Transplantation has, from its inception as a clinical therapy, challenged community attitudes, legal definitions of death and health system organizations. The field has driven the need for clarity on the definition of death; has required all governments to face decisions on how to operate organ donation programs; has sought to ensure that every individual has considered and made a decision about whether or not they wish to become a donor after death; and for families of individuals who have not made the decision, it has forced them into considerations that go far beyond absorbing the fact of the sudden death of their relative.

Far more than any other field of modern medicine, with the possible exception of human reproductive technologies, transplantation has demanded government policy attention and legislation in nearly all developed countries and emerging economies in the world. Figure 128.1 shows the countries that currently have active and regulated human organ donation and transplantation. Emanating from the 1980s in some countries and the 1990s in most of the rest, at least for the initial legislation, transplantation has been regulated and controlled within legal boundaries set by the national and international community through their legislators. In the last decade both international and governmental attention has been drawn to the problems that successful global spread of transplantation technology has created, specifically around human organ trafficking and illegal commercialization of the human body.

This chapter describes how international organizations and governments have responded around the world, specifically detailing the drivers and purposes of legislative and governmental control in the US, considering the impact of these policies on US transplant programs and practices. Although detailing US policy as an example, this chapter also covers the common issues that have required attention globally, and in broad terms, the means by which these issues have been regulated in geographic regions around the world. Also described are major international associations tending to global transplant practice, and burgeoning international agreements attempting to gain international consensus on aspects of transplant practice. The focus is on organ donation and transplantation rather than cell or tissue transplantation. Additional treatment of broad-reaching policy in transplantation can be found in Chapter 143.

Health and Human Services oversight of the US donation and transplantation system

The broad reach of transplantation is evident in the attention given to it by a vast number of governmental organizations and agencies, and by the numerous laws developed for its conduct. The US Department of Health and Human Services (HHS) is the principal agency for protecting the health of all Americans. This work is advanced through many of its agencies including the Centers for Medicare and Medicaid Services (CMS), the Health Resources and Services Administration (HRSA), the Centers for Disease Control and Prevention (CDC), the Food and Drug Administration (FDA) and the Public Health Service (PHS). From the perspective of organ donation and transplantation, HHS' leading oversight agencies are CMS and HRSA.

In 1965 the US Social Security Act (Act) gave the HHS Secretary the authority to formulate and publish rules and regulations for delivering quality healthcare to Medicare beneficiaries [1]. Through this authority, all Americans benefit. CMS is responsible for establishing the minimum standards deemed necessary to protect patient health and safety and for implementing oversight mechanisms to ensure healthcare entities provide quality care to Medicare beneficiaries. Hospitals, transplant programs, organ procurement organizations (OPOs), dialysis centers and clinical laboratories are among the entities required to meet Medicare standards so they may receive financial reimbursement for services provided to Medicare and Medicaid-eligible recipients.

Section 1138 of the Act, passed in 1972, extended Medicare coverage to certain individuals with chronic renal disease. In 1978 the Act was further extended to provide for coverage under Medicare for end-stage renal disease (ESRD) patients to receive kidney transplantation services.

The HRSA's responsibilities for donation and transplantation resulted from the growing success of transplantation and the ever-increasing need for donor organs. In 1984 Congress passed the National Organ Transplant Act (NOTA) to, among other things, create the Organ Procurement and Transplantation Network (OPTN), the Scientific Registry of Transplant Recipients (SRTR), and an administrative unit within HHS to administer these activities, the Division of Transplantation (DOT) within HRSA [2].

Table 128.1. Department of Health and Human Services donation and transplantation regulations (1998–2007)

Year	Agency	Regulation
1998	HRSA	OPTN Final Rule (42 CFR, Part 121)
1998	CMS	Hospital CoPs for Organ, Tissue and Eye Donation; Final Rule (42 CFR, Part 482)
2006	CMS	Conditions of Coverage for OPOs; Final Rule (42 CFR, Parts 413, 441, et al.)
2007	CMS	Hospital CoPs and Requirements for Approval and Re-Approval of Transplant Centers to Perform Transplants; Final Rule (42 CFr, Parts 405, 482, 488 and 498)

Table 128.2. Centers for Medicare and Medicaid Services outcome measures for organ procurement organizations and transplant programs

Covered Entity	Outcome Measure
OPO	Donation rate of eligible donors as a percentage of eligible deaths is no more than 1.5 standard deviations (SD) below the mean national donation rate.
OPO	Observed donation rate is not significantly lower than the expected donation rate for 18 or more months of the 36 months of data used for recertification
OPO	At least two out of the three following measures are no more than 1 SD below the mean: organs transplanted per standard criteria donor; organs transplanted per expanded criteria donor; organs used per research per donor.
Transplant Prog.	Perform ten transplants per month in a 12-month period
Transplant Prog.	Observed patient- or graft-survival rate is lower than expected AND the following three thresholds are all crossed: **1** One sided *P* value is less than 0.05 **2** Observed minus expected events is greater than three **3** Observed divided by expected events is greater than 1.5

Passage of all of this formative legislation (with subsequent amendments) established the foundation by which the US Federal government oversees the organ donation and transplantation system. In the late 1990s, HHS activities built on this legislation in ways that would have important consequences on the future of donation and transplantation. From 1998 through 2007 HHS issued regulations (Table 128.1) spanning the continuum of donation and transplantation that included requirements for donor hospitals, OPOs, transplant programs and laboratories [3]. These regulations also impacted the operations of the OPTN and the SRTR, and the relationship between HHS and the organizations holding contracts to operate both entities.

The CMS published the first of three final rules, the Hospital Conditions of Participation for Organ and Tissue Donation on June 22, 1998 (42 CFR 482.45) with an effective date of August 21, 1998. This rule is better known as the "routine referral" rule requiring hospitals to identify and refer potential organ and tissue donors to an OPO or a third party designated by the OPO. Next, CMS published the OPO Conditions of Coverage on May 31, 2006 (42 CFR 496, Subpart G) in response to the Organ Procurement Organization Certification Act of 2000 that directed HHS to establish outcome and process performance measures based on empirical evidence. Finally, CMS published the transplant program final rule March 30, 2007 (42 CFR 482, Subpart E). Prior to the transplant rule, kidney transplant was governed through the ESRD regulations and the extra-renal organs were governed through the National Coverage Decisions published in the Federal Register. The implementation of these rules as a whole was unique and precedent setting for DHHS.

The Studer Group, a 2010 recipient of the Malcolm Baldrige Award for Quality, coaches healthcare organizations to achieve and sustain excellent performance outcomes. Studer recommends using organizational pillars to provide the foundation for setting goals and directing service [4]. Although regulations differ significantly from organizations, the concept of using pillars to align goals and focus behaviors can be applied to both. In the context of governance and oversight, four pillars that can be used to generate successful outcomes are: accountability, transparency, quality assurance and performance improvement (QAPI), and collaboration and co-operation.

Pillar 1: accountability (stewardship of resource and funds)

From an oversight perspective, accountability is the acknowledgment and assumption of responsibility for actions, decisions, and policies and being answerable for resulting consequences. In the US donation and transplantation system, there are two prime levels of accountability: individual organization performance and overall system performance. Both CMS and HRSA hold individual OPOs, transplant programs and hospitals accountable for performance outcomes. Congress and the US general public hold HRSA and CMS accountable for the overall performance of the national donation and transplantation system.

The CMS holds entities accountable for performance through the process by which they become entitled to receive Medicare money for services provided. This pathway to approval differs for donor hospitals, OPOs and transplant programs. For hospitals, initially, CMS must certify, or affirm, the organization is capable of providing the desired service. For OPOs, CMS designates the OPO (assigns the OPO a geographic service area), then certifies it is capable of service delivery. Transplant programs initially must be members of the OPTN, then be certified by CMS as capable of delivering effective transplantation services. The certification process consists of a review validating the organization's ability to perform donation and/or transplantation services. CMS reviews each applying organization's process and outcome measures to determine whether taxpayer money would be well spent by purchasing services from the applicant. Once certified, entities qualify to receive Medicare reimbursement for services delivered. No entity other than CMS, not even the OPTN, can designate, certify or in any way approve OPOs, donor hospitals or transplant programs to receive Federal funds.

CMS-certified institutions span the continuum of donation and transplantation. CMS has established Conditions of Participation (CoPs) for transplant hospitals regarding the evaluation, listing, in-hospital and postoperative care of transplant patients. Recognizing that the continuing success of transplantation relies on the supply of available organs, CMS established expectations for all US acute care and critical access hospitals to fully co-operate with OPOs in the identification, referral, management and recovery of organs from authorized donors. Finally, CMS has established conditions to be met by OPOs for the effective and efficient evaluation, management, recovery and transportation of transplantable organs from authorized donors.

For OPOs and transplant programs, CMS has established performance outcomes that must be met if the covered organization wishes to maintain its certification and/or designation to receive Medicare reimbursement (Table 128.2). Although CMS has not

specified organ donation performance objectives in regulations for donor hospitals, there are national performance goals established by HRSA that, if not met, could result in reviews by organizations such as The Joint Commission.

In fulfilment of its oversight of the national OPTN granted by NOTA, HRSA published a regulation (OPTN Final Rule, 42 CFR, Part 121) in 1999 describing its expectations of the OPTN's operations and objectives [2]. Among its requirements, HRSA charged the OPTN with developing and publishing allocation policies and performance goals; membership and designated transplant program requirements; review and evaluation processes; and practices by which OPTN members would be held accountable for policy compliance. As a result of the regulation not only did OPTN members become more accountable for their own compliance with OPTN policies, the OPTN itself became more accountable to HRSA and to the general public for providing quality care to deceased and living donors, transplant candidates and recipients.

HRSA, through the OPTN regulation, requires publication of center-specific performance outcomes for OPOs and transplant programs. Each OPTN member must submit donor, candidate and recipient data that are analyzed and published by the SRTR. Members performing at lower than expected levels must undergo the OPTN's peer review process and, when required, implement corrective action plans.

Similar to HRSA, CMS also tracks OPTN member performance to coincide with the biannual SRTR Center Specific Report publications. Similar to the OPTN, underperforming entities are notified and asked to submit an improvement plan that will ensure successful outcomes over the period allowing them to qualify for recertification. OPOs are recertified every four years while transplant programs are recertified every three years, which may be extended based on achieved performance measures. Although OPO and transplant program reviews by both CMS and the OPTN may seem duplicative, they serve to hold programs accountable to the federal entity charged with maximizing organ utilization (HRSA) and the entity charged with funding effective healthcare delivery (CMS). By both using the common set of data submitted to the OPTN, CMS and HRSA hope to minimize the regulatory burden on OPTN members.

Pillar 2: transparency

Transparency, in science, engineering, business and the humanities, generally implies openness, communication and accountability. The concept of transparency in organ donation and transplantation can apply equally to both the policy/regulatory process and to publication of performance outcomes.

All CMS donation and transplantation requirements are publicly available on the CMS website at www.cms.hhs.gov. Published information includes the regulations Conditions of Participation (CoP), interpretive guidelines (how compliance with the CoPs can be demonstrated) and the State Operations Manual (SOM) (how surveyors will conduct a performance review). Under the Freedom of Information Act (FOIA), CMS can disclose the results of any survey it performs to any interested party who requests them after the donor hospital, transplant program or OPO has submitted an acceptable plan to correct accessed deficiencies. CMS actions in response to non-compliance are governed by published regulations under Title 42 Code of Federal Regulations (CFR) sections 498 and the survey procedures are published at 42 CFR 488.

The proposed rule making process instructs CMS to consult industry experts and organizations while developing a regulation. After a proposed rule is published, CMS allows a comment period so the public can inform CMS of possible improvements to, implications for, or unintended consequences of its proposed rule. CMS will then consider the comments and publicly respond to them when it publishes the Final Rule and the date the Rule becomes effective. CMS responses to the public comments are always published in the preamble of the Final Rule. If public comments result in substantial changes to the proposed rule, CMS must publish another proposed rule with an additional comment period prior to publishing the revised Final Rule.

After the regulations are published in the form of Final Rules, CMS develops surveyor interpretive guidelines to be used during the survey process. The purpose of the survey is to establish whether the transplant program, OPO or donor hospital meets all of the regulations conditions (referred to as condition level compliance) for the purpose of certification or recertification. Many entities, including hospitals, are surveyed by accreditation organizations such as the Joint Commission, because these organizations have been granted "deeming authority" by CMS. Having deeming authority means an entity, such as the Joint Commission, can officially determine which facilities meet Medicare and Medicaid certification requirements and which do not [5]. CMS or its contractors do not routinely survey entities that are certified by an organization possessing deemed status. However, CMS does perform validation surveys of all accredited entities. Because there is no organization with deemed status for transplant programs and OPOs, CMS, state surveyors or CMS contractors must perform all certification surveys. Surveys are always conducted on an unannounced basis so covered entities are expected to deliver high quality care at all times and use quality management principles to be "ever ready" for unexpected visits.

In the event the results of a survey cause CMS to consider termination of a donor hospital, transplant program or OPO's Medicare eligibility, the entity has the opportunity to provide a plan of correction and if acceptable to CMS, an unannounced resurvey will be conducted to verify the plan of correction has been implemented. If the plan of correction is not acceptable, CMS continues with the termination process but the entity can request a re-consideration based on substantive grounds. If CMS denies the reconsideration, the termination process continues and the entity can file an appeal. All appeals are considered through the established appeal process (which is clearly outlined in the regulation) and the resulting decision is final.

The HRSA's process for developing and publishing regulations is identical to CMS'. Through its Final Rule, HRSA has established requirements for the OPTN's policy-making process, which is separate and distinct from that of the Federal government. According to the Final Rule, the OPTN must develop and publish policies within the mission of the OPTN such as equitable allocation of deceased organs, prevention of transmission of infectious diseases; reduction of inequities resulting from socio-economic status; training and experience of transplant surgeons and physicians in designated transplant programs; nominating officers and members of the Board of Directors; and other matters as the Secretary directs, such as living donation. A full description of the OPTN's policy development process can be found at www.unos.org.

The Rule further requires the OPTN Board of Directors to provide opportunity for the OPTN membership and other interested parties to comment on proposed policies and for OPTN committees to take the comments into account in developing and adopting policies for implementation by the OPTN. This process assures that any individual, organization or geographic region of

the US affected by a new or revised policy is able to comment during the development process.

All OPTN proposed and adopted policies and bylaws are available at www.optn.transplant.hrsa.gov. Any interested individual or organization, regardless of whether they are OPTN members, may review and comment on proposed policies in writing or via the OPTN's internet-based public comment system. OPTN policies continue to undergo plain language revisions so the intent and purpose of each policy is understandable to both professional and lay readers.

Both the OPTN and the SRTR are required by the OPTN Final Rule to "make available to the public timely and accurate program-specific information on the performance of organ procurement and transplant programs. This shall include free dissemination over the Internet, and shall be presented, explained, and organized as necessary to understand, interpret, and use the information accurately and efficiently". Any interested person or organization has access to program-specific, regional and national donation and transplantation data. Investigators, journalists or anyone conducting bona fide research or analysis, provided the requests are reasonable, may request OPTN data. The HHS Secretary also may direct the release of OPTN or SRTR data at his/her discretion. Complete transparency of OPTN data is one of the most important ways HRSA holds itself, the OPTN, and all donation and transplantation programs accountable for system performance.

When necessary, the OPTN and SRTR are permitted to recoup the costs of complying with data requests in the form of reasonable charges to the requester. This is done to minimize the financial burden of responding to data requests. If the Final Rule did not permit this, the cost of responding to data requests would be passed along to transplant programs and OPOs in the form of higher candidate registration fees. The Final Rule also permits the release of patient-identified data to researchers "showing a legitimate research designed (that) requires such data for matching or other purposes". In these cases the OPTN and SRTR require evidence of "appropriate confidentiality protections, including destruction of patient identifiers upon completion of matching."

Pillar 3: quality assurance and performance improvement (performance sustainability and patient safety)

The CMS defines Quality Assurance and Performance Improvement (QAPI) as a comprehensive data-driven program designed to monitor and evaluate the performance of all services, including services provided under contract or arrangement [6]. It is an ongoing evaluation of operating systems and clinical process that achieves measurable improvements in healthcare.

A review of CMS' donation and transplantation CoPs for donor hospitals, transplant programs and OPOs reveals the QAPI conditions are inter-related. In the interest of continuity of care, CMS has carefully ensured the QAPI rules are synchronized in such a way that optimum levels of care and successful outcomes can result when the QAPI conditions are diligently applied as intended. For example, in the donor hospital CoP there is a requirement to co-operate with the OPO to perform medical record reviews to assess the number of potential donors at the institution in a given time period. In the OPO rule, there is a requirement to provide data reports to hospitals and transplant hospitals of outcomes of medical record reviews to assess the hospital's organ donation effectiveness. In the transplant rule there is a requirement to establish outcome measures for organ donor recovery, which needs the co-operation of the OPO and the information obtained from the donor hospital during the medical record review

To ensure entities meet their performance standards, CMS requires all donor hospitals, OPOs and transplant centers to have robust QAPI programs that track and act on metrics that identify areas of underperformance. CMS expects all entities to maintain compliance with requirements and continuously strive to improve quality of care and patient and living donor safety in pursuit of optimal outcomes.

One example of a recently developed QAPI activity at the national level is the OPTN's ad hoc Disease Transmission Advisory Committee (DTAC). The Committee examines individual potential disease transmission cases reported to the OPTN in an effort to confirm transmissions where possible. DTAC also reviews aggregate data on all reported cases to assess the risk of donor disease transmission in organ transplantation in the US All OPOs and transplant programs are now required to identify a specific patient safety contact person and report all instances of proven or suspected transplant-related disease transmission to the OPTN Patient Safety System within 24 hours [7].The emergence of DTAC begins to close a long-existing knowledge gap about the true incidence of disease transmissions caused by transplantation of donor organs.

Prior to 2003, it was impossible to perform an effective QAPI analysis of the national organ donation system. Donation data related to potential donor referrals, eligible deaths, donation authorization rates and missed opportunities for donation were neither collected nor publicly available. In fall 2002, HRSA required OPOs to begin submitting these data to the OPTN and by the spring of 2003, the Nation was armed with information on which it could act to drive improvements in the number of organ donors and transplantable organs. The availability of these data altered the organ donation performance improvement culture from one of instinctive, anecdotal change process to a data driven process that could give rise to intelligent improvement. Organ donation took its first steps toward evidence-based practice.

To ensure both donation and transplantation remain on a data-driven improvement path, CMS' OPO and transplant regulations now mirror and reinforce the OPTN's existing data submission requirement of 95% of specified data due 90 days after the OPTN due date. Full compliance with the OPTN's data submission policies equates to full compliance with CMS' transplant program condition of participation. In this regard, the OPTN now plays a consultative role to transplant centers and OPOs in complying with Medicare requirements.

Pillar 4: collaboration and co-operation

Collaboration and co-operation are the means by which the components of a system work together to achieve a specific goal.

Everyone involved in donation and transplantation must be good stewards of a rare and medically valuable resource. Over the last five years, an average of 26 857 solid organ transplants was performed in the US from both deceased and living donors (Figure 128.2). In 2010, of the 14 508 organ donors, 53.4% were from deceased donors and 43.2% were from living donors. In 2000 living donation drew within 40 donors of deceased donation and surpassed it in 2001 continuing through 2003 (Figure 128.3) [8]. For the five years prior to 2003, the industry experienced a meagre 2.6% annual average increase in organ donation. In 2003, HHS launched the Nation's first Organ Donation Initiative with the vision of creating a "Donation Friendly America."

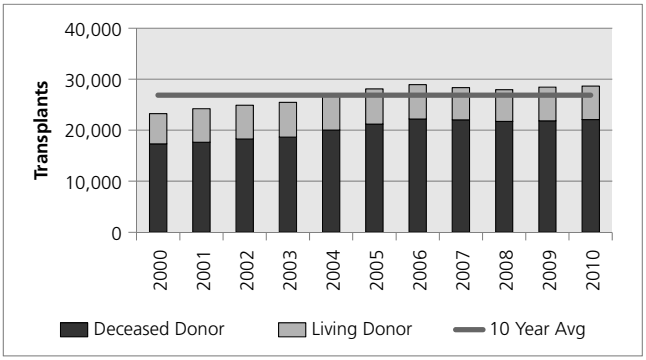

Figure 128.2. US annual organ transplants. Based on OPTN data as of January 11, 2013.

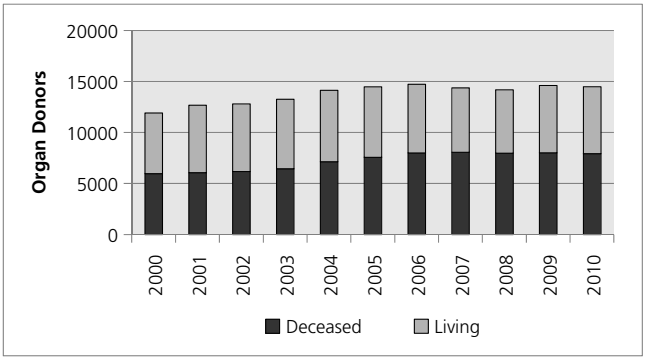

Figure 128.3. US deceased and living donors. Based on OPTN data as of January 11, 2013.

The HHS' premier example of donation and transplantation collaboration and co-operation is HRSA's Organ Donation Breakthrough Collaborative (ODBC) that was established to achieve significant increases in the number of US organ donors [9]. The collaborative's charge was to identify best practices in OPOs and hospitals leading to high donation (conversion) rates and spread those practices to all 58 donation service areas (DSAs) in the US. Through this initiative, the Nation experienced previously unimagined increases in deceased donation from 6190 organ donors in 2002 to 8019 in 2006 (29.5%). The ODBC evolved into the Organ Transplantation Breakthrough Collaborative (OTBC) intended to maximize the donation gift from every donor to increase the number of organ transplants. As with the ODBC, the increases were outstanding, with transplants increasing from 18 291 in 2002 to 22 208 in 2006 (21.4%).

The Collaborative translated the best practices identified in HRSA's two published reports by stressing the importance of using existing performance improvement methods, such as Plan, Do, Study, Act (PDSA) cycles to test and adapt changes for local use. Performance improvement progress was tracked at both the hospital and DSA levels. Collaborative teams (comprised of representatives from OPOs, donor hospitals and transplant programs) demonstrating rapid improvement were invited to share their progress and methods with similar teams from throughout the nation at joint learning sessions.

The original goal of the breakthrough collaborative was to increase the national conversion rate from 58 to 75% through the use of best practices and outcome oriented relationships between OPO and donor hospitals. The 75% conversion rate goal was achieved in 2010 and has subsequently been achieved each month through September 2011 [10]. In addition to increasing the national conversion rate, the Collaborative sought to maximize each donation opportunity by increasing the number of organs transplanted per donor (OTPD) from the existing 3.03 in July 2005 to 3.75. And although some individual OPOs have intermittently reached the national goal, most have not, so the national goal of 3.75 OTPD has yet to be realized. However, opportunities for improvement still exist. It is likely partnerships between critical care physicians and organ procurement professionals to maintain a high degree of organ viability from the time a potential donor enters a hospital until donation authorization is obtained could increase the number of healthy organs that could be procured. Such sophisticated partnerships do not yet exist in most areas of the country. It also is possible that closer involvement of certified QAPI professionals to review and evaluate OPO donor management processes and practices could shed light on previously unrecognized opportunities for improvement.

HRSA's Collaboratives have served as a catalyst to encourage ongoing co-operation among donor hospitals, transplant centers and OPOs at the local, regional and national level and to assure alignment of their QAPI activity to better serve the needs of donors, donor families, transplant candidates and recipients.

The Collaboratives also provided HRSA and CMS an opportunity to partner in pursuit of a common goal and with the purpose of establishing a viable platform based in the private sector that could maintain and sustain the work and momentum of the Collaborative into the future.

Transplant program perspectives

CMS Transplant Center Conditions of Participation (COP) went into effect on June 28, 2007 in an effort to improve oversight to transplant programs. This 84-page document published in the Federal Register required all previously approved transplant centers to submit a letter to CMS by December 26, 2007 requesting approval to continue to perform transplant procedures under the new CoP [6]. By virtue of this letter, transplant programs in the US were committing to conform to the regulatory requirements established by CMS. This meant CMS would survey each transplant program or the transplant program's State Department of Health every three years to ensure compliance with the new CoP's. Included in these regulations were volume and outcome requirements for solid organ transplantation. Directives and guidelines such as these had not been previously established and some programs and professionals questioned the need for such requirements. Transplant programs now were required to report any significant changes in their volumes or outcomes to CMS as well as any changes in key personnel such as a primary transplant surgeon or physician. To maintain clinical experience, volume requirements were established for each specific organ with heart, liver, intestines and lung programs requiring ten transplants each year and kidney programs requiring at least three transplants annually. No annual requirements were established for heart-lung combinations or pancreas transplants. Pediatric programs were also exempt from volume requirements.

Initially there were concerns from transplant professionals about the number of regulations being imposed from the OPTN and now CMS. Recognizing that the CoPs were tied to payment, transplant centers began reviewing their programs to ensure compliance.

Without approval by CMS to continue transplantation, programs would be at risk of losing private payors as well. Several professional transplant associations issued a crosswalk describing and comparing regulatory requirements from the OPTN and CMS. Both now would be surveying transplant centers. The OPTN provides a notice of surveys several weeks in advance with a list of patient records they will audit. CMS surveys are unannounced and occur every three years with requests for patient records upon their arrival. In 2011, The OPTN began specialized surveys of living donor programs separately from their regular chart audits of recipients and transplant candidates. Therefore, it is possible for a transplant program to have two OPTN surveys and a CMS survey in the same year. The OPTN surveys are usually 2–3 day audits whereas the CMS surveys may last a week or more depending on a transplant center's volume. When one considers the fact that transplant programs had not experienced such oversight from regulatory agencies prior to this, these surveys generated considerable concerns within the transplant community.

Data generates outcomes

Data requirements are also included in both the OPTN and CMS regulations. Each transplant program must submit data to the OPTN on a monthly basis. Transplant centers are expected to collect and submit 95% of required data within 90 days of the due date. This data is then transferred to the SRTR for analysis. Once analyzed the data is sent to the respective transplant programs for review prior to being released to the public. Transplant programs have approximately four weeks to review the data, make corrections and supply any missing data. Upon returning the data it is reanalyzed by the SRTR and released to the public on the website: www.srtr.org. Here the public has complete access to each transplant center's risk adjusted patient and graft survival rates at 30 days, 1 year, and 3 years. Other data such as deaths on the wait-list and a center's transplant rate are also reported. Both CMS and the OPTN monitor these outcomes. Expected one year graft and patient survivals are compared to one year observed patient and graft survivals using the following thresholds:

- observed minus expected >3
- observed divided by expected >1.5
- 1-sided P value <0.05

CMS considers a transplant center to be non-compliant with outcomes if the program crosses all three of the above thresholds in 2 out of the last 5 SRTR releases. SRTR reports one and three year outcomes that are based on cohorts within a 2.5 year period. Therefore following graft and patient survival in real time is important to allow programs to proactively intervene with problems identified and analyzed early rather than waiting for program specific reports issued by the SRTR.

Systems improvement agreements

Transplant centers that do not meet volume or outcome requirements may receive a Systems Improvement Agreement (SIA) from CMS. This document describes the program's requirements to remain active. Programs receiving an SIA are essentially considered on probation until their outcomes or volume improves. This requires that a letter is sent to every patient listed with the transplant program and to provide the patients with contact information for other transplant programs should they wish to transfer to another program as the center works to improve their volume and outcome requirements. This often is very costly for transplant programs and has been estimated by several programs to cost between $600 000 to over $1 000 000 to rebuild. Programs must pay for a peer review group to evaluate their program and make suggestions to CMS on what must be done for the transplant program to improve their outcomes and/or volume. This peer review group usually consists of a surgeon, physician, transplant coordinator, social worker, transplant administrator, and a quality consultant. The curriculum vitae of each professional must be sent to CMS for approval. Peer review members may not be selected from programs that are currently under an SIA themselves. The group surveys the transplant program for 2–3 days and submits a report to them based on their findings. This report provides suggestions for program improvements that the peer review group thinks will promote an improvement in outcomes. This report to the program is followed by a conference call with leadership and staff from the transplant program, the peer review team and staff from CMS. Recommendations from the peer review group are outlined during this call as the program begins the process of implementing changes.

Following the peer review group that consults with the transplant program under an SIA, a quality consultant must also be hired to work with the transplant program for eight days a month for approximately one year. This consultant remains on site with the transplant program for the allotted amount of time working with the program to improve their quality programs and to track data in real time to ensure the program is making progress in their outcomes. The quality consultant also helps update policies, protocols and monitoring of any adverse events. CMS requirements for an SIA may vary from program to program depending on the severity of the deficiencies.

It is interesting to note that a time when OPOs are being asked to increase organ donation rates, many transplant centers are becoming more risk averse. To improve outcomes some programs have taken less risk on DCD or ECD donors. Programs under an SIA are also being more cautious about patient and donor selection to ensure improvement in their outcomes. Determining the criteria for patient selection requires a process that must be taken seriously by transplant programs. Often the criteria is written into a protocol but may not be followed as written. CMS and the OPTN review patient selection criteria closely during surveys to determine if what is documented in a policy or procedure reflects current practice. According to CMS CoP, patient selection criteria used to accept or reject a patient for transplantation must be documented in the patient's medical records. Many programs have developed checklists that contain the selection criteria used to accept a patient for transplantation as well as absolute or relative contraindications used to deny transplantation. The checklist is completed, signed by a physician and coordinator and placed in the patient's chart. A letter is then sent to the patient with the team decision. This letter must be sent within ten days of the decision.

Quality assurance and performance improvement in transplant centers

All transplant programs now are required to have comprehensive quality assurance and performance improvement (QAPI) programs with performance measures that reflect regulatory requirements and program specific metrics that monitor outcomes in real time. These programs should demonstrate integration within the hospital's QAPI program in terms of reporting data on a quarterly or half yearly basis. This report is often shared with administration and the hospital's Board of Directors. A strong QAPI program requires a plan that describes a steering committee with oversight on the transplant program. If a transplant program has more than one

organ system being transplanted, a quality committee for each organ is needed to meet on a monthly or quarterly basis to review data. The program's QAPI plan and policy determine the frequency of meetings. Goals for a QAPI program plan should include:

- identification of opportunities for improvement based on real time metrics
- prioritization of performance improvement projects
- continuous tracking of patient care and organizational process outcomes
- monitoring regulatory requirements
- ensuring policies and procedures are evidence based, regularly reviewed and audited for compliance
- monitoring outcome data to ensure it is statistically aligned with national standards and expectations.

Changing practice to incorporate QAPI into the busy schedule of transplant professionals often requires a change in program culture, perspectives and priorities. Education is required to bring the various members of the multidisciplinary teams on board with this new era of transparency through QAPI and regulatory environments. Most have not been educated on the processes involved in QAPI. Thus, presenting programs on QAPI to explain its relation to transplantation in terms of structure, process and outcomes, helps teams understand the rationale for developing comprehensive data driven programs. Educating staff about SRTR outcomes is an important part of helping teams understand how CMS and UNOS are reviewing programs. Understanding how SRTR analyses the data each center submits, helps staff value the importance of reporting data accurately. A strong QAPI program also includes monthly meetings to address morbidity and mortality issues as well as adverse events. Staff must be included in these meetings to participate in discussions that address these issues in depth within a multidisciplinary team environment. Drilling down to assess and analyze the root cause of identified or potential problems allows programs to give serious consideration of changes that may be needed in the program's clinical practice or policies.

Global policies

The challenges set for the international community by the rapidly advancing field of transplantation, started in the 1960s as clinical transplantation became a clinical reality. Early experimental clinical programs had substantial practical difficulties with finding and using potential organ donors, operating as they were, within a legislative vacuum. What was needed for consent to donate after death? Who could provide consent? Who could over-ride consent in the face of disagreement? When was the donor dead? Heart transplantation took over from kidney transplantation to strike at the core of what death actually was for a general pubic attuned to the concept of death as a cold corpse resulting from cardiac standstill. The media role in promoting each new transplant as a miracle in each developed country of the world, raised the attention to a level that could not be ignored by governments and legislators.

Despite these uncertainties and the silence of most legislatures on organ donation, it was the medical profession that drove the clinical field forward and demanded legislation that defined death. The Harvard committee that, in 1976, developed criteria for death based on the function of the brain stem, opened the way to use of organs from heart beating donors to be accepted in most but not all countries. Japan, for example, prosecuted a surgeon undertaking the first heart transplant in that country, using these principles, demonstrating that public attitudes, opinion and standards impacted variably by country, community and religion. That event in Japan paved the way for more than 20 years of legislated stagnation, which has only very recently been relaxed to permit family consent to donation after death.

During the 1980s, with a number of countries legislating for the use of brain death criteria, it became evident that model legislation would be of assistance to national governments and that global consideration and agreement on a limited number of principles would also be of benefit. In particular the scientific progress achieved in human organ led to a trade for profit in human organs among living human being that contravened the Universal Declaration of Human Rights. Thus the World Health Organization (WHO) was tasked to bring to the World Health Assembly a considered and fully consulted set of guiding principles for Member States to use as a template for their individual national legal instrument to regulate transplantation activities.

World Health Organization and World Health Assembly

The World Health Organization (WHO) is the health arm of the United Nations, based in Geneva and in six global regional offices. It is governed by the World Health Assembly (WHA), which is itself the creature of the contributing Ministers of Health of its 194 Member States. See http://www.who.int/governance/en/.

The WHA, which guides and governs the international efforts to control disease and improve the human condition, directed the WHO to bring guiding principles forward for endorsement, which was first accomplished in 1991 (resolution WHA44.25). These principles provided the basis for development of modern transplantation practices and served the clinical programs well until the late 1990s. Two phenomena then drove the Assembly to request re-examination of the WHO Guiding Principles in 2004: the demonstrable failure of transplantation to meet clinical demand through inadequate donor numbers in developed countries; and the spread of technical expertise, with the subsequent rise of illegal commercial transplantation in emerging economies across Asia, Eastern Europe and Latin America.

Following an extensive consultation process, the revised WHO Guiding Principles on Human Cell, Tissue and Organ Transplantation were endorsed by the 63rd World Health Assembly (WHA63.22) on 21 May 2010. See http://www.who.int/transplantation/en/ and Table 128.3.

WHO encourages collaboration between professionals and authorities from all region of the world and promotes a common global attitude to challenges arising from the success of transplantation. The WHO has taken on additional projects designed to assist national health authorities with the implementation of the revised guiding principles. These projects include: The Global Knowledge base on Transplantation and Global Observatory of Donation and Transplantation, conducted in partnership with the Spanish national agency Organización Nacional de Trasplantes (ONT), which documents global transplantation activity annually (Figures 128.4 and 128.5). The website provides a standardised international database of all organ transplantation activity and contains much useful data about different national legislations and acts as a repository of international documents [11,12].

The 4Ds programme, "Developing Donation From Deceased Donors" was initiated in 2006 in Kuwait and culminated with The Madrid Resolution resulting from the third global consultation on organ donation and transplantation [13] (for table of contents

Table 128.3. The 2010 World Health Organization (WHO) guiding principles on human cell, tissue and organ transplantation

1 Cells, tissues and organs may be removed from the bodies of deceased persons for the purpose of transplantation if:
(a) any consent required by law is obtained; and
(b) there is no reason to believe that the deceased person objected to such removal.

2 Physicians determining that a potential donor has died should not be directly involved in cell, tissue or organ removal from the donor or subsequent transplantation procedures; nor should they be responsible for the care of any intended recipient of such cells, tissues and organs.

3 Donation from deceased persons should be developed to its maximum therapeutic potential, but adult living persons may donate organs as permitted by domestic regulations. In general living donors should be genetically, legally or emotionally related to their recipients. Live donations are acceptable when the donor's informed and voluntary consent is obtained, when professional care of donors is ensured and follow-up is well organized, and when selection criteria for donors are scrupulously applied and monitored. Live donors should be informed of the probable risks, benefits and consequences of donation in a complete and understandable fashion; they should be legally competent and capable of weighing the information; and they should be acting willingly, free of any undue influence or coercion.

4 No cells, tissues or organs should be removed from the body of a living minor for the purpose of transplantation other than narrow exceptions allowed under national law. Specific measures should be in place to protect the minor and, wherever possible the minor's assent should be obtained before donation. What is applicable to minors also applies to any legally incompetent person.

5 Cells, tissues and organs should only be donated freely, without any monetary payment or other reward of monetary value. Purchasing, or offering to purchase, cells, tissues or organs for transplantation, or their sale by living persons or by the next of kin for deceased persons, should be banned. The prohibition on sale or purchase of cells, tissues and organs does not preclude reimbursing reasonable and verifiable expenses incurred by the donor, including loss of income, or paying the costs of recovering, processing, preserving and supplying human cells, tissues or organs for transplantation.

6 Promotion of altruistic donation of human cells, tissues or organs by means of advertisement or public appeal may be undertaken in accordance with domestic regulation. Advertising the need for or availability of cells, tissues or organs, with a view to offering or seeking payment to individuals for their cells, tissues or organs, or, to the next of kin, where the individual is deceased, should be prohibited. Brokering that involves payment to such individuals or to third parties should also be prohibited.

7 Physicians and other health professionals should not engage in transplantation procedures, and health insurers and other payers should not cover such procedures, if the cells, tissues or organs concerned have been obtained through exploitation or coercion of, or payment to, the donor or the next of kin of a deceased donor.

8 All health care facilities and professionals involved in cell, tissue or organ procurement and transplantation procedures should be prohibited from receiving any payment that exceeds the justifiable fee for the services rendered.

9 The allocation of organs, cells and tissues should be guided by clinical criteria and ethical norms, not financial or other considerations. Allocation rules, defined by appropriately constituted committees, should be equitable, externally justified, and transparent.

