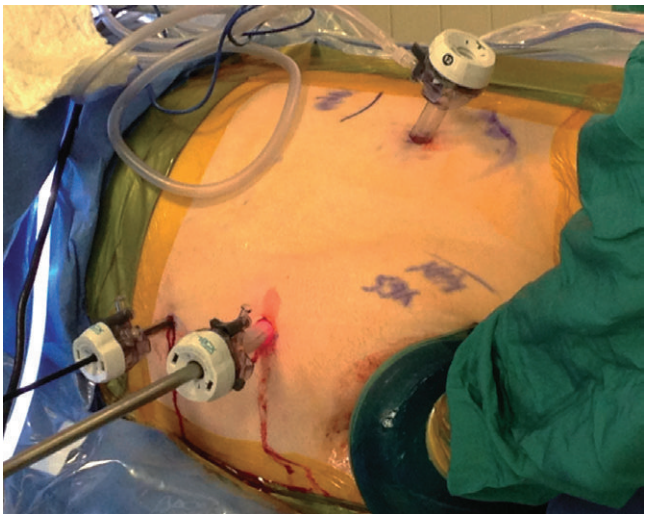

Figure 23.2. Typical positioning and port site placement for left-sided, hand-assisted laparoscopic donor nephrectomy. The patient is placed in a modified lateral decubitus position, ensuring appropriate precautions are taken to avoid iatrogenic injuries associated with nerve traction or skin pressure.

Hand-assisted laparoscopic donor nephrectomy

The patient is placed in a modified lateral decubitus position, ensuring appropriate precautions are taken to avoid iatrogenic injuries associated with nerve traction or skin pressure. (Figure 23.2) The side of interest is placed in the upright position; this is usually the left as most donors undergo left-sided donor nephrectomy. The table is flexed to expand the area between the costal margin and the iliac crest. If so equipped, a kidney bar may be raised to help with this. The patient is secured in place with a beanbag and tape or other methods as needed. The table can then be rotated safely as the procedure requires. A 7-cm midline incision is made below the umbilicus. A gelport or similar handport device is inserted and a pneumoperitoneum is established. Additional ports are then inserted with the hand inside the abdomen. For a left nephrectomy, we ordinarily place three additional ports under direct vision: a 12-mm port (dissecting port) in the anterior axillary line midway between the iliac crest and costal margin; a 5-mm port (assistant port for retraction) just lateral to the midline and two to three finger breadths below the costal margin; and an additional 12-mm port (camera port) superior and just lateral to the umbilicus. A similar set of trocars is required for right-sided procedures and commonly an additional 5-mm port may be placed for a liver retractor.

For left-sided procedures, the descending and sigmoid colon are taken down from their lateral attachments using an ultrasonic device such as the harmonic scalpel. If necessary, the attachments of the splenic flexure may be divided and occasionally the diaphragmatic attachments of the spleen may need to be mobilized to allow the spleen to fall forward and medial away from the kidney. The colon is the reflected medially in order to expose the

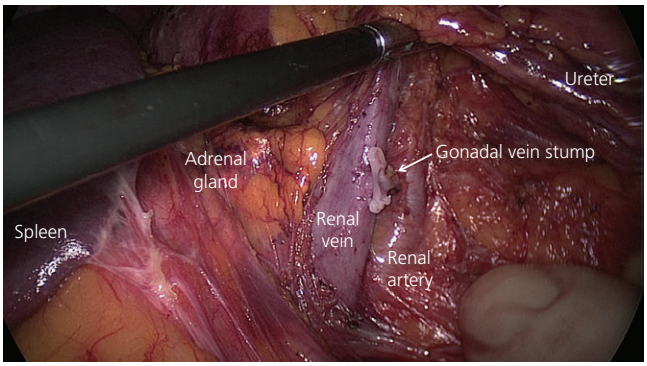

Figure 23.3. Operative picture illustrating the relationship between the gonadal vein (now divided), renal vein, ureter, and renal artery.