10 High-quality, safe and efficacious procedures are essential for donors and recipients alike. The long-term outcomes of cell, tissue and organ donation and transplantation should be assessed for the living donor as well as the recipient in order to document benefit and harm. The level of safety, efficacy and quality of human cells, tissues and organs for transplantation, as health products of an exceptional nature, must be maintained and optimized on an ongoing basis. This requires implementation of quality systems including traceability and vigilance, with adverse events and reactions reported, both nationally and for exported human products.

11 The organization and execution of donation and transplantation activities, as well as their clinical results, must be transparent and open to scrutiny, while ensuring that the personal anonymity and privacy of donors and recipients are always protected.

see: http://journals.lww.com/transplantjournal/toc/2011/06151). The Madrid Resolution stresses the responsibility of governments in striving toward self-sufficiency to fulfil the global needs in transplantation expressly by maximizing organ donations from deceased persons within their own national borders. It also promotes the complete evaluation of national responsibilities and accountabilities for diseases treatable by transplantation extending from educational and preventative measures to avoid disease, through bridging therapies such as dialysis, to donation, and transplantation safety and outcome measurement. The 4D programme exemplifies the complementarities between professionals and authorities and is currently on-going with the development of new global tools and national and sub-regional initiatives.

Project NOTIFY, conducted in partnership with the Italian national organization Centro Nazionale Trapianti (CNT) this project brings together the regulatory agencies and academic efforts to identify and reduce the transmission of disease from donors to recipients, but also to identify other adverse events and reactions occurring as a result of the donation, occurring in the recipient, that could jeopardize transplantation services [14].

Regional policies

European Union

The Council of Europe has, for more than two decades, acted to collate and generate collaboration in Europe over organ donation and transplantation. The Council of Europe's donation and transplantation committee has served to provide data and to stimulate interest in transplantation issues within Europe, especially around the ethical and practical donation related aspects of the field. The Council of Europe, based in Strasbourg, was founded in 1949 and is an inclusive organization of 47 European countries seeking to protect individuals, based on common and democratic principles through the European Convention on Human Rights, from which it derives its mandate in organ transplantation.

The European Union (EU), in distinction, is an economic and political partnership between 27 countries focused on economic co-operation as well as promotion of human rights and democracy. The EU parliament has regulatory powers across the member countries and has produced two main directives impacting clinical transplantation. The first directive covered cells and tissues which has impacted hematological stem cell transplantation and tissue banking, but the more recent European Legislative Framework on Quality and Safety aspects of Organ Donation and Transplantation has laid down a required organ donation and transplant framework for countries in the EU [15]. The binding nature of the directive requires national "competent authorities" to be established or designated — the various equivalents of the FDA — with responsibilities for a quality and safety structure to cover clinical donation and transplant activity. The EU Directive is accompanied by a fairly detailed and prescriptive Action Plan which must now be implemented (outline plan: Table 128.4) [16]. Work is now underway to establish a Europe wide standard safety reporting system for adverse events such as transmitted infections or malignancies, a Europe wide transplant outcomes registry and promotion of organ donation programs across the less developed economies of Europe.

South America

The Ibero Americana Council provides a structure for co-operation within South America across many fields of education, agriculture, science and technology, and health as well as projects designed to strengthen public institutions. In that context Spain and Portugal have engaged with the Ibero-Americana co-operative structure to support and enhance organ donation and transplantation services across the continent. In parallel and in co-operation with the

Table 128.4. European Union's ten point action plan for organ donation and transplantation [16]

Priority actions
1 Promote the role of transplant donor coordinators in every hospital where there is potential for organ donation.
2 Promote quality improvement programs in every hospital where there is potential for organ donation.
3 Exchange of best practices on living donation programs among EU member states: Support registers of living donors.
4 Improve the knowledge and communication skills of health professionals and patient support groups on organ transplantation.
5 Facilitate the identification of organ donors across Europe and cross-border donation in Europe.
6 Enhancing the organizational models of organ donation and transplantation in the EU member states.
7 Promote EU-wide agreements on aspects of transplantation medicine.
8 Facilitate the interchange of organs between national authorities.
9 Evaluation of post-transplant results.
10 Promote a common accreditation system for organ donation/procurement and transplantation programs.

Regional professional society: the Sociedad de Trasplante de America Latina y El Caribe (STALYC) this collaboration has ensured a dialogue between the countries in the region, some of which have well developed transplant programs like Argentina, Brazil, Chile, Uruguay, and some of which have more problems than solutions.

There has been a focus on Colombia and Peru during the past ten years, driven by problems with transplant commercialism and incoming transplant tourists. The government of Colombia has established a strong central organization designed to take control of the organ transplant programs in the three main cities and has been successful in reducing the transplantation of "foreigners for cash" from high levels in the years 2000–2005, to much smaller numbers — perhaps less than 20 per annum by the end of the decade. Israelis and Japanese transplant tourists constituted the bulk of the traffic but that has been reduced to a small trickle of Israelis, despite the action taken in Israel to ban funding by Israeli insurance companies of programs that would be illegal if conducted in Israel. Japan curtailed the trade through the same mechanism and highlighted that regulation of foreign transplantation by prosecution of patients returning after illegal transplants.

The difficulties in two countries cannot be allowed to overshadow the significant successes elsewhere in the continent, such as in Brazil — globally providing the third largest number of transplants each year to its population — and Chile, Uruguay, and Argentina undertaking excellent standards of transplantation for large numbers of their respective populations. The co-operation evident in the Ibero Americana Council will need to extend to regional capacity sharing if the smaller countries, especially in the isthmus, are to be able to meet the needs of their communities. Too small and too poor for sophisticated tertiary care facilities, some of these countries may not be in a position to support transplant programs without many decades of development.

China

China now performs the second largest number of transplants of any nation (after the USA) and has great technical expertise in a number of large centres, but has proved to be the most contentious transplant program in the world. China stands alone in using executed prisoners' organs and has also permitted — through the latter half of the 1990s and the first half of the first decade of this century — unfettered commercialism to govern use of those organs. The result was in 2005–2006 they were broadly accused of executing political prisoners from the "Falun Gong" movement and selling those organs to the wealthy-sick of the world. The annual number of transplants is hard to gauge accurately, but it is likely, based on a self-proclaimed number of 3500 deceased donor liver transplants, that totals of 8000–10000 total transplants from executed prisoners is a reasonable estimate.

The widespread expression of outrage at these practices and the looming 2008 Beijing Olympic games lead, in 2007, to legislation designed to control organ donation and transplantation, to prevent foreigners receiving Chinese organs and to ensure licensing of hospitals permitted to undertake transplantation. An allied decision was made to bring the final arbiter of the decision to execute an individual under the direct control of the courts in Beijing and not delegate it to the provincial level. The combined effect of these actions was positive in that the number of executions reduced, individuals were arrested for breaking the law (such as murderers selling organs surgically retrieved from their victims), 600 transplanting hospitals were reduced to around 167 licensed facilities and a few of those had their licenses revoked for breaking the law. The number of foreigners travelling to China for organs diminished and a number of countries, especially in the Middle East and Asia that had relied on Chinese venality to resolve their own incapacities in organ transplantation, focused instead on providing for their own citizens in their own country [17].

The current situation in 2014 is that control of commercialism remains a major policy concern. Foreigners have been transplanted in China more openly than in the year of the Olympics, no longer pretending to be Chinese through assumption of Chinese names. Extortion remains a concern, specifically that patients are kept waiting in China for an organ and charged enormous sums to advance their allocation of a kidney or liver, or pay for additional dialysis at high cost while waiting. Extension of organ donor sources to paid living kidney and liver donors is thought to have occurred, with a well publicized story in 2012 of a young man selling his kidney for an iPAD.

Concern for the stories of endemic corruption throughout the organ transplant trade have perhaps lead the new Chinese leadership to reinvigorate their control of organ sources and transplant programs. A new determination to turn to standard organ donors in intensive care has yielded more than 1000 transplants in the last year and many transplant programs are signing up to cease the use of executed prisoner organs [18].

The outside world is continuing to carefully observe the developments in China which, within the next decade, will probably surpass the United States as the country transplanting the most patients.

International associations

The Transplantation Society (TTS) has had, since its inception in 1966, a strong role in not only the scientific and educational aspects of the field but also in the legal, regulatory and ethical facets of this unique clinical practice. TTS and its membership have played a role in development of transplantation in almost every country of the world with a clinical transplant program. The International Society of Nephrology (ISN) has likewise had a major role in bringing education and capacity building to renal programs across the world and especially in emerging economies. Both societies have had a significant role in forging the professional view of the ethical

aspects of transplantation clinical practice, with ethics statements for membership and guidance documentation for their members.

TTS first developed a formal ethics statement on organ donation and aversion to the commercialization of the human body in the 1980s and has subsequently revised it on several occasions. The response to the problems presented by Chinese practices for example lead to a specific statement on interaction with Chinese transplantation programs promulgated in 2006 (see: http://www.tts.org/images/stories/pdfs/StatementMembs-ChineseTXProg.pdf).

TTS engaged with the World Health Organization as expert technical advisors, becoming a non-governmental organization in official relations with the WHO in 2006. The role of TTS was to assist the WHO in developing and consulting on the revision of the Guiding Principles. This was accomplished across all regions of the world and through three global consultations and resulted in the adoption of the principles as discussed above. This connection between professional associations and governmental and official international organizations, such as the WHO, is not seen as natural in official circles, since it is perceived that professional organizations usually have a conflict of interest, which prevents objectivity and their engagement simply enhances vested interests. That the WHO-TTS engagement was both relevant and important to the outcomes of the review of the WHO Guiding Principles, is a testament to the individuals on both sides of that collaboration.

Declaration of Istanbul

Creation of guidelines for professional clinical practices remain an important role for national, regional and international societies and there are many guidelines that are testament to that role in the field of organ donation and transplantation. It was out of this facet of work that TTS and ISN addressed the ethical and practical issues of organ donation and the rights of the organ donor, especially the living organ donor. A summit meeting of more than 150 individuals from 78 countries with backgrounds as diverse as philosophy, law, public administration and medicine, was convened in Istanbul in 2008. That meeting addressed a series of topics and created a declaration on organ trafficking and transplant tourism.

The resultant Declaration of Istanbul (DOI) [19,20] has been designed to stand beside the Declaration of Helsinki in guidance across both clinical practice and research. While the well-established Declaration of Helsinki protects the rights of human research subjects, the DOI protects the rights of human organ donors. The DOI contains four important definitions (Table 128.5) which provide guidance against which to evaluate specific instances or issues in question. The six principles and seven proposals contained in the DOI were designed to address the manner in which this world can escape from the denigration and actively destructive progression of transplant commercialism, the commoditization of the human body and the increasingly rampant preying by the rich on the poor and vulnerable communities of the world through the medium of healthcare.

The DOI has since been endorsed by more than 100 professional societies, national governmental and non-governmental organizations. A custodianship group has been formed to encourage implementation and taskforces of individuals from around the world focus on individual aspects of the DOI. The number of countries on active watch lists for indulging in transplant commercialism has reduced since 2008, the volume of illegal transplantation has decreased, but the driving force of long waiting lists and insufficient organs to meet the needs of the wealthy will continue to combine with poverty to create the deceptive but destructive illusion of a win-win solution which is in fact demonstrably and fatally delivers a lose-lose outcome.

Table 128.5. Definitions from the Declaration of Istanbul [19,20]

Organ trafficking	The recruitment, transport, transfer, harbouring or receipt of living or deceased persons or their organs by means of the threat or use of force or other forms of coercion, of abduction, of fraud, of deception, of the abuse of power or of a position of vulnerability, or of the giving to, or the receiving by, a third party of payments or benefits to achieve transfer of control over the potential donor, for the purposes of exploitation by the removal of organs for transplantation.
Transplant commercialism	A policy or practice in which an organ is treated as a commodity, including being bought or sold or used for material gain.
Travel for transplantation and transplant tourism	The movement of organs, donor, recipients or transplant professionals across jurisdictional borders for transplantation purposes. Travel for transplantation becomes **transplant tourism** if it involves organ trafficking and/or transplant commercialism or if the resources (organs, professionals and transplant centers) devoted to providing transplants to patients from outside a country undermine the country's ability to provide transplant services for its own population.

Table 128.6. A timeline for critical elements of global regulation of organ donation and transplantation

2007	USA — CMS transplant program Final Rules
2008	Declaration of Istanbul
2008	EU — European action plan on organ donation and transplantation
2010	World Health Assembly WHA 63.22 — WHO revised guiding principles on organ donation and transplantation

Summary

Transplantation is, no matter how clinicians may view it, one of the areas of clinical practice deemed, probably rightly, to carry not only great benefits but also great risks and challenges to civil society. For this reason it is more heavily and specifically regulated than most clinical work (Table 128.6). Without that oversight and legislation organ donation from deceased donors would have remained in legal limbo, community values could not have been engaged to support removal of organs after death, safe practices would not have been developed and supported, investments in workforce development and hospital infrastructure would have been more piecemeal that they are. Transplantation has emerged from a phase of expensive experimentalism through contested clinical applications and approaches, towards a phase where transplantation becomes a normal and accepted part of standard clinical care throughout the world. Co-operation and collaboration of governmental and non-governmental agencies with professionals remains the cornerstone of that remaining transition.

CHAPTER 129

Abdominal Solid Organ Transplantation Fellowship Training

Rachel C. Forbes[1] and Mitchell L. Henry[2]
[1]Department of Surgery, Vanderbilt University, Nashville, TN, USA
[2]The Ohio State University, Columbus, OH, USA

Introduction

Transplantation is, by its nature, a surgical endeavor; one that involves comparatively complex procedures on individuals with end-stage organ failure. This juxtaposition of surgical manipulation and grave illness has required that transplant surgeons exhibit exceptional technical skill and knowledge of underlying disease that arguably exceeds that of many surgical subspecialties. As transplantation has grown to become a standard treatment for most causes of end organ failure, the requirements for formalized training have become recognized and codified under the auspices of the American Society of Transplant Surgeons (ASTS). This chapter discusses the history of transplant fellowships, the process of fellowship selection, requirements for fellowship training in the US, innovation in education, and future prospects for transplant surgery trainees. Fellowship training for medical subspecialties is specifically addressed in Chapter 130.

History of transplant fellowships

In 1954, the first successful organ transplant was performed from an identical twin to his brother at the Peter Bent Brigham Hospital. Dr. Joseph E. Murray, a plastic surgeon, performed the recipient operation and Dr. J. Hartwell Harrison, a urologist, performed the donor operation. Over the following decades, transplantation continued to flourish as a specialty aided by the advent of potent immunosuppressants, particularly cyclosporine. It allowed for successful lung, pancreas, and heart transplants to occur during the 1980s. The availability of organs became and remains the limiting factor. In 1974, a group of surgeons, most without formalized transplantation training, set out to form the ASTS. They envisioned the ASTS would promote scientific scholarship, have a commitment to education, and recognize the welfare of transplant patients. The leadership of the ASTS initiated and, to this day, oversees surgical transplant fellowships in abdominal solid organ transplantation [1].

James Cerilli, president of the ASTS from 1980–1981, established the Education Committee as part of his vision to formalize the training certification process for transplantation. Dr. Cerilli initiated discussions with the American Board of Surgery, the American College of Surgeons, and the Residency Review Committee of the American Medical Association to establish and review transplantation training programs [2]. After much deliberation with these established administrative programs, it was decided that these established review processes were not the "right fit" for transplantation training programs and it was apparent that the ASTS would be the supervisory umbrella for postgraduate transplant education and would assume responsibility for the quality of transplantation fellowships. Dr. Cerilli notified programs interested in having a transplant surgery fellowship to submit an application to the Education Committee. Programs would then undergo a site visit by the Education Committee, which would make a formal report to the ASTS council to recommend approval of qualified programs. At that time, fellowship training focused on renal transplantation and candidates had to be certified by either the American Board of Surgery or the American Board of Urology. The duration of the program had to be at least 12 months with a volume of 35 new transplants per year. Alternatively, a program could be two years with a volume of 50 new transplants during that time.

In 1985, ASTS President A.P. Monaco formally extended the fellowship duration to a total of 24 months. He believed there should be an emphasis on basic science and immunology, and advocated for at least one year of investigational science within fellowship training. He also supported a review of each training program, conducted by the Education Committee, at least every two years. In 1987, Robert Corry, then ASTS president, established that all transplant centers have at least one transplant surgeon with at least one year in an ASTS approved fellowship or ASTS Accredited Program, which was essentially adopted as a requirement by United Network for Organ Sharing (UNOS). As liver, pancreas, and intestine transplants increased in volume, a minimum number of transplants performed to maintain certification was established.

From the 1980s to 2000s, programs trained transplant surgeons with relatively complete local control and little oversight from the ASTS on a national level. Eventually, Sandy Feng and others suggested to the then chair of the Education Committee, Mitchell L. Henry, that a match be established. The goal of the match was to provide assurance to the finishing resident that the program would

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

honor their commitments to train the resident and the resident would honor his/her commitment to participate in the program. With some controversy, the Education Committee recommended, and the ASTS Council subsequently approved, moving forward with an official matching program between the candidate fellows and the transplant programs to be administered by the National Resident Matching Program (NRMP).

Requirements for program certification

As per the NRMP, the objective of an Abdominal Transplant Surgery Fellowship Training Program is to develop proficiency in the surgical and medical management of patients with end-stage organ diseases amenable to transplantation. This objective should be achieved through a structured supplemental program for the study and treatment of these diseases in an accredited and properly supervised abdominal transplant surgery fellowship.

The recommended transplant volume guidelines for ASTS Accredited Programs require 75 transplant patients be available for each fellow in the program to serve as primary surgeon over the course of their training. Currently, a fellow must perform 30 kidney transplants, 45 liver transplants, 15 pancreas transplants, and ten intestine transplants to receive a certificate from the ASTS, as recognition that the fellow finished an approved fellowship program for that specific organ. Each fellow is responsible for submitting a case list with the minimum numbers in order to receive their certificate of training from an ASTS Accredited Program. UNOS requires that transplant surgeons complete essentially the identical number of cases outlined above to complete an ASTS-approved fellowship in order to be the director of an organ specific program. That is, to be a director of liver transplantation, an individual must have been trained in an ASTS-approved fellowship training program for livers and completed the requisite number established.

Philosophically, from the beginning, the leadership of the ASTS has felt strongly that the ASTS has the ability and responsibility to accredit the training programs. However, the individual leaders in the training programs are then responsible to ensure that the fellow has met all the criteria for completing the fellowship and that he or she is competent, safe, and ready to perform independently. As such, the ASTS does not supervise individual performance. Therefore, individuals are not certified by the ASTS to do particular solid organ transplants; individuals receive a Certificate of Completion from the ASTS that signifies they have successfully completed an approved training program. At present, 74 ASTS-approved transplant fellowship programs exist in the North America (Table 129.1).

Matriculation into a solid organ transplant fellowship

In 2005, with overwhelming favor by programs, solid organ abdominal transplant fellowships became part of a match program. Qualified candidates for the fellowship must have completed a residency that satisfied the educational requirements for certification by the American Board of Surgery or the American Board of Urology, or foreign equivalency. The NRMP conducts the match program for the ASTS. The NRMP clearly specifies that the applicant is responsible for contacting the programs they are interested in, which can be found on the ASTS website. Program directors review the candidate's credentials and are responsible for conducting their own interviews. Fellowship applicants rank their program preferences accordingly in their Rank Order List (ROL) and programs rank their applicants accordingly. Each June, on the third Wednesday, the NRMP runs the match and announces the results. Unmatched applicants and programs often participate in the post-match scramble to fill vacant positions. The NRMP Match Statistics since its inception in 2006 are listed in Table 129.2 [3].

Future directions for abdominal transplant surgery fellowships

Work-hour restrictions

The current supervision of the abdominal transplant surgery fellowships is still under the direction of the ASTS Education Committee, now known as the Fellowship Training Committee. At this point there are no current plans to include these fellowships in the Accreditation Council for Graduate Medical Education (ACGME) or have them reviewed by the Resident Review Committee (RRC), nor is it felt that this would be a simple accomplishment should transplant surgery ask to have ACGME-approved status. There has been huge focus on ACGME resident work-hours and this has not gone unnoticed by the ASTS. Fellows' schedules for time off are ultimately at the discretion of programs, but workload practices were formally addressed in guidelines issued by the ASTS in January 2008.

The guidelines state that:

1 transplant fellowship training programs have a responsibility to ensure safe and responsible work habits;
2 such habits will promote a healthy state of mind in the fellow and lay the groundwork for routines that will form the foundation for a successful career as a transplant surgeon; and
3 working to the point of exhaustion is both unhealthy for the fellow and potentially unsafe for patients.

Furthermore, due to the non-standard timing of transplantation, the guidelines enumerate the following four principles that should lay the groundwork for fellow workload practices:

1 programs should be mindful of the workload they are placing on fellows with respect to all facets of their responsibilities (e.g., clinic, operating room, inpatient service, phone calls, etc.);
2 the fellow must feel comfortable saying that s/he needs to rest;
3 the program's faculty must recognize it may be necessary to tell the fellow to rest; and
4 the impact of activities which are neither educational for a fellow nor require their level of experience needs to be scrutinized on an ongoing basis.

While these principles provide guidance, the following structural elements are considered requirements of ASTS-approved fellowships:

1 the training program should designate formal continuing medical education time for the fellows, including attendance at least one national meeting a year that does not count toward vacation time;
2 the fellow should be provided at least two weeks of vacation every year, and up to three weeks if only one week a year is designated for meeting time;
3 aggregate vacation and meeting time away from the training program should not exceed four weeks per year; and
4 the fellow should be off call and free from clinical responsibilities at least one weekend per month and at least two additional 24-hour periods every month, exclusive of vacation.

American society of transplant surgeons (ASTS) curriculum

Experiential learning based on organ transplant quotas for cases and the care of patients has been a requirement for trainees since the inception of postgraduate transplant training. It has been recognized that formal didactic teaching may be quite variable between programs. For this reason, the ASTS leadership charged the Curriculum Committee to develop a comprehensive, web-based curriculum, named the Academic Universe. The Academic Universe is composed of the following four features:

1 curriculum,
2 online surgical log,
3 credential storage, and
4 usage reports.

As per the ASTS, the curriculum is composed of discreet learning modules and defines the key areas of knowledge necessary for mastery of the field of transplantation surgery. Topics included in the Academic Universe include: immunobiology and transplantation research; pharmacology and immunosuppression; organ procurement; medical complications of transplantation; kidney transplantation; liver transplantation; pancreas transplantation; access for renal replacement therapy; public policy for organ allocation; ethics; and the economics of transplant. There are currently 13 units, containing more than 160 presentations that are approximately 20 minutes each. Each module includes a voice-narrated presentation; text summary; recommended references; self-assessment; and feedback mechanism. The ASTS now requires that fellows complete these online learning modules in addition to the established organ transplant quotas in order to receive their certificate of completion.

Additional certification possibilities

At many liver transplant programs, the liver transplant surgeons also perform hepatobiliary cases for a variety of malignant and benign indications. Fellows can garner significant experience by performing anatomic and non-anatomic hepatic resection, laparoscopic hepatic resections, pancreatic resections, etc. It has been suggested that future directions include a special certification for those individuals who complete an ASTS-certified program with significant experience in elective hepatobiliary surgery.

Since renal transplantation involves patients with end-stage renal disease (ESRD) and is a vascular surgery discipline, transplant surgeons have often performed vascular access for hemodialysis. Indeed with the growing number of patients with ESRD, vascular access procedures are rapidly approaching the second most commonly performed operation by general surgeons. Fellows may perform a large volume of vascular access cases during their transplant fellowship training, and it may be worthwhile to develop a program to signify advanced experience with vascular access for hemodialysis.

Critical care may also represent a significant portion of fellows' time during training, particularly the perioperative care of those patients with end-stage liver disease who subsequently undergo liver transplantation. A distinction in the certificate of these fellows for advance training in transplant critical care may also be explored.

Summary

Transplant surgery continues to grow in demand and success since the first transplants many decades ago. The ASTS has certainly been

an entity responsible for shaping transplant surgery, and can be credited with recognizing the need for formalization of transplant surgery fellowship training. Through many ASTS leaders' ideas and efforts, transplant surgery is a recognized subspecialty with a recognized and self-governing system for training transplant surgeons. Individual transplant fellowship programs and their leaders expend great effort to train future surgeons, researchers, and leaders in the field of transplantation.

CHAPTER 130

Medical Solid Organ Transplant Fellowship Training

Deirdre Sawinski and Roy D. Bloom
University of Pennsylvania Perelman School of Medicine, Philadelphia, PA, USA

Introduction

The expansion of solid organ transplantation over the past six decades has seen the field evolve from the early phase of a quasi-experimental clinical science targeting highly selected individuals, to a mature discipline that now impacts the lives of hundreds of thousands of patients and their families world-wide. From the very beginning, medical transplant subspecialists with specific organ system expertise have performed essential and complementary functions to their surgical counterparts. The primary responsibility of medical transplant subspecialists is to maintain optimal health of organ transplant candidates and recipients, including diagnosing and managing complications in this complex patient population. Transplant is an ever expanding field and the continued improvement in patient and graft outcomes has resulted in an increased demand for medical subspecialists with organ system-specific transplant training. This chapter discusses medical transplant fellowship training programs in terms of their history, current requirements and processes within North America, opportunities and future potential changes. Surgical training programs are discussed in Chapter 129.

History

The role of medical subspecialists in caring for organ transplant candidates and recipients dates back to 1954, when Peter Merrill, a nephrologist at the Peter Bent Brigham Hospital, and Harvard Medical School, was universally recognized as a critical member of the team that pioneered the first successful human kidney transplant. In the early days of transplantation, there was no formalized process by which physicians/trainees that were interested in becoming organ-specific medical transplant subspecialists could receive this training. Rather, trainees in the medical subspecialty fields of nephrology, gastroenterology, cardiology and pulmonology, in the course of fulfilling specialty-specific Accreditation Council for Graduate Medical Education (ACGME) requirements, received some basic instruction in transplantation medicine as part of their general subspecialty training. These ACGME requirements, by and large, remain in effect to this day in terms of general subspecialty training. In the case of General Nephrology training, for example, transplantation comprises approximately 10–15% of the overall two-year clinical experience needed to meet the eligibility requirements for subspecialty board certification. Historically, by completing the general nephrology fellowship training requirements, board-eligible or board-certified nephrologists would then be "qualified" to subsequently practice as transplant nephrologists. Such newly trained individuals would then typically acquire ongoing transplant experience under the mentorship and tutelage of more senior transplant clinicians.

In 1981, after their proposal to the incumbent American Society of Nephrology (ASN) leadership for an increased commitment to scientific and clinical transplant discourse was turned down, a group of transplant nephrologists decided that a separate society for transplant physicians should be formed. The decision by these charter members led to the founding of American Society of Transplantation (AST, formerly the American Society of Transplant Physicians, ASTP) in 1982. One of the major goals of the AST, now one of the largest of its kind in the world, was to promote and encourage education and research with respect to the science and clinical practice of organ and tissue transplantation and immunology. The first Annual Meeting was held in 1982 and subsequently a Fellows' symposium on Transplant Medicine was created in 1996. Two years later, the AST/ASN Renal Transplant Fellowship Training Program was created.

At the present time, transplant hepatology and advanced heart failure/transplant cardiology are the only ACGME-accredited medical transplant subspecialties for which (1) formal training requirements *must* be met in order to practice in the field, and (2) there is a formal board examination administered by the American Board of Internal Medicine (ABIM). The leaderships of most non-ACGME-accredited organ specific medical transplant subspecialties have recommended detailed requirements that *should* be completed in order for trainees to be considered to have been adequately trained in that subspecialty. Since these subspecialty training programs are not ACGME-accredited, this additional transplant-specific training is not enforceable for board-eligible and board-certified subspecialty physicians. However, United Network for Organ Sharing (UNOS) requires that these prerequisites be met in order for a physician to become the medical director of an organ specific transplant program [1]. Moreover, most transplant programs now preferentially look to recruit transplant physicians that have done additional organ-specific transplant training and have fulfilled the recommended requirements at a minimum, as a barometer of their experience and expertise. The requirements for each organ-specific medical transplant subspecialty are discussed in a later section.

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

General principles of transplant fellowship training

The major purpose of Medical Transplant Fellowship Training is to provide trainees with an intense and expansive experience in Transplantation, focusing primarily on their subspecialty-specific organ. Trainees can therefore, in a structured setting, acquire the necessary exposure and skills required to become independent transplant clinicians and scientists and to develop expertise in the field. To this end, medical transplant fellowship training may encompass instruction and exposure in the areas of organ allocation, transplant ethics, organ donation and procurement, candidate evaluation and waitlist management, HLA laboratory management, transplant surgery for recipients and donors where relevant, early and late post-transplant complications and care. In some cases, there may a requirement for scholarly activity as well.

Current organ-specific training requirements

Kidney

In 1998, the ASN and AST jointly established the AST/ASN Renal Transplant Fellowship Accreditation Program, administered by the AST/ASN Renal Transplant Fellowship Accreditation Committee. This Committee is charged with accrediting institutions that have developed programs to provide specialty training in kidney transplantation. Accreditation is based on in-depth site visits, both at initiation as well as at periodic intervals thereafter, and submission of annual reports on the transplant training program. The goal of the AST/ASN Renal Transplant Fellowship Accreditation Program is to provide a basis for the standardization of transplant training and a method of uniform documentation of education for those who wish to lead renal transplant programs. As part of this standardization process, the AST/ASN Renal Transplant Fellowship Accreditation Program has recently developed a minimum list of topics that an accredited transplant center is expected to cover during fellowship training [2] (Table 130.1). Transplant nephrology training is only recognized if the fellowship program is associated with a UNOS-approved renal transplant program in good standing and that is also affiliated with an ACGME accredited general nephrology fellowship. At the present time, approximately 60 transplant programs, mainly in the US and Canada, have been accredited by the AST/ASN Renal Transplant Training Program Accreditation Committee.

Table 130.1. Renal transplant fellowship topics. Data from [2] AST/ASN renal transplant fellowship accreditation program: transplant fellowship topics. www.a-s-t.org

Transplant immunology
Immunosuppression
• induction
• maintenance
Medical complications of transplant
• infection (CMV, BK, EBV)
• hypertension
• hyperlipidemia
• post-transplant hyperglycemia
• transplant associated malignancy
Organ allocation
Recipient evaluation
Living donor evaluation
Graft dysfunction
• rejection
• recurrent and de novo disease
Transplant outcomes
Pediatric transplantation
Ethics
Pancreas transplantation
Kidney transplant in other solid organ recipients
ABO or crossmatch incompatible transplant
Paired kidney exchange
Transplant pathology

Transplant nephrology fellows are required to have matriculated in an ACGME accredited general renal fellowship training program, and must therefore be either board certified or board eligible nephrologists. The supporting center must have sufficient renal transplant volume to provide ten new kidney transplant patients for each first year general nephrology fellow as well as 30 new kidney transplant patients per renal transplant fellow. Transplant nephrology fellows should follow at least 30 inpatients during their initial hospitalization for transplantation as well as at least 30 kidney recipients in the outpatient setting during the first three post-transplant months. Clinical training should focus on the immediate and long term care of kidney transplant recipients, and patient management should be conducted in conjunction with the surgical team. Transplant nephrology fellow participation should primarily be to provide medical care/support in decision making in regards to dialysis, hypertension management, post-transplant hyperglycemia management and immunosuppressive regimens. Transplant fellows must observe at least three organ procurements and at least three kidney transplant procedures. Transplant fellows must perform at least ten kidney transplant biopsies and must be familiar with the indications for biopsy, the technique, potential complications/management of complications, and the interpretation of pathology findings.

At the time of writing, there is only one transplant nephrology fellowship track. This track consists of 12 continuous months of training, of which at least six months must comprise dedicated inpatient clinical training while the remaining time should be spent in other related activity (e.g. experience in an HLA laboratory or another organ transplant service) or research pursuits in the area of transplantation. In essence, this track emphasizes "clinical" transplant experience and most trainees that are certified through this program end up in clinical transplantation. A proposal to create an alternative track that caters more to research-oriented trainees has recently been approved by both the ASN and AST boards but has not yet been implemented. This alternative "research" track would enable fellows interested in pursuing clinical or basic scientific careers in transplantation the opportunity to meet minimal clinical requirements in the course of a more intensive research focus. Upon successful completion of the renal transplant fellowship, the program director must provide a letter to each fellow stating that the fellow has met all of the above criteria and is capable of being certified as a UNOS transplant physician. Copies of this letter along with a statement validating the transplant fellow's participation in the required didactic sessions and patient management experiences must be sent to the AST National Office and to the graduating fellow.

Pancreas

Fellows training in pancreas transplant can be trained in either endocrinology or more commonly, nephrology. The fellowship requires one year of transplant training, of which six months should be dedicated to clinical activity and six months can be research based. Fellows must manage at least eight pancreas transplant patients and follow at least eight pancreas transplant outpatients for at least three months. Three or more of the transplant patients

followed should be a combined organ recipient (simultaneous kidney pancreas or pancreas after kidney). Fellows should observe at least three organ procurements and at least three organ transplants. As pancreas transplant biopsy is not routine at most centers, there is currently no procedural requirement for pancreas biopsy associated with pancreas transplant fellowship training.

Liver

Transplant hepatology fellowship programs are overseen by the ABIM via the ACGME. The ABIM is an independent, non-profit organization that is charged with evaluation of medical professional. The ACGME is responsible for accrediting post-MD medical training programs, via a peer-review process that is based on established standards and guidelines. Liver transplant fellows are required to have completed an ACGME accredited Gastroenterology fellowship before pursuing additional training in transplant hepatology. The transplant hepatology fellowship consists of 12 months of liver transplant-focused training; in order to meet all of the programmatic requirements, most of the year is dedicated to clinical training, with limited opportunities for formal research activities. Training must be completed at an ACGME accredited program that is affiliated with a UNOS sponsored liver transplant program. The sponsoring center must have interventional radiology facility capable of performing transjugular intrahepatic portal system shunts and the center must perform at least 25 liver transplants per year [3]. The program must provide formal didactic instruction in hepatology and transplantation as outlined by the ACGME [3] (Table 130.2).

Fellows are expected to participate in the primary evaluation, presentation and discussion of at least ten liver transplant candidates. As per the ACGME requirements, fellows are required to care for at least 20 liver transplant recipients, and must follow at least 20 recipients as outpatients for a minimum of three months. Fellows must also manage at least 20 liver transplant recipients who have survived more than one year post-transplant. UNOS recommends that at least three recipients should have combined organ transplants that include the liver [1]. Fellows are required to maintain their own continuity clinic throughout the clinical year. Fellows must observe at least three liver procurements and at least three liver transplants. Trainees are required to perform at least 30 percutaneous liver biopsies, must be familiar with the indications for biopsy, the technique, and the potential complications/management of complications. In order to gain experience in pathology, they must interpret the pathology findings of at least 200 liver biopsies (native and/or transplant). At the end of their transplant training, fellows may sit for the certificate of added qualification boards, and a passing grade on the Transplant Hepatology Certification Exam is required for practice. In the past, established practitioners without formal fellowship training but reasonable practice experience could also qualify for the board exam via the "Practice Pathway" but this mechanism has since been eliminated.

Table 130.2. Liver transplant fellowship topics. Data from [3] ACGME program requirements for graduate medical education in transplant hepatology. *www.acgme.org*

Acute and chronic end stage liver disease (ESLD)
Evaluation and management of ESLD patients
Complications of ESLD
• refractory ascites
• hepatic hydrothorax
• hepatorenal syndrome
• portopulmonary syndrome
• portal hypertensive bleeding
Hepatocellular carcinoma and cholangiocarcinoma
Chronic viral hepatitis
Fulminant liver failure
Transplant immunology
Drug hepatoxocity
Nutritional support
Diagnosis and management of portal hypertension
Ethics

Heart

As of July 2012, heart transplant fellowships are also ACGME certified. This fellowship is unique in that the training encompasses all aspects of the heart failure patient management and is not limited to transplantation alone. Fellows are trained in heart failure, cardiac devices (ventricular assist devices, pacemakers, implantable cardioverter defibrillators) and transplant. Fellows must have previously completed an ACGME-certified fellowship in cardiovascular medicine. The 12 month fellowship training period must be conducted at a UNOS member cardiac transplant program, performing at least 20 heart transplants a year. Training focuses mainly on clinical transplantation with limited time allotted for formal research activities, fellows are expected to become familiar with the management of acute and chronic heart failure, the use of mechanical assist devices, recipient selection and postoperative immunosuppression management. The ACGME has outlined didactic topics that are to be taught in the training period [4] (Table 130.3) and a continuity clinic is again required.

Fellows should evaluate at least five patients for heart transplant or mechanical assist device placement. Fellows must follow at least 20 heart transplant recipients in both the inpatient and outpatient settings. Of these patients, UNOS recommends that at least three should be combined organ recipients [1] (heart-lung), but this is not required by the ACGME. Trainees must observe at least three organ procurements and three heart transplant operations. Fellows should follow at least 50 recipients of implantable cardioverter-defibrillators as well as at least 30 recipients of mechanical assist

Table 130.3. Cardiac transplant fellowship topics. Data from [4] ACGME Program Requirements for Graduate Medical Education in Advanced Heart Failure and Transplant Cardiology (Internal Medicine). *www.acgme.org*

Transplant immunology
Immunosuppression
Medical complications of transplant
• opportunistic infections
• hypertension
• renal insufficiency
• transplant associated malignancy
Organ allocation
Recipient evaluation (implantable devices, resynchronization, transplant)
Acute decompensation of chronic heart failure
Graft dysfunction
• rejection
• cardiac allograft vasculopathy
Infiltrative and inflammatory cardiomyopathies
Pulmonary hypertension
Inherited xardiomyopathies
Heart failure due to:
• chemotherapy
• congenital heart disease
• pregnancy
Heart failure in other solid organ recipients
Arrhythmias
Hypertrophic cardiomyopathies
Transplant pathology

devices in both the inpatient and outpatient setting. In order to demonstrate technical proficiency, the fellow should also perform at least 40 endomyocardial biopsies, be familiar with potential complications, and be able to interpret pathologic findings. The fellow must perform at least 100 interrogations of implanted devices, be able to interpret the results and adjust device settings. Performance and interpretation of cardiopulmonary stress tests in this specific patient population is also required. Upon the completion of the fellowship year, trainees may sit for the ABIM Advanced Heart Failure and Transplant Cardiology Certification exam. Established practitioners in the field who have not completed an ACGME transplant fellowship but have a minimum of three years practice experience will be permitted to take the certification exam via the "Practice Pathway" through 2014.

Lung

While there are over 45 UNOS certified lung transplant centers nationwide, very few of them are large volume centers able to support a formal fellowship training program. Lung transplant fellowships are not ACGME accredited at this time, nor are they overseen by the International Society for Heart and Lung Transplant; usually UNOS guidelines for training are applied. Lung transplant training can be completed as an additional year after a pulmonary or critical care medicine fellowship, or it can be incorporated into the standard three year pulmonary fellowship training. The fellowship is usually of 12 months duration if training is solely clinically based, but if there is a research component to the training period can be as long as 24 months.

Per the UNOS requirements [1], fellows should be involved in the primary management of at least 15 lung or heart-lung transplant recipients. Of these patients at least half must be single or double-lung recipients. Fellows must observe at least three lung procurements and at least three lung transplant operations. Fellows should be familiar with the management of acute and chronic lung failure patients, the use of cardiopulmonary bypass, ventilator management, in addition to donor and recipient selection. Fellows should perform endobronchial biopsies, be familiar with potential complications and be able to interpret pathologic findings.

Infectious disease

The transplant infectious disease fellowship is also often, but not necessarily, an extra year of training embarked upon after completion of an ACGME-approved Infectious Disease (ID) fellowship. ACGME requirements for general ID training take up a substantial proportion of available clinical time, but if the general ID fellowship is three years (or longer) it may be possible to incorporate a formal Transplant fellowship into the general training period. Transplant-specific training should be 12 months with at least six months clinical exposure, and include both inpatient and outpatient clinical care. The Transplant ID fellowship program should be affiliated with a multi-organ transplant program with sufficient patient volume to expose fellows to a variety of disease processes. Ideally this center should have an active allogeneic stem cell transplant program as well. If the training center does not perform lung transplants, ID fellows should complete an elective rotation at a center performing lung transplants during their training. Per the recommendations put forth by the AST Infectious Diseases Community of Practice Educational Initiates Working Group [5], training should emphasize the major post-transplant opportunistic infections as well as infectious diseases related to specific organ failure (e.g., dialysis access, spontaneous bacteria peritonitis, cystic fibrosis, ventricular assist devices). Education should also incorporate: donor derived infectious complications; postoperative infectious complications; hospital acquired infections; fever of unknown origin; and prophylaxis strategies. Laboratory or research exposure should emphasize laboratory testing techniques for common post-transplant pathogens. There is currently no supervising board or society for Transplant ID fellowship and no additional board certification exams are required.

Multidisciplinary training model

Transplant patients are complex patients, with multiple co-morbidities and are best cared for using a multidisciplinary approach. During the training period it is important for the transplant fellow to learn how to function as part of the multidisciplinary team and to co-manage patients with both their surgical colleagues and often, physicians from other medical transplant subspecialties as well. The fellow should understand the contributions of all members of the team, including but not limited to transplant pharmacy, social work, nutrition, physical therapy, and nursing. The medical transplant fellow should focus on the medical issues of transplant recipients, namely immunosuppression dosing, management of transplant related complications and antibiotic dosing for liver/renal function.

Educational opportunities

Since a major goal of medical transplant fellowships is to acquire knowledge and skills about transplantation through a process of immersion, structured educational opportunities are critically important adjuncts. There are several educational meetings during the course of a year that specifically target medical transplant fellows. The most well-known and widely attended event is the AST Annual Fellows Symposium, where in-depth basic and clinical transplant topics are presented by faculty with distinct expertise in these areas. This Symposium, held over 2–3 days, provides a unique learning opportunity and incorporates some content common to all organ systems as well as organ-specific breakout sessions. There were over 125 registrants from various medical and surgical subspecialties for the 2011 Symposium. There are also smaller scale, industry-sponsored Fellows Symposia, where fellows have opportunities to present their research.

The American Transplant Congress is the annual meeting of the American Society of Transplantation and the American Society of Transplant Surgeons. Fellows can apply for Young Investigator Travel Awards to offset the cost of participation in the American Transplant Congress. These awards are applied for during the abstract submission process and awardees are selected based upon the abstract's scientific merit. The Transplant Congress is an excellent opportunity for fellows to be exposed to cutting edge scientific research in transplantation and meet other transplant professionals.

The American Society of Transplantation has numerous "Communities of Practice". Communities of Practice are self-selected volunteer groups within the AST that work on member generated projects and advocate for issues important to their area of interest. Membership is open to everyone and provides the opportunity for involvement in the AST to members at every training level. The Trainee and Young Faculty Community of Practice is one such group, and was created by young transplant professionals to network, interact with senior faculty, and to provide educational programs. In recent years the Trainee and Young Faculty Commu-

nity of Practice initiatives have included an Early Career Development Symposium, networking sessions at the American Transplant Congress and the creation a directory for employment searches.

Multiorgan transplantation

Dual organ transplant is a small but growing proportion of transplant recipients, with special selection criteria and considerations. Ideally fellows should have experienced evaluating these patients as potential transplant recipients and following them post-transplant. Indication for simultaneous transplantation and recognition of roles/input of the various organ transplant teams should be emphasized.

Pathology

Transplant fellows should be familiar with the diagnostic histological criteria for acute/chronic T-cell mediated and antibody mediated rejection, as well as the diagnosis of organ-specific recurrent versus de novo diseases. Clinico-pathological biopsy conferences should be encouraged.

Pediatrics

Most transplant fellows are internal medicine graduates and trained in the care of adult patients. However in the course of many transplant fellowships, the transplant fellow may encounter former pediatric patients that have transitioned to adult care. The transition from pediatric to adult care is often a difficult one for patients, and exposure to this patient population during training, with attention paid to their specific issues (e.g., autonomy, adherence, burden of chronic illness) will enable physicians to better assist these patients as they make this challenging adjustment to their care.

Procedures

All transplant fellows should be familiar with the indication for allograft biopsy, the procedure itself, as well as the complications of biopsy and how to treat them. Fellows should perform the minimum required number of biopsies to be certified by the ABIM, but additional biopsies are suggested to achieve mastery.

Living donors

The selection and care of living donors is an important part of the renal, liver and occasionally lung transplant training process. Transplant fellows should have clinical experience in the evaluation of living donors and actively participate in donor selection meetings. They should learn the absolute and relative contraindications to living kidney and liver donation, with an emphasis on immediate and long term risks to donors. Fellows should be involved in the immediate postoperative care and be familiar with the most common surgical complications. Fellows should also follow donors at their routine postoperative outpatient visits.

Funding

Funding for trainees is a growing concern in medicine in general. Since most transplant fellowships are not ACGME certified and since this training is considered over and above general fellowship training requirements for most subspecialties, transplant fellows are not considered "true trainees" and are therefore not eligible for funding via Centers for Medicare (CMS). A variety of approaches has been used to support medical transplant fellowships. Unrestricted educational grants, once a major mechanism for supporting medical transplant fellows, are becoming obsolete in the era of increasingly stringent pharmaceutical industry guidelines, as well as the widespread economic downturn. A more common funding mechanism that has emerged to support medical transplant fellow training is the hiring of trainees into very junior faculty level positions (e.g. instructors). Since these individuals are usually board-eligible or board-certified, they can bill for the clinical services that they provide, structured in a manner that enables them to support their salary. In the future, when/if a research track for medical transplant fellows is formally implemented, the clinical component of the training could be covered within the restrictions of a developmental or training research grant. An additional avenue that may occasionally present itself is the use of philanthropic contributions to support medical education efforts.

Research

During the transplant fellowship, fellows are encouraged to participate in transplant related research. This may be original contributions to transplant science or may involve rotating in the HLA lab in order to familiarize them with the laboratory techniques used in clinical medicine. For those wishing to have an original research project there are three avenues of investigation open to them — clinical research, basic science research and translational research. While original research is ideal, fellows may not have the requisite time or scientific training to make this feasible during the training period. Fellows should be encouraged to write review articles, case series and single-center retrospective data reviews if more formal project are not possible, and writing exercises provide an invaluable opportunity for faculty mentorship of fellows.

Work hours regulations

Fellows who are part of an ACGME accredited transplant fellowship are required to adhere to ACGME work hours regulations (no more than 80 hours total per week, no more than 24 hours per shift and at least one day off per week). The majority of medical transplant fellowship programs are not ACGME accredited and are therefore not subject to these regulations. Sensitivity to the needs of medical transplant fellowship trainees is recommended and teaching programs are encouraged to follow ACGME guidelines.

Unaddressed needs

UNOS and ACGME training guidelines emphasize the clinical and research aspects of transplant fellow training, but practical issues, such as the transition to independent/attending practice and the search for employment are often left unaddressed. Transplant fellowship is an in-between state; fellows are board-certified or board-eligible in their general subspecialty but in the process of obtaining additional transplant related expertise. The transition to independent clinical practice can be challenging, and mentoring by more senior faculty is beneficial. The expectations and responsibilities of attending practice are enormous and senior faculty often serves as a model for interactions with colleagues, other trainees and patients.

Employment after fellowship concludes is of great concern to trainees. The path to an academic position is often obscure.

Senior faculty mentorship can be instrumental to guiding this process, as is networking through society memberships and meeting attendance.

Summary

Medical transplant subspecialists with specific organ system expertise are essential to a successful transplant program. As the field of solid organ transplantation has grown, training for transplant clinicians has evolved into a more structured and organized enterprise, with uniform training criteria and expectations. The ACGME has joined UNOS in its regulatory role. Fellowship training now reflects the more scientific and interdisciplinary nature of modern clinical transplantation.

CHAPTER 131

Transplantation in General Medical Education

Rowena Delos Santos[1] and Douglas J. Norman[2]
[1]Washington University in St. Louis, St. Louis, MO, USA
[2]Oregon Health & Science University, Portland, OR, USA

Introduction

According to Organ Procurement and Transplantation Network (OPTN) data [1] from December 2011, approximately 528 000 patients have received a solid organ transplant between January 1988 and December 2011. In addition, each year adds another 28 000 new transplant recipients. These patients ultimately receive their care from a myriad of practitioners throughout their post-transplant lives. This includes transplant specialists, but also involves general internists and surgeons, family physicians, subspecialists, residents in medicine and surgery, nurses, pharmacists, midlevel practitioners, and medical students. With the growing number of solid organ transplant patients in the community, it is imperative that providers have a baseline understanding of the complexity of these patients, their medications, and their care.

Knowledge of the nature of generally disseminated transplant knowledge is useful to the transplant specialist in that it provides a reasonable expectation of what can perhaps be delegated outside of the transplant center. In this chapter we discuss the current general medical education in transplantation for several groups of medical providers, and then discuss further methods of education and training possibilities. The groups of medical providers that will be discussed include: general surgery residents, internists, subspecialists (including nephrologists, cardiologists, gastroenterologists/hepatologists, pulmonologists), nurses, pharmacists, and medical students. The training requirements for transplant surgical and medical specialists are covered in Chapters 129 and 130, respectively. The training requirements for specialized transplant nurse coordinators and transplant pharmacists are covered in Chapters 122 and 123, respectively.

Current education

General surgery residents

General surgery residents have several required rotations to complete prior to their matriculation as general surgeons. These include surgical procedures and management of the abdomen, breast, endocrine system, alimentary tract, skin and soft tissues, surgical critical care, head and neck surgery, trauma and non-operative trauma, pediatric, head and neck, vascular, and surgical oncology [2]. There are rotations that might exist at institutions that are not classified into general surgery residency requirements, including cardiac, neurologic, orthopedic, urologic, gynecologic, and burn rotations [2]. Currently, a rotation in solid organ transplantation is a requirement under the US Accreditation Council for Graduate Medical Education (ACGME) for general surgical residents [2]. The general expectations outlined for a rotation in transplantation include an understanding of immunosuppression and immunology as well as the general surgical management of transplant patients before, during, and after their allograft placement.

However in recent years, especially in the last decade with the implementation of resident work hour limitations, there have been concerns over the ability of residents to remain active members of the transplantation services. In coming years, a change might occur in the transplant service, with the previous ACGME requirement of a transplant rotation transitioning to a transplant experience [2]. The interpretation of this may differ among training centers. Training programs that perform large numbers of transplants might not adjust the number of residents on their transplant services, while other smaller centers might not require all their residents to rotate through the service. Other training programs that do not perform transplants might choose not to send their residents to other centers to rotate, as previously done.

In addition to this, resident feedback regarding the transplant experience has led to concerns over the need for changes to the rotation. Residents who commented on the rotation have identified several areas for improvement (Table 131.1). Among their major concerns are high service requirements and a low perceived educational benefit [3]. In addition, low numbers of operative procedures due to the difficulty obtaining cases from surgical transplant fellows can affect the education of residents [3]. In an effort to improve the general surgical resident experience on the rotation, the American Society of Transplant Surgeons (ASTS) has made recommendations to enhance the training experience for general surgery residents assigned to the rotation [3]. Several significant recommendations have been made and their implementation is underway to improve residents' training (Table 131.1).

First, the identification of a specific transplant attending for the team will help guide the education experience for the residents on rotation, including didactics, inpatient and outpatient clinics. Educating the transplant team members on expectations for the service will help define roles for each member. Including physician extenders to help with patient care will help decrease the service load of the residents, thus allowing them more operating room time.

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Table 131.1. Transplant surgery rotation issues and recommended changes. Adapted from: [3] Fryer, JP and Magee, JC. Optimizing the surgical residents' educational experience on transplant surgery. *J Surg Educ.* 2009;66:196–200.

Rotation issues
1 High service requirements in the era of work hour limitations
2 Low perceived educational benefits
3 Competitiveness for cases between residents and surgical fellows
4 Low interaction with attending transplant surgeons
5 Residency training centers lacking transplant programs send residents to other centers
Recommended changes to improve rotation
1 Identifying a specific transplant surgeon as attending for the rotation to help guide learning
2 Maintain ongoing feedback system for resident and program improvement
3 Establish designated surgeries to optimize learning opportunities for residents and sustain educational experience
4 Physician extender addition to the team to assist with patient care
5 Educate all team members regarding expectations and the importance of teamwork

Establishing a designated minimum number of transplant surgeries for residents and fellows will help optimize learning opportunities during the rotation for both types of trainees [3]. There have been studies evaluating the learning curve for residents and their proficiency at performing procedures, as indicated by the decrease in operative time for these procedures. According to one study, which investigated performance of laparoscopic donor nephrectomies, residents had a statistically significant improvement in their surgical performance of this procedure after participating in 13 surgeries (assistant in the surgery) or six surgeries (as surgeon who performed the exposure and mobilization with ligation of the venous branches and ureter) [4]. In a specialty that has a history of variable numbers of cases, having an improved quality of teaching and a minimum achieved number of procedures will help enhance the learning experience of surgical residents.

The classic model for educating residents involves a multidisciplinary center at which the resident is exposed to a high volume of patients, and through immersion the skills necessary to independently care for future patients are learned. This model is changing with the new work hours and emphasis on standardized quality of education. There has even been some debate over whether organ specific centers, such as a hepatobiliary and liver transplant centers and other organ focused centers, would affect the training of post graduate surgical residents [5]. It is especially important for surgical fellows to focus their training in their respective field at a specialized center, as these centers provide focused care to patients. However, this is not necessarily the case for general surgical residents. Creating centers dedicated to a disease or organ would decrease the presence of these patients in hospitals where residents train, thus limiting or even eliminating their exposure to these complex patients [5]. This is true especially for rotations that are not required by ACGME. Though specialized centers do have benefits for fellow trainees and can provide specific care to their patients, the training of general surgery residents could suffer, and hence their ability to care for these complex patients in the community could also suffer. At least for now, the classic teaching institution for training residents remains the mainstay for most programs. Arguments for and against specialized centers continue, and the two competing models of training remain.

In this new era of surgery and surgical residency where new procedures and equipment are developing, the general surgical trainee requires education in multiple areas prior to their matriculation. The exposure of surgical residents to solid organ transplantation allows them experience in several areas important to their training as surgeons.

First, the transplant rotation provides surgical residents the opportunity to perform vascular procedures during each transplant surgery. The vascular anastomoses required for each organ provides residents the ability to perform open vascular anastomoses. In addition, general surgical procedures such as intra-abdominal and alimentary tract procedures are also performed on transplant patients after their initial transplant surgeries. Especially useful for resident training is the treatment and management of end-stage organ failure and their related surgical procedures, such as fistula creation for renal transplant candidates and hepatobiliary procedures for those with liver disease [6].

Second, the rotation provides ample opportunity for interdisciplinary interactions when treating these patients. As a field that provides care for very complex patients, transplantation virtually requires a multidisciplinary approach to care. This approach to patient management is important to the educational growth of a resident surgeon.

Third, residents develop an understanding of immunology, immunosuppressive drugs and the management of patients who are immunosuppressed [6].

Fourth, residents are able to perform surgeries while on the transplant service that they would not have the opportunity to perform otherwise, such as laparoscopic or open donor nephrectomies. These experiences help make them better prepared to care for the surgical complexities that accompany a patient with any solid organ transplant.

Internal medicine

Unlike their resident colleagues in general surgery, internal medicine residents do not currently have a rotation requirement for solid organ transplants. If required for service needs by the institution, the ACGME limits residents to a maximum of one month of service on transplantation over the course of their three years of residency [2]. Some residency programs might have inpatient services dedicated to specific solid organ transplants, and so might have residents rotate through. Other residency programs might not have dedicated services for transplant patients, and so the residents might only obtain experience of caring for transplant patients through individual transplant patients who are admitted to their team.

Some residency training programs have dedicated organ medical teams, such as gastroenterology with hepatology, renal, pulmonary, and of course cardiology. This is in addition to their general medicine teams. On these subspecialty teams, a variety of patients with organ specific diseases are admitted to the service, including patients with solid organ transplants. On these services, residents can have a significant portion of their census composed of transplant patients. They would be able to focus their attention on the organ transplant patients to improve their knowledge of the pathophysiology, infectious complications, and medication interactions for this population of patients.

For residency programs that divide all patients between general medical teams, residents may have fewer clinical interactions with transplant patients. The lack of exposure may lead to internal medicine graduates who are less comfortable managing these complex patients in their careers. This is not an ideal situation given that the numbers of solid organ transplant patients is increasing, making the likelihood higher for these patients to present as inpatients or

outpatients. This can lead to higher risks for over or under dosing of medications, possible interactions between newly prescribed medications and immunosuppressants that can lead to adverse outcomes in these transplant patients.

There are virtually no formal studies that have investigated the education of internal medicine residents in the care of solid organ transplants specifically. Much of their education on transplantation is likely in the form of didactics presented by transplant faculty. Residents may supplement their education by reading relevant texts and articles presented during the didactics. Internal medicine residents' education on these topics is also dependent on their attendance to scheduled didactics. There has been a previous study evaluating the attendance of residents to didactics and the association with scores on the internal medicine board exam [7]. This single center study found that scheduled mandatory didactics were only attended by an average of 34% of their residents, and improved whenever lunch was provided [7]. However, attendance had no correlation with residents' scores on the American board of internal medicine certification examination [7]. This study underscores the need for improvement in our presentations of didactics, or modification of didactics into a more interactive presentation, similar to a problem-based learning method.

Subspecialists

The ACGME does not mandate transplant rotations for gastroenterology/hepatology, pulmonology, or cardiology fellows [2]. However, each subspecialty does require formal education in their respective fields. This could be though continuity clinics, in-patient consults, or even didactics if the training facility does not perform transplants. Each of these specialties offer dedicated transplant fellowships to train individuals interested in gaining expertise in transplantation for their respective organs. Table 131.2 lists the different subspecialties with required clinical training service months for transplant and the presence of specialized training in transplant.

There has been a movement among subspecialties toward requiring specific transplant certification for physicians seeking special training in transplantation. For instance, after seven years of preparation, the board initiated the transplant hepatology certification examination in 2006 [8,9]. Between 2006–2010, examinees who had prior experience with transplants and liver diseases could take the exam without enrolling in a transplant fellowship. However, beginning in 2011, all applicants for the certification exam must have completed a transplant hepatology fellowship [8,9]. This could potentially lead to some gastroenterologists/hepatologists in the community feeling less comfortable with caring for complex hepatology or transplant cases. This would potentially have the effect of the community gastroenterologists referring all cases to hepatology specialists, which would overload the hepatologists' referral clinics.

Table 131.2. Subspecialties and required transplant rotations and specialized training

Subspecialty	Required transplant rotation during general fellowship training	Specialized fellowship training in transplant
Gastroenterology/hepatology	–	X
Cardiology	–	X
Pulmonology	–	X
Nephrology	X	X

There was a recent task force formed of representatives from several gastroenterology societies who provided recommendations on the training of gastroenterology fellows. They specifically advocated that the general fellowship remain a gastroenterology/hepatology fellowship [10]. They also specifically recommended a modification to certification in transplant, where a fellow would normally complete the general fellowship in three years, then have another three years of practice focusing on transplant alongside a transplant mentor. The first maintenance of certification would be after the three years of transplant work where an individual could re-certify for gastroenterology and have what they define as a focused recognition of transplant hepatology [10].

Cardiology is another subspecialty that has just initiated a new certification examination, with the plan similar to gastroenterology/hepatology. The first examination was just administered in 2010. In 2012 training for advanced heart failure and transplantation at ACGME accredited facilities began. [2]. This training will add another twelve months of training to the already required 36 months of training for those who wish to pursue a career in advanced heart failure and transplantation [2]. A committee was formed and defined the training and expected knowledge and skills of an advanced heart failure and heart transplant specialist. A heart failure/transplant specialist would be able to assist other practitioners who care for patients with less severe heart failure, assist with the advanced care, and cardiac devices that some of these patients require, and assist in the evaluation of patients for candidacy of heart transplantation [11].

The exception to the subspecialties is nephrology, which outlines specific ACGME requirements for transplantation training during a nephrology fellowship. First, ACGME requires that fellows have at least two months of transplant clinical experience on an active transplant service, as well as incorporate procedures such as transplant biopsies into the rotation [2]. This includes the evaluation of both pretransplant patients and living donors. In addition, fellows should have the opportunity to follow at minimum ten new post-operative transplant patients. This provides them the experience of managing their patients' immunosuppressive medications. Fellows should also have at least twenty post-transplant patients who they follow for at least three months in a continuity clinic [2]. Besides the required clinical months of transplantation during general nephrology fellowship training, there is another twelve months of focused clinical transplantation training for those who wish to gain additional instruction.

The rigorous and well defined expectations for nephrology fellows in transplant training are understandable. Kidney transplantation has the longest history, thus renal transplant patients are more abundant in the community, and nephrologists are much more likely to encounter kidney transplant patients in their facilities than are other subspecialists to find transplant patients in theirs. In addition, the general nephrologist is the physician who usually has the longest continuity with their patients, and can follow these patients from their diagnosis of chronic kidney disease, to initiation of dialysis, to transplantation, and at times, back to dialysis in the event of kidney transplant failure. Unlike other specialties whose organ is a life-saving organ, renal patients can survive without kidneys by undergoing dialysis. Thus, it is now becoming more common to have patients who have had more than one kidney transplant in the past. The increasing numbers of transplant patients highlights the need for practitioners with the knowledge and skills necessary to care for these complex patients. It is understandable that subspecialties are moving toward requiring further training for

advanced care for their transplant patient population. Transplant fellowship education is discussed separately.

Nurses

Little data exist regarding the general education of nurses in transplantation. Much of the nursing management for transplant patients occurs during the pre and post-transplant period, where nurses play an integral part in the management of these patients. In addition, the care for these patients immediately postoperatively requires intensive care units in most cases, with the exception of perhaps kidney transplant patients. Several years ago, significant changes to nursing education regarding transplantation and donation were made during a five year long program [12]. Nursing students were educated through the use of pamphlets, booklets, and direct interaction with transplant nurses and other team members. In addition, nursing schools have implemented nursing rotations in transplantation for centers that perform transplants, and included transplant topics on the nursing certifying examination [12].

Pharmacists

Over the last several decades, it has become increasingly evident that specialists, including pharmacists dealing with transplant patients require training beyond the typical training period. Prior to the 1990s, pharmacists who wished to gain further education on transplantation pharmacology usually learned through experience while working [13]. Over time there has been a transition to increased formal training to attain transplantation specialization through a year of general pharmacy residency followed by another year of transplant focused residency [13]. This transition is likely due to the requirement in 2004 by both the United Network for Organ Sharing (UNOS) and Center for Medicare Services (CMS) to have an identified pharmacist within the institution with defined roles and responsibilities as a member of the transplant multidisciplinary team [13].

The importance of transplant pharmacists in the care of transplant patients has been studied previously. Their education and expertise in medications and pharmacotherapy is exceedingly helpful in the inpatient and outpatient setting. Transplant pharmacists are invaluable in patient and family teaching about medications as well as with medication compliance prior to and after discharge [14,15]. In addition, pharmacists provide important recommendations for medication dosing and information on drug-drug interactions to help prevent potential adverse events [15,16].

Medical students

There has been some research evaluating the education of medical students about transplantation. Many of these studies have been surveys on medical students and their knowledge and exposure to transplantation [17,18]. One study conducted in the UK used a questionnaire to evaluate fourth year medical students' knowledge of transplantation. Approximately 54% of the students completed the survey, and of those students, only 42% ever rotated through one of the hospitals that performed transplants [17]. Of the total number of students, only 14% had ever witnessed a transplant surgery [17]. Only 46% of students ever examined a patient with a transplant, while 43% could identify the correct incision and placement of the allografts [17]. Two-thirds of students understood that several types of donors were available for transplanted organs [17]. Only 53% of students could identify at most one immunosuppressant [17].

A similar study was conducted among three different medical schools in Ohio, administered to a total of 537 first and second year students [18]. The authors used a previously validated questionnaire and had a high response rate of 93%. Only 11% of students received any formal education on transplantation and donation prior to medical school, and only 22% ever received education up to that point in medical school training. Of those who completed the survey only 8% had ever cared for a solid organ transplant patient [18].

Another cross-sectional study conducted in Germany evaluated levels of knowledge regarding transplantation and donation among 1645 medical students in their early and later years of education, and among physicians from multiple fields [19]. This study had a response rate of 67% and found that knowledge on transplantation and donation increased with an increasing level of education. In addition, those with a higher education level tended to be more comfortable with approaching families for organ donation. This number, however was only 8% of the total population studied, and among the physicians, only 14% perceived themselves trained adequately to approach families [19].

These studies show that the target stage for introducing the key concepts for transplantation to physicians is throughout the early years of medical school. In addition, the reinforcement of these key concepts throughout residency, and/or fellowship training will help solidify the knowledge and confidence of practitioners in the care of solid organ transplants. As the majority of providers are not transplant specialists, all providers should possess a baseline knowledge and understanding of transplantation to provide the appropriate care or refer to subspecialists who can assist with the care of transplant patients. The following section provides suggestions for education throughout medical training to forge a lasting knowledge of the management of solid organ transplant patients.

Further methods for education and training

This section describes the ways in which transplant concepts can be incorporated into general medical education at several levels of training. Included are education and training in medical school, residency, subspecialties, and continuing medical education. These are suggestions, and are not necessarily implemented throughout institutions that teach individuals who care for transplant patients.

Medical school

The proper integration of solid organ transplant training into general medical education should begin in medical school. Medical students are most curious and eager to learn, thus making these years the most impressionable. There are currently two methods of teaching students during the first two years, either lecture based or the newer problem based learning. Core transplantation concepts as listed in Table 131.3 can be introduced into both systems of learning.

If a school maintains lecture based learning through the major core courses of anatomy, physiology, biochemistry, immunology, pharmacology, ethics, microbiology and pathology, transplant related topics are easily integrated into these courses. For instance, discussions on the locations of allografts can be discussed during anatomy. Pathology and Physiology are the ideal courses to discuss the diseases and end-stage appearance and function of transplantable organs. Longer term outcomes related to malignancies and cardiovascular disease can also be introduced during the pathology and physiology component. The importance and central ideas

Table 131.3. Suggested core transplantation topics for introduction to medical students

Transplant statistics – waiting list and recipient lists
Indications for transplantation
Improvement in quantity and quality of life after transplantation
Recipient evaluation, selection, contraindications for transplant (some organs, donor evaluation)
Donor-recipient allocation
Human leukocyte antigens and histocompatibility matching
Transplant surgical procedure and surgical complications related to transplanted organ
Immunology, types of rejection, pathological diagnosis
Immunosuppressive medication and side-effects
Significant drug-drug interactions with immunosuppressive medications
Infectious complications after transplantation months to years post-transplant (viral, bacterial, fungal)
Long term risks for malignancy and cardiovascular disease in transplant patients
Recurrence rates of disease in the transplanted organ

behind organ transplant immunology, histocompatibility and matching, and rejection should be introduced during the core Immunology course. Subsequently, the concepts behind immunosuppressive medications and their mechanisms of action and side effects can then be discussed in depth in the Pharmacology course. The Microbiology course could be used to introduce the students to concepts in infectious diseases, both common and opportunistic. Lastly, due to the significant ethical issues that arise with organ donation, students can have engaging discussions regarding the ethics surrounding transplantation and tissue donation.

When students attend medical schools that have adopted a problem based curriculum, students can also be effectively introduced to and instructed in solid organ transplantation. An example of how transplant concepts can be incorporated into a problem based learning system, is a case of an end-stage renal disease patient on hemodialysis who comes in to receive a renal transplant. The case can discuss the anatomical position of both the native kidneys as well as the allograft. Following this, the case can discuss the immunology surrounding recognition of self and non-self antigens, as well as types of rejection. The pharmacology, mechanisms of action and significant drug interactions of the various anti-rejection medications can then be discussed. If one wanted to extend the case further, it could continue with the patient presenting several weeks or months later with an infection. The students could then discuss the differential for types of infections, both common and opportunistic, as well as medications and potential interactions with immunosuppressive drugs.

Upon students' introduction to the wards, multiple different services could help educate them in caring for solid organ transplant patients. Whether the students are on a surgery or medical service, or even on the subspecialty services, they can gain further experience in treating and managing solid organ transplant patients. The various aspects of the care for transplant patients can be learned through the management of several patients by the student. The student will be able to read about the history, medications and pathophysiology regarding the transplanted organ and assist with formulating an appropriate plan for managing the patient with the background information that they have learned previously in the first two years of their medical school instruction.

Some clinical service months for students can provide better exposure to transplant patients than others. For instance, the infectious disease consultative service can be regularly requested to evaluate transplant patients with infections to provide guidance on antibiotics. The gastroenterology/hepatology, nephrology, pulmonary, and cardiology services may also have ample consultations on transplant patients. In addition, the dedicated transplant clinics for these subspecialties allow for immersion of students into the care for these patients. Adequate exposure of medical students to solid organ transplant patients will improve their recognition of the need for medication reconciliation and close follow-up, as well as increased vigilance for infection prevention and health maintenance.

Internal medicine

The lack of data regarding the education of internal medicine residents in transplantation topics has already been discussed. Also previously presented is the low numbers of residents attending formal didactics, where much of the formal education is usually presented. Methods for improving didactic attendance, or changes to didactic style can be done to improve the attendance of residents. Usually, formal didactics are presented by faculty in each clinical division, where relevant topics, including transplant didactics, can be discussed. The didactics covering transplantation should provide information on the indications and contraindications for transplantation, advantages of transplantation, basic immunology, human leukocyte antigen (HLA) matching and histocompatibility, immunosuppressive medications, transplant rejection, infectious complications, long term outcomes and management, similar to that presented to medical students, but more in-depth than provided to the students.

The above topics are complex enough to subsume hours of didactic teaching. However, given the time constraints provided for these sessions, focused presentations should be given on the more clinically relevant topics that residents will require to care for solid organ transplant patients. For instance, focused lectures on immunosuppressants and their common interactions and the need for dose adjustments can provide valuable information. In addition, another didactic discussing infectious complications and the differential diagnosis for transplant organ dysfunction, including rejection, should also be discussed.

Several previously identified factors can adversely affect resident attendance. A previous article has provided methods of diagnosing and classifying the etiologies of lectures that are unable to adequately deliver their material to their audiences [20]. Some of these factors include poor judgment in didactic topic, poor choice of lecturer, overestimation or underestimation of audience baseline knowledge, poor organization of the didactic, and poor delivery of the lecture material [20]. Residents continue training for three years, making some didactics repetitive. However, as much of learning tends to be through repetition, a lecturer who presents the same material that has difficulty engaging their audience will eventually have a waning attendance. Given this, another shortcoming that some lecturers and presenters may have is the inability to obtain and adjust their presentations according to audience feedback [20]. Those who give didactics to residents should regularly solicit feedback with the intention of improving the presentation for the following year.

There are emerging methods for improving resident attendance through active participation. An example is to incorporate a mechanism of participation with the use of anonymous audience responses. This allows the residents to absorb information and review their knowledge within the presentation thus reinforcing what was just presented. Residents may also find that this system allows them more freedom to express their thoughts without being

the focus of attention [21]. These response systems can also lead to further questions and discussions by residents who will then become more curious and request clarification or further information [21]. One study that evaluated the utilization of an audience response system found that their audience was much more engaged in the discussion than previously. The audience also had the perception that they comprehended the material more when using the response system [21]. There are caveats to designing questions using the interactive response system. Recommendations for formulating questions are reviewed in several articles [21,22]. Some recommendations include creating questions that are brief and easy to read without overly complex answers, and to use questions for emphasis and discourse [21,22]. One important recommendation is to design the presentation and questions with time enough for discussions throughout the didactic [21,22]. A group in the UK has provided a guide to lecturers who are preparing presentations [23]. Their suggestions include improvements in methods of lecturing, styles of presentations, the skills necessary to present a clear didactic, and uses of audiovisual material and handouts [23].

Educators should also recognize that others may have different preferences for learning. Some residents may learn better through repetitive self-study than through didactics. In these cases, lecturers can post their didactics onto an on-line resource site or folder accessible to residents. These lectures would require updating each time the presentation has occurred to remain current. Others could post recordings of their lectures along with a copy of the slides as an on-line resource. A folder of seminal articles for transplantation can be created to provide residents with additional resources to review independently. On-line interactive tutorials have recently become more common as education tools.

General surgery

General surgery residents' education in transplantation is undergoing fluctuations with the potential changes in ACGME requirements. A rotation in transplant may no longer be required and some residents might not have an opportunity to rotate through a transplant service. Other residents may have an abridged experience on the transplant service rather than the typical several week rotations.

There have been concerns over the education of general surgery residents. More procedures that were previously thought to be under the auspices of general surgery residency training are slowly becoming part of the fellowship training realm. For instance, some general surgeries such as cholecystectomies and appendectomies are becoming surgeries that fellows in a minimally invasive gastrointestinal surgery fellowship increasingly perform. This is unfortunately a result of several factors. Many additional fellowships that are based in general surgery (e.g. minimally invasive gastrointestinal surgery, breast surgery, surgical oncology, transplantation, trauma) have become increasingly common [24]. Due to an increased number of fellows performing surgeries, more residents feel that they require specialized training. In fact approximately 70% of residents seek subspecialty training in surgery after completion of their general surgery residencies [24].

The number of logged procedures for general surgery residents has been closely followed. One study looked at the number of procedures that were completed by graduating residents that program directors believed were most important [25]. In this survey of 254 residency program directors, the response rate was 45%. The authors found that of the 121 surgical procedures considered core procedures requiring competency by the end of their training, residents performed 68% of them less than five times during their residency [25]. Due to concerns over the education and training of surgery residents, a committee composed of several key stakeholders was formed in 2002 to address concerns and offer solutions [26]. After this, they formed a consortium called the Surgical Council on Resident Education (SCORE) whose purpose is to continue to improve residency education in general surgery [26,27]. SCORE members include representatives from the American Board of Surgery, American College of Surgeons, American Surgical Association, Association of Program Directors in Surgery, Association for Surgical Education, the Residency Review Committee for Surgery of the ACGME, and the Society of American Gastrointestinal and Endoscopic Surgeons [27]. Since their formation, SCORE has been making recommendations to improve the education of surgery residents through the creation of a national curriculum for educating trainees [27].

Key recommendations by SCORE regarding transplant education for general surgery residents include an understanding of the indications for solid organ transplantation, determination of brain death, organ preservation and donor selection, immunosuppressive medications, post-transplant surgical and medical complications including malignancies and infections [27]. The operations associated with transplantation including donor procurement, donor nephrectomies, and combined organ transplants are not required for residents to be proficient, though an exposure to these procedures is recommended [27]. As changes are occurring, key learning points should be maintained throughout the programs. The recommended learning goals presented by SCORE are reasonable to maintain for all programs, as many can be presented through didactics that all surgery residents attend. Other goals such as the surgical rotation/experience should be provided for all residents prior to the completion of residency. If a full rotation cannot be achieved, an abridged rotation could be developed for trainees. It would be preferable to have residents also experience a minimal number of transplant surgeries (procurement and implantation) prior to their graduation. However, a minimum quota may not be achievable in all instances given the unpredictability of transplant donor availability. Possible avenues to help residents learn about transplant-related surgeries are through simulators that can provide a similar scenario for a transplant surgery. An understanding of the anatomical position and possible surgical complications will be important educational points about which residents should be aware. As more patients undergo transplantation surgeries, it becomes more likely that these patients will present to hospitals where resident graduates are employed. The recognition and understanding of both the surgical and medical complications of transplantation will allow these residents to provide timely and appropriate care to transplant patients.