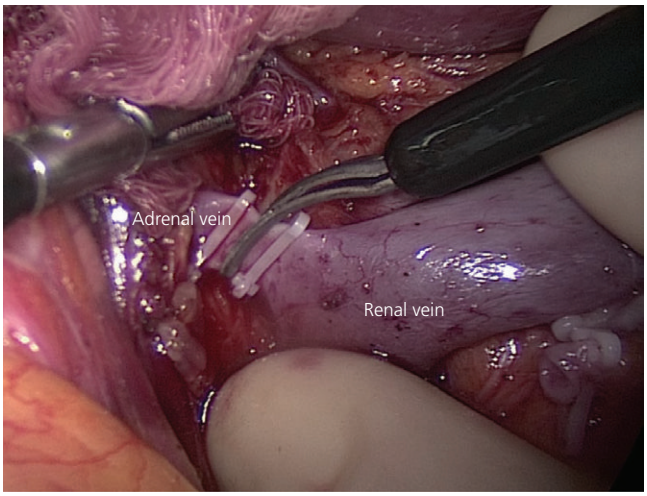

Figure 23.4. Division of the adrenal vein between clips on the superior aspect of the renal vein.

kidney enclosed in Gerota's fascia. Care is then taken to develop the natural plane between the mesocolon and retroperitoneum. Much of the dissection can be accomplished bluntly by sweeping the tissue medially, paying particular attention to avoid creating a buttonhole within the mesocolon. Once the colon and mesocolon are sufficiently medialized, the gonadal vein and ureter are identified. After confirming that the structure is indeed the gonadal vein, tissue from the anterior surface of the vein is dissected free from the pelvis to the level where the gonadal vein enters the left renal vein on its inferior edge. This dissection continues in a cephalad direction to expose the anterior surface of the renal vein. The ureter is identified during this dissection and the gonadal vein along with the ureter are swept laterally as a bundle to ensure an adequate packet of periureteral tissue is harvested. Superiorly, the gonadal vein may be used for retraction as the renal vein is mobilized and dissected circumferentially, but care must be taken not to avulse it from its origin on the renal vein. Eventually, it is often easier to divide the gonadal vein, near the confluence with the renal vein, allowing for greater visualization of posterior lumbar branches that must be clipped and divided (Figure 23.3). As the renal vein is exposed, the adrenal vein will appear on the superior aspect and will need to be ligated with clips and divided (Figure 23.4). The renal vein is then mobilized medially to ensure adequate

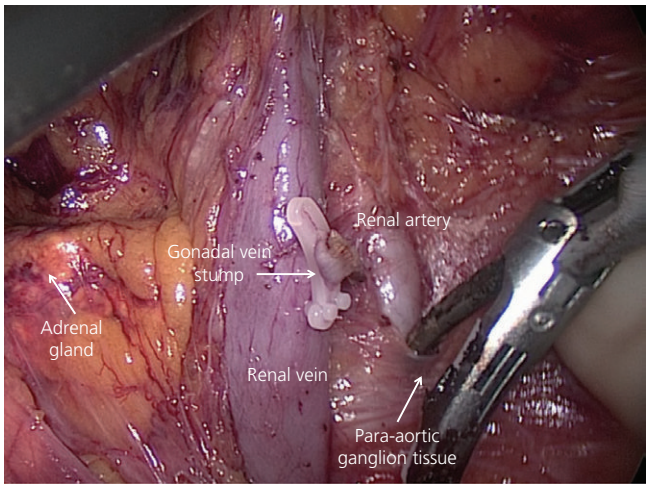

Figure 23.5. Anatomic relationship of the renal artery and renal vein. The renal artery lies posterior to the renal vein. To fully expose the renal artery, the surrounding ganglion tissue must be divided to the level where the artery meets the aorta.

length, usually to the point where it passes anterior to the aorta is sufficient. The renal artery lies posterior to the renal vein and can be exposed by lifting the lower pole of the kidney with a blunt grasper or by rotating the kidney medially and approaching the vessels from the posterior. To fully expose the renal artery, the surrounding ganglion tissue must be divided carefully down to the level where the artery meets the aorta (Figure 23.5) At this point, with the vascular anatomy defined, it is helpful to mobilize the kidney from its attachments.