Subspecialists

Subspecialists are in a unique position to care for patients with transplants. They are provided with the specialized education in their respective specialties, and in many cases may be the first consultant contacted regarding transplant patients who present to primary care offices or urgent/emergency care facilities. Thus, subspecialists should have baseline knowledge of transplantation, complications, and be able to provide recommendations. All subspecialists require an education component to their fellowships regarding transplantation. Didactics can be minimal (few lectures) to extensive (several weeks) depending on the training program. Similar to the student presentations (Table 131.3), the lecture series

Table 131.4. Numbers of subspecialty fellowships and transplant fellowships and transplant patients. Data regarding fellowships were obtained from the Accreditation Council for Graduate Medical Education (ACGME) and American Society of Transplantation (AST) websites [2,28]

Subspecialty	General training fellowship	Transplant fellowship	Transplanted patients^
Cardiology	168	Undergoing accreditation	52 658
Gastroenterology	157	51 (36 ACGME certified)	113 962
Nephrology	146	53 (AST accredited)	331 765
Pulmonary/critical care	133	N/A	24 035

^Numbers of patients transplanted since 1988 per OPTN data [1].

given to subspecialists should cover all relevant topics with one exception. This syllabus should be covered in-depth compared to what medical students receive. Each topic should be presented separately to allow the lecturer time for extensive discussion, providing the most information and data. The reason for expanding on each topic presented is illustrated in Table 131.4. The table lists various subspecialties, the number of general training fellowships, transplant fellowship, and transplanted patients for each organ since 1988. Transplanted patients increase by approximately 28 000 per year [1]. Similar to the situation in which transplant surgeons are limited compared to general surgeons, the number of medicine subspecialists trained in transplantation is not substantial, while the number of transplant patients is substantial. Subspecialists need the education and knowledge required to make preliminary recommendations and refer patients to transplant centers if needed.

If possible, general subspecialty medicine fellows should be provided at least some exposure to transplanted patients through their fellowship. This could be through continuity clinics or inpatient consultations. Although lectures are extremely informative, providing care directly to transplant patients is an invaluable experience. Through direct patient interactions, fellows can systematically go through the various items necessary to care for transplant patients including transplant function, immunosuppressive medications and interactions, inquiring about infectious and cardiovascular problems, and reminders on health maintenance.

Continuing medical education

Care providers of solid organ transplant recipients require continued education to maintain and update their knowledge of transplant patient management. Continuing medical education in transplantation for subspecialists in gastroenterology, pulmonology, nephrology, and cardiology is a regularly occurring event at yearly national meetings. These sessions are presented by transplant specialists within the field who provide updated information for their fellow subspecialists. Some transplant groups also provide information sessions to their colleagues in the community through regional meetings and clinic outreach programs.

The continuing medical education of general internal medicine physicians and hospitalists is not as robust at national meetings. Thus it becomes the responsibility of the internal medicine physician to independently seek updated information regarding transplantation and the management of solid organ transplant patients. Some physicians can obtain continued education through their respective hospitals where transplant specialists present at grand rounds. Others may seek to attend specialized conferences given by other national societies. Transplant specialists can offer to provide a review and update to general internists within their hospitals and at national meetings.

Summary

Solid organ transplantation is a field in which the patient population is growing steadily. Advances in immunosuppressants and management post-transplant have led to increasing survival among transplant recipients. The care providers for these patients require a baseline amount of knowledge and experience with patients to adequately care for this patient group. Education for the care of transplant patients begins in medical school, and should continue throughout the training of general surgery residents, internal medicine residents and subspecialty fellows. The use of new methods of teaching including interactive didactics and audience response systems, as well as simulators will help further educate care providers. Transplantation is a field that continuously evolves over time, requiring those who provide medical care to solid organ transplant patients to also maintain their knowledge through regular updates in education and national meetings. Transplant patients will benefit the most when all their care providers continue their education in transplant management.

SECTION 10

Clinical Trials and Data Management

CHAPTER 132

Building and Sustaining a Local Transplant Data Management Program

Regina Eady, Tim Morris, Marc J. Overcash, and Jeff Weaver
Emory University, Atlanta, GA, USA

"Without data, you are just another person with an opinion."
Anonymous

Introduction

Few fields of medicine are as data driven as transplantation. This extends beyond the reporting requirements imposed by federal regulations to include acquiring highly granular data relevant to an individual patient's day-to-day needs, and the centers ability to deliver them. Accordingly, a sound local data management program is instrumental in the success of any transplant program. Indeed, an integrative and sustainable one can be transformative. Through the application of local data management strategies and practices, a transplant program can:

- Track and perform trending analysis on cohorts of patients on their post-transplant graft and survival rates, drawing comparisons with national baseline and outcome data.
- Interrogate an integrated collection of outcome, research, clinical, national, and reference data. Through data mining and analysis techniques, patient characteristics and interventions can be investigated, modeled, and analyzed to improve standard care practices and facilitate discovery opportunities.
- Establish an early warning notification system to consistently monitor trends and when the trends move in an undesired direction, facilitate proactive interventions. This system could operate at both an individual patient level or across the entire transplant program.
- Track and present outcome data to practitioners to identify variations in standard of care practices and reinforce positive outcomes.
- Measure and evaluate key performance indicators (KPIs) with stoplight (red, yellow, green) symbols to quickly ascertain how the transplant program is performing based on its objectives and goals. These KPIs can range from tracking patient waiting times to meeting fiscal goals to trends in laboratory values.
- Deliver tracking reports and checklists highly customized to facilitate decision-making and enable a standard set of practices for clinical care and scientific inquiries. Drawn from the local data store, these reports can be formatted to prioritize specific data points and dynamically generated with logic to calculate data based on if-then scenarios (e.g., if creatinine levels in renal post-transplant recipients are 115% above baseline, then the measurement is considered functionally significant and may indicate acute rejection of the transplanted organ [1]).
- Perform population counts based on a wide range of variables to determine potential subject pool and evaluate feasibility for clinical trials recruitment opportunities.

For this discussion, local data management is defined as the strategies, principles, and ongoing procedures necessary for a transplant program to manage the various data requirements and sources in a unified approach. It is distinct from, but at the same time integral to, national data which is typically held in centralized registries. National data management will be discussed in Chapter 133. The successful local data management program delivers a framework that facilitates access to the appropriate data at the appropriate time to make informed and effective decisions about the clinical care, research, education, quality outcomes, personnel, investments and operations of the Transplant program.

This chapter introduces the Transplant practitioner to key concepts associated with local data management programs. It describes a process for building and maintaining a data management program as well as guidance and recommendations on important data management principles.

Case study

The following case study contextualizes the value of a local data management program. Performed at Emory University's Transplant Center, weekly tracking conferences and post-transplant monitoring reports were implemented to improve adherence to treatment pathways for renal transplant recipients and to identify patients at risk. The weekly tracking conferences took place in the outpatient transplant clinic, during which time post-transplant coordinators and physicians reviewed patient charts at set intervals, including one, three, six, nine and twelve months post-transplant. The reports were created to provide a centralized view of patient data for use during weekly tracking conferences.

Prior to creation of the post-transplant tracking reports, the follow-up review of patients was complex and labor intensive. The volume of new patients tracked was approximately 160 per year. Data acquisition from the Organ Transplant Tracking Record

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

(OTTR), Emory's system of record for transplant patient care, took approximately two hours per patient, leading to approximately four hours of weekly overtime per transplant coordinator. With the data decentralized, eight patients could be reviewed per hour during conference. In an effort to increase the number of patients reviewed during conference, a tracking worksheet was implemented, completed by the transplant coordinators, and used for patient review. The time required by coordinators to gather and record the data in the worksheet was further extended, but it served as a template for the tracking reports.

While the tracking worksheets organized patient data in a readily reviewable format, a more efficient methodology for assembling and presenting data was required to increase throughput for patient reviews. This led to the development of an automated data reporting tool, a collection of post-transplant tracking reports customized for the one, three, six, nine and twelve month review periods. The reports pulled data from the OTTR system and could be run at any time by any approved practitioner from the OTTR user interface. The reports expanded the focus of the tracking conferences to include adherence to pathways, identifying patients at risk and referring physician communication. They reduced labor required for data acquisition from two hours to ten minutes per patient, and coordinator overtime was eliminated. The post-transplant tracking reports provided a centralized view of all of the data points and could be run on demand for specific cohorts of patients. Conference capacity increased from eight to twenty patients per hour.

A key benefit of the reports was better protocol adherence, which, in turn, led to a statistically significant improvement in graft survival rates among renal transplant recipients within the transplant center. Other observed benefits included: BK virus protocol testing adherence increased from 50% to 90%; compliance with protocol immunosuppressive target levels was facilitated; and referral physician letter communication improved. The project was approximately six months in duration and required a single data analyst working with multiple subject matter experts. Leadership concluded the investment was well worth the effort and initiated several additional local data management initiatives.

Challenges and scope

Transplant local data management programs face many challenges. Within a transplant program, critical clinical data can reside in a variety of systems across multiple geographic locations and organizations, including:

- Complex infrastructure of healthcare systems that are used to manage a range of clinical information related to imaging, prescriptions, laboratory, surgery, scheduling, billing and others.
- Distinct, and non-connected healthcare information systems managed by multiple institutions in which a transplant program may operate (e.g., Children's Hospital, Geriatrics Hospital, Veteran's Affairs, etc.).

Add the complexity of operating a large clinical and basic science research enterprise and another layer of systems data sources and management challenges are introduced, including:

- Numerous and sundry disease- and study-specific databases created in different, sometime incompatible, technologies and formats using varying terminologies, values, and units of measurements based on the sponsor or investigator's direction.
- Instrument-specific consoles in the research laboratory that are highly customized to a specific vendor solution and may require proprietary programming to extract the data in an automated fashion.
- Spreadsheets and documents stored on local file servers and on workstations in personal directories organized by individual preference and retrieved through one's memory of where the latest version is stored.
- Handwritten notes meticulously documented sequentially in notebooks and stored on shelves or in file cabinets.

At a high level, the challenge becomes bringing the right data together from this landscape of systems and records to inform decision-making. The process, subject matter expertise, technologies, and the time and effort to integrate data systems is significant and resource intensive. It involves lobbying for changes in institutional systems to enable the collection of and access to specific sets of data, reconciling differences in values in data fields across multiple data sources or systems, and, almost certainly, introducing changes to the processes and policies within the transplant program itself. As such, establishing and sustaining an integrative local data management program should be approached through a methodical process guided by multiple levels of leadership. Done correctly, the data management program will be a continuous process of evolution, growing as the transplant program itself grows, looking at new ways of measuring its own performance, exploring new research for discovery, and evaluating new pathways for improving care.

There are no prefabricated or "out-of-the-box" solutions for a local data management program that can easily be bought and installed. The local data management program is heavily dependent on the principles and objectives of the transplant program as well as the culture and technology environment of the institution. However, there are core components, principles, and concepts that, though they may be implemented with different technologies and techniques, are applicable for most institutions.

Figure 132.1 visualizes the high-level concept of a transplant local data management solution. On the left side, there are multiple data sources of interest. They could include local databases created by investigators conducting clinical trials or laboratory tissue banks; institutional systems, such as the electronic health record that tracks and manages the care for all hospital inpatients, including transplant patients; and national data sources, such as the United States' UNet, an online database system storing and analyzing all Organ Procurement and Transplantation Network (OTPN) data related to waiting list, organ matching and transplantation [2].

Subsets or the entire set of the data can be integrated into a transplant program specific repository to provide a consolidated source for reporting and analysis. There are various ways to accomplish this. The repository might be a physical database managed and operated by the transplant program or it could leverage existing data infrastructure at the institution-level. The data might be physically moved to a separate repository, linked to an existing repository, federated through middleware, or some combination thereof. The final solution will depend on the information technology direction and infrastructure. However, there must be a location, either physical or virtual, where the transplant program can access an integrated set of data designed and optimized to meet the transplant program needs.

Utilizing data from the transplant program repository, reports, dashboards, analytics, and other tools facilitate the display and analysis of data to facilitate decision-making.

Supporting and shaping this solution are the management processes and structures that ensure the solution is meeting the needs of the transplant program, guide the day-to-day operations of the

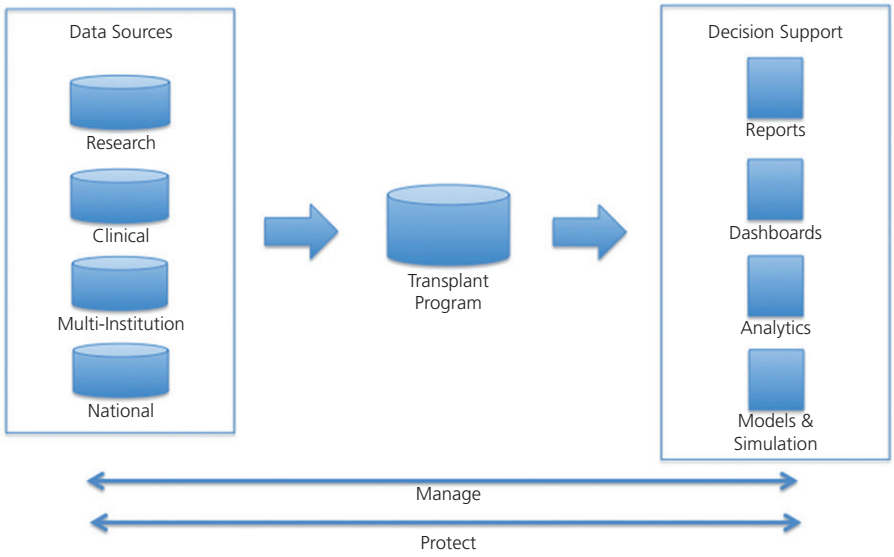

Figure 132.1. High-level data management solution.

program, and map out and continuously refine a strategic direction. Finally, there are controls in place to protect the confidentiality, integrity, and availability of the data.

Process

It is rare that a program has the opportunity to start its data management program from a blank slate. Rather, there is a dependency on institutional systems, national data sets, and a variety of existing local data repositories. Moreover, there are business processes and functional needs that are already in place and met, in one fashion or another, through the use of data. One can employ strategies to leverage, expand, and improve upon these existing infrastructure, technology and practices to develop a local data management program that remains flexible for future growth. This section describes the process that can be used to evaluate existing data management practices and plan strategically for a more effective data management program. The local data management program should support the organization by moving it closer to achieving its goals. In turn, the organizational goals will define the objectives for the data management program.

The steps involved in developing a local data management program are:

- Plan. Understand the current state of the program, specifically eliciting input from the clinical team at all levels, determine the future state, and prioritize the path and sequence to move from current to future state.
- Design. Based on the priorities and sequence defined in the plan, the design will usually include multiple phases of implementation allowing an iterative approach along the path from current state to desired future state. Iterative approaches provide more flexibility as implementation proceeds and allow for changes as new needs are discovered or priorities are adjusted. In general the design phase will collect requirements, analyze different options, and set forth the necessary specifications to create a solution.
- Deploy. Implement the design as specified, ensuring appropriate testing is conducted and incorporation into the support structure. From the local data management perspective, data governance and active engagement with the Transplant community should continue.
- Evaluate. Assess the program by evaluating it based on metrics, aligned with the Transplant Program's goals and objectives. Any gaps should be incorporated into the next phase of planning.

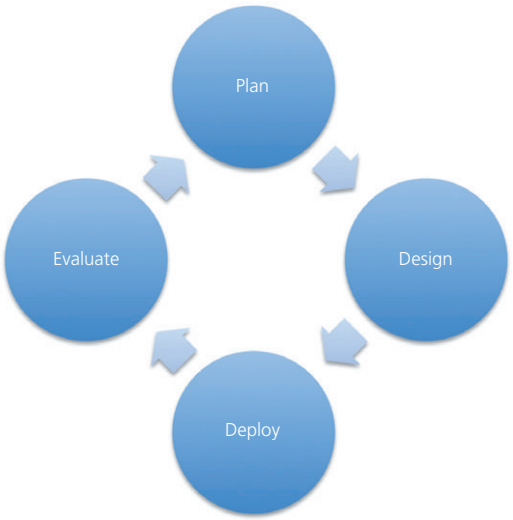

Figure 132.2. Local data management process.

The local data management process is cyclical, as depicted in Figure 132.2. Importantly, it cannot be created without buy in from the clinical (and if applicable, research) staff, the institution, and a dedicated data management design team actively collaborating with one another.

Plan

The planning stage involves evaluating the current state of the environment, building a vision for the future state, and prioritizing the activities that need to take place in moving from current to future

state. The mission, objectives, and key principles must drive the future state of the transplant program. For example, a key principle that "every patient is a potential research subject, and every research subject is a potential patient" would drive a series of fundamental design principles within the core local data management program. While this concept may seem simple on the surface, the complexity introduced by regulatory constraints on the use of patient clinical data for research and integration of these data with data sources designated as research-only makes the task complex. The creation of a common core data set for all patients for quality metrics and outcomes management that also serves as the core research record for patients can facilitate management of information across both research and clinical domains. Use of this core record with extensions for specific clinical specialties, clinical trials and research studies could be an approach for fulfilling the design requirement based on the key principle above. In addition to these key principles, understanding how the transplant program will evaluate its own progress should, in turn, focus the local data management program on the associated data variables and sources to facilitate the analysis and predictive modeling of the metrics.

Together with key principles and performance metrics, the future state should be driven by the business (or practice), not by the technology. To facilitate this process, there are a number of methodologies for documenting current state and sustaining the development of successive future state iterations. One overarching methodology is Enterprise Architecture. An enterprise architecture is an overarching description of the goals, business entities, processes, relationships, information, and systems of an organization or business. There are many enterprise architecture strategies and frameworks, and in many cases, sub-methodologies from multiple frameworks may be used depending on the scope and focus of the project. Emory University has implemented a business architecture modeling methodology in lieu of a full enterprise architecture approach. Our business architecture modeling approach focuses on business processes and the relationship of those processes to systems and data.

In a nutshell, the business architecture model process documents the current operating environment through a series of diagrams, workflow analyses, business scenarios, and system diagrams. Business functions are mapped to their supporting business workflows, which, in turn, are mapped to their supporting information systems and data repositories. Through analysis work, the future state can be derived by understanding business functions and ensuring alignment at the top levels first, then optimizing the business processes and evaluating the supporting technology and data. This approach attempts to minimize the practice of building a data management program in isolation of the business it should be supporting and avoids building the program on inefficient business processes and practices.

Success with this particular methodology depends heavily on working closely with subject matter experts and leadership. As the current state is being defined, a number of broad and detailed diagrams are created. A business function, such as research, is documented with details about the key roles, major processes that enable the function, technology domains, and types of data. For an example, please see Figure 132.3.

Working from this diagram, a deeper level of analysis is performed on the current state processes, documenting what role performs which major step in what sequence and what data types are stored in what system. A frequent way to represent these activities is through a swim lane diagram, an example of which is Figure 132.4. Based on the complexity or issues associated with a particular process, additional levels of detail might be documented. The workflow documents should be simple and clear. In conjunction with the workflow documents, supporting narrative in a form of a business scenario can help to provide more context and details to

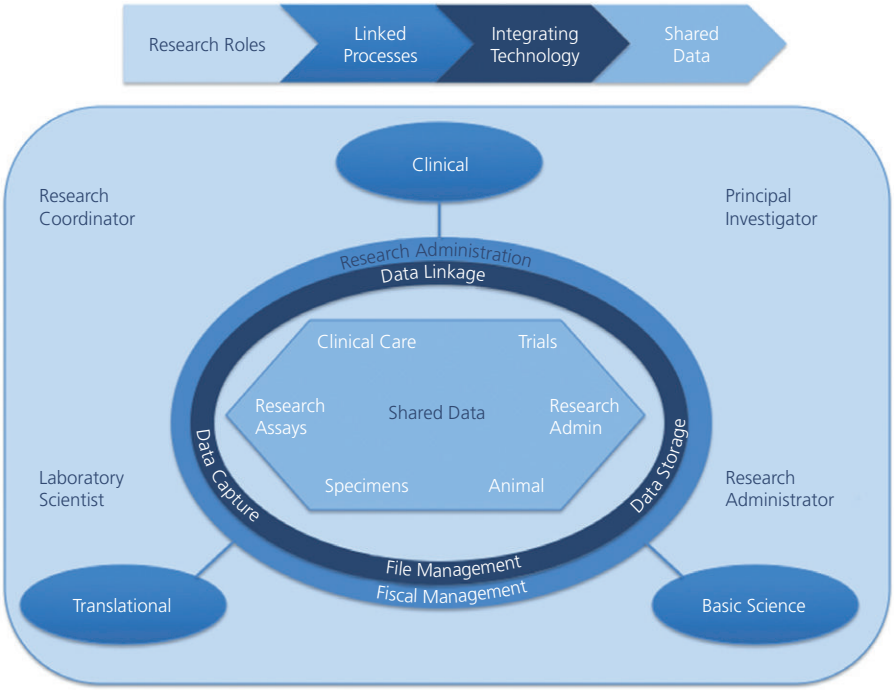

Figure 132.3. Example of a business function diagram (Emory's Transplant Center).

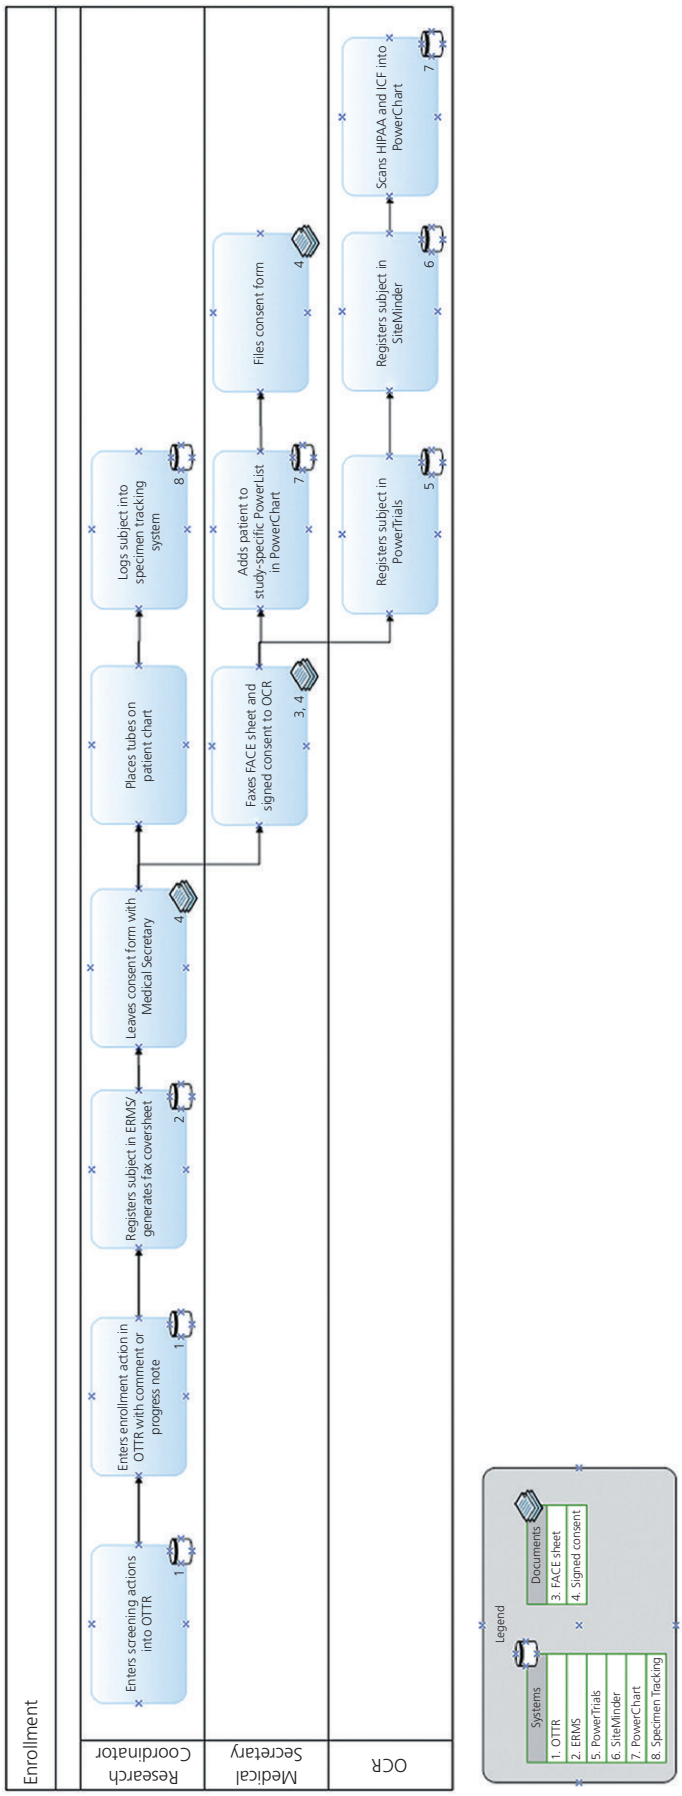

Figure 132.4. Example of a swim lane diagram (current state enrollment process).

the workflows. This current state documentation provides opportunities to understand and analyze how work is currently being conducted in addition to pain points expressed from the subject matter experts and the individuals who perform the work on a daily basis.

From the analysis work on the current state, one can start to build the picture for the future state. By looking at opportunities to optimize processes, reducing the number of duplicative systems storing similar data, developing solutions to resolve the expressed problems, and determining gaps in capacities or functions, the future state will start to emerge. To assist in the analysis, there are business architecture process applications that will model the impact changes in the current process could have on resources, time to completion, and other metrics; however, the analysis can be performed without such an application. The end goal of a future state document is defining goals and capacities for the data management program with the understanding that the future state will continue to evolve and be refined.

With an understanding of the current environment and the target goals of the program, the next step is to develop a transition plan, which defines intermediate steps for achieving the future state. Once the current state analysis is complete, there will probably be a number of quick wins that are self-evident and easy to achieve. As these analyses can take some time and effort, showing progress by completing quick wins can help keep the momentum going and build support for the overall effort. The next step is to develop a list of projects that need to be accomplished, and for each project, establish an estimated level of effort, resource requirements, and any dependencies (i.e., a specific project needs to be accomplished before another project can commence). The list can then be taken to the appropriate governance body (see discussion of governance in the Deploy section) for prioritization and leadership for ultimate approval.

In addition to the planning process, there are a number of planning principles that the transplant program should consider:

- Major authoritative sources of data, such as a clinical data warehouse, should be an early target for integration. These institutional level sources typically have specific policies and required controls that influence the overall design and operations of the data management program. In general, it is usually more cost effective to build these into the program earlier than retrofitting them after major components have been built. In addition, data warehouses are systems built specifically for integrating data across multiple systems. As such, with the appropriate permissions, access into a data warehouse might provide additional data from multiple systems, and a path to gain more data as they are integrated into the institution's data warehouse.
- As soon as possible, establish an identifier strategy for your data management program. As data is integrated from different sources, it is critical that each distinct entity (i.e., person, specimen, etc.) has an identifier that is consistently and persistently unique. It is common for multiple systems across clinical care enterprise to store different medical record numbers or other identifiers. In many cases there is a master patient index that binds all system identifiers to an enterprise-wide identifier. The master patient index number can be used to link data from multiple clinical care systems together for data analysis. However, linking data across research data sources is a much larger challenge as these data sources may be a local study spreadsheet developed by an investigator or a stand-alone database with study or function-specific identifiers. With research data sources it is important to develop a strategy for linking a research subject across multiple sources early in the design of the research systems and the overall data management plan. In addition to linking across research sources, a link must be maintained to clinical records to enable the fusion of data sourced from research and clinical care systems. A sound identifier strategy enables the linkage of data across these multiple data sets so that a person's clinical data stored in an electronic health record can be paired with their specimen data stored in a separate and distinct laboratory information management system.
- As feasible, establish standards for information systems and their supporting data repositories. Through standardization, templates can often be built to facilitate consistency in terminology and values as well as controls for data quality assurance and privacy.
- Be certain to leverage existing institutional resources whenever possible. As mentioned in the first bullet, access to a data warehouse will provide a wealth of data. Partnering with these institutional teams and resources will also provide different perspectives, assist with the strategic planning, and present opportunities to reuse infrastructure and tools.

Design

Whether it is for establishing a core component of the data management program or adding a new data set, there are certain data management concepts and principles that should be investigated. These principles include: evaluating the data sources, capturing data discretely, preparing data for integration, establishing quality controls, assuring the data use complies with regulations and policies, and protecting the data.

Scoping data management solutions

While planning may yield broad strategic data management objectives, there may be constraints with limited funding, resources or infrastructure. As such, there may be the need for an interim solution while waiting for the constraints to be removed so that the longer-term solution may be achieved.

Though not always ideal, interim solutions have some advantages. They provide short-term value and quick return on investment, especially when implementations of more strategic, longer-term based solutions are held up due to infrastructure requirements or policy issues. Interim solutions often provide a basis for gathering requirements for long-term strategies. For example, an interim solution may be an isolated database with a limited dataset and a small number of reports that support a very specific scenario or research question. This prototype database may contain information that is applicable to other scenarios and may facilitate the design of a data model that is flexible and scalable for broader use. Finally, interim solutions may help establish building blocks, design strategies or satisfy contingencies for implementation of more complex systems. However, interim solutions do have a tendency to become permanent solutions without the appropriate governance and willpower to make changes later in the future. So, when selecting whether to move forward with a "less than optimal" solution, be certain to weigh the benefits and limitations of each approach.

Regardless of scope, many of the design principles described in the sections that follow are applicable to data management implemented on any scale.

Evaluating data sources

Effective local data management will make use of a variety of data sources yet each data source may not have equal value to the transplant program. Origin, purpose, and format of data are significant factors when considering the value of a data set. Origin and purpose are usually considered together when evaluating a data source as these factors will determine the context in which the data was captured and if it requires some transformation, abstraction or interpretation to be most useful. The most important data formatting considerations include whether the data is encoded as discrete fields with explicit or unambiguous meaning or consists of mostly blocks of narrative text that must be abstracted.

Capturing data discretely

In an ideal world, all information collected during clinical care could be discretely captured and easily analyzed. In actuality, clinical care is still very narrative based (e.g. physician notes) and the corresponding data reflects that lack of structure. As such, strategies must be taken to either: (1) capture additional discrete elements during clinical care, or (2) manually or programmatically abstract discrete information from the narrative text.

Medical record abstraction

A common, often used method for capturing clinical data is through manual medical record abstraction. Abstraction allows for the synthesis of the complete record in order to answer the specific question at hand for a researcher or clinician. Medical record abstraction is often considered the gold standard when comparing other methods of data extraction from medical records. Electronic data collection tools [3] can be used to increase the efficiency and integrity of clinically abstracted data, but the process of medical record abstraction is often an expensive and time-consuming endeavor. In addition, medical record abstraction has the same risks as any secondary-use data capture when the abstracter must interpret notes and variables captured in a setting not within their control or knowledge.

Combining medical record abstraction with extraction of data from sources with discrete elements can significantly enhance manual abstraction and minimize data entry burden. An analyst can pull discrete variables that are easily extracted from the medical records, such as vital signs and lab values, allowing the abstracter to focus on collecting variables that are not readily available through extraction. This hybrid approach proves valuable when collecting large sets of data where data extraction cannot provide all variables needed for a data set.

Clinical workflow data capture

Based on the guiding principles of the program, such as "every patient is also considered a potential research subject", a local data management program can shape its data acquisition strategy to capture data for both clinical care and research purposes. Using the normal clinical care workflow, variables intended for research can be collected within the Medical Record using tools such as nursing flow sheets and physician templated notes. The variables should have either distinct choices or discrete measurements. Free text fields should be avoided.

It is important to minimize the burden of data collection while maximizing compliance of data entry when determining what variables can be collected during clinical care and where in the workflow they can be collected. Questions that should be considered are:

- How accessible is the variable during the stage of the workflow? Variables such as cold ischemia time should be collected during or soon after surgery, not during the patient discharge.
- Is the information inherently discrete but currently collected in non-discrete form? Variables that can be easily made discrete are good candidates for data capture.
- Is the variable novel to a particular study or does it have application to multiple questions or projects? The number of variables collected may quickly become unmanageable if care is not given to general usefulness of variables.

Natural language processing

An additional strategy for discrete data capture worth mentioning is the practice of natural language processing (NLP). NLP attempts to extract meaning from narrative texts by processing the text through a computer system of complex algorithms. In the context of medical text, NLP systems will often map the text with one or multiple medical terminologies [4]. Interest in NLP is on the rise due to the improving precision of NLP systems [5]. Because much of EMR information exists in non-discrete narrative form, NLP's future as a more concise, accurate information source is promising in both the clinical and research arenas.

Data sources

For the purposes of this text, data sources that might be used in a local data management program will be divided into two categories, secondary and primary. Data for which the principal use is for direct clinical care or administrative objectives, but could be reused for non-clinical care purposes are described as a secondary data source. Data collected specifically for non-clinical care purposes are primary data sources. The distinction between secondary and primary use is an important one. Data collected in the clinical setting are readily available but may be inaccurate or have meaning not useful in the healthcare quality measurement and research settings. Data collected specifically for a specific purpose such as quality metrics or research are generally more accurate and potentially useful because, in most cases, specific data collection systems or tools are created to suit the purpose. However, collecting data in a clinical setting with tools or systems that are not integrated into the clinical system workflow can be cost and time prohibitive. An effective data management program will make use of both sources of data.

Secondary data sources

There is a wealth of information to be found in administrative and clinical data collected during the normal care of a patient. These data will often be loaded into a data warehouse or other data repositories for easier extraction and analysis.

Administrative data

Administrative data from hospital and provider billing systems are by far the most widely available. Health system payers rely on standardized diagnosis and procedure codes to process billing reimbursement, so as a result, administrative data can be compared across institutions. ICD codes in particular are used in one form or another by most clinical care facilities throughout the world. In addition, billing codes have been used for decades and thus provide

a large longitudinal resource. Unfortunately, research has found that administrative data are limited in providing accurate clinical information due to coding errors [6] and limited diagnostic and prognostic detail of the codes used [7].

Re-purposing administrative data is particularly problematic when attempting to infer a result from missing administrative information. Administrative codes are usually recorded for the purpose of billing reimbursement. A clinically relevant condition may not be included because it is unnecessary for justifying a procedure or visit. For example, a patient with Stage Four kidney disease may never have a Stage Four ICD code recorded for a visit if that code is not needed for administrative purposes. While the limitations of administrative data must be considered when it is used in analysis, this large, accessible body of coded data can be very valuable. The most effective uses of administrative data are in instances when absolute accuracy is not important, such as summary data or in initial identification of a patient population. When a transplant program extrapolates detailed clinical meaning such as co-morbidities, disease severity and complications, it is best to use other data sources.

Electronic medical record data

Data captured for clinical care from an Electronic Medical Record System (EMR) provides a wide array of both discrete and narrative elements. The EMR's primary purpose is to collect data around clinical care and is therefore an ideal source for local data management needs. Modules of an EMR of interest include orders, nursing documentation, medication information, lab and pathology information, computer-assisted physician documentation and results from medical devices. Availability and format of these sources will vary by institution, but recognition of the value of these data is driving increased investment in these areas. A transplant program has much to glean from data captured for clinical care, but as with administrative data, re-purposing clinical data will require careful attention to the original meaning of the variables and purpose of collection. A PRN medication order, for example, may only indicate that a medication was available to a patient, but will not indicate whether that medication was administered. Because of these potential misconstructions, it is important to always include a subject matter expert when interpreting EMR information.

Primary sources of data

Capturing data directly for local data management is a strategy for compiling accurate information without some of the complications associated with re-purposed clinical data. Data may be captured in a variety of settings but differs from secondary-use datasets in that one of the intended uses of the dataset is for research and quality reporting. Primary use data capture has a clear advantage over secondary use data capture because additional control over the quality, meaning and context of the variables is typically implemented. For instance, a variable such as "history of smoking" may be available in medical records, but:

- the precision — was the question asked the same way each time?
- the meaning — smoked in the last year? smoked more than a pack a week?
- or the context — was the question asked when family members were present?

of the variable captured may be unknown or unclear. With primary use data capture, specific protocols can be defined around the collection, definition and reporting of variables.

Local databases

A common method of managing pertinent data for a transplant program is to create and maintain a database separate from a data warehouse or other data repository. This practice is very popular among investigators because it can be directly managed and requires little infrastructure. The data is often stored in a Microsoft Excel spreadsheet or Access database. There are multiple ways a local database can be populated, but often the data is manually abstracted or periodically extracted from a larger data repository such as a data warehouse. A local database can befall an unpleasant demise if not managed vigilantly. An investigator managing a local database needs to pay attention to data integrity issues such as:

- accuracy — is the variable coded exactly as the definition warrants?
- data validity — is the value correct and verifiable?
- and, consistency — is a value for the variable recorded the same way each time?

The investigator should also avoid free-text fields when possible. Other issues to consider are:

- versioning — which version of the database is current?
- temporal changes — how do you manage changes in demographics and medical history?
- changes in variables — will a modification in a variable definition orphan historical data?

A local database will require substantial effort on the part of the investigator to create and maintain but if information technology infrastructure is limited, a local database with the appropriate security controls in place may be an effective method of local data management.

Multi-institution registries

There are multiple transplant registries currently in existence. Participation in national registries may be mandated by government entities or could be driven by projects in a transplant program. Data maintained in registries are often strictly defined and curated. Information from registries is valuable to transplant programs because it allows for comparison of key performance indicators and practices to peer programs. Also, because of the reliability of the data collected in a registry, transplant programs can often get detailed information on their internal populations. In the US, some key registries that will provide data to investigators are the Scientific Registry of Transplant Recipients (SRTR), the United Network of Organ Sharing (UNOS) and the United States Renal Data System (USRDS).

Electronic case report forms

Clinical trial information is often captured through a Case Report Form (CRF). Information collected in CRFs consists of observations collected during clinical trials, which, in many cases, may be transcribed or abstracted from clinical care systems. Historically, CRFs have been paper-based, but with the proliferation of web-based electronic data capture tools, CRF data are increasingly being captured directly or indirectly through electronic CRFs (eCRFs). The use of web-based data collection tools over paper-based collection provides multiple benefits to the researcher in cost, efficiency, data integrity and security [8].

Biorepository data systems

Biorepositories are used to store specimens and their associated clinical information for a specific population that will be used in future research studies. A Laboratory Information Management System (LIMS) supports biorepository operations through

management of information related to specimen collection, processing, storage, retrieval, and distribution. Most LIMS solutions also provide audit tracking, electronic signature, and barcode labeling and scanning as well as workflow automation and enable a more efficient and secure means of tracking specimen information than log books and spreadsheets. LIMS functionality is optimized for management of specimen data, thus most LIMS solutions are not designed for collection of patient clinical annotations. Rather, a biorepository providing a mechanism to link the specimen data in a LIMS to the clinicopathological profile of the specimen from one or more other data sources is a more scalable approach.

Research laboratory data

Laboratory assays such as flow cytometry, image analysis, and gene expression profiling produce large amounts of data. A data management program that attempts to use the results from these instruments must consider how to effectively store, analyze, and archive these data. In addition, specimens and assay results are less meaningful without also understanding the clinical profiles of the patients from which the specimens are collected. Furthermore, for most longitudinal specimen collections, the clinical information linked to a specimen is a snapshot at the time of collection and specimens must be matched temporally to clinical information. Keeping this link between specimen and patient while maintaining anonymity when appropriate requires a well-designed workflow, incorporating clinical care, specimen collection and specimen analysis.

Preparing the data for integration

Data integration involves the retrieval and combining of data from multiple sources. When integrating heterogeneous data sources or joining small data sets with a larger data source, controls should be in place to ensure that the data is valid, consistent, accurate and complete. Data quality problems are often present in data sources, such as files or databases due to inaccurate data entry, missing information or invalid data. When integrating data from multiple data sources, the need for establishing quality controls increases because the sources may contain duplicate data, different representations, and inconsistent identifiers [9]. There are several principles that can be applied when integrating data sets to ensure high quality data.

- data validation when collecting data through electronic data capture
- consistency in data definitions
- cataloging common variables
- understanding derived data elements (categorically, quantitatively and temporally derived data)
- understanding the use of coded concepts
- identifier strategies for joining data across systems.

Data validation

Data is frequently collected via electronic data capture through the use of desktop applications or web-based online forms. There are several design strategies that can be employed when creating the interface for data collection that will promote the capture of high quality data:

- use drop-downs and pick lists to limit input options to a defined set of terms or concepts
- limit the use of free text fields
- limit or eliminate "comments" fields
- when appropriate, make fields required so that the user cannot proceed without providing a value
- when possible, limit any calculations the user has to perform manually.

Many form-based electronic data capture platforms enable validation logic to be programmed into the forms. Form validation enables the assignment of rules to a specific field to limit data entry to valid values. Examples of constraints that may be placed on data entry fields include:

- specifically formatted text
- specific data type, such as numeric
- numbers within a set range.

Consistent data definitions

When retrieving data from clinical or other systems for quality or research purposes, there should be consistency in definitions of common data elements, including variables and their sources, methods for extraction, standard interpretations and consistent formulas for calculating derived data. For example, a standard lab value, such as serum creatinine, should have a definitive data source and retrieved the same way every time. In another example, interpretation of serology results for transplant recipients is frequently based on specific laboratory test results, but may also be recorded in a separate location by program staff, as in a call center. In cases where the data may have more than one source, a standard source of truth and definition should be established and used for the same variables every time they are retrieved.

Cataloging common data elements

To promote consistent reuse of data, common variables should be cataloged to provide a point of reference for a core set of data elements and in some cases to provide the mappings for an automated process to extract, transform, and load the variables into a target database. The catalog should contain metadata or "data about the data". At the most basic level, the catalog may only provide documentation for a core set of attributes and list the following:

- variable name
- description
- domain or subject area (e.g., demographics, labs, medications, procedures)
- data source, identifying the source system or database
- data type (e.g., text, numeric, date)
- business rules (identifying derived data elements and logic or formulas for calculating results).

For a transplant program specific data repository, which may be a shared resource, the catalog should also include information on how to access the data in the repository by specifying the table name and column where the variable is located.

For automated processes, the metadata is stored in a metadata repository, in which all of the information about the source, target, transformation, mapping, workflows, sessions and other information required to automatically extract, transform and load the data is stored [10].

Derived data elements

Raw data obtained from clinical data sources, including clinical information systems and clinical data warehouses, are not always informative, complete, or structured in a format that is useful for analysis [11]. Clinical data sources include any information systems used for patient care, and a clinical data warehouse is a place to gain

access to clinical data gathered in the patient care process [12]. The data may be organized in different tables or structured differently and from different sources. As a result, the raw data must be transformed into a structure that is more useful for analysis [13]. Many of the concepts valuable for analysis are more complex than single values, and may be derived from a combination of many data points or some inference on one or more variables captured at event-specific time points.

Derived data consists of alternative representations based on rules applied to one or more native elements to create new data. The elements can be categorically, quantitatively or temporally derived. The source fields may be native to the source systems or derived elements themselves. While derived data is not written back to the data sources, it may be displayed as the result of a query performed on those sources or stored in a local data repository.

Categorically derived values are represented as a text result or symbol based upon logic applied to one or more fields. Categorically derived data may capture a binary value or status (e.g., "yes" or "no", "positive" or "negative", "+" or "−", "1" or "0"). In other cases, the result may indicate one of several states (e.g., 1 = male, 2 = female, and 3 = unspecified.). In a clinical research database, a status field could represent a diagnosis, lab result, or medication status at a specific time point with a "yes" if the diagnosis, lab, or medication is indicated at the time point or "no" if it is not.

Quantitatively derived data is generated by performing numeric calculations on one or more fields and storing the resulting value. Examples of quantitative results include descriptive statistics and predefined or user defined formulas applied to any combination of numerical fields. Variables used in quantitatively derived data may be constrained by temporal elements, such as maximum value of a specific variable over a fixed interval.

Temporally derived data analysis applies to data that occurs at a specific time point relative to an anchor event. The data may be constrained or calculated by the time point specified. In a clinical research setting, anchor events may describe diagnosis date, procedure date, encounter date, discharge date, date and time medication was administered, or date and time a lab specimen was collected. Temporal data describing data captured at specific time points is usually constrained by intervals of time relative to the anchor event or may be calculated over the set interval. For example, a time point representing three months post-transplant may be calculated as an interval of days from the day of surgery and may be used to constrain the selection of data, such as lab values, medications or adverse events recorded around this time point. Temporal data may also be used to calculate postoperative days for the purpose of reporting patient or graft survival.

Coded concepts

Coded concepts apply to any data element that uses an encoded value in lieu of a textual representation for the value supplied for the data element. Any data element used in a data set or system represents some concept (e.g., resting heart rate, systolic blood pressure value or gender). The concept represented by a data element may require a text or numeric value as with resting heart rate and systolic blood pressure or it may require a set of predefined values as with gender. These predefined values are coded concepts which can either be some locally defined set of values or code sets (e.g., 1 equals male and 2 equals female) or could be sourced from a standard terminology (e.g., SNOMED or ICD). It is important to note that a given data element used in different contexts might represent a different concept and thus be bound to a different code set. Therefore it is important to understand the context of usage of data element and any code sets bound to it to appropriately interpret the meaning of the element.

In addition to providing encoded value lists for data elements in local data sets, code sets are used for other purposes including:

- defined for computable representation
- compliance with data standards required by some governing body
- integration with other data sources with the same data elements and coded values
- concept not part of standard vocabulary.

Assuring data compliance

Data compliance ensures that data adheres to the appropriate guidelines and specifications, whether they are legal regulations, institutional policies, or contractual obligations. The scope of these requirements may include protections to ensure the integrity of the data, stipulations on how long the data must be kept, or even assurances of how the data must be cited. Data compliance requirements can often be complex and multi-layered with multiple guidelines driven by international, national, state, or local laws, contractual requirements or guidelines. In addition, the same compliance domain/area may vary by geography. One major compliance area, for example, is the protection of personal privacy. Although varying in specificity and scope, most countries have some regulation around the protection of personal privacy in electronic communications. In the US, there is the Health Insurance Portability and Accountability Act, Title II (HIPAA); Canada has the Personal Information Protection and electronic Documents Act (PIPEDA) [14]; the European Union has the Data Protection Directive, also known as Directive 95/46/EC [15]; and South Africa has the Electronic Communications and Transactions Act, 2002 [16]. Due to the variety, complexity, and nuances associated with data compliance in general, it is very important to have someone with expertise in compliance review and provide guidance to the local data management program.

One key challenge in data compliance is the assurance that the use or disclosure of data is consistent with the parameters to which the individual consented at the time he/she provided his/her data to the institution. Data provided for clinical care, for example, should not be utilized for research purposes without following the appropriate compliance regulations and attaining appropriate authorization. It is therefore of especial importance that the local data management program institute a process by which the consent is tracked and managed. Research data is particularly challenging as all nuances associated with the informed consent and any associated information use authorization must be understood and complied with before data is disclosed or used. For clinical data, the data management team must understand under what circumstances it is acceptable to use or release the data, especially if that data will contain personally identifiable information. Also, data might undergo one use, followed by a later second use outside the scope of the original intended use. One example of this scenario arises when data and analysis used for a clinical care quality review (a use typically defined as a part of healthcare operations) is subsequently proposed for use in research or publication in a research journal, a secondary use that would require additional compliance steps. Due to these complexities, it is important to have clear, documented standard operating procedures for the local data management program describing permitted circumstances and required processes for such data use. Not only will this assure compliance in

general, it also will help protect the individuals whose data was released to the transplant program.

The following represents a small sampling of national and potential local regulations that a transplant program should be aware of. These are specific to the US, though other countries may have similar type of regulations.

Health insurance portability and accountability

The Health Insurance Portability and Accountability Act of 1996 (HIPAA) consists of multiple rules and sections. Of particular note for the local data management program are the following rules: Privacy Rule, Security Rule, the Patient Safety Rule, and the Breach Notification Rule as part of the Health Information Technology for Economic and Clinical Health (HITECH) Act. Overall, these rules outline a series of national standards to protect the health information of individuals. For most institutions, HIPAA provides the baseline to design their information security and privacy policies, procedures, and supporting infrastructure.

The Privacy Rule dictates the type of data that is protected by HIPAA, as well as the circumstances under which institutions can use and disclose protected health information. The Security Rule covers the standards necessary to protect electronic protected health information (ePHI). The Breach Notification Rule details under what conditions and to what extent institutions and their business associates must notify affected individuals following a confirmed breach of unsecured data.

These rules in HIPAA apply to institutions that are part of a covered entity, which is defined by HIPAA as "a health care provider that conducts certain transactions in electronic form; a health care clearinghouse; or a health plan" [17] or one of their business associates. More information on HIPAA can be found at: http://www.hhs.gov/ocr [17].

21 CFR Part 11 compliance

The 21 CFR Part 11 establishes a series of regulations "under which the [FDA] considers electronic records, electronic signatures, and handwritten signatures executed to electronic records to be trustworthy, reliable, and generally equivalent to paper records and handwritten signatures executed on paper" [18]. Part 11 focuses on approaches to assure the reliability and integrity of the data, with particular focus on electronic signatures, audit trails, and access control.

This regulation applies to institutions that work in or collaborate with FDA-regulated industries, and encompasses clinical trials. More information on Part 11 compliance can be found at: http://www.accessdata.fda.gov [18].

Federal information systems management

Federal Information Systems Management Act (FISMA) of 2002 is a federal law that mandates that all federal agencies establish an agency-wide information security program "for the information and information systems that support the operations and assets of the agency, including those provided or managed by another agency, contractor, or other source" [19]. The law identifies a framework maintained by NIST to build, monitor, and continuously improve upon. Unlike other regulations, such as HIPAA and Part 11, there are very specific processes, procedures, and security controls detailed at a granular level that must be adopted for FISMA compliancy.

This law applies to federal agencies as well as institutions wanting to contract with a federal agency. As government contracts are a viable vehicle for transplant programs, it is important for the program to review and understand the effort and cost it takes to be FISMA compliant. More information on FISMA can be found at: http://csrc.nist.gov [19].

Patient safety and quality improvement

This Patient Safety and Quality Improvement Act 2005 (PSQI) was established with the intent to improve patient safety within healthcare institutions in the US. As summarized by Cartwright-Smith et al. PSQI "was intended to prompt providers to report patient safety and other health care quality information by using the legal tool known as 'privilege' to encourage robust examination of quality and safety without fear that the results of such efforts would be 'discoverable' by a plaintiff during a liability trial" [20]. Of particular interest to a local data management program is understanding what information is considered patient safety work products (PSWP), and as such, are considered protected by this Act. More information on this Act can be found at: http://www.iso.org/ [20].

Record management policies

Each institution should have its own set of record management policies that stipulate how records, both electronic and paper-based, should be handled through their lifecycle of acquisition to eventual destruction. Typical record management programs categorize records into distinct classes, such as clinical research records or healthcare administration records, and ascribe different policies for each class of records, such record retention periods. At times the sponsor may dictate specific rules that can influence how records are managed, such as data dissemination requirements.

Record management policies will apply to each local data management program and vary by institution. More information on Records Management can be found at: http://www.iso.org [21].

Protecting the data

Whether it is to protect patient privacy, safeguard intellectual property, or comply with any of the various local, state, national, or international regulations or policies, an information security and privacy program must strike an appropriate balance between protecting the institution from risk and providing access to the data for programmatic use. For a transplant program, there are a number of security controls that the program should ensure are in place. The implementation of these controls will vary based on the expertise of the staff and the available resources and funding, but, at the very least, the program should understand and authorize how they have been implemented. The following is a small sampling of controls and guidance on how to think through their implementations.

Data recovery

This process addresses the risk of data being irrevocably destroyed through a hardware failure, disaster, computer virus, or other means. To mitigate this risk, the program should determine how frequent they would like the data backed up. This generally is determined by how much data they can afford to lose. If the data is critical, back ups can occur almost instantaneously, though at relatively larger expense, while if the repository is an aggregation of multiple authoritative sources, the back up strategy might be less frequent (e.g., once a week).

In general, many institutions back up their data on a daily basis and store snapshots of it offsite every month. Large data, such as

genetic sequence data, might have a different backup strategy due to the sheer cost of backing up such a large volume of data.

In addition to the frequency of the back up, the program should determine what data should be backed up. One maxim is any data that you cannot recreate in a timely manner should be backed up. For example, original data acquired through interviews with a research subject or specialized tests performed on a tissue sample might merit a full back up plan. Due to the costs and time to back up, some programs may choose to not back up all variations of a data set, but rather, simply keep a backup of the raw data and notes on what algorithms were run against it to produce the analyzed set.

Other items to consider include:

- If data is backed up to an external device (e.g., tape or external hard drive) and it contains sensitive information, it is important to encrypt the external device or the data on the encrypted device. This prevents a breach if the external device is lost or stolen.
- If the data must comply with HIPAA regulations and is stored offsite, there must be a business associate agreement in place with the offsite hosting vendor and the institution.
- The integrity of the backup should be tested by establishing a process to restore the entire data repository at least once a year.

Separate the identifiers from the data

Assuming individually identifiable information (i.e., name, medical record number) are necessary for research, it is often best to separate the identifiers from the core data set and store them in a separate data repository with limited access. Instead of the individually identifiable information, substitute a local identifier that is mapped to the individually identifiable information through a translation key to enable de-duplication of records and the ability to integrate data from additional sources. In most situations, the individually identifiable information, such as electronic medical records, names, and addresses, is not necessary for most research, education, and outcomes usage. In addition, dates can be rolled backwards or forwards a consistent number of days to obfuscate them while retaining their pertinent to certain types of analysis. Without the individually identifiable information, the confidentiality risks significantly decrease.

Train and set expectations

Many security controls depend on individuals of widely divergent skill sets knowing the right thing to do. Whether it be not disclosing their passwords to anyone or not clicking on links embedded in emails, there is a set of expectations and standard operating procedures that a person should know before they have access to any data, especially sensitive data.

Although most institutions have an information security course that faculty, residents, post doctorates, students, and staff can take, the course might not address specific procedures and processes that the transplant program has created. Establishing a course specific to transplant can provide a greater level of specificity and relevance to their day-to-day jobs. Moreover, it can provide them with the knowledge and tactics to protect critical data.

In addition to training, visual cues and rules of behavior can be implemented within each electronic system to help set expectations on how sensitive the data is and how it should be utilized. For example, login screens of each application can be modified to insert language to remind individuals accessing the system of the sensitivity level of the data. Links to additional information can also be included in order to remind them what are the "rules of behavior" associated with the system, for example, the data cannot be downloaded and distributed to anyone outside the protocol team.

Conduct a security assessment by a third party

An assessment by an objective third party provides a method of testing the security of the system. These tests are often called "application security assessments". Working with a reputable vendor with excellent references, a set of objectives should be established and the exact systems for testing should be documented. The vendor then conducts a series of tests to identify and quantify any vulnerability associated with the system. Based on the objectives, these tests may be conducted from inside or outside the transplant program's network. If the application is developed internally, the vendor might have access to the actual code to conduct a more detailed review. Though engagements may differ, the transplant program should receive a list of vulnerabilities, an explanation of the vulnerability, and some rating to help quantify the risk the vulnerability has introduced. Based on how the contract is established, there may be an option to re-run the assessment after the program has a chance to resolve the vulnerabilities.

Due to the sensitivity of these types of engagements, it is important to ensure the contract appropriately protects the institution from intentional or unintentional disclosures of information. Also, since it is important to test actual production systems that might contain sensitive data, the contract should specify any and all constraints with how this data should be accessed. Finally, before any test is conducted, all appropriate parties, including the institution's security and information technology teams, should be brought into the loop and sign off on the engagement.

Deploy

In the Deploy stage, the local data management program constructs a solution based on the design and incorporates it into the production environment. Based on the type of solution, the deployment activities will vary. However, whether the solution is a new or a modification to an existing data source, report, or functionality, there needs to be a level of assurance that adequate testing has been conducted and that the new solution is incorporated into the support structure.

In addition to deploying a specific solution, activities that support and advance the overall management and operations of the local data management program should continue. Key areas of data governance and engagement of the transplant community are of particular importance to the transplant program.

Role types in the data management program

In describing the governance structure and operation support, it is helpful to have a description of the type of roles within the data management program. Of course, some individuals might be part of multiple role types based on their expertise and position in the organization.

- **Stakeholders.** Individuals with a level of ownership of a particular program, process, or area within the transplant program. They help guide strategy, prioritize resource investment, and review project objectives to make sure they are aligned with organizational objectives. Stakeholders may represent different organizations within the institution and may include physicians, principal investigators, administrators, technical directors and other members of the transplant program who provide input on data management activities.

- **Subject matter experts (SMEs).** Recognized experts in a particular subject domain (e.g., liver transplants). In general, the data management program will seek out these individuals to help address specific questions about the data associated with that domain or to lend their knowledge in the design of complex reports or data structures to assist with decision making.
- **Data producers and data consumers.** Interact directly with the data, each from different sides of the data. Data producers typically own the major systems that acquire and source data, such as clinical information systems, laboratory information systems and study management systems. Data consumers utilize the data for analysis, decision making, and research. Both groups of users play a critical role in communicating how data is used and how processes can be improved [22]. Data producers are on the front-line interacting with the data and can provide feedback from a process perspective on data collection and when it is most appropriate to record specific data points as part of their workflow. Meanwhile, data consumers provide feedback to the data management team on the applications, utilities and mechanisms for delivering data — what works and what does not.
- The **data management team** consists of several roles and is ultimately responsible for data extraction, collection, analysis, delivery, security, management, handling release of the data in compliance with information management policies, and maintaining ownership of the metadata. A data management team may consist of multiple roles, including:
  - **team lead** role that is responsible for overseeing and managing the program in general, assuring that requests and projects are delivered on time;
  - **business analyst** role that gathers and documents business requirements;
  - **data analyst** role that translates business requirements into data acquisition and delivery processes;
  - **biostatistician** role that provides expertise in study design and statistical analysis;
  - **data steward** role that reviews the release request and ensures the appropriate steps have been taken before authorization the release of the data; and
  - **honest broker** role that ensures that released data is appropriately de-identified before released to an individual investigator.

Depending on available resources, many of the roles described above may be held by a single or small number of analysts.

Testing

As data is used to support decision making, new solutions should not be released without conducting formal testing. Before conducting a test, a test plan should be created that enumerates in granular detail the steps each tester will be taking. This activity provides consistency across all testers and also enables any errors to be traced back to a specific step. The test plans should incorporate a number of scenarios, including a "blue sky" scenario, which involves the steps a user would take assuming everything worked perfect; an unconventional scenario in which the tester attempts to perform tasks that purposefully divert from the blue sky approach; and a security scenario in which the tester attempts to access information they should not be able to access. In addition to the formal testing, requesting actual users to test drive the new solution and provide feedback is always highly informative. It is important to not only test to ensure the new solution functions as designed, but also to test for accuracy and usability of the data as well as assure that the new solution does not introduce any unanticipated issues with the current data management system.

Support structure

Without a solid support structure, a local data management program cannot be sustainable. The program would depend on informal communications to carry its messages, it would lack common documents and processes to provide consistency in how the program operates, and the ability to remediate issues would depend on the goodwill of volunteers. Overall, the support structure, though not as innovative as the planning and design portions of local data management program, is still a critical factor for success.

Support structures should have individuals who are customer friendly, active participants in the program and knowledgeable in subject matter, highly analytical in their ability to think through problems, and strong communicators in articulating the root cause of problems and their associated solutions. The individuals who provide support might be the same individuals who help plan, design, and deploy solutions. In addition to the personnel, it is important to have the right documents and processes continuously updated. As solutions transition from design into production, the processes and documentation for supporting the local data management program should be updated to reflect any new changes. Standard operating procedures should have detailed instructions on how to handle and process requests and data. The data dictionary, or metadata repository, should be consistently updated to reflect the latest fields and values. Training material and support documentation should be posted on internal web sites to help provide self-independence and expand the support structure beyond the local data management team.

Finally, it is critical for all members of the local data management team, in particular the support team, to understand the rules and standard operating procedures for the disclosure and use of each type of data. As mentioned in the Data Compliance section, different steps and authorizations may be required based on the consent associated with the data and intended use of the data.

Data governance

Data governance provides the opportunity to bring together individuals representing multiple roles and subject matter expertise to discuss and recommend strategic directions, policies, and priorities associated with the data management program. For the local data management program, the governance body provides a sounding board to discuss challenges and validate intent. Generally, individuals who agree to serve on the data governance board are committed to the success of the program and become strong and collaborative advocates. By incorporating data governance into the process, the local data management program abdicates some of its authority to make decisions, but gains a broader insight into how data is utilized, provides a greater level of transparency in the decision making process, and incorporates a shared sense of accountability and responsibility for the program as a whole.

In forming and operating a data governance process, the local data management program should consider:

- Data governance should govern, not manage. Governance bodies should be focused on guiding principles and policies that, in turn, influence how the data management program operates. Governance inserted at a lower, tactical level can often disrupt or delay the day-to-day operations of the data management program.

As an example, the governance body should review and make recommendations on the standard operating procedure for disclosing data; however, it should not be the approving body for each data disclosure request.

- Governance should be linked into the Transplant Leadership structure and have the authority to make a specific class of decisions, as articulated by the governance charter. Having a member of the Transplant Leadership team chair or co-chair the data governance board will facilitate alignment with leadership.
- Key areas for a data governance body to deliberate on include: standard operating procedures; opportunities to standardize on data capture forms, data values, and terminologies; security and privacy policies; prioritization of data sources to incorporate into the data management program; and methods and metrics to evaluate the success of the program.

Engagement

The stronger the engagement with the community, the stronger the partnership between the data management program and the population it serves. As such, it is important to reach out to all levels and all roles in the Transplant Program. From these engagements, the local data management program should receive help from the community with the identification of issues and challenges, new opportunities to expand the program whether through new ideas or funding opportunities, and positive and critical feedback on the specifics components of the program.

A successful data management program is fluid in its approach and needs constant realignment to ensure that its principles and priorities are consistent with the goals of the transplant program. As such, the local data management group should ensure there is a formal, regularly scheduled meeting with the Transplant Leadership team. In these meetings, the team should report out on key performance metrics, project status, issues and risks encountered, and finally, success stories.

Evaluate

In this final phase, the local data management program, working with leadership and the governance structure, puts into place a series of key performance indicators, evaluates its performance against them, and based on the evaluation, incorporates changes into the planning phase to improve the program. Though many evaluations are performed informally, having a formal evaluation of the program at specific intervals will help quantify the overall performance of the local data management program.

Although each program will have its own distinct set of metrics, the following are some examples of areas to consider:

- Efficiency. Reduction in the number of systems, steps or time required to querying or gathering information. Examples of metrics supporting this include reduced staff hours spent gathering data for reporting or querying a single repository for data rather than multiple source systems. This has significant impact in cases where staff can move from a manual process of gathering and recording information for reporting toward an automated process, such as running a report.
- Process improvement. Standardization and optimization of processes within the Transplant Program due to automation of workflow and supporting systems. Examples of metrics or evidence include ability to track and improve upon protocol adherence, reduction in paperwork, or reduction in number of systems or steps required for data entry.
- Decision support. Number of reports and data artifacts that are used to inform members of the Transplant Program in key decisions.
- Data quality. Number of records that are identified through data assurance scripts and techniques that have incorrect values associated with them.
- Mission support. Use of the data management program by investigators and quality programs to conduct research, quality improvement projects, public health surveillance, and other activities that support the Transplant Program's mission and objectives.
- Cost-benefit analysis. Analysis of the total cost of ownership versus the value of the benefits received. Important evaluation component to determine whether the program is worth the investment.

Summary

An active and integrated data management program can be a valuable asset for any Transplant program. However, as with any critical component, the local data management program needs nurturing and refinement, and a continuous process of plan, design, deploy, and evaluate can help shape the program to meet the ever-changing needs of a Transplant Program. In the end, an effective data management program will provide a framework to deliver appropriate data at the appropriate time to enable evidence-based decision-making related to care for defined populations of patients, support opportunities for continuous quality and outcomes measurement and interventions, provide for data intensive clinical research, support comparisons of local populations to national or international data sets, and aid in fulfilling reporting requirements for quality and outcomes.

CHAPTER 133

National Transplant Data Registries and Population Studies

Allan B. Massie and Dorry L. Segev
Johns Hopkins School of Medicine, Baltimore, MD, USA

Introduction

Transplantation remains a growing field, with rapidly evolving treatment protocols and ongoing policy changes. Flexible, up-to-date scientific inferences are critical to advancing knowledge in our field, informing policy and designing optimal treatment protocols for patients.

Properly conducted randomized controlled trials (RCT) have long been acknowledged as the gold standard for evidence in scientific research, and the specific factors making up a well-designed RCT are covered in depth in Chapter 134. However, RCTs suffer from several disadvantages:

- RCTs require long follow-up time. The most clinically relevant outcomes in organ transplantation are patient survival and graft survival which may require years to measure properly. Long follow-up times not only make a trial expensive to conduct, they also delay any scientific benefit until follow-up is complete.
- RCTs are expensive. Most affordable clinical trials are powered only to detect large differences. In order to perform an RCT of a relatively rare outcome (such as post-transplant mortality) with adequate power, hundreds or thousands of patients may be required, often rendering the trial unaffordable.
- RCTs require strict selection criteria to draw inference about a given population. Even if funds were available, the number of participants required for a properly powered RCT may exceed the total number of eligible patients transplanted in the US in a given study period.
- An RCT may be impossible, or unethical, to conduct. For example, the question of whether diabetes worsens transplant outcomes cannot be answered through an RCT because the exposure (i.e. diabetes) is not modifiable. The question of whether cigarette smoking worsens transplant outcomes cannot be answered through an RCT because it would not be ethical to randomize patients to cigarette smoking, even if patients were willing to participate in such a trial.

Long-term, prospective, observational studies — in which participants are followed with no experimental intervention — avoid some of the feasibility and ethical problems potentially posed by clinical trials, but otherwise suffer from many of the same drawbacks, such as cost, recruitment, and long gaps between exposures studied and outcomes of interest. Retrospective data collection addresses (to some extent) cost and follow-up gaps, but suffers from recall bias, survivor bias, and other biases which may distort inference.

However, studies of registry data, which are collected prospectively and analyzed retrospectively, marry the advantages of prospective data collection (avoiding recall and survivor bias) with those of retrospective analysis (cost and long follow-up). Furthermore, mandated reporting in some countries makes registry data readily available and free from any selection bias. For this reason, the transplant community relies on registry-based data for many of its important inferences. It is important to understand techniques for performing studies of registry-based data, as well as the advantages and shortcomings of a population-based approach.

The goals of this chapter are to describe the various registries available to researchers, to review the advantages and limitations of registry-based analyses, and to provide an overview of analytical approaches and study design. Although the focus of this chapter is analysis of data from organ transplant registries, many of the principles elucidated will be relevant to any observational, population-based research.

Advantages of registry-based and population-based research

The field of organ transplantation is well-suited to the creation of registries, since the maintenance of a deceased-donor waiting list and the mechanics of deceased-donor organ allocation lend themselves to a centralized database with detailed, up-to-date information on the health and characteristics of transplant candidates as well as deceased organ donors. Moreover, the number of treatment providers is relatively small. As of July 2011, there were 265 transplant centers performing kidney transplantation in the US, and smaller numbers of centers performing extrarenal organ transplants [1]. Consequently, a relatively high degree of standardization in data collection and recording is attainable.

Registries typically include all relevant patients within a country or region, meaning that the complete population of transplant candidates or recipients over a given time frame can be included in a registry-based study. The large numbers available through registry studies make robust statistical inference possible. Moreover, the population is more diverse than that attainable through single-center or even multicenter studies, which tend to over-represent

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

large-volume academic centers. Registries also allow for the analysis of multilevel effects (e.g. center-level or Organ Procurement Organization [OPO]-level effects). Since patients are followed for the duration of their interaction with their treatment provider, long-term follow-up is possible. Lastly, transplant registries can potentially be linked with other registries (e.g. the Social Security Master Death File, administrative claims databases, or cancer registries).

Limitations of registry-based and population-based research

It is important to understand several shortcomings inherent to registry-based studies. Although data are submitted to registries in a standardized format, the data are collected by hundreds of healthcare workers, with varying degrees of training and expertise. In most national registries, there is no mechanism for centralized quality control of data collection (although some auditing does occur in some registries). Missing data are common for some measurements in registries in the US; some of the missingness is random, and some is systematic, and the distinction is critically important. Data collection errors or recording errors can lead to flaws in the data that may be difficult to detect; particularly in cases where these errors are systematic, significant bias can arise.

Additionally, registry-based studies suffer from two major drawbacks common to all observational research. First is the problem of *unobserved (latent) confounders*. Much important information about transplant patients is not captured in registries. For example, an investigator may wish to study the biological relationship between age and risk of graft loss in pediatric patients. Teenagers are less likely than younger children to comply with post-transplant immunosuppression regimens, and non-compliance is a major cause of graft loss [2]. Consequently, the investigator would want to adjust for medication compliance in the analysis. However, no data on medication compliance are available in organ transplant registries in the US. Therefore, a registry-based analysis of the biological association between age and risk of graft loss will be *confounded* by compliance (technically, in epidemiologic terms, compliance would be a *mediator*, which is analytically treated like a confounder for most intents and purposes).

A related concept is *residual confounding*. For example, a researcher may wish to study the relationship between age in deceased donors and post-transplant outcomes, independent of recipient diabetes (in other words, adjusting for any confounding effect of diabetes). If data are available on which patients have diabetes, this variable can be included in a statistical model to adjust for diabetes status. However, without data on diabetes severity (e.g. duration of disease, glycemic control, insulin therapy history), patients with mild diabetes and severe diabetes will be treated the same by the model. Therefore, the relationship between age and mortality will continue to be partly confounded by severity of diabetes.

Another drawback of registry-based studies is *confounding by indication*, also known as *treatment selection bias*. Confounding by indication occurs when sicker patients are more likely to receive a treatment than healthier patients [3]. Patients who receive the treatment may have poorer outcomes, not because the treatment is inferior, but because of the severity of disease which led to the treatment. Confounding by indication is of particular concern in studies of pharmacological therapies and other treatment interventions [4].

Examples of national and regional transplant registries

The Organ Procurement and Transplantation Network (OPTN) transplant registry

Since 1986, the United Network for Organ Sharing (UNOS) has operated the Organ Procurement and Transplantation Network (OPTN), under contract with the US Department of Health and Human Services [5]. All deceased donor organs in the US are allocated through the OPTN; moreover, participation in the OPTN has been a requirement for transplant programs wishing to participate in Medicare/Medicaid since 1987 [6]. The same year, the OPTN began collecting medical data on organ donors and transplant recipients [7]. Since 1999, data on transplant candidates, living and deceased donors, and transplant recipients have been stored in UNOS's integrated database known as UNet^{SM}, with data entered electronically by transplant centers via a secure online interface [7]. These data are made available, in de-identified form, to researchers.

As of June 2012, the main online forms collected by the OPTN include [8]:

- The Transplant Candidate Registration (TCR) Form, required at the time a patient is registered for an organ waiting list, containing patient demographics, health history, clinical information, and organ-specific information.
- The Transplant Recipient Registration (TRR) Form, required for all transplant recipients at the time of hospital discharge or death, containing updated patient demographics and health history, information about the transplant procedure, and other treatment information (e.g. immunosuppression during the initial transplant hospitalization).
- The Transplant Recipient Follow-up (TRF) Form, requested at six months after transplant and at every one-year anniversary of the transplant for recipients who remain alive with a functioning graft, containing information on current patient status and interim treatment.
- The Deceased Donor Registration (DDR) Form and Living Donor Registration (LDR) Form, containing donor demographics, health history, and details of recovery (deceased donors) or post-operative clinical information (living donors).

Other OPTN forms include the Post Transplant Malignancy Form, the Liver Recipient Histocompatibility Form, Donor Histocompatibility Form, Recipient Histocompatibility Form, and Living Donor Follow-up Form. All OPTN forms are available online at http://www.unos.org/. Additionally, the registry contains wait list updates reported by transplant centers (such as changes in Model for End-Stage Liver Disease (MELD) score for deceased donor liver candidates) and administrative data generated by the OPTN (such as deceased donor organ offers). OPTN data can be obtained for analysis from UNOS; these analytical files are linked to the Social Security Death Master File (SSDMF) to allow more accurate ascertainment of death, since many deaths are not captured by OPTN reporting mechanisms.

The Scientific Registry for Transplant Recipients (SRTR) standard analysis files

The Scientific Registry for Transplant Recipients (SRTR) also produces Standard Analysis Files (SAFs) for research of transplant outcomes in the US. Like the UNOS datasets, the SRTR datasets are based on OPTN data supplemented with a link to SSDMF data. However, unlike the UNOS datasets, the SRTR datasets also link to data from the Center for Medicare and Medicaid Services (CMS),

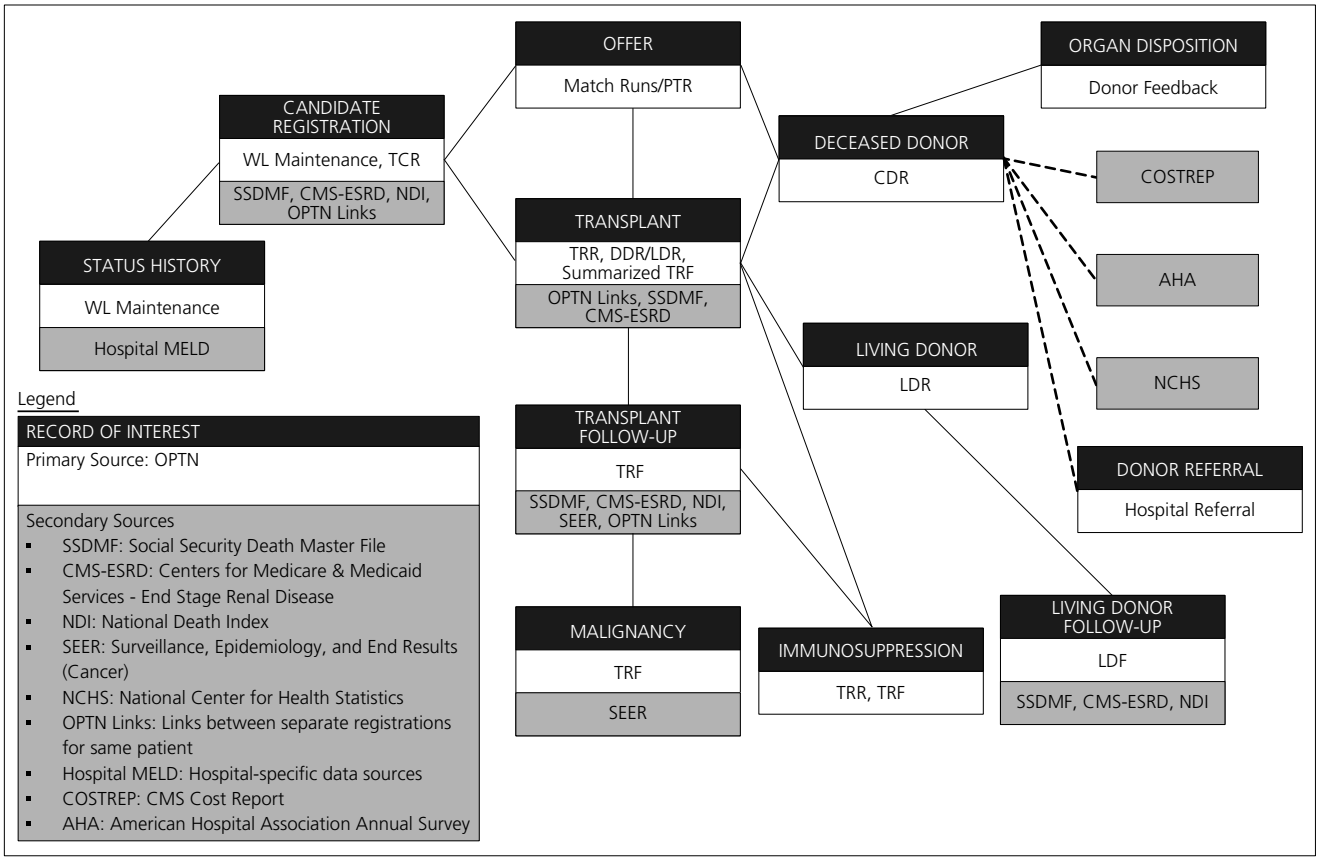

Figure 133.1. Schematic diagram of data sources and organization of Standard Analysis Files (SAFs) made available by the Scientific Registry for Transplant Recipients (SRTR). Modified from [9] Levine G et al. *American Journal of Transplantation* 2006; **6**(5p2):1228–1242, with permission from Wiley.

allowing for more accurate ascertainment of kidney graft failure in surviving patients, since many graft losses are not detected by OPTN reporting mechanisms [9]. The CMS data draw from the CMS Medical Evidence Report as well as from administrative claims data. The Medical Evidence Report (also known as Form CMS-2728) collects demographic and diagnostic data and is completed for all patients diagnosed with end-stage renal disease (ESRD) in the US [10]. A schematic of the data organization of SRTR SAFs appears in Figure 133.1. The UNOS and SRTR datasets organize OPTN data in different ways and follow different variable naming conventions. Details of the organization of the SRTR database can be found at http://www.srtr.org and in various descriptions in the literature [9].