Now that the ureter/gonadal vein complex has been mobilized medially, it is necessary to free it laterally. The ureter is traced distally near the pelvic inlet where it crosses the left iliac artery. The ureter can then be gently grasped and retracted medially as a packet of tissue with the gonadal vein and investing fat and connective tissue. The lateral attachments of the mesoureter are then divided with the harmonic scalpel in a caudad to cephalad direction, moving along the top of the psoas muscle towards the lower pole of the kidney. The plane of dissection is continued along the lateral surface of the kidney, dividing Gerota's fascia to expose the kidney. The posterior attachments are then divided, freeing the kidney from its shell and driving towards the upper pole. In order to divide the upper pole attachments many times, it is necessary to grasp the kidney and pull it inferiorly and rotate it from side to side. The last plane of dissection proceeds along the superior edge of the renal vein between the adrenal vein and the upper pole of the kidney. Vascularized tissue in this region is divided between clips, and using the harmonic scalpel the final attachments to the upper pole of the kidney are liberated.

The kidney is then completely mobilized from the upper to lower poles and along its lateral aspect. It should be noted that care should be taken not to disturb the triangle of tissue between the ureter and lower pole of the kidney as dissection can jeopardize blood flow to the ureter. Similarly, it is important to preserve, if present, any accessory renal artery supplying the lower pole of the kidney, as it is also responsible for supplying the ureter (Figure 23.6). With the kidney completely mobilized and all of the vascular structures defined and freed, it is now time for removal. After administering a dose of systemic heparin, we first divide the ureter distally where

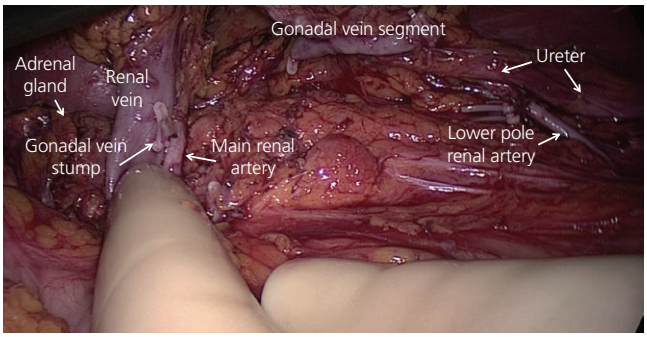

Figure 23.6. Donor kidney prepared using the hand-assisted laparoscopic technique. The gonadal vein has been divided at its origin on the renal vein and distally near the pelvic inlet. The isolated segment is removed with the ureter and periureteral tissue. Care should be taken during the dissection to preserve any accessory vessels such as the lower pole artery, as illustrated here.

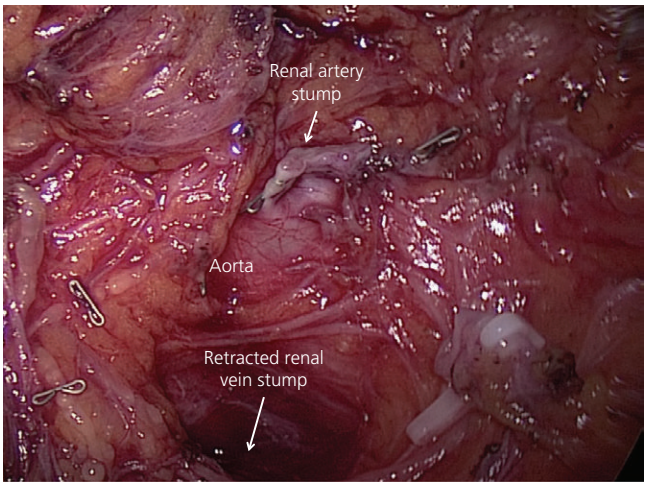

Figure 23.8. Inspection of staple lines on the renal artery stump and retracted left renal vein.