Other registries

Registries outside the US

Data on organ transplantation and ESRD in Canada are captured in the Canadian Organ Replacement Register (CORR) [11,12]. The Eurotransplant registry contains data on organ transplantation in Germany, the Netherlands, Belgium, Croatia, Luxembourg, Austria and Slovenia [13,14]. National registries exist in Australia/New Zealand [15,16], Sweden [17], Japan [18], Malaysia [19], Brazil [20], and elsewhere. Each of these registries have data collected that is similar to that found in the US registries, and can serve to facilitate similarly useful analyses with similar caveats. However, the standardization of the data collection methods can vary, and in those countries with socialized healthcare systems, the overall healthcare system can facilitate standardized data reporting to include elements beyond those directly related to transplantation.

The role of registry and population-based research

Descriptive statistics

Registries (especially those with mandatory data reporting that capture all patients) are often the best tools for obtaining descriptive statistics about a population. In transplantation, questions answered with descriptive statistics may include:

- How many transplants of a given type are performed per year?
- How many patients join the waiting list?
- What is the demographic breakdown of patients who receive a transplant?
- How do these numbers change over time?

The SRTR publishes a yearly report which provides descriptive statistics relevant to transplantation [21]. In addition, many published papers have focused on providing descriptive statistics that give an overview of the state of the field of transplantation, or describe one aspect of transplantation in detail [22–28].

Inferential statistics

Inferential research involves estimating an association between an exposure and an outcome; for example, finding that transplantation with extended donor criteria (ECD) kidneys is associated with decreased graft survival relative to standard donor criteria (SCD)

kidneys [29]. The large numbers of patients included in registries, and the rich variety of clinical variables available, makes registries well suited for inferential research. Registry-based inferential studies have examined the role that patient demographics [30–32], deceased donor characteristics [29,33–35], policy [36–40], and many other factors play in organ transplantation. Although carefully performed inferential analyses can minimize the risk of mistaken inference, statistically significant associations must be interpreted with caution, since an association does not demonstrate causality.

Prediction models

A history of donor cigarette smoking is associated with slightly increased risk of graft loss after deceased donor kidney transplantation (hazard ratio = 1.05 in one study, $P < 0.05$) [41]. Yet knowing only a donor's smoking history conveys very little information about the risk of accepting an organ for transplant, since many other qualities (e.g. donor age, history of hypertension, cause of death, terminal serum creatinine) have much stronger associations with risk of graft loss [29]. Zero-mismatch deceased donor kidney transplants are associated with much lower risk of graft loss (relative risk = 0.65 in one study, $P < 0.001$) [42], but, again, knowing zero-mismatch status conveys limited information about the risk of graft loss since only about 15% of deceased-donor transplants are zero-mismatch [43], and since a zero-mismatched kidney from a 72-year-old with hypertension and a terminal creatinine of 2.4 is likely far worse than a 6-antigen mismatched kidney from a 25-year-old otherwise healthy donor. The goal of a *prediction model* is to draw inference about the risk to an individual patient, based on many factors. Often, composite scores are used. Registry-based studies have been used to create composite risk scores for kidney graft loss [44–48], mortality in patients with end-stage liver disease [49], liver graft loss [50] and kidney discard or delayed transplant [51].

Simulation-based research

Simulation-based studies are useful for estimating the effect of an experimental intervention when the experiment would be impractical or unethical to conduct in practice. Simulation studies are often used to predict the effects of changes in organ allocation policy. To test the effect of a policy change experimentally would require extensive administrative changes and months to years of follow-up, but a simulation can compare the effects of many different strategies on virtual patient outcomes. Simulations have been used to model the effects of policy changes in allocation of deceased-donor kidneys [52–54], livers [55,56], hearts [57,58], and lungs [58]. Additionally, simulations have been used to compare strategies for matching patients to compatible living donors for kidney-paired donation (KPD) [59–61].

Simulations are only successful if their representation of actual patients and policies is accurate. Registry data are useful for populating simulations with a case mix that mirrors actual patient populations and for constructing time-to-event models to estimate the probability of key events (e.g. organ offers, receipt of a transplant, death on the waiting list, graft failure after transplant).

Study design considerations in registry-based research

Prospective studies require detailed planning before enrollment begins. Funding agencies and institutional review boards will not support studies with poor design or small chances of success. Before a prospective study can launch, the researchers must show that the research is feasible. The population of interest must be identified. A plan must be made for collecting and preparing data. An appropriate method of statistical analysis must be chosen, and contingency plans must be made for problems that may arise once the study is underway.

Preparation for a retrospective study is simpler and less burdensome from a regulatory standpoint, but involves many of the same considerations. Advance planning before beginning a retrospective study will make data analysis easier and minimize the risk of mistaken inference. The actual analysis should reflect the execution of a well-chosen study design.

Hypothesis

Since clinical trials are expensive and time-consuming, it is reasonable to expect that they are driven by a well-defined, biologically plausible hypothesis for which the investigators believe there is equipoise. In the case of registry-based studies, hundreds of variables are at a researcher's fingertips, and a cursory investigation of correlation or association between two variables may take only seconds. The chance that a single statistical test will be statistically significant due to chance is low: by definition, it is the statistical α, by convention usually set at 5%. But in any national transplant registry, hundreds or thousands of spurious correlations certainly exist. Conditions are ideal for publication bias [62], in which these spurious associations are identified by investigators on "fishing expeditions" in the data, tested, found to be significant, and published. To avoid publication bias and type I error, investigators should take care to only perform analyses that are driven by a carefully considered, biologically plausible hypothesis.

Population selection

A well-defined research question is targeted to a particular population. For example, when investigating the association between cause of liver failure and survival after liver transplant, the population of interest is liver transplant recipients. Atypical patients (e.g. multiorgan recipients, patients with a history of prior transplant, or pediatric patients) are often excluded in order to provide accurate inference for a specific category of patients (e.g. adult first-time liver-only transplant recipients), depending on the research question.

There are three populations to consider in planning a study:

- the *target population* (the population about which we wish to draw valid inference);
- the *source population* (an enumerable list of potential participants in the study, representative of the target population);
- and the *study population* (the individuals whose data are actually included in analysis, drawn directly from the source population).

The research question should drive the definition of the target population, which in turn, along with feasibility and data availability, should drive the definition of the source and study populations. In prospective studies, the study population may be smaller than the source population because it is infeasible to enroll all eligible individuals, or because some individuals refuse consent. In a registry-based study, the source population and study population are often the same. However, the study population may be a subset of the source population when using certain analytical techniques (e.g. in a matched cohort analysis in which the study population is drawn from a pool of eligible matches) [63,64].

The precise inclusion criteria for a registry-based study vary depending on the research question. However, typical inclusion criteria may include a date range (e.g. all transplants performed in the years 2005), an age range (e.g. adult patients), and an organ/procedure type (e.g. lung wait list registrants, live donor kidney recipients) to ensure some degree of homogeneity.

Data integrity/exploratory data analysis

Transplant registries typically make use of data that were originally gathered for a purpose other than research. The primary purposes of OPTN data collection efforts are to manage deceased donor waiting lists, to facilitate organ distribution, and to provide data for the SRTR program-specific reports. Data are of variable quality. Missing data and erroneous data are common, particularly for fields which do not address the primary purposes of the OPTN. Proper exploratory data analysis is essential to avoid bias in a population-based analysis.

Missing data

Data may be missing by design. For example, collection of the international normalized ratio (INR) of prothrombin time, a measure of liver disease severity, was added to the OPTN database in 2002 [65]. Therefore, this information is missing for all liver wait list registrants before that date. Alternatively, information may be missing because it was not submitted by treatment providers. For example, cold ischemia time (CIT) was not reported in 30.3% of live donor kidney transplants between 1990 and 2005 [66].

Missing data may be *missing completely at random* (MCAR), when any record is equally likely to have missing data; *missing at random* (MAR), when there is a systematic mechanism of missingness that is predictable from another covariate (e.g. missingness is less likely for more recent records but otherwise random); or *missing not at random* (MNAR), when there is a systematic mechanism of missingness, but this mechanism cannot be predicted from other available data (e.g. if CIT is less likely to be recorded for smaller CIT values) [67]. Any missingness that is MAR or MNAR may lead to biased inference if not properly handled in analysis. Exploratory data analysis should include careful consideration of missing data and a search for patterns in missingness (e.g. more often missing in a given era or for a given category of patient). Common strategies for handling missingness include deletion of missing records, creation of a missingness indicator variable, and advanced techniques such as imputation [67,68].

Errors in measurement and data recording

Even when not missing, data in a registry come with no guarantee of accuracy. There are several reasons why a measured value might be inaccurate. There may be an error in the measurement process (e.g. a flawed lab result). Patients may not remember their health history accurately. The wrong measurement units may be used (e.g. recording patient height in inches instead of centimeters). Health care providers may make typing errors when entering data into a registry. A *sentinel value* may be used as a placeholder or to indicate missing information (e.g. an age of 99 if age is unknown) and later mistakenly interpreted as data. The probability of any one of these events is low, but even a handful of truly erroneous values can bias an otherwise robust analysis. Furthermore, any registry that contains hundreds of measurements on thousands of patients is likely to contain a large number of errors.

In considering the problem of measurement and data-recording errors, investigators should bear in mind how reliable measurement of a particular variable is likely to be. Transplant centers have a high incentive to accurately report some variables. For example, allocation of deceased donor livers is largely dependent on the MELD score [55]. If MELD scores are misreported, transplant centers run the risk of denying patients a chance to obtain a liver transplant. They are consequently likely to take great care in measuring and reporting MELD. As another example, the SRTR uses certain patient co-morbidities for case mix adjustment in the preparation of program-specific reports (PSRs) [69]; centers with poor adjusted outcomes in the PSRs run the risk of losing patients to competing centers, or even losing eligibility for Medicare reimbursement. Consequently, centers are likely to report those patient co-morbidities included in the PSRs as accurately and completely as possible. Conversely, variables for which non-reporting or erroneous reporting have no consequences for a center (e.g. immunosuppressive regimens, history of malignancies), especially those that are difficult to collect properly (e.g. follow-up data), are more likely to be missing or erroneous.

Erroneous data points might be *outliers*, falling outside the typical range of a variable. For example, if a patient's true height is 170 cm, but the height is entered as 70 cm, that height may be the shortest recorded height among adult patients. Outlier values may be *influential*, meaning that their presence or absence in a dataset may change a co-efficient estimate. Even a small number of high-influence points can affect regression co-efficients; if the high influence comes from measurement errors or data-recording errors, these values can lead to mistaken inference [70]. A variety of techniques exist for detecting and handling high-influence points [70,71]. At a minimum, investigators need to explore the distribution of variables used for analysis, and carefully consider the treatment of values that seem outside the normal range for a variable.

Statistical approaches to registry-based studies

The main statistical methods used in analysis of registry-based studies are techniques that are widely applied in the health sciences. A detailed description of all available statistical methods is beyond the scope of this chapter, and statistical issues related to transplantation studies are covered in depth in Chapter 134. Nevertheless, this section provides an overview of techniques that are common to population-based studies and other large-sample studies in the field of transplantation. More detailed reviews can be found in transplant-specific articles [72] or general textbooks of biostatistics and epidemiology [70,73].

Survival models

A *survival model* is any statistical model in which individuals are followed over time, and at any time are at risk of having an event of interest. Most survival models also allow for *incomplete follow-up*, which is a natural component of observational studies in transplantation (since not all patients undergo transplant on the same day, so at end-of-study there are different follow-up times for each patient). The event of interest may be, for example, mortality on the waiting list, receipt of a transplant while on the waiting list, graft failure, or mortality after transplant. Survival models require a *time origin* which may be, for example, date of wait listing or date of transplant (birth is also a possible time origin, though infrequently used). At the end of follow-up (which can vary, as above), an individual will either have the event of interest (often referred to as a

failure) or will no longer be followed (often referred to as *censorship*). Note that, despite the emotional valence of the terms "survival" and "failure", the event of interest may be a desirable outcome (e.g. an organ transplant is technically a "failure" in a model assessing time to transplantation). A survival analysis requires data to be in a specific format, depending on the statistical software used; typically, data management will be required to transform registry data into a format suitable for survival analysis. The data management and analysis techniques for survival analysis are described in reference manuals for several common statistical packages [71,74,75].

The most basic statistical technique for survival analysis is the *Kaplan-Meier estimator* [36,76,77]. The Kaplan-Meier estimator is a *non-parametric* technique, meaning that it does not incorporate any prior assumptions about the distribution of survival. Kaplan-Meier curves can only be produced for unadjusted data, and allow only basic comparisons between different categories of patients. Another common statistical technique for survival analysis in organ transplantation, as in other fields, is the *Cox proportional hazards model* [24,29,32,34,66,76,78,79]. Cox models are *semi-parametric* models which make no assumption about the shape of the hazard curve (distribution of risk over time) for any one subject, but assume that the hazard curve for one subject is proportional to that of any other subject. Other survival models include parametric models such as the *Weibull model* [56] and the *generalized gamma model* [80], which assume a specific shape for the hazard curve, and *competing-risks regression* [81]. It is important for researchers to understand that every statistical model relies on certain assumptions about the distribution of the data; these assumptions should be thoroughly checked as part of any study. Many excellent references exist for survival analyses [70,71,75].

Binary outcomes

The most common technique for modeling binary outcomes is *logistic regression* [40,82–85]. Logistic regression models the association between an exposure and odds of a binary outcome (odds = probability/[1-probability]) [70]. Logistic regression therefore implicitly incorporates the *rare disease assumption*: that a positive outcome is rare. If the rare disease assumption is violated, then the odds ratios (OR) returned by logistic regression will be artificially large compared to the relative risk (RR), causing a bias in the apparent effect size of a variable [38]. In other words, in a cohort study it is inappropriate to interpret an odds ratio of 2.0 as a "twice the risk" but rather as a "2-fold higher odds of risk." A well-developed set of diagnostics exists to check the fit of logistic regression models [86]. An alternative to logistic regression, with a more recognizable interpretation of the co-efficients (namely as a relative risk), is modified Poisson regression with a robust variance estimator [87].

Considerations for prediction models

Prediction models require *validation* to assess their predictive accuracy. For example, a well-constructed model to predict risk of delayed graft function (DGF) after kidney transplant should on average assign a high probability of DGF to transplant recipients in whom DGF is observed, and a low probability to patients in whom DGF is not observed. Predictive accuracy can be broken into two components:

1 Among all patients predicted to have an X% probability of DGF, is DGF in fact observed in about X% of them? and
2 Do patients predicted to have a high probability of DGF in fact have DGF more often than those predicted to have a low probability of DGF?

The first component is known as *calibration* and the second is known as *discrimination* [88]. Calibration can be assessed using the Hosmer-Lemeshow test [89]. Discrimination in binary or survival models can be assessed using the c statistic [89]. In the context of binary outcomes, the c statistic is also referred to as the area under the receiver operating characteristic (ROC) curve, or simply the AUC [90]. The predictive accuracy of two models can be compared using the methods of Delong et al. [91]. The net reclassification index (NRI) and the integrated discrimination index (IDI) [92] are alternative techniques for comparing two statistical models, based on clinically relevant metrics.

Predictive models run the risk of being overfitted to the data used to generate them, in general, this occurs when the model is overly complex, and as such, describes random variations in the data rather than meaningful trends. For this reason, a model should be validated against a population not specifically used to construct the model. *Internal validation* involves validation from other points in the same dataset; techniques include cross-validation [93] and the bootstrapping technique of Steyerberg et al. [94]. *Temporal validation* involves constructing a model on data from one time period, and validating it on data from a different time period [88]. Other kinds of validation (e.g. independent validation, in which a study is repeated at a different site to account for differences in case mix) are of less concern in population-based studies, although case mix may differ from one country or region to another. These techniques have all been used in the transplant literature [46,51].

Some pitfalls in registry-based studies

Identifier issues

Registry data are typically provided to researchers in a de-identified format, with a unique, arbitrary numeric/alphanumeric identifier (ID) assigned to each record. One patient may have several individual IDs. In the OPTN dataset, patients may have or be associated with the following IDs:

- wl_id: an ID assigned to each registration on a deceased donor waiting list
- trr_id: an ID assigned to each recipient of a transplant
- donor_id: an ID assigned to each organ donor
- multiorg_id: for multiorgan recipients, an ID to link two records corresponding to the same transplant event (e.g. to link a kidney record and a liver record for a kidney-liver transplant)
- pt_code: an idea assigned to each person, possibly spanning multiple wl_ids or trr_ids

For all of the above, each listing generates a separate ID. So a single patient who lists at two different centers, or who receives more than one transplant, may be represented with several different values for wl_id or trr_id. Similarly, a patient who receives two transplants separated by some amount of time will have a different trr_id for each transplant. Care must be taken to manage ID variables properly, particularly when merging information from several datasets (e.g. waitlist, donor, and transplant).

Informative censoring

Most statistical models used for survival analysis assume *non-informative censoring*; that is, among patients who are lost to follow-up or administratively censored, their subsequent risk of

having the outcome of interest (had they not been censored) would have been equivalent to the observed risk among patients with subsequent follow-up. For example, in a study of post-transplant survival in patients who received a heart transplant between 2005 and 2010, with follow-up through 2011, patients who received a transplant in 2010 can be followed for at most one year. The assumption of non-informative censoring states that these patients' risk of mortality in the (unobserved) second year after transplant will follow the same distribution as the observed risk of mortality in the second year for patients who received a transplant between 2005 and 2009. Censoring is *informative* if this assumption is violated. For example, liver transplant candidates believed to be at the highest risk of short-term mortality receive the highest priority in liver allocation [39,40,55]. Therefore, a study of wait list mortality must account for the fact that patients who are censored for transplant would have been more likely to die (had they not received a transplant) than most other patients followed for a similar amount of time [40]. Informative censoring can create substantial bias, but is unfortunately often disregarded in registry studies in transplantation.

Competing risks

Patients on deceased donor waiting lists may have several outcomes. They may receive a transplant; they may die on the waiting list; they may be removed for deteriorating condition; they may remain on the waiting list. These outcomes represent *competing risks* [95]; in other words, once a patient dies, they are no longer at risk for receiving a transplant, and, similarly, once they receive a transplant, they are no longer at risk of dying while on the waiting list. As an illustration, there is evidence that patients with MELD exceptions due to hepatocellular carcinoma have a lower risk of death than patients with the equivalent allocation priority due to a laboratory-derived MELD score [39,40]. The lower risk of death does not affect hepatocellular carcinoma (HCC) patients' *hazard* of transplant; the chance that a patient on the waiting list will receive a liver transplant on any given day is, in principle, the same for patients with and without HCC exceptions. However, since patients without exceptions are more likely to die before they receive a transplant, the *cumulative incidence* of liver transplant is higher in patients with HCC exceptions; a patient entering the waiting list today with an HCC exception is more likely to receive a liver transplant than a patient with equivalent allocation priority but no exception (because they are less likely to experience the competing event of dying) [40]. Conversely, factors that affect the time to transplant — for example, increased wait times as the wait list grows — affect cumulative incidence of death, but not hazard of death [95]. Death after transplant and death-censored graft failure represent another example of competing risks in the field of transplantation [15].

Investigators wishing to study determinants of survival time or time to transplant must decide whether to study hazard or cumulative incidence. A hazard analysis considers the outcome of interest as if competing risks were not present (e.g. patterns of mortality in the absence of transplantation); a cumulative incidence analysis accounts for how competing risks affect the event of interest. Traditional survival analysis techniques (e.g. Cox regression, generalized gamma) model hazard, while specialized techniques specific to competing risks must be used to model cumulative incidence in a survival framework [96]; unfortunately, often the choice of analytical technique is not consistent with the study design (in which competing risks may naively have been disregarded).

Non-proportional hazards

Cox models incorporate the *proportional hazards assumption*: that the ratio of any two individuals' hazard of an outcome is constant over time. For example, if diabetic patients on the deceased donor kidney waiting list have 40% higher risk of mortality than equivalent non-diabetic patients at the time of listing, then they have 40% higher risk of mortality three months after listing and also 40% higher risk of mortality three years after listing. Many medical interventions — including, notably, surgery — violate this assumption. The day that a patient receives a deceased donor kidney transplant, the risk of mortality is higher than if they had remained on dialysis; however, among patients who survive the perioperative period, mortality risk decreases to a risk lower than that for patients who remain on dialysis [31]. Cox models and related techniques are not appropriate when the proportional hazards assumption is violated, unless techniques such as stratification [97] or time-dependent covariates with time-varying effects [98] are used. Other techniques for modeling non-proportional hazards include Poisson regression [99], the generalized gamma distribution [80], and Markov models [100].

Effect modification

On average, black patients on dialysis have lower mortality than white patients with similar risk factors; however, among younger patients, black patients have higher mortality than white patients with similar risk factors [32]. Age is therefore an *effect modifier* for the relationship between race and mortality in this population (and, conversely, race is an effect modifier for age). This relationship can also be described as an *interaction* between race and age.

Standard regression techniques assume that the relationship between an exposure and an outcome is the same for all subgroups of patients: for example, that race affects mortality on the waiting list equally in young patients and in older patients. Overlooking interactions can lead to mistaken inference about subgroups of patients. Investigators should test interactions between key variables through the use of interaction terms in regression models [101].

Summary

This chapter has provided an overview of the uses of registry-based studies in the field of organ transplantation, and common techniques for analysis of registry-based data. Large, rich datasets and fast microprocessors put a wide array of tools at the researcher's fingertips. When used without care, these tools may yield biased or mistaken results. When used properly, these tools can yield powerful, novel insights that advance the field of transplantation and improve patient care and clinical outcomes.

CHAPTER 134

Clinical Research Methods and Analysis in Organ Transplantation

Jesse D. Schold[1] and S. Joseph Kim[2]

[2] University of Toronto, Toronto, ON, Canada

Introduction

Clinical transplantation has developed in close association with many companion sciences and has been the initial testing ground for numerous novel techniques, medications and practice patterns. This close association with medical advancement has required an almost continuous relationship between clinical transplantation and clinical research. As such, a working knowledge of research methods is necessary for even general transplant practice, and is an important means of guiding rational treatment decisions. Indeed, in order to generate appropriate data summaries and inferences about any population, it is necessary to utilize the appropriate statistical methods and analyses. In this chapter, we describe fundamental methodological principles and common analyses utilized with examples from the transplant literature. Regardless of the size, study design, or scope, an important guiding principle for all forms of research is the proper application of the scientific method throughout the course of study (Figure 134.1). Without this, the validity and reliability of study findings, even with the use of appropriate study design and analyses described in this chapter, may be unclear. Importantly, when a relevant, important, and novel research question is posed, the goal would be to pursue research that furthers science, regardless of whether the results of the study are "positive" or "negative."

Clinical research, as compared to basic science research, focuses on the outcomes of patients in response to specific interventions or risk factors, for example exposure. In order to examine these relationships and quantify the impact of a given exposure on an outcome of interest, a study must be thoughtfully designed so that valid inferences can be drawn from its results. The first section of this chapter will outline the major issues in the conduct of clinical research as they relate to study design while the second part will focus on study analysis.

Major types of study designs

A useful classification system for the different types of clinical research study designs is depicted in Figure 134.2 [1]. If the study investigator assigns the exposure or intervention, the study is considered *experimental* in design. If the assignment of exposure or intervention is not under the control of the study investigator, that is not for the purposes of the study protocol per se, then the study is *observational* in design.

Experimental study designs

Once a study has been deemed experimental in design, the next step is to decide on the mechanism by which the intervention or exposure will be allocated. If it involves a process whereby every patient recruited into the study has a fixed probability of receiving the intervention or the comparator, then the study is called a *randomized controlled trial* (RCT). If a non-random mechanism (e.g. alternation) is used for allocation, then the study is called a *non-randomized controlled trial*. The latter study design is uncommon in the current era of clinical research since randomization offers considerable advantages with respect to study validity (as described further on). As a result, non-randomized controlled trials will not be discussed further.

The term *random* in statistics is not synonymous with haphazard. Instead, it refers to a probability distribution that defines the likelihood of some event occurring. In the context of a classic one-to-one, 2 arm, parallel-group RCT, this probability distribution would have two possible values, intervention and comparator, and the probability of each is 50% (i.e. a coin flip). Similarly, in a two-to-one, 2 arm, parallel-group RCT, the probability of intervention would be 67% and the comparator would be 33%. In a 3 arm RCT with equal sized groups, the probability of receiving any of the three treatments would be 33%. An extension of this principle may be applied to a 3 arm RCT with unequal sized groups.

One of the most important features of randomization is that every patient who enters the study has the same probability of receiving the intervention. Effectively, this reduces the likelihood that prognostic characteristics of the study patients will be unequally distributed between the intervention and comparator arms. As the sample size increases, the probability that important factors will be imbalanced across treatment groups will decrease. Moreover, this uncoupling of the link between treatment allocation and patient prognosis ensures that, on average, both *known* and *unknown* baseline characteristics of study patients will be balanced across treatment groups. This balancing property of randomization for known and unknown factors is the key feature that elevates randomized controlled trials to its "gold standard" status among all study designs.

An example of a well-conducted RCT in kidney transplantation is the ALERT study [2]. This study evaluated the efficacy of fluvastatin versus placebo in reducing cardiovascular events in a

Diabetes	197 (18.8%)	199 (18.9%)
Hypertension	798 (76.0%)	777 (73.9%)
History of cerebrovascular disease	62 (5.9%)	60 (5.7%)
History of PVD	80 (7.6%)	78 (7.4%)
Current smoker	204 (19.4%)	185 (17.6%)
Known family history of CHD	91 (8.7%)	124 (11.8%)
Concomitant cardiovascular medications*		
Any cardiovascular drug	1001 (95.3%)	999 (95.0%)
Aspirin	371 (35.3%)	353 (33.6%)
Dipyridamole	21 (2.0%)	26 (2.5%)
Coumarin or warfarin	90 (8.6%)	94 (8.9%)
β blockers	649 (61.8%)	627 (59.6%)
Calcium antagonists	728 (69.3%)	738 (70.2%)
ACE inhibitor or AIIRA	520 (49.5%)	529 (50.3%)
Diuretics	590 (56.2%)	573 (54.5%)
α blockers	176 (16.8%)	170 (16.2%)
Other	316 (30.1%)	373 (35.5%)

population of kidney transplant recipients. The table from the original paper outlining the baseline characteristics across treatment groups is reproduced (Table 134.1) to highlight the balance achieved between groups on all known (and measured) baseline prognostic factors. As mentioned above, the balance achieved in known prognostic factors provides assurance that unknown prognostic factors are also likely balanced since a random allocation scheme (with 50% probability of receiving the intervention) was used to determine who received fluvastatin versus placebo.

Observational study designs

If allocation of the intervention or exposure was not in the control of the study investigator, then the study is considered *observational*. The presence or absence of a comparator group must then be ascertained. The specific use of registries in observational studies is covered in depth in Chapter 133.

Descriptive observational studies

An observational study with no comparison group, for example patient(s) exposed to a novel treatment, is considered a *descriptive*

study. This is the domain of case reports and case series where the outcomes of patients on a novel treatment may be described. Alternatively, the course of patient(s) with a rare disease or an unusual presentation of a common disease may be presented. Trends in disease incidence over time or utilization of health care resources are also examples of descriptive observational studies. Although these studies may be helpful in highlighting findings of clinical interest, therapeutic importance, or health policy relevance, the absence of a comparator group prevents investigators from quantifying the association of a novel treatment, risk factor, or policy with an outcome of interest. The latter can only be achieved in a study with at least two groups for comparison (i.e. an analytical study).

Despite their shortcomings, descriptive observational studies can provide the basis for more rigorous, hypothesis-driven, analytical studies to examine the effect of a novel intervention or risk factor on clinically important end-points. An example of a descriptive study that has led to the design of more definitive analytical studies is the case report by Locke et al. [3]. This report described a patient with refractory acute antibody-mediated rejection who, upon treatment with eculizumab, had an improvement in kidney function and histology, both of which returned to baseline within two months of treatment. This report was followed by an analytical observational study by Stegall et al. that has subsequently formed the basis for an RCT evaluating eculizumab in the prevention of acute antibody-mediated rejection in high-risk kidney transplant recipients [4].

Analytical observational studies

There are three major types of analytical observational study designs in clinical research. They are described below.

Cohort studies

Figure 134.3 displays the structure of a cohort study. In a cohort study, patients from a population are recruited into the study using clearly defined and prespecified inclusion/exclusion criteria. At the time of recruitment, an exposure or risk factor, such as delayed graft function or current smoking, is measured in each patient and the development of the outcome or disease in the "exposed" group is examined against a comparable group of patients who are "unexposed". Exposures can be grouped into categories (as shown) or may be measured on a continuous scale (e.g. systolic blood pressure). Continuous exposures can also be categorized into clinically meaningful groups (e.g. systolic blood pressure <140 versus ≥ 140 mmHg).

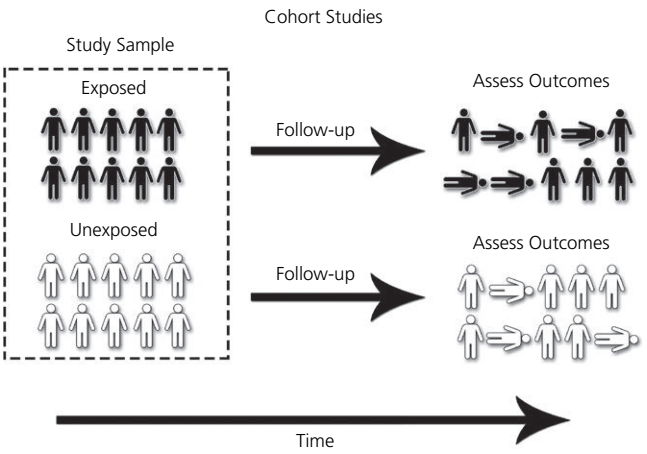

Figure 134.3. The structure of a cohort study.

Since all patients entering a cohort study are free of the outcome or disease of interest at the time of study recruitment, the *incidence* or new case rate of a disease over follow-up can be estimated from the cohort. The time from study recruitment , that is the time when patients come under observation, to the time of the outcome of interest can be measured in cohort studies, therefore this is the only study design that permits survival analysis. Importantly, only patients at risk for the outcome of interest should be included in a cohort study. For example, a study of risk factors for recurrent acute rejection should only include patients who have already had one episode of acute rejection. Patients with no history of acute rejection would not be eligible to have a second acute rejection until they have already had their initial episode.

Cohorts of patients may be assembled in the present and followed into the future for the event(s) of interest. This is known as a *prospective* cohort study. Alternatively, existing datasets may be used to assemble cohorts from the past and then track the occurrence of the outcome over time. This is known as a *retrospective* cohort study. Both designs are fundamentally cohort studies since they assemble patients at some clearly defined time point (either in the present or past) and then follow them forward in time to measure the outcome of interest. An alternate way of expressing this concept is that a cohort study ascertains exposure status at the time patients enter the study and then outcomes are tracked in each exposure group over time. Retrospective cohort studies are often assumed to be inherently inferior to prospective cohort studies in terms of study validity. This is not necessarily so. The key issue is the quality and breadth of data collection and use of the basic principles of the scientific method. An existing dataset may not have been meant to answer a specific scientific question, but if the relevant data have been rigorously captured, the rigor and quality of a retrospective cohort study can rival any prospective cohort study.

Sometimes, instead of entering exposed and unexposed patients into the cohort over a similar time period, unexposed patients from the more distant past (also known as historical controls) may be compared to exposed patients from the more recent past or the present. This study design is known as a *non-concurrent* (as opposed to *concurrent*) cohort study. Non-concurrent cohort studies are typically performed when a new treatment has been widely adopted and the outcomes under the new treatment are compared to the outcomes under an older treatment that was more commonly used in the past. For example, the aforementioned study by Stegall et al. compared the acute antibody-mediated rejection rates of consecutive living donor kidney transplant recipients receiving prophylactic eculizumab post-transplant with historical patients receiving prophylactic intravenous immunoglobulin and plasmapheresis post-transplant [4]. The major shortcoming of this design is that changes in the general medical management of patients and other secular changes cannot be effectively accounted for since most (if not all) of the more recent patients will have been treated differently from past patients. This may be less problematic if the time period during which exposed and unexposed patients are recruited is relatively short.

A cohort study is the preferred study design in the setting of a rare exposure. For example, the long-term implications of acute radiation exposure at the end of World War II have been studied in

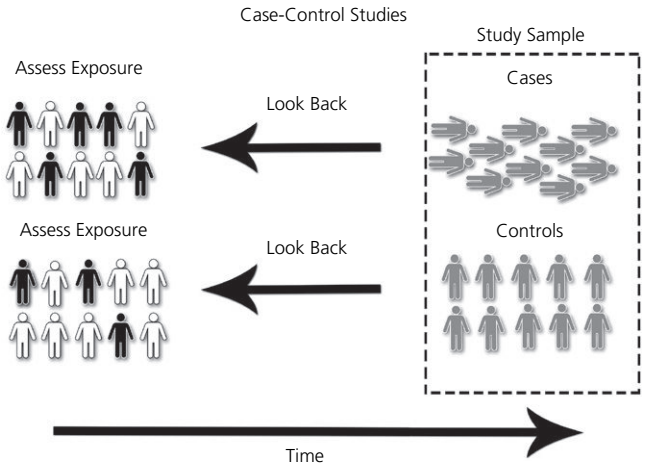

Figure 134.4. Structure of a case-control study.

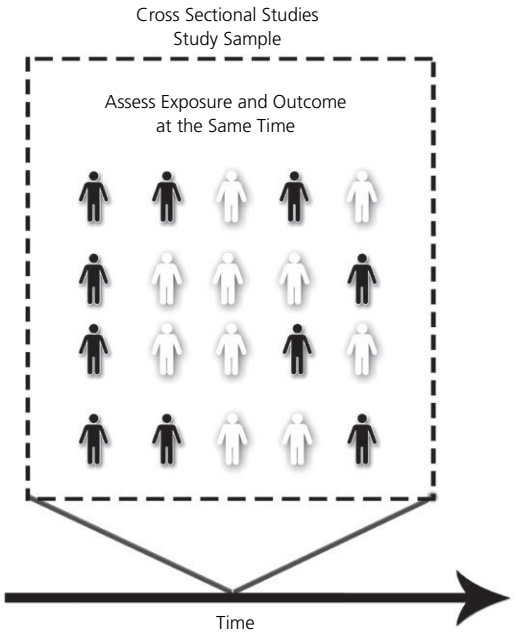

Figure 134.5. Structure of a cross-sectional study.

a cohort of atomic bomb survivors from Japan [5]. This cohort is special in that the exposure of interest is, thankfully, uncommon but provides a unique opportunity to study its health effects over many years of follow-up.

Cohort studies are considered the central study design in epidemiology. All other study designs are ultimately derived from a cohort. In fact, an RCT is also a cohort study except the treatment, intervention, or exposure is randomly allocated in the context of the study protocol. In contrast, exposures measured in observational cohort studies are typically allocated in non-random ways by the patients themselves (e.g. smoking) or their caregivers.

Case-control studies

Case-control studies are less common in the transplant literature but are widely used in other areas such as genetic epidemiology. The structure of a case-control study is depicted in Figure 134.4. Case-control studies initially assemble patients on the basis of their outcome, such as diseased versus non-diseased patients. Subsequently, the exposure status of diseased patients at some time point in the past is ascertained and compared to the exposure status among non-diseased patients. Inherently, case-control studies are retrospective in the sense that both the exposure and outcome have already occurred by the time the study is conceived. Note that the case-control study is still an analytical observational study since the investigator did not assign the exposure or risk factor and there are at least two comparison groups (Figure 134.2).

The case-control study is the most efficient design for evaluating rare diseases or outcomes that take many years to develop since it takes advantage of existing datasets with exposures and outcomes that have already been captured. Moreover, if there is additional effort needed to measure the exposure, for example through chart review, patient interviews, or testing of stored blood samples, a case-control study will allow investigators to estimate the association between exposure and disease in a more timely and economical way than in a traditional cohort study.

One of the major drawbacks of case-control studies is that the incidence of disease cannot be estimated since the proportion of patients with the disease of interest is determined by the number of cases and controls that are sampled by the investigator and not by the disease frequency in the target population. Also, there may be a greater tendency for biased results (versus a cohort study) if non-diseased controls are selected inappropriately (see *Major types of bias in clinical research* further on in this chapter). In general, controls should be selected from the pool of patients from which the diseased cases in the study are derived. This pool of patients is also known as the *study base* or *source population* (since it is the source of the cases). However, this population may be difficult to determine in advance and thus the approach to control selection requires careful thought and execution.

A recent case-control study examined the association of betapapillomavirus (betaPV) and squamous cell carcinoma (SCC) among organ transplant recipients [6]. A total of 210 cases of SCC and 394 controls were recruited from dermatology and transplant clinics at five European medical centers. Human papillomavirus DNA genotyping and betaPV serology were performed on eyebrow hairs and blood respectively. To improve comparability between cases and controls, the investigators matched patients based on age, sex, and time since transplantation. Using a logistic regression model, the investigators found significant relationships between several betaPV serotypes and SCC in this study population. Note that the study question was well suited for the case-control design since the occurrence of SCC requires long-term follow-up and is a relatively uncommon occurrence. Moreover, the measurement of specific biomarkers was efficiently performed on a sample of cases and controls instead of all organ transplant recipients at the five study centers.