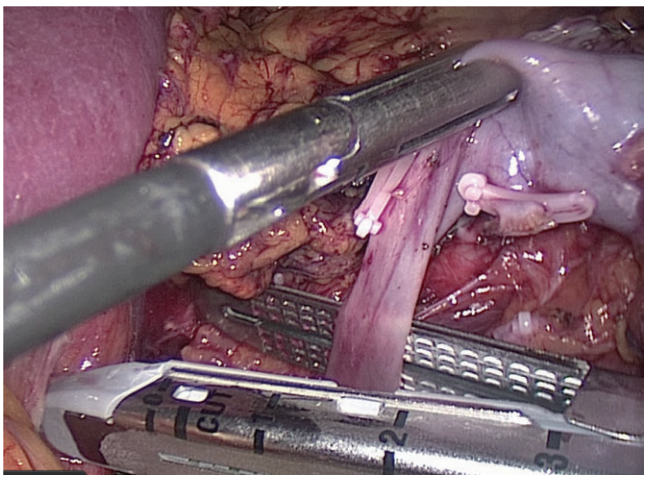

Figure 23.7. Division of the renal vein using an endovascular stapler. The vein can be retracted laterally and the stapler is then used to divide the vein as it drapes over the aorta, ensuring adequate length for the reconstruction in the recipient.

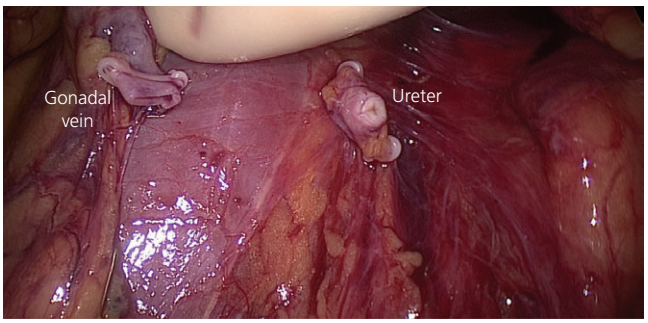

Figure 23.9. Cut ends of the ureter and gonadal vein are examined for any evidence of bleeding.

it crosses the iliac artery; a clip is used to control the distal side which will stay with the patient. The gonadal vein is ligated and divided distally if this has not been done earlier. The kidney is then either grasped and lifted up by the surgeon or retracted laterally by the assistant in order to stretch out the renal artery and vein. Retracting the vein cephalad provides excellent exposure to the renal artery. Alternatively, the kidney may be rotated medially to expose the origin of the renal artery from the posterior. The artery is then divided using a laparoscopic vascular stapler. While the stapler is removed and reloaded, the kidney is rotated laterally if needed and the vein is grasped and stretched by the assistant. The vein can then be divided with the stapler as it crosses over the aorta, ensuring adequate length (Figure 23.7). The kidney is then removed through the handport and transferred to the waiting recipient surgeon for flushing. A careful check is then made for hemostasis, specifically at the staple line on the renal artery stump as well as the location for the staple line where the renal vein was divided (Figure 23.8). Finally, the divided ureter and gonadal vein stumps are inspected (Figure 23.9). The fascial defects at all of the larger ports sites are closed with absorbable suture, as is the lower midline incision.

Intraoperative/postoperative management

Similar to any surgical procedure, the anesthetic management of a living donor is of critical importance and requires effective communication between the anesthesiologist and the surgeon. Like any laparoscopic procedure, the patient must be kept completely relaxed to provide adequate working space. This is particularly important during the time when the renal vessels are about to be transected and the kidney extracted. We find it helpful to communicate directly with the anesthesia team prior to this event to ensure that removal of the kidney remains uneventful. In the past, we routinely treated the donor with a dose of furosemide prior to explant to ensure "adequate diuresis" in the recipient. This was followed by a repeat dose of furosemide and additional administration of mannitol to the recipient near the time of reperfusion. We have since terminated this practice and have chosen to keep the donor euvolemic, titrating fluid to an adequate urine output instead of aiming for a brisk diuresis.

Most donors undergoing laparoscopic nephrectomy remain in the hospital for 2–3 days after surgery. During the first 2 weeks following donation, they gradually return to their normal daily

activities. At 2 weeks, most donors are able to tolerate mild exercise. We advise that they wait 4–6 weeks before reinitiating any strenuous activity or heavy lifting. We favor utilizing intravenous ketorolac to minimize postoperative pain and narcotic requirements, thereby decreasing ileus and nausea.

Impact of laparoscopic techniques

Much like other laparoscopic techniques in general surgery, minimally invasive techniques to remove a donor kidney have quickly gained favor at most transplant centers. Today, laparoscopic donor nephrectomy is considered the standard of care almost universally. Several studies have shown that laparoscopic donors experience less pain, as indicated by a decreased use of narcotics after surgery, and enjoy shorter hospital stays and a quicker return to full activity and work [24,27–31]. Short-term follow-up of laparoscopic donors has failed to reveal any increased risk of complications when compared with open donors. Long-term outcomes, however, remain unknown and await further study.

The advantages of the hand-assisted technique when compared to conventional laparoscopy include tactile feedback, a perceived margin of safety with the ability to use digital pressure to control bleeding, potentially better exposure and dissection of structures, as well as rapid removal of the kidney, resulting in shorter warm ischemia times [32–35]. These features are particularly appealing in centers where training programs exist. Most studies describing hand-assisted laparoscopic donor nephrectomy conclude that the hand-assisted technique is superior to the full laparoscopic technique with regards to operative time and blood loss [34,36–41]. In addition, one meta-analysis suggested that the risk of open conversion is less with the hand-assisted technique [42].

The disadvantages of the hand-assisted techniques include a slightly larger incision than would be required to deliver the kidney and restricted areas where the incision can be placed to facilitate reaching the kidney. The pure laparoscopic technique offers the advantage of placing the incision low, where it is better concealed and usually a smaller incision size since the kidney is delivered using a bag. There is some theoretical suggestion that a lower, smaller incision may lead to less postoperative, pain but there are no studies to support this.

Other techniques

There are various other techniques that have been described and are employed at a number of centers throughout the US and Europe. One of the more commonly described is a retroperitoneal approach that can be performed with and without hand assistance. The retroperitoneoscopic approach has an advantage over the standard transperitoneal laparoscopic technique in that the peritoneum remains intact with a lower theoretical risk of visceral injuries and perhaps a lower rate of ileus. In a few small studies, the hand-assisted retroperitoneoscopic approach had significantly shorter operative time compared to standard laparoscopic donor nephrectomy [43–45]. Overall, other clinical outcomes were similar and this may reflect patient selection or surgeon familiarity with the procedure. Currently, the retroperitoneal approaches have not gained widespread favor.

More recently, various surgical subspecialties have employed robotic assistance in their procedures. There are several reports of early use of robotic-assisted donor nephrectomy and we anticipate that this will be an increasingly common technique [46–48]. The theoretical advantages of the robotic-assisted technique includes increased degree of freedom for movement facilitated by the 360° articulating wrist of the operating arms, resulting in greater flexibility and maneuverability. An additional advantage is the benefit of a tremor-free operation due to the built-in stabilization system. Decreased fatigue and operative technique-related injuries to the surgeon are also potential advantages to the robotic-assisted approach. One significant disadvantage to the robotic technique is the required financial investment as well as the learning curve associated with the device.