Cross-sectional studies

Cross-sectional studies sample patients at one point in time or over a short duration and both exposure and outcome are assessed simultaneously without additional follow-up. The structure of a cross-sectional study is shown in Figure 134.5. Since patients can be categorized into exposure groups, and the proportion of patients with the outcome of interest can be calculated among exposed and unexposed patients, this design qualifies as an analytical observational study. Surveys performed on a population of patients where

information on exposures (e.g. smoking status) and outcomes (e.g. history of myocardial infarction) are assessed at the same time are the most common examples of cross-sectional studies.

Cross-sectional studies can be performed quickly, since no follow-up is necessary, and at little expense. It can also provide clues to scientifically interesting associations that may be later confirmed in cohort studies or an RCT. As a result, cross-sectional analyses have been typically referred to as *hypothesis-generating* studies. Furthermore, since there is no follow-up of patients, the new case rate or incidence cannot be calculated (as in a cohort study). Instead, the *prevalence*, or the proportion of patients with the outcome or disease at a given time, is the main metric of interest while the prevalence of disease in the exposed versus non-exposed is the main comparison of interest.

The major weakness of cross-sectional studies, however, is that the temporal relation between exposure and outcome may not be clearly delineated and thus associations derived from these studies may be susceptible to *reverse causality*. The latter refers to situations where the outcome has affected the exposure such that the association measured in a cross-sectional study may be biased. For example, a survey of patients' current smoking habits and a history of lung cancer may erroneously suggest that smoking is protective against lung cancer. However, the development of lung cancer may have altered the taste for cigarettes leading to a reduction in smoking frequency versus the non-cancer group.

Experimental versus observational study designs

The RCT has become the gold standard study design for evaluating treatments or health care technologies since random allocation of the intervention improves the validity of causal inferences about the effect of intervention on the outcome(s) of interest. This primarily results from the balancing property of randomization for both known and unknown prognostic factors. However, there are settings in which the RCT is infeasible or unethical. Exposures or risk factors that cannot be readily allocated by the investigator, such as delayed graft function or hyperhomocysteinemia, must be studied in an observational setting. In addition, potentially harmful exposures such as smoking cannot be ethically allocated to patients, and thus can only be evaluated using observational study designs.

Typically, only one or two hypotheses can be formally tested in an RCT with sufficient statistical power whereas multiple hypotheses can be examined in observational studies. In transplantation, a significant challenge of RCTs is also the relatively small eligible population for enrolling a sufficient number of patients to test research hypotheses. Often, RCTs must utilize surrogate endpoints rather than traditional hard endpoints (such as death or graft loss) due to resource demands or lack of long term follow-up. While these surrogates can be important indicators of mechanisms of effects of interventions, they also can detract from inferring the broad impact of a given treatment [7]. Moreover, RCTs tend to include a relatively homogeneous, well-defined, population of patients treated under ideal conditions. This may limit the generalizability of the results. In fact, transplant patients that participate in research are systematically different from patients that do not participate and have significantly different outcomes [8]. Thus, investigations of research questions with observational studies often serve as important complements to RCTs, which can examine the impact of interventions in practical application and typically with more statistical power. The non-trivial tradeoff of observational studies is the potential for bias associated with non-randomized designs.

Random and systematic error

The major types of errors in clinical research can be categorized into random and systematic.

Random error

Random error refers to variability in measurement that may impact the reproducibility or reliability of study findings. Sources of variability include:

- the observer — that is the person making the measurements;
- the instrument — a sphygmomanometer for blood pressure readings;
- the subject — the individual on which measurements are being made.

A reproducible or reliable measure is said to have good *precision*. Therefore, random error and precision are inversely related; less random error implies greater precision (and vice versa).

In general, studies with larger sample sizes improve the precision of summary measures (e.g. hazard ratio) derived from the study subjects (Figure 134.6). Moreover, standardizing approaches to measurement, properly training research personnel, and calibrating instruments are other ways to improve precision. The implication is that the greatest gains in precision are made during the *design and conduct* phases of a study. Although there are statistical methods that can improve precision in the analysis phase, the gains are relatively minor in comparison.

Systematic error

Systematic error refers to a fixed deviation from the true value of the measurement of interest. Unlike random error, it is not improved or reduced by increasing the sample size of the study (Figure 134.6). Another term for systematic error is *bias* (which will be further explored in the next section). Sources of systematic error can be classified in a similar fashion to random error:

- the observer — how patients are selected to be included in the study
- the instrument — measurement of key variables
- the subject — tendency to possess other prognostically important risk factors along with the exposure of interest.

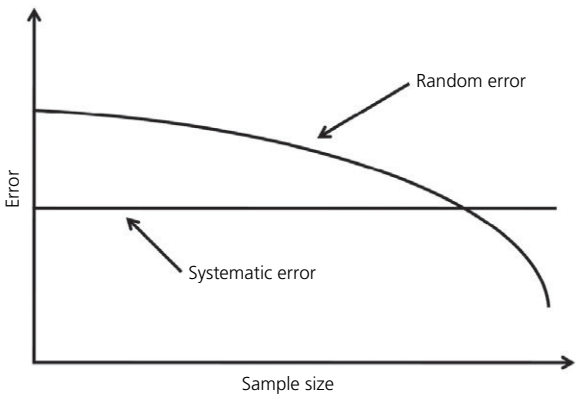

Figure 134.6. Random and systematic error as a function of sample size. Adapted from Rothman KJ. *Epidemiology: An Introduction*. Oxford University Press. 2002 [53].

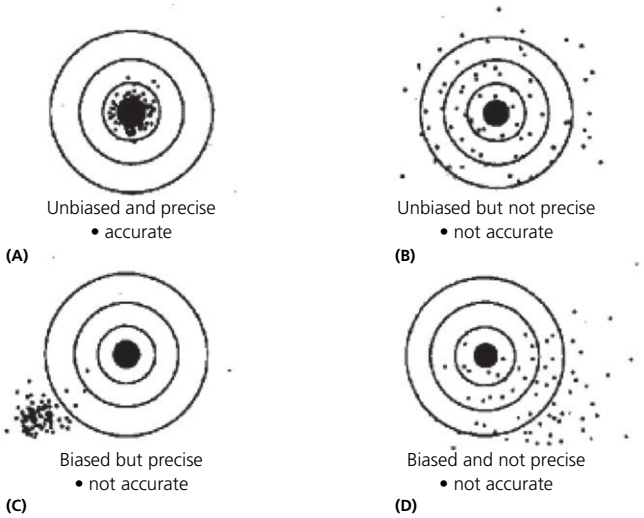

Figure 134.7. Bias versus precision.

Note that precision is to random error as *validity* is to systematic error. Thus, greater bias means less validity. Approaches to reducing systematic error will improve the validity of measurements. Furthermore, akin to random error, these approaches are most effective when implemented during the design and conduct phases of the study. Statistical adjustment is most helpful in the setting of confounding bias (see further on) but requires that the relevant variables are considered and measured during the earlier phases of the study.

Relationship between precision and bias

The goal of every clinical researcher is to have his/her study provide both a precise and unbiased/accurate measure of association for the exposure-outcome relationship of interest. This is reflected in Figure 134.7a. However, the results of a study may be highly precise but biased (Figure 134.7c). This is typical of large population-based observational studies of therapy where the measure of association is precisely quantified but may be erroneous due to biases that have not been taken into account. Alternatively, some studies may provide a valid measure of the relation between exposure and outcome but it may be imprecise (Figure 134.7b). This can be observed in the setting of a well-conducted randomized clinical trial where a valid measure of the treatment effect can be obtained but the sample size is insufficient to allow a precise calculation of this effect.

Internal versus external validity

As previously mentioned validity is inversely related to bias, a study with less bias is more valid and vice versa. A valid study provides an estimate of the exposure-outcome relationship that approximates the true value of interest. However, the "true" value may depend on which population one is referring to when making epidemiologic inferences.

A study that sampled an appropriately representative group of patients (i.e. no selection bias), made accurate measurements of all relevant variables (i.e. no information bias), and controlled for factors that can confound the relation between exposure and outcome (i.e. no confounding bias), is said to have *internal validity*.

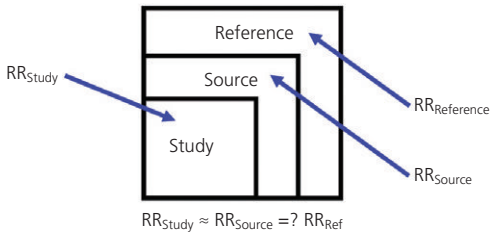

Figure 134.8. Generalizability of study findings (internal vs. external validity).

Effectively, this means that the measure of association (such as the risk ratio (RR)) calculated for an exposure-outcome relationship from the study population is a good estimate of the RR that would have been calculated from the source population (Figure 134.8).

Note in Figure 134.8 that the study population is nested within the source population, which in turn, is nested within the *target* or *reference* population. As mentioned above, internal validity relates to the RR in the study being a good estimate of the RR in the source population. Moreover, if the latter is also a good estimate of the RR in the reference population, then the study result is said to have good *external validity*. An example of study, source, and reference populations include a sample of kidney transplant recipients from a given center, all kidney transplant recipients from that center, and all kidney transplant recipients from similar centers throughout the world, respectively. Similarly, US nurses recruited into a study cohort, all nurses in the US, and all women in the US may constitute the study, source, and reference populations for the Nurses' Health Study [9].

Based on the definitions outlined above, internal validity is required before external validity can be established. Most times, internal or external validity cannot be established independent of the data from the study itself. One must rely on the characteristics of the study design, conduct, and analysis to infer that the results are likely internally valid. External validity may be partially assessed by the characteristics of the study participants and their similarity to a reference population of interest. However, there may be other unmeasured or unknown factors that differ between study subjects and the reference population. It is also important to note that the source and reference populations to which the results of a study may apply are specific to a given study's objectives and design. There is no absolute source and reference populations, only those that are relevant to a given study.

Major types of bias in clinical research

There are three major types of study bias in clinical research that encompasses all the ways that the results of a study can be misleading or incorrect (apart from the play of chance).

Selection bias

Selection bias is the distortions that can be observed in the exposure-outcome relationship due to the way patients are recruited into a study or the way they are lost over follow-up. The factors that determine participation in a study may also be related to health status such that those who are included in a study may be more or less healthy than those who were theoretically eligible to be studied (but were not included). Note that the selection of specific patient subgroups into a study is common but bias only occurs when the exposure-disease relationship is altered as a result of this selection

process. In this setting, the measure of association calculated in the study population is different from the relation in the source population.

A recent example of selection bias can be seen in the observational studies relating intake of hormone replacement therapy (HRT) to the development of cardiovascular disease among a cohort of US nurses. Analysis of the Nurses Health Study (a large prospective cohort study of US nurses followed over several decades) showed that HRT significantly reduced the risk of cardiovascular events [9,10]. However, a large clinical trial of HRT subsequently showed that the risk of cardiovascular disease is not reduced, and in fact, may be increased in the early period after initiating treatment [11]. This suggested that nurses who participated in the study may be different from the general population of women with respect to their health status and these differences were difficult to measure and adjust for in the original analysis.

Although one of the most effective ways to eliminate selection bias during study recruitment is to randomize the exposure or intervention of interest, this is not feasible in many settings. Selection bias may occur during recruitment of patients into a cohort study or as a result of inappropriate selection of controls in a case-control study. Furthermore, the potential for selection bias exists over follow-up in both clinical trials and cohort studies. If exposed (or unexposed) study subjects with the best (or worst) prognosis are preferentially lost to follow-up, the remaining cohort may provide a biased estimate of the association between the exposure and disease.

The control of selection bias is critically dependent on the design phase of the study. Adjustment for selection bias during the analysis phase is difficult, if not impossible. Careful recruitment of study subjects who are representative of the source population should be undertaken. Moreover, strategies to optimize retention in clinical trials and cohort studies will be necessary to reduce the risk of selection bias developing over follow-up.

Information bias

Information bias results from errors in the ascertainment of exposure, outcome, and/or confounders leading to invalid assessments of the association between exposure or treatment and the outcome of interest. This bias is also referred to as measurement error or misclassification (for categorical variables). Errors of this kind are ubiquitous in clinical research and are often underappreciated. In most cases, the degree of bias caused by measurement errors is difficult to predict in advance. If the errors are consistent across binary exposure or disease categories (e.g. the rate of misclassifying hypertensives versus non-hypertensives is the same regardless of the future risk of cardiovascular disease), then the association will tend to be attenuated towards the null effect. This is also referred to as non-differential misclassification. In the setting where the misclassification is differential (i.e. error rates vary as a function of exposure AND disease), then the direction and magnitude of the bias is difficult to predict.

Reducing the risk of information bias involves the proper training of research personnel, calibration of measuring instruments, and appropriate codification of all data elements to be collected. In addition, if the exposure, outcome, and/or confounders were captured using a surrogate measure (versus the gold standard), it would be useful, when feasible, to perform a sub-study where a smaller group of subjects undergo measurements by both surrogate and gold standard approaches. This will provide a means to assess the degree of measurement error associated with the former. For example, a food frequency questionnaire that collects data on dietary patterns based on recall over an extended period of time should be validated against a daily food diary performed in a sub-set of patients. Validation work of this kind can also be used to support future research that uses this questionnaire.

Confounding

Fundamentally, confounding refers to a confusion of effects. Confounding of a measured relation between exposure and disease occurs when this relation may be fully or partially explained by the influence of an extraneous third factor.

In order to cause confounding, the third factor must have the following three properties:

1 It is an independent risk factor for the outcome (in the unexposed).
2 It is related to the exposure (in the source population).
3 It is not affected by exposure or disease.

The first property implies that the third factor is causally related to the outcome. This relationship should exist independent of the exposure (i.e, a relation between the confounder and the outcome should be observed among the unexposed). The second property highlights the need for the third factor to be related to the exposure among those who have not yet developed the disease, such as the source population, since the exposure and third factor will tend to be related among the diseased, regardless of their relation in the source population. The last property includes settings in which a third factor may mediate the effect of an exposure on the outcome (i.e. an intermediate in the causal pathway). For example, the impact of statin therapy on cardiovascular disease is, at least partially, mediated by its influence on LDL cholesterol levels. In this setting, LDL cholesterol does not confound the relation between statin therapy and the occurrence of cardiovascular disease.

An extraneous third factor that is responsible for differences in disease frequency among exposed and unexposed individuals is called a *confounder*. Moreover, related variables that can act as surrogates for these extraneous factors may also be considered confounders. These factors are *extraneous* in the sense that they are not part of the causal pathway from exposure to disease (as noted in the third property above).

Control of confounding is dependent on measuring the factors that confound the relation between exposure and disease and then accounting for them in the study design or analysis phase. Study design approaches to control for confounding including randomization, matching, and restriction (study analysis approaches will be discussed in the second part of this chapter). Although randomization is the most effective way to control for both known and unknown baseline confounders, it is infeasible or impractical in many settings (e.g. if the exposure is a biomarker in the blood).

Matching refers to pairing exposed and unexposed subjects at the same level of the potential confounder(s) of interest. For example, matching on gender will ensure that it no longer acts as a confounder in the exposure-outcome relationship since the frequency of males (and females) will be comparable in exposed and unexposed individuals. Multiple confounders can be matched simultaneously but this tends to reduce the number of matched pairs that can be created. Moreover, once matched, these confounders cannot be assessed in terms of their relation to the outcome.

Restriction involves limiting the study population to only a certain level of a given confounder to eliminate its influence on the

exposure-disease relationship. For example, if gender is a potential confounder, then studying only females will eliminate confounding by gender. Although it can be a powerful way to control for confounding, there are some disadvantages to restriction. This method tends to reduce the sample size and thus adversely impact on the power. As a result, one needs a large dataset in order to employ restriction effectively. In addition, if the association between exposure and disease differs in males versus females, then restriction to only females will prevent the investigator from examining the potential for effect modification by gender. Finally, the generalizability of the results may be diminished since the study population has been altered from the original one that was being evaluated.

Power and sample size issues

In designing a clinical trial or observational study, one of the main goals is to show a difference in the effect of the intervention or exposure on the outcome of interest, if it truly exists. The target sample size needed to show this difference depends on several factors. These include:

- the hypothesized effect size;
- the baseline rate of the outcome in the control or unexposed population;
- an estimate of the variability around the outcome;
- the type 1 error rate, such as the probability of finding a difference when there is really no difference (typically set at 0.05);
- the power or one minus the type 2 error rate, such as the probability of finding a difference when there really is a difference (typically set at $\geq$0.80);
- subject attrition rate (or lost to follow-up);
- the recruitment period; and
- the follow-up period [12].

The specific elements that are relevant to a given situation depend primarily on the type of outcome being evaluated (i.e. continuous, categorical, rate, or time-to-event).

Sometimes, the sample size for a study may be relatively fixed and thus a calculation of power for various effect estimates is necessary. Regardless of which quantity is desired, sample size and/or power calculations are necessarily artificial since one needs to make various assumptions about the values of the parameters mentioned above. These assumptions may be guided by existing data in other populations or theoretical estimates but the true values are not known in advance of conducting the study but can have a marked effect on the actual sample size required to conduct a study [12]. Appropriate sample size/power calculations are not only important to increase the likelihood that there will be adequate precision in the estimated treatment or exposure effect, it provides study subjects the assurance that their participation in the study will yield useful information to clinicians and future patients.

A number of proprietary statistical software packages have built in sample size/power calculators (e.g. Stata or SPSS). There are also excellent sample size/power calculators that can be freely downloaded from the web (e.g. http://biostat.mc.vanderbilt.edu/PowerSampleSize).

Data sources: strengths and weaknesses

The opportunity and quality of research is often dependent on the data source. Without careful evaluation of the quality of data, findings may be erroneous or misleading or do little to guide prospective practices. It is also important to consider that data derived from different sources can also be utilized for unique purposes and have a different variety of strengths and limitations. Researchers and consumers of research must be cognizant of these in order to best design studies and interpret and implement findings into practice. Data sources can be broadly categorized as deriving from prospective trials or observational studies. A further distinction for observational datasets is those derived from single- or multi-center studies and those from national registries. The general strengths and weaknesses of these data sources are considered below.

Randomized controlled trials

As discussed previously, well-designed RCTs provide the best evidence for a research hypothesis while mitigating the presence of selection and confounding biases that are endemic to observational studies. Despite the advantages of RCTs, it is important to recognize that the design, conduct, and reporting of the trial remain critical to the interpretation of results.

The primary limitations of clinical trials relate to significant resource constraints, inability to test for rare events, or address study questions that may be considered unethical to test (e.g. testing the efficacy dialysis versus kidney transplantation will likely never be validated in a clinical trial). In addition, there is substantial literature to suggest that clinical trials are both designed and conducted with varying degrees of quality [13]. The CONSORT group has published numerous articles in an attempt to standardize trials based on best practices [14,15]. Consumers of this research should be cognizant of potential pitfalls or sources of potential bias that may accompany results of clinical trials.

Clinical trials are typically designed and statistically powered to answer one research question based on a primary endpoint. One common misconception is that failure to detect significance for secondary endpoints suggests non-significant differences. Secondary endpoints are rarely powered to show differences, and as such, lack of statistically significant findings cannot be interpreted in the same manner as primary endpoints. A source of contention about clinical trials is the use of subgroup and post-hoc analyses [16]. While these analyses may provide additional information about the effects of an intervention, they cannot be assessed in the same manner as the primary research hypothesis for which a trial was designed. Most prominently, secondary analyses often do not maintain the benefits of randomization and each test may not be sufficiently powered. In addition, it should be clear whether hypotheses were tested a priori and whether adjustment for multiple testing was incorporated into the analysis.

An important consideration for the interpretation of clinical trials includes whether results are applicable in practice. One must consider the potential for "study effects" in which, based on the conditions of the trial (e.g. reduced medication prices, enhanced follow-up protocols, or selected populations), results may not always be applicable outside of the study setting. More recently, trials in transplantation have been designed with non-inferiority endpoints. The attraction of these designs is reduced resource requirements and potentially more rapid findings. However, there are also significant notes of caution about non-inferiority trials including the use of a somewhat arbitrary effect sizes and the choice of control groups [17]. Finally, due to resource constraints, trials often utilize composite endpoints (for kidney transplantation these may include acute rejection, renal function, serious adverse events along with death and graft loss). An important consideration for these trials is how to reconcile results in which each component of a composite endpoint may have different clinical

ramifications and may occur with different frequency between study arms [18].

Single-center observational studies

One of the advantages of research deriving from single centers is acquisition of data with granular information that is specifically related to a given research hypothesis. That is, rather than relying on existing data sources, research from single center studies have an opportunity to collect specific information pertinent to a study question. This type of specificity may yield novel findings that are difficult to replicate across different settings. Another advantage of these studies is that findings often reflect observations with a homogenous environment and care protocols. Based on this, the variability that may be attributed to different models of care at different institutions is not salient for the interpretation of study findings.

A primary limitation of single-center studies is potential lack of generalizability to other contexts. As an example, a given center may utilize protocol biopsies as a standard of care and report rejection events at different rates than centers that only perform biopsies for cause. As such, validation of findings from single centers is often critical towards understanding the implications of study findings. Single-center studies may also lack statistical power to test hypotheses for "hard endpoints" such as patient death unless aggregated over a broad era. Moreover, acquiring data over a broad era may lead to potential bias related to secular trends. These aspects should be considered for both the design and interpretation of studies from single centers.

Multi-center observational studies

The general principles of observational studies derived from a single institution apply to multi-center studies, often referred to as collaboratives. The advantages of combining data across institutions include (a) an increase in sample size and (b) validation of findings between settings with potentially diverse populations and care practices. As compared to single-center studies, findings derived from multiple institutions may be considered more externally valid and more likely applicable in novel settings. However, a limitation of multi-center studies is often a lack of data consistency, which may compromise the ability to pool data in a standardized form. As such, prospective planning of these studies prior to any data collection is often critical to study completion.

National registries

The field of transplantation is fortunate to have a mandatory data collection process such that information on virtually the entire census of patients in the US is available [19]. Data collection on transplant candidates, recipients, and donors is administrated by the United Network for Organ Sharing (UNOS). This agency oversees the collection of forms and compiles data for research files and study reports. In addition, the US Renal Data System (USRDS) and the Scientific Registry of Transplant Recipients (SRTR) are contracted agencies that also utilize these data to produce research files. The SRTR also contains data on all non-kidney solid organ transplant recipients and donors. National registries have been utilized extensively for research and present a rare opportunity in medicine to evaluate a complete cohort of patients. However, as with smaller observational studies or randomized trials, national registries are also associated with various strengths and weaknesses. More details regarding population studies and transplant registries are discussed in Chapter 133.

Exploratory data analysis

One of most important and perhaps underappreciated aspects of any research study is a comprehensive evaluation of the applicable data elements. Exploration of the pattern of these data can be important to identify outliers and influential observations, determine if there are linear or non-linear patterns of continuous data, describe the shape of data elements, and examine bivariate relationships between variables. This process can also be critical to avoid utilizing data with miscoded information or for variables that may have been used in different forms over time (e.g. UNOS forms collected the same data element using a different scale) as well as verifying the data are in an appropriate format. In general, investigators should be comfortable with the structure of data prior to conducting more complex analyses.

Univariable analyses

Univariable analyses typically involve depicting the distribution or shape of a variable, estimate measures of central tendency and variability or dispersion. The applicable statistics that reflect these characteristics depend on the type of individual variables. As such, identifying the type of variable within a study is critical to inform the descriptive statistics and further modeling of these variables for subsequent analyses. There are multiple purposes for univariable analyses including: investigating the presence of outliers and influential observations, assessing the validity of distributional assumptions of variables, and initially examining whether a given sample compares to standards in a known or broader population. For data that does not meet desirable distributional properties for a given analysis, univariable analyses can also be utilized to examine appropriate transformations of variables on different scales.

Multivariable analyses

For most research studies, the primary hypotheses examine the association of two or more variables. Bivariate associations are common analyses applicable to both categorical and continuous variables in contexts in which one variable represents a response, and another an explanatory variable, or when variables do not have such a relationship. Examples of bivariate analyses include Spearman's correlation Fisher's Exact test, Student's t-test, Wilcoxon signed-rank test and Kappa statistics among many others. For each type of bivariate analyses, there are different assumptions concerning the type, distribution and size of the variables that are important for the appropriate application and interpretation of the findings. Failure to utilize the appropriate analyses for a given set of data can significantly impact the interpretations and tests of significance. One of the limitations of bivariate analyses in the context of observational studies is to determine whether any observed associations between variables are strongly influenced by additional factors. Thus, while it is often interesting and important to evaluate the relationship between two variables, models incorporating additional factors are also typically useful in practice.

One of the most common frameworks for statistical models is the least squares (or linear) regression model. Basic assumptions of this model include that errors are additive, normally distributed, and independent with a common variance. Violation of these assumptions can variably impact the point estimates and conclusions of a hypothesis test. However, it is not uncommon for some data to have departures from these assumptions and the impact of these departures depends on (a) the magnitude of violation(s) and

(b) which assumption(s) is violated, and (c) the sample size. Least squares analyses (such as common t-tests and F-tests) assume that the residuals of the model are normally distributed. Failure of this assumption impacts the conclusion of hypothesis testing and confidence intervals of parameters. One potential remedy for variables that do not meet these assumptions is to transform the data (e.g. logarithmic or square root). In addition, other modeling strategies such as non-parametric models or models that have different distributional requirements (e.g. Poisson, Survival or Logistic models) may describe the relationship between variables more appropriately.

Another common violation of statistical assumptions for models is the independence of observations. Specifically, many standard models assume that the errors are uncorrelated between observations. The impact of correlated errors leads to loss in precision of estimates. Data that represents multiple observations for single patients or observations that can be clustered within a broad characteristic should be modeled to account for this dependence. In the context of transplantation, this may arise when patients are matched (e.g. paired donor kidney studies), when study populations are treated within larger units such as centers or individual physicians or when longitudinal data is collected for a given patient over time.

Survival analysis

One of the most common approaches for analysis of outcomes among the transplant population is the use of survival analyses. Survival models (otherwise known as time-to-event models) are appropriate for examining the time to specified events (such as patient death or graft loss) in a cohort of patients from a specified initiation time. These models allow investigators to evaluate the relationship of an explanatory factor and an endpoint of interest while considering that patients may have differing amounts of time at risk for the endpoint to occur. This allows models to incorporate patients with highly variable follow-up periods into a single analysis.

The most common examples of these are the Kaplan-Meier plots and the Cox proportional hazard models. Kaplan-Meier plots demonstrate the cumulative incidence of a given endpoint without adjustment for subject covariates while the Cox models can be developed with or without adjustment for covariates. One of the important principles of these models is the concept of censoring. Models are censored at time points that represent the last at-risk period (right censoring) for subjects that is not defined as an event. For example, most survival plots are censored at the time of last patient follow-up or known status, such as the time point when patients are no longer at risk for an event to occur. Of note, the censor time can be different for each patient in a given model but the models assume that the censor mechanism is not related to event of interest. As such, if models are censored at time points that are not distributed randomly, the estimates deriving from the models can be biased. For example, a common endpoint in transplantation is death-censored graft loss, which treats deaths as a "non-informative" censoring event. This implies that patients who die are no more or less likely to experience graft loss if they had remained alive versus those that actually remain at risk for graft loss. In many contexts, this can be an egregious violation of the assumption of a random censoring. One approach to handling non-random censoring is the use of competing risks analysis [20]. These analyses allow for estimates of cumulative incidence for events that are correlated over time and can vary significantly from the standard product-limit (Kaplan-Meier) methodology.

Diagnostic testing

A common research question relates to whether a specific parameter can serve as an accurate diagnostic test for a particular outcome. This may be in the context of a diagnostic parameter for identifying the presence of a disease state or as a prognostic evaluation of a subsequent event of interest. For example, there may be interest in understanding whether a given biopsy reading from a deceased donor has prognostic value for transplant outcomes. In a similar fashion, we use screening tests to rule out donors for disease transmission based on criteria from the Centers for Disease Control and Prevention [21,22]. We may also be interested in understanding the predictive value of surrogate makers, such as renal function as a surrogate for graft loss [19,23]. For these examples and others, the salient question may be how well a diagnostic parameter predicts a given outcome. We can quantify that in several ways. In the context of a "2 × 2" table with a binary outcome and predictor, we can calculate:

- the sensitivity — probability of a positive test when an outcome is present
- specificity — probability of a negative test when an outcome is absent
- the positive predictive value — probability of an outcome present when a test is positive, and
- the negative predictive value — probability of an outcome absent when a test is negative.

Each of these statistics can be helpful for quantifying the predictive accuracy of a given diagnostic parameter but the value of each statistic may vary depending on the clinical context. In certain circumstances, it may be more helpful to understand the sensitivity and positive predictive value (evaluating how well positive cases are identified), while in others the specificity (evaluating how well negative cases are identified) may be more salient. These data can also be utilized to determine a cut-off value or a threshold at which a diagnostic parameter can best be utilized for prognostic application.

Importantly, the criteria for a diagnostic parameter to truly be predictive are different and typically more rigorous than the criteria for a parameter to have an association with a given outcome [24]. There are many examples of parameters that have well known associations with clinical outcomes that have poor discriminatory power which would be characteristic of a highly predictive diagnostic parameter. As such, in research, it is important to distinguish those parameters that are highly predictive and to utilize appropriate statistical methodology to demonstrate the predictive capacity of a diagnostic parameter.

Risk adjustment

In order to generate inferences about a broader population (e.g. all transplant recipients in the US) from a sample or to compare characteristics or outcomes between two study groups, it is desirable to minimize the effects of characteristics other than the exposure(s) of interest (Figure 134.9). For any non-randomized clinical research study, there is almost certain variation of donor, recipient or other transplant-related factors between exposure groups. As such, in order to evaluate the independent effect of exposure on a particular outcome, statistical methods to adjust for differences beyond the

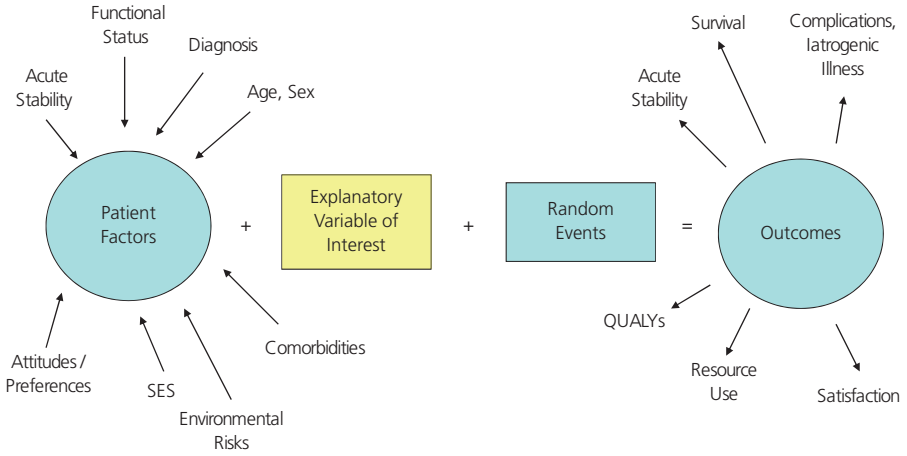

Figure 134.9. Risk adjustment in clinical research. * Adapted from [25] Iezzoni LI. *Risk Adjustment for Measuring Healthcare Outcomes*, 3rd edition. Chicago, IL: Health Administration Press, 2003, (Chapter One, p.5, Reasons for Risk Adjustment).

exposure groups are critical. However, it is important to recognize that "risk adjustment" is not developed through uniform or cookbook methodologies. Exactly how to account for variation in risk factors depends on several conditions including: (a) the outcome of interest; (b) the temporal relationship between the exposure and outcome; (c) the purpose of the study; and (d) the population(s) evaluated [25]. In this sense, investigators and consumers should be cognizant of the particular nuances of each study and not necessarily apply the same risk adjustment techniques to every analysis.

In the US, we are fortunate that we have a wealth of data collected on donor, recipient and transplant characteristics on a mandatory basis for every solid organ transplant candidate, recipient, and donor by the Organ Procurement and Transplantation Network (OPTN). As such, there are opportunities for standardized and comprehensive risk adjustment using statistical models across and between transplant centers. However, it is important to recognize that even with risk adjustment for these clinical parameters, the discriminating power of models is relatively modest [26]. In fact, compared to many other high profile medical contexts, this predictive capacity is substantially lower suggesting there are non-codified factors that substantially explain outcomes and/or there is a relatively high degree of random variation for explaining events in these patients. This does imply that, in many transplant studies, there may be a serious threat of confounding from factors not consistently documented and the potential role of these factors should be considered in the context of a study and the appropriate interpretation and cautions acknowledged.

Subgroup analyses and effect modification

An important, and often interesting, component of any statistical analysis assessing any study population is to evaluate whether findings are consistent for all groups of subjects within the population. An interaction (or effect modification) exists when the relationship between two variables differs with respect to the level of a third variable. For example the association of an immunosuppressive regimen on the risk of acute rejection may be modified by patients' age or immunological status. The effects of exposure on the outcome in different subgroups can be visualized in a Forrest plot with the tests of interaction included to indicate whether there is a significant difference of the main effect in each subgroup (Table 134.2). Analyses of interaction can have important clinical implications, especially when they are adequately powered, namely whether a given finding is likely to be generalized across a population or might be more or less applicable for certain strata of patients.

Interpretation of models

For any non-randomized study, it is rare that causation can be strongly inferred from documented statistical associations. This is primarily due to the potential for confounding and the impact of intervening factors not ascribed to study group assignment that may explain the observed associations. The argument that an explanatory variable is likely in the causal pathway of a given response can vary based on the strength of the association, the biological plausibility of the effect, whether the effect is observed in different settings and among different populations and in some contexts if there is a dose-response effect. However, as there are often a variety of pathways in which explanatory factors may be related to outcomes acknowledgment of the hypothetical role of unmeasured factors is important for the interpretation of results.

Another important but often overlooked aspect of the interpretation of statistical results is the probability of detecting a difference given a true effect (i.e. the statistical power of a model). In general, the capacity to demonstrate statistically significant findings is highly dependent on sample size, variability of the effects and study design. Importantly, failures to demonstrate an effect do not necessarily indicate that an association does not exist. This is particularly salient in the context of smaller samples in which the probability of finding a statistically significant effect is limited by the observations and variability of the effects. The corollary to the failure to detect effects in smaller observational studies, is the potential result of studies based on large registries (e.g. UNOS data). For these latter studies, it is not uncommon that statistically differences can represent very minor, potentially clinically irrelevant, differences. However, it is important to understand that even small differences can be important to document since they can still reflect an important association even if such differences may not represent an effect that is useful in day-to-day clinical decision-making. The interpretation of study findings should distinguish between results that are

clinically useful and statistically significant versus results representing an important mechanism but with modest clinical relevance.

Missing data

A common occurrence in clinical research is to encounter records with missing data. This may include data missing for response or explanatory variables and can present significant challenges both for analysis and for the interpretation of study results. Importantly, for many standard analyses, missing values may lead to the exclusion of observations (i.e. complete case analysis) which can reduce the statistical power of models, limit the external validity of findings, and potentially create biased comparisons. Thus, it is important to: (a) document the presence of missing data; (b) understand why the data are missing (e.g. randomly missing, missing due to loss of follow-up, high acuity cases likely to have missing data, etc.); and (c) consider different analytic strategies for handling missing data. Options for treating missing data include ignoring these cases, which may lead to exclusion of observations from models, simple imputation for missing cases (e.g. mean or modal levels) or multiple imputation [27]. In general, deleting observations due to missing data elements or simple imputation methods have been shown to lead to biased results. More sophisticated methods in which assumptions of the data hold can improve model performance and estimation [28].

Endpoints in transplantation

Acute rejection

Acute rejection has been one of the primary endpoints in transplantation for observational studies and randomized controlled trials. One of the challenges for use of acute rejection as an endpoint in research is the lack of a uniform definition. Acute rejection may be based on treatment for the condition (i.e. a clinically relevant need for care), biopsy proven rejection (including histological grade), or based on other clinical indicators (e.g. decline in renal function in the context of kidney transplantation). The variability in definition may lead to wide variations in the estimated effect of acute rejection on graft loss or death. Other considerations for the use of acute rejection as an endpoint include the timing of acute rejection events and rejection episodes that do not lead to permanent reductions in renal function (which may have no significant impact on graft survival) [29,30]. Finally, some patients may experience multiple acute rejections episodes following transplantation. These repeated events require different analytic approaches as well as some consideration for whether each episode is clearly a distinct event or a product of ongoing processes.

Delayed graft function

Delayed graft function (DGF) is a primary endpoint following the kidney transplant surgery. DGF is a form of acute kidney injury, which is most commonly defined as the recipient's need for dialysis within the first week following transplantation. One of the analytical challenges for assessing the impact of DGF on outcomes is distinguishing the event from other surgical events (i.e. technical failures) that may lead to early dialysis treatment among recipients. Center practice patterns may also impact the treatment of patients with dialysis and thus the incidence of DGF [31]. Thus, despite a relatively uniform definition of DGF that is conventionally used for research, there may be different causal factors that are important for the interpretation of study findings.

Infections

Transplant recipients are susceptible to various types of infections due to immunosuppressive therapy, the surgical procedure, onset of other complications and other co-morbid factors [32–34].

Common types of post-transplant infections evaluated in clinical research include cytomegalovirus (CMV), BK-virus, Epstein-Barr virus and various other types of bacterial and fungal forms [35–37]. Some infections may be asymptomatic or poorly documented and each varies substantially in severity, which may impact systematic documentation of incidence rates. For certain types of infections, prophylaxis can strongly mitigate the likelihood of developing clinical infections and may need to be considered in the analysis. Moreover, the particular inception and ending dates of infections is difficult to quantify in a systematic manner yet important to guide analyses. Cumulatively, infections are common sequela of transplantation, but vary widely in incidence and severity, are not always clearly documented, and may be strongly correlated with treatment protocols.