Lastly, recent advances in minimally invasive surgery have focused on single incision/site laparoscopic surgery (SILS) and natural orifice translumenal endoscopic surgery (NOTES). There are several studies examining the utility of single-site laparoendoscopic donor nephrectomy [49–51]. As expected, the total incision length was less and there was a suggestion of a quicker recovery time in recipients undergoing the single-site procedure. These studies also pointed to longer operative times and possibly a higher conversion rate to the standard technique [52,53]. There was limited sample size in these studies, impacting the power and our ability to draw any concrete conclusions. There is currently a randomized, prospective clinical trial sponsored by Cornell University evaluating the use of conventional laparoscopic donor nephrectomy versus laparoendoscopic single-site donor nephrectomy. Endpoints in the trial include operative times, pain scores, analgesic requirements, length of stay, surgical scar satisfaction, as well as function and survival of the transplanted kidney. It will be interesting to see if there are any appreciable, significant differences between these techniques. Future techniques will push the envelope of technique and technology using unique approaches such as natural orifice surgery or NOTES. The first report of natural orifice surgery in a donor nephrectomy described a right-sided nephrectomy procured laparoscopically, but instead of extracting the kidney through a standard Pfannenstiel incision, the surgeon elected to remove it through the vagina in a woman who had previously undergone a hysterectomy [54]. Interestingly, another group recently described combining the robotic technique with transvaginal extraction of the donor kidney with the uterus in place [55]. In both reports, the donor did not receive any postoperative narcotic intravenous analgesia and was discharged home after 24 h.

The future of living donor kidney surgery will likely include some iteration of these techniques. We must, however, ensure that whichever technique we employ, it must remain as safe as humanly possible for those who choose to undergo a procedure not for their own benefit, but for the betterment of someone else.

Donor outcomes following living kidney donation

Unlike most types of surgical procedures that have acceptable rates of major complications and mortality, the fact that living kidney donors derive no physical benefit from the surgical procedure has resulted in a zero tolerance policy for major morbidity and mortality related to either the surgical procedure itself or the act of kidney donation. While not achievable in practice, this mindset likely reflects appropriate concerns within the transplant community that potential living donors be safeguarded from excessive risk. Transplant programs are mandated to report donor deaths and acute complications related to the donor procedure (defined as those that occur within 6 weeks of donation or before the donor is discharged from surgical care) to the OPTN. The risk of procedure-related donor death is estimated to be approximately 1

in 3000. This is consistent with reports that of the 51 153 living kidney donor surgeries performed between October 1999 and December 2008 there were 14 deaths identified by center reporting and examination of the Social Security Master Death File [56]. During this time period, an additional 39 donors died within 1 year of donation with the identified causes reflecting conditions common in the general population, such as cancer, accidents, cerebrovascular and cardiovascular disease, homicide, and suicide. There is some evidence to indicate that the operative and early postoperative risks of living kidney donation are decreasing. OPTN data indicate that there were only three deaths occurring within 30 days of the procedure for living donor nephrectomies performed between 2005 and 2009 [2]. During this time period, the number of living donor deaths occurring for any reason within 1 year of donation ranged from 0.03% to 0.08%. With respect to acute complications of living kidney donation, the most common occurrence is hemorrhage requiring transfusion, which occurs in approximately 2% of all donors. The need for reoperation is approximately 1 in 100 living donor nephrectomies. Aside from hemorrhage, the most common complications requiring reoperation include incisional hernias and bowel obstruction, each reported to occur in approximately 1% of living kidney donors. As the vast majority of donor nephrectomies are performed laparoscopically, conversion to an open procedure is considered a complication and was reported to have occurred in $<1\%$ of all laparoscopic donor nephrectomies performed in 2009. In the current era, readmission rates are also low, with approximately 1% of living donors requiring readmission primarily related to intra-abdominal concerns such as abdominal pain, constipation, ileus, nausea, or vomiting. Other less commonly reported causes for readmission include deep venous thrombosis, pulmonary embolism, chylous ascites, pancreatitis, or intra-abdominal infection. Of note, there is no evidence to suggest that the choice of the operative approach affects the incidence of complications in the donor or the function of the transplanted kidney.