Graft loss

Graft loss is a primary "hard" endpoint for clinical research investigation. Graft loss is generally defined as either a graft failure requiring a return to dialysis or retransplantation (in the context of kidney transplantation) or patient death (this composite endpoint is also known as overall graft loss). Patient deaths are typically included in this outcome based on the assumption that many deaths are related to organ decline, and as such, it is difficult to separate the mechanisms of these endpoints from each other in all cases. At the very least, it is important to evaluate the individual contribution of death and graft loss for any comparison of study groups. A challenge for clinical investigation is that graft failure rates are relatively low in the immediate post-transplant periods. As such, either longer follow-up periods or large sample sizes are required in order to test research hypotheses with sufficient statistical power. As a result, there have also been extensive efforts to develop and understand good surrogate markers for long-term graft loss that can be utilized to assess treatment interventions with limited follow-up accrual periods [7,29,38].

Patient death

The primary limitation of death as a study endpoint is a lack of statistical power for comparing study groups. Most trials cannot be designed for patient survival, particularly in the field of transplantation. For research and study design, we often assume that patients who are more likely to experience acute rejection, infections, or DGF are also more likely to subsequently lose their graft and ultimately more likely to die. Despite this, patient survival should at least be considered a secondary endpoint. Studies designed for other complications should incorporate a separate analysis including mortality or composite endpoint to ensure that the findings are not misleading based on differential mortality rates between study groups.

Costs and resource utilization

An important endpoint for research and the application of most scientific inquiry is costs. Cost-effectiveness of a given intervention is commonly related to patient characteristics, therapeutic strategies, type of complications, and can have important practical and policy implications [39–42]. Principles of health economics can also effectively guide optimal utilization of scarce resources, which is particularly salient in the context of organ transplantation [43]. Cost-effectiveness analyses are clearly important for comparing interventions but they should also be used to study care that is effective for some individuals but results in inefficient use of resources and may lead to diminished care for other patients. Econometric methods often have unique considerations such as discounting of costs over time, modeling behavior, provider and patient decision-making, and quantifying life-years. Although it is often difficult to place economic analyses in the context of clinical efficacy studies, they are a pivotal component of the delivery of healthcare in the context of organ transplantation.

Provider quality of care

There are numerous studies evaluating the impact of provider practice and outcomes [44,45] In the US, transplant centers are currently evaluated for performance by the SRTR. The SRTR reports risk adjusted graft and patient survival on a publicly available website [46]. These data include wait list and post-transplant outcomes and demographic characteristics of the population. One of the primary metrics by which transplant centers are evaluated is the Standardized Mortality Ratio (SMR). The SMR is a commonly applied statistical metric that can be utilized to assess risk-adjusted outcomes at a provider or regional level based on indirect standardization of results to a normalized reference group (e.g. the US transplant population). SMRs are utilized to assess performance of transplant centers comparing the observed number of events (graft losses or deaths) with the expected number of events after adjustment for donor, recipient, and transplant covariates over a given follow-up period and using the national experience over a contemporaneous time period as a reference group. SMRs equal to one indicate that centers have outcomes equivalent to what is expected based on the acuity level of their transplant population while higher SMRs are indicative of poor performance relative to the number of expected events in the population. One limitation of the SMR as currently utilized in transplantation is that larger centers are more likely to receive statistically significant differences when compared to smaller centers due to increased statistical power. SMRs are also a metric by which quality of care is evaluated by CMS and other insurance companies in order to gauge transplant centers [47].

Patient satisfaction and quality of life

Perhaps one of the most overlooked but important endpoint in healthcare is patient satisfaction. Patient satisfaction is often difficult to assess objectively but is not always a primary focus of research. Proxies for quality of life in transplantation include complication rates, rehospitalizations, and graft survival. However, clinical endpoints alone clearly do not fully characterize patient satisfaction and quality of life. Prospective studies designed to capture patient satisfaction in a uniform manner are important in transplantation and further application of these data for the clinical application of interventions, allocation policy, and decision-making are needed.

Special topics

Beyond the many standard forms of analyses in the field of statistics and epidemiology are refinements to modeling strategies and novel approaches that have been developed and incorporated more broadly into clinical research. Often, these new modeling strategies are embedded into statistical packages but may also require more sophisticated programming and understanding of the underpinnings of the methodology. As with any model, it is critical for analysts to be cognizant of the assumptions of these approaches as well as the proper interpretation of the results. Some of the more sophisticated modeling strategies utilized in contemporary medical research are briefly discussed here.

Propensity score analyses are aimed at achieving a pseudo-randomized study design. The concept of this approach is generally to "recreate" a randomized experimental design comparing interventions by identifying factors that are related to the initial allocation of treatment assignment. For example, it may be challenging to compare recipients directly that received two different immunosuppressive agents given that many codified and non-codified factors were considered for treatment selection for a patient that could be related to their prognosis [48]. However, in a context in which the factors that relate to treatment assignment are known and risk factors have a strong relationship with outcomes, propensity score analysis is considered a method to minimize potential confounding [49].

Another attractive modeling strategy is the use of instrumental variables. Unlike standard multivariable analyses and propensity score analyses, an instrumental variable can be used to estimate the effect of an intervention accounting for the impact of *unmeasured factors* [50]. This unique opportunity to account for latent variables however comes with two strong assumptions: (a) the instrumental variable is associated with the likelihood of receiving the intervention, and (b) the instrumental variable is not directly associated with the outcome of interest. The latter assumption is often very difficult to identify in a standard clinical setting and limits the application of this form of analysis. However, when utilized correctly, instrumental variable analysis can serve as a powerful tool in clinical research by minimizing sources of unmeasured confounding.

As discussed previously, one of the common limitations of observational research is the inability to draw inferences regarding the causal mechanisms between exposure variables and responses of interest. In more recent years, there has been tremendous attention on analyses that can be utilized to draw causal conclusions, even in the context of non-randomized observational data. One of these analytical tools utilized to infer causality are marginal structural models. These models in essence simulate a randomized setting by empirically evaluating the probability of being treated over time [51,52]. While there are a number of complex analytics that are needed to develop these models, the value of advancing statistical analyses beyond associations has great appeal in both the theoretical and applied sciences.

Summary

One of the core misperceptions about clinical research is that models used for analysis involve little more than implementing a common algorithm on a new set of patients or new endpoints using standard statistical packages to generate results. For those that have not actively participated in research, there may be limited understanding of the many underlying processes that evolve from the conception of an idea to a finished clinical research project. At the same time, the individual steps and processes required to conduct rigorous and thorough analyses are critical to the validity and rigor of a study. Understanding these processes may evolve from intuition, training and experience and allow researchers to make sense of what is typically a compilation of complex information. Scientific rigor involves not only adherence to statistical methods and analysis but appropriate interpretation of results and transparency about how research is conducted. As both a consumer and conductor of clinical research, understanding and use of these methods are fundamental to moving science forward.

CHAPTER 135

Comparative Effectiveness in Transplantation

Edward A. Meister[1] and Bruce Kaplan[2]

[1] University of Arizona, College of Medicine, Tucson, AZ, USA

[2] University of Kansas Medical Center, Kansas, MO, USA and Alberta Applied Genomics and Transplant Center, University of Alberta, Canada

Introduction

Comparative effectiveness research (CER) is, to some extent, an American repackaging of the evidence-based medicine (EBM) developed by the Scottish epidemiologist Archie Cochrane, and is a conceptual framework that shifts the orientation of medical research from de novo discovery to clinical applications that facilitate both the conveyors and consumers of health care to better utilize research results and improved medical decision-making. CER became formalized into American medical research efforts with the passage of the American Recovery and Reinvestment Act of 2009 (Pub.L 111-5), which allocated $1.1 billion for CER, and created the Federal Coordinating Council for CER [1,2]. These monies are to fund CER in three departments of the federal government (Agency for Healthcare Research and Quality, National Institutes of Health, and Office of the Secretary of Health and Human Services) that will foster the [1] conduct, support, or synthesize research that compares the clinical outcomes, effectiveness, and appropriateness of items, services, and procedures that are used to prevent, diagnose, or treat diseases, disorders, and other health conditions; and [2] encourage the development and use of clinical registries, clinical data networks, and other forms of electronic health data that can be used to generate or obtain outcomes data (Title VIII).

The Institute of Medicine (IOM) promulgated the definition of CER as follows:

> Comparative effectiveness research is the generation and synthesis of evidence that compares the benefits and harms of alternative methods to prevent, diagnose, treat, and monitor a clinical condition or to improve the delivery of care. The purpose of CER is to assist consumers, clinicians, purchasers, and policy makers to make informed decisions that will improve health care at both the individual and population levels [3].

The Congressional Budget Office (CBO) adds the proviso that CER "analysis may focus only on the relative medical benefits and risks of each option or it may also weight both the costs and benefits of these options [4]. Clearly the operative word is effectiveness versus the more narrowly focused clinical efficacy standard that dominates the typical Phase III clinical trial. The efficacy model is singularly focused on what intervention will work for the so-called "average patient." The conceptual shift with CER is to enhance clinician and patient knowledge of how effective a therapy is for particular types of patients, creating a more patient-centered outcomes approach [5]. With the passage of the Patient Protection and Affordable Care Act of 2010, the Patient-Centered Outcomes Research Institute (PCORI) was created with the mission of fostering research that achieves high-integrity, evidence-based information that includes the values and interests of patients to achieve improved health care. PCORI is charged with developing a patient-centered translation framework tool that will guide patient-centered effectiveness research [6]. Inherent in any robust data-driven research is access to reliable data. Specific discussions regarding the acquisition and analysis of local and national data sets can be found in Chapters 132 and 133, respectively.

Limitations of random clinical trials for CER

Random clinical trials (RCT) have long been considered the "gold standard" of clinical research and as such are uniquely appropriate for establishing drug, device, and procedure efficacy in a homogeneous patient population. This singular focus of RCT is its strength, for determining efficacy, and its weakness, for determining effectiveness. First, all RCT protocols specify strict inclusion and exclusion criteria for patients who may or may not qualify to participate in the trial. Those patients meeting inclusion criteria tend not to approximate the typical clinical practice patient by being less sick, having fewer co-morbidities, higher treatment expectations, and greater adherence ambitions. Inclusion criteria functions as a sampling sieve to populate the trial arms with a population of patients as homogenous as possible, while clinical practice is populated by the truly sick and in need of reparative therapy. Secondly, any RCT that has a placebo arm inherently lacks an effective comparator since the entire basis of CER is that two viable therapies are being compared to establish the therapy with the greatest good, most tolerability, lowest cost, and fewest adverse side effects. The placebo is a void treatment arm, and without a real CER the practicing physicians are left with doubt as to which therapy is the most proficient for each particular patient [7]. Transplant RCTs are typically designed without a placebo, yet the emphasis is still on determining the relative efficacy between or among comparators.

The central strength of the RCT is to establish causal efficacy by means of a narrowly focused group of subjects, yet this deductive method renders internal validity primarily for those chosen types in the study, and as such the results have limited external validity [8,9]. Manifest external validity is enhanced by random selection of subjects from the subpopulation into the study population, yet this is rarely undertaken. Even if this were entertained, there is still no guarantee that the factors of interest would be represented in the

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

subjects randomly sampled. The RCT is based on the deductive notion of probabilistic causality; such that X intervention causes Y outcome in some homogeneous portion of the experimental subpopulation, such as. X causes Y in Θ if probability of Y >P(Y|-X). Thus, the RCT results establish probabilistically that the intervention X worked in some subjects, yet this is of limited utility for policy formulators and decision-makers trying to determine if the X will work in their context [9].

Proponents of RCT in CER point to the intention to treat (ITT) as a strategy to better approximate clinical effectiveness. ITT is employed to enable salvaging a RCT when patients do not receive the intervention they were supposed to get based on their study arm assignment. Take an example of a three-arm RCT; arm 1 is standard therapy, arm 2 is new therapy low dose, and arm 3 is new therapy high dose. Often RCT are multi-center based, and multi-country based, and inevitably patients end up being placed in a different study arm than they were randomized to. In a three-arm study design there are six possible mistakes for any three randomizations; patient 1 is randomized to arm 1, and is placed in arm 2 or 3, patient 1 is randomized to arm 2 and ends up in arm 1 or 3, and patient 1 randomized to arm 3 ends up in arm 1 or 2 (n permutation k: 3p2 = 6). The ITT strategy is a stated protocol commitment to analyze the final data as per the arm allocation, such as there will be no artificial re-assignment of patients back to the arm with the intervention they actually received. ITT has the effect of diluting efficacy by analyzing the patient data inconsistent with the intervention they actually received. This is because randomization is presumed to equally disperse unmeasured confounding factors (i.e. patient heterogeneity) among the arms of the study. Proponents of ITT argue that it is precisely this dilution of efficacy that permits characterization of RCT as achieving greater real-world context by better approximating clinical practice where patient compliance is never 100% perfect [10,11].

ITT is not necessarily a means to improving the clinical relevancy of a RCT. Diluting efficacy does not assure an increase in effectiveness. Efficacy is establishing therapeutic plausibility in a tightly controlled circumstance, while effectiveness addresses the question of how well the therapy works in the clinical setting [12]. By reducing efficacy ITT diminishes internal validity of the results, and not necessarily the results' correspondence to clinical practice. Patients may favor or disfavor taking the regimen prescribed in the RCT protocol, resulting in reduced or increased adherence in an unpredictable manner. In other words, efficacy can be underestimated or overestimated by ITT given the indeterminate nature of patient adherence [13]. Secondly, misallocation to study arms introduces selection bias of unknown patient characteristics, and is not equivalent to clinical practice. Clinical practice renders therapy in a patient-specific manner by continuous monitoring of efficacy and adaptation of therapy-based ongoing measurement outcomes. RCTs are designed to minimize data noise; the randomization tries to neutralized potential confounding factors that the patients bring to the study but remain unknown, while the exclusion criteria excludes patients with confounders that are of crucial interest to clinical practice [14]. Finally, there is little evidence that increasing RCT within-trail variability of patient's characteristics or clinician practices will augment external generalizability [15].

Given the limitations of RCT to manifest clinical effectiveness, such as generalizability of results to a diverse heterogeneous patient population, a spate of recent articles have proposed extensive modification to RCT designs and even entirely new research design models. These new trial designs are referred to as explanatory or pragmatic clinical trials that focus on answering the question: Does this therapy work under normal treatment conditions [16]? Inclusion and exclusion criteria are relaxed, if not eliminated, to permit heterogeneity in the patient sample to approximate the diversity of patient characteristics encountered in clinical practice. A hybrid design of pragmatic randomized control trial design is the cohort multiple randomized control design. This CER design involves creating a large cohort of patients with the disease of interest, where some patients are then randomized to the option of an intervention trial and are subsequently compared to patients not randomized [17]. Clearly RCTs have been granted an exaggerated level of faith in the evidence-based medicine community of researchers, to the point that all other study design results are conveyed with an implicit apology and generate the requisite nod that future RCTs are necessary before definitive conclusions can be made [18].

The use of N-of-1 study design in CER

Given the limitations of the RCT design to advance CER, it would seem counter-intuitive to contend that a trial with a sample size of one has any relevancy or utility for advancing clinical effectiveness. Most clinicians have a bias against small sample size studies, often considering them exploratory, yet powering a study and conducting it to meet the stated sample size regardless of any practical constraints or ignoring the declining marginal utility of each additional subject enrolled into the study is equally misguided, particularly in the context of innovative research [19].

To begin, an N-of-1 trial can easily be seen intuitively as an approximation of the therapeutic trial that the clinician conducts on a day-to-day basis with each patient constituting a subgroup of the patient population [20]. The N-of-1 experimentation comes famously from a tea party attended by one R.A. Fisher and Dr. Muriel Bristol in 1925 who politely declined a cup of tea that had tea poured into the cup first. Dr. Bristol insisted that tea tasted far superior when tea was added to a cup with the milk already present, rather than the reverse, and that she could tell the difference [21]. Fisher quickly designed an experiment to test this hypothesis, preparing eight cups of tea, four with milk first and four with tea poured first into the cups. Fisher determined that there were 70 ways the eight cups of tea could be divided into two groups (8!/4!4!). Fisher then randomly presented the cups to Dr. Bristol, and used an alpha significance of .01428 (1/70), reflecting the probability of correctly choosing all eight cups correctly by chance. How did Dr. Bristol do? According to an account in a biography of Fisher by his daughter (Joan Fisher Box), Dr. Bristol was successful in correctly discerning the type of all eight tea and milk combinations.

The standard design of an N-of-1 trial involves randomly assigning times to a single patient of two different treatments (one of which could be a placebo). Suppose we had two treatments A and B, and eight times where the patient is exposed to each treatment four times. There are a total of 70 possible permutations (8!/4! 4!), and one of possible schedule could be AABABABB. For N-of-1 designs to be useful the disease condition needs to be chronic, since acute conditions would have excessive symptomatic fluctuation to attribute their resolution to the intervention. Likewise, the therapy itself needs to have an on-off pharmacokinetics of a known timeframe to enable the investigation to avoid carry-over effects [22]. Carry-over effects are a particular concern given the potential for some drugs to remain potentiated in vivo, and hence distort subsequent effects in additional times of intervention [23]. Therefore, the need is evident to have precision in the washout period for both

pharmaceutical and behavior interventions, the latter of which can manifest a fatiguing or learning effect. In addition, it is necessary to have an intervention that achieves therapeutic dose in a rapid manner in the prescribed time interval between time blocks [24]. The N-of-1 also needs an appropriate baseline period at the outset of the trial, a wash in period, and follow strict double blinding of patient and clinician to minimize the placebo effect. The central objective of the N-of-1 trial is establishing personalized efficacy between two repeated therapies [25].

Recently Scufham et al. used N-of-1 trials to identify optimal drug regiment to reduce health care costs of patients with osteoarthritis, chronic neuropathic pain, and attention-deficit hyperactivity disorder (ADHD) [26]. The study design involved utilizing results from several N-of-1 trials. In all N-of-1 trials a large variability of patient response within the individual poses a threat to internal validity, and the addition of more treatment times would manifest more useful information. Likewise, when within-subject variability is modest, then adding additional times of measurement does not generate more useful knowledge [27]. Thus, in N-of-1 trials it is useful to minimize the patient burden for participating in the trial to diminish the dropout rate, since their loss to follow-up reduces validity and effectiveness of therapy in clinical practice.

N-of-1 trials certainly have potential to enhance the research efforts in CER and patient-centered medicine. The future use of wireless monitoring devices will dramatically augment the data collection and enhance patient's willingness to participate in N-of-1 trial. The deployment of multi-center coordination N-of-1 trials, meta-analysis N-of-1 studies, and electronic medical records all will serve to enhance the adoption and use of this research design.

Observational Data and Meta-Analyses in CER

Observational data can be generated retrospectively or prospectively. The former typically involves using existing databases or chart reviews. The latter involves following a cohort forward in time, and measuring factors and events of interest, for example the Nurses' Health Study (Cohort I, II, and III), a longitudinal cohort study. Another prospective design is referred to as quasi-experimental, with two or more study arms that form comparison groups (rather than control groups), because subjects choose their preferred arm. Quasi-experimental designs include the interrupted-time-series that has a sequence of preintervention measures and a sequence of postintervention measures. When there is more than one intervention to be tested, a quasi-experimental design used is called counter-balanced or Latin squares. The order of patients receiving the intervention is rotated across time, hence safeguards against carry-over effects need to be established [28].

The central argument in favor of observational designs is that contrary to RCT they permit, if not necessitate, strong external validity (i.e. generalizability) because the data are gathered that more closely approximate the heterogeneity of patients found in the clinical setting. Observational designs are completed in a timelier manner than RCTs, hence reducing expenditures per unit of analysis; and typically benefit by amassing a large data set for analysis. However, the extent of internal or external validity in either RCT or observational designs is a function of how the study is put together. A poorly executed RCT may achieve less internal validity than a well-structured observational design [29]. Advocates of observational research point to their utility for rare disease, since in case-control designs the subjects are selected on the basis of their disease status. Observation studies can investigate multiple therapies simultaneously, and capture additional patient-centered outcomes, like therapy preferences, and are particularly useful when RCT are ethically, temporally, politically or financially infeasible [30,31].

The pivotal concern with observation study designs is systematic bias, which tends to limit causality conclusiveness [32]. For example; sicker patients may be shunted into more aggressive therapies while the more frail patients are relegated to less invasive (i.e. non-surgical interventions) depending upon their need or ability to tolerate the treatment. This creates a disproportionate heterogeneity among the comparison groups, such that potentially confounding factors (e.g. patient frailty) unduly influences the outcomes of interest. Careful designs, large numbers, and innovative analysis (e.g. propensity scoring regression, randomization statistics), can minimize the effects of bias and confounding to a large extent [31]. However, when it comes to confounders, what is not measured or measured incompletely cannot be accounted for in the analysis, and can lead to partial estimates of the effect size associated with the treatment modality [33].

There is ongoing debate as to the epistemological nature of medical research models in generating knowledge. The standard perspective is that the observational designs are so-called hypothesis-generating studies that will be later confirmed by a rigorous RCT [34]. This view contends that science, and medical science in particular, is an open-ended never-ending system that generates testable hypotheses that spawn unanswered questions which is the genesis for further testing of new hypotheses, and the RCT constitutes the gold standard of distinguishing the factual from the artifact as a deductive model. As such, observational research can play a pivotal role in the ongoing process of medical knowledge acquisition, in part, by generating newly testable hypotheses. This common conceptualization of the scientific process has been challenged in light of the pressing needs of CER to more efficiently advance medical care [20]. The new emphasis placed on patient-centered research invites a new theoretical framework, of hypothetical-deductive empiricism. As Figure 135.1

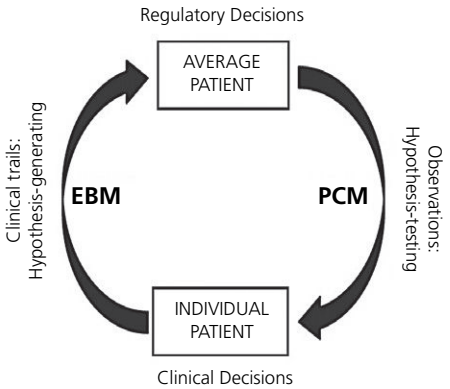

Figure 135.1. PCT and RCT: The directional flow of scientific reasoning, from the aggregate based average patient, and hypothesis testing in the domain of patient-centered medicine to improving individual based clinical decision-making, back to hypothesis generating RCT. Reproduced from [20] Sacristan JA. Exploratory trials, confirmatory observations: a new reasoning model in the era of patient-centered medicine. BMC medical research methodology. 2011;11:57. Epub 2011/04/27 [Open Access].

conveys, RCT would serve to generate hypotheses regarding the average patient, while patient-centered CER would engage observational studies to test hypotheses for the individual patient [20].

Observational research can also utilize large national data base registries. With improved electronic medical record keeping, and integrated IT systems data mining can function to investigate research questions. However, since the data bases were constructed to be repositories of patient-specific information, any abstraction of data for use in a study should realize that their utilization is inherently a secondary level analysis. Currently there are many nationally based data bases that lend themselves to data mining investigations. National Surgical Quality Improvement Program (NSQIP) is a risk-adjusted data set that focuses on clinical outcome data, with 69 clinical measures, and 30+ procedure-coded variables. There is the National Trauma Data Bank (NTDB) maintained by the American College of Surgeons, which is a national convenience sample data set, based on trauma data voluntarily submitted by participating hospitals. The US Organ Procurement and Transplantation Network (OPTN) and the Scientific Registry of Transplant Recipients (SRTR) maintain the largest data set in organ transplantation and publish an annual report on all organ transplants, graft-survival analyses, and wait-list statistics. SRTR processes all requests for organ transplant data for secondary research projects.

Large registry databases do have limitations, chief among them is the so called "Z-bias" and "M-bias" [35]. These registries may measure a plethora of variables that are related to the exposures considered harmful, yet miss variables related to outcomes. Z-bias occurs when z-variables are included in the statistical model. These z-variables are impacting the outcome by unmeasured confounders, thus adding them to the model actually increases bias, which may seem peculiar since these variables are only related to the exposure. M-bias or collider-stratification bias results when adjustments to the model are made for a non-confounding variable (i.e. the collider) that is not related to the exposure or the outcome of interest, but sits at the crossroads of variables related to the outcome of interest. This M-bias is a kind of over-adjustment for a variable that is a descendent of the exposure, yet is not really in the causal pathway [36,37]. Additional discussions of national datasets are found in Chapter 133.

Despite the limitations of observational research, and particularly the potential for selection bias that can occur from the inclusion criteria use for national data bases, there are critical instances when a disease process is virulent and the treatment options are limited, and as such decisions must be made with less than perfect data. Observational data are particularly useful for CER studies; for example when diseases have a low prevalence and therapeutic interventions manifest large differences in patient response. Large studies are able to locate rare diseases, and allow comparison of simultaneous therapies. Observational studies are useful when patient adherence rates differ, when providers vary greatly in their level of training and expertise, and when investigating off-label drug side effects.

Systematic reviews, more commonly known as meta-analysis when the review includes a statistical combination of several studies that have similar research hypotheses being researched, have long been given a prominent evidentiary status in the pantheon of research techniques. Meta-analysis in essence is a process of compiling the results from a group of related studies that focus more or less on the same working hypothesis to enable ascertaining a summary result. The key is establishing a priori precise inclusion criteria for the studies to use in the final quantitative synthesis of results. All meta-analyses involve retrospective data collection; hence this form of research is relatively inexpensive and quick. Secondly, most important aspect to a meta-analysis is determining the effect measure that is to be summarized for comparative purposes. Examples of effect typically include odds ratio (OR), relative risk ratio (RR), or hazard ratios (HR). Effect size is the estimation of the size of differences between the treatment group and the non-treatment (or lesser treated) group. Individual results are not being pooled into one big study; rather each study's effect is being pooled.

The primary concern of meta-analysis is the extent of heterogeneity among the studies, which can undermine the validity of the results: the so-called "apples versus pears" problem. Study heterogeneity can be from stochastic random differences between studies, or individuals in each study may actually be from different populations. Assessing for true heterogeneity is done using Cochran's Q test [38]. The Q test is computed by summing the squared deviations of each study's effect estimate from the overall effect estimate, weighting the contribution of each study by its inverse variance. Under the hypothesis of homogeneity among the effect sizes, the Q statistic follows a chi-square distribution with k – 1 degrees of freedom, k being the number of studies. Not rejecting the homogeneity hypothesis usually leads the meta-analyst to adopt a fixed-effects model because it is assumed that the estimated effect sizes only differ by sampling error. In contrast, rejecting the homogeneity assumption leads to applying a random-effects model that includes both within-studies variability (from sampling error) and between-studies variability (lots and lots of differences in study characteristics, design quality). The typical P-value cut point of a significant Q statistic is .20. The newer technique to assess heterogeneity is called the I^2 Index, which is similar to the intra-class correlation and is calculated as follows:

$I^2 = [Q - (k - 1)/Q] \times 100 =$ and k is number of studies.

The I^2 Index is essentially a measure of inconsistency among the studies, and if greater than 50% is considered to be an unacceptable level, or lacking in sufficient intra-study similarity [38].

Meta-analyses have long been known to have the ripe-strawberry problem, that of publication bias, in that journal editors and reviewers tend to favor positive studies that exhibit statistically significant results over negative studies (unless the authors pledge to have their study "properly power" the next time around). In this bias, meta-analysts who comb through the published literature tend to find positive outcome studies rather than retain null hypothesis studies [39].

Another thorny issue is whether to combine the results from RCT and observational studies [40]. This is because observational studies are inherently more prone to confounding by unmeasured confounders. Yet there seems to have emerged a general consensus that non-experimental and quasi-experimental study design should be included because they are "data rich" sources of information with large sample sizes and can have utility to assess potential therapy harms. A more recently identified problem has been named "meta-bias" [41], which delineates a bias introduced by single-center studies versus multi-center based studies. The single-center studies demonstrated an elevation in effect size by as much as 26% [42]. What the researchers did was to examine the odds ratio effect sizes comparing single-site versus multi-site studies among 48 meta-analyses totaling 421 RCT, with 233 conducted at a single site, and 198 that were multi-center based. Dechartres and colleagues found that single-site RCT's had a much larger intervention effect compared to RCT's that were multi-centered. Goodman [41] speculates

that metabias may simply reflect another variation of publication bias that favors multi-center studies, or that single-center studies have fewer people involved and as such there is reduced strictness and control over the study operations, allowing the researchers to achieve their desired results.

A no less intriguing bias was demonstrated by a meta-analysis by Danaei and colleagues [43] involving the use of statins and prevention of cardiovascular diseases. What they found was that when the RCT compared statin use between current users and non-users (secondary prevention) the hazard ratio was .84 (a 16% reduction in CVD mortality in patients with history of CVD), while observational studies that compared statin use between new users versus non-users (primary prevention) had a hazard ratio of .54 (a 48% reduction in CVD mortality in patients with no history of CVD). The authors comment that, given the considerable discrepancy found between RCT and observational study effect measurements, future research needs to control potential bias by structuring the inclusion criteria for observational designs that more closely match those of RCTs, and to take into consideration incident (new) versus prevalent (existing) users of medications.

A fairly new and innovative variation of pair-wise meta-analyses is termed "network meta-analysis" which involves meta-analytic comparisons across multiple interventions or treatments. Network meta-analysis takes direct evidence from RCTs (e.g. drug A vs. B, and drug B vs. A), and combines it with indirect evidence obtained across RCTs (e.g. drug A vs. C). This technique yields pooled effect estimates for several outcomes of interest, rather than just one effect in standard meta-analysis [44,45].

Meta-analyses do hold substantial promise for CER, by permitting greater latitude in study heterogeneity, by combining study estimates of costs, and scaling adverse drug reactions, which all contributes to the driving question as to the most effective course of treatment. Proper consideration of potential bias is simply incumbent upon any research project and necessitates engaging those with sufficient expertise to undertake meaningful research. Meta-analyses provide the needed synthesis and unification across a plethora of disparate studies, and thus creating a more comprehensive portrayal of the answers to critical clinical questions [46]. Research analysis imparts empirical results, while meta-analyses provide coalescence; and it is this mutual interaction of results and synthesis that advances clinical understanding [47].

Decision analysis and cost utility effectiveness in CER

Perhaps no other fields of analysis are more appropriate for CER than decision analysis (DA) and cost-effectiveness (CE). DA is a highly sophisticated and structured analytical technique that came out of game theory and economic behavior to aid in decision making. DA is highly useful when there are competing alternative components of medical decisions, which involve costs, risks, and probabilities of outcomes. DA is best used when the focus is on an individual's decision, yet DA can also assist and inform the development of consensus guidelines in clinical practice [48]. The heart of DA is the construction of a Decision Tree see Figure 135.2. In an example by Best, et al.[49], regarding smallpox inoculation in 1736, to inoculate or not is the first decision node, and the circles represent the chance nodes. Notice in the first tree branch of Inoculate, the results are Live or Die, and below each of those branches are the probabilities of that event; staying alive probability is .9790 and dying probability is .021. At the end nodes (triangle) are the utilities of that outcome which range from 0 (dead) to 1.0 (perfect health).

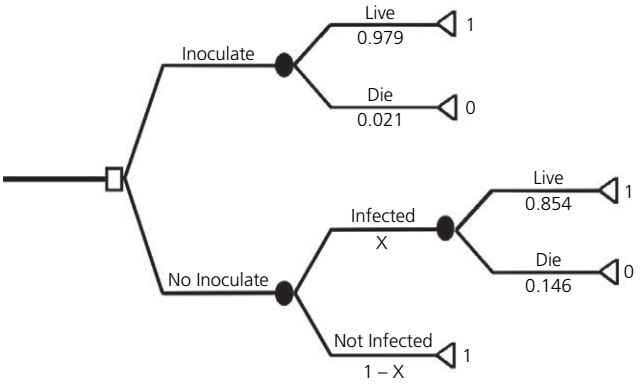

Figure 135.2. Decision Tree: Decision tree of mutually exclusive decisions to inoculate or not to inoculate, leading to the probability-based consequences of living or dying after inoculation or getting smallpox infection and then living or dying, or not getting infection of small pox. Reproduced from [49] Best M, Katamba A, Neuhauser D. Quality & safety in health care. 2007;16(6):478–480 with permission from BMJ Publishing Group Ltd.
Root node/decision node (square); event (chance) node (circle); and end points (triangle)

The Decision Tree diagram, is a simple example of DA; a more thorough analysis would include the costs associated with each tree branch, to enable obtaining the expected value for an uncertain alternative (calculated by multiplying each possible outcome by its probability and then summing the results). With the inclusion of costs, we can determine the expected value decision criterion, such as selecting the option that manifests the best expected value. This is the essence of CE: determining which optional decision leads to the highest monetary outcome.

A special type of CE is termed cost-utility-analysis, in which the health benefits obtained are quantified into measurement units called quality-adjusted-life years (QALYs) (Figure 135.3). QALYs are the preferred unit of time, usually expressed in years, which has been adjusted by a human-derived preference weight termed "utility." A utility is value a person gives to a preferred outcome measured under conditions of uncertainty, which typically ranges from zero (defined as death) to 1.0 (defined as a state of perfect health). In the Basic QALY Diagram a person is expected to live until they are 75 years old, and currently they are age 25. In the linear QALY model we assume their less-than-perfect health utility weight is .75, and we can calculate their remaining QALYs as follows:

$$\text{QALYs} = (75 - 25) * (.75) = 37.5$$

We subtracted their current age from their expected life expectancy of 75 to get the number of years remaining, and then multiplied this by the utility weight of .75 to get 37.5 QALYs to represent the number of years living that are "adjusted" by the perceived quality of those years.A QALY then can easily be understood as a quality-adjusted-life year, which combines a person's years of life and the perceived quality of that time.

Take a simple example: we can estimate a person's remaining years of life, and they would be questioned as to how many years they would give up to attain perfect health given a condition of non-perfect health. We then can calculate as follows:

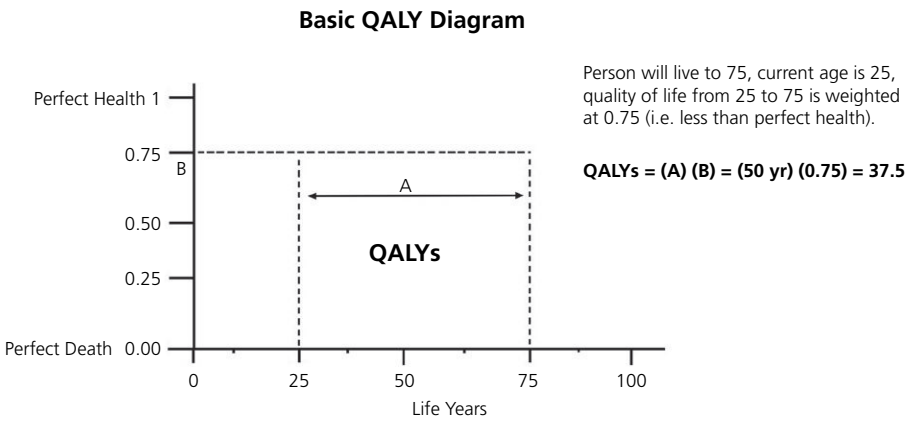

Figure 135.3. Basic QALY: The vertical axis displays the range of utilities: from zero of death to +1 of perfect health, with expected life-years on the horizontal axis from birth to death. Notice the example of a person expected to live to age 75, with current age of 25, and a linear utility of .75. Thus, QALYs are calculated as the product of A and B; (50 years) * (.75 utilities) = 37.5 quality-adjusted-life-years.

$$\text{Utility} = (\text{NYEL} - \text{NYWTT})/\text{NYEL} = ?$$

NYEL is the number of years expected to live, and NYWTT, are the number of years willing to trade. This calculation is often more formally written as; $U(H_i) = x/t$, where x is the number of years in perfect health (i.e. expected years of life minus years willing to trade), and t is the number of years in non-perfect health, H_i, that are remaining. Taking a published example regarding imagined hand amputation [50], a hand transplant patient is expected to live 45 years as an amputee, and is willing to give up four years of life for the transplantation ,so the utility can be calculated as follows:

$$U(H_1) = (45-4)/45 = .9100$$

The QALY is used extensively in cost-utility analysis because a QALY captures a person's preference for a health status in a single index measure [51–54]. A QALY is derived from the captured utility as follows: QALY = Utility * Years of Life Remaining [48]. Thus, a QALY is the product of expected remaining life and the value attributed to that time (i.e. the utility weight). Let us consider two patients receiving a kidney transplant that has a utility of .70; Patient A expects 30 years of life, and Patient B expects 25 years of life.

$$\text{QALY}_{\text{Patient A}} = .70 * 30 = 21$$

$$\text{QALY}_{\text{Patient B}} = .70 * 25 = 17.5$$

Clearly Patient A is driving more quality life years measured in QALYs than Patient B. We can also use QALYs to compare the difference between two treatment options, deriving the difference net benefit. A recent study obtained 9.456 QALYs for combined liver and kidney transplantation to the same patient versus splitting the organs to different patients of 8.650 QALYs, for a net difference benefit of .806 QALYs, demonstrating that combined organ allocation was the better approach when end-stage-renal disease (ESRD) was certain [55].

The question arises, where exactly do the weighted utility factors come from? Utility weights can be generated from two basic methods:

1 direct valuation techniques such as; time-trade-off (TTO) questionnaire, visual analogue scales (VAS), and standard gamble (SG); or
2 indirectly using a standardized questionnaire-based health utilities index, such as SF-36, EQ-5D, or HUI-3 [56–59].

TTO technique poses questions in a survey that present the respondent with a choice between X years in a poor health state and assesses the number of years they are willing to trade measured in Y years to return to a perfect health state. The Basic TTO Diagram (Figure 135.4) demonstrates the willingness to trade off years of diminished health utility to gain perfect health utility.

In this hypothetical example the patient has 25 years to live (75-50=), but at a reduced quality of life of .75 utilities. They are willing to trade five years of expected life to move up to perfect quality of life. The gain in QALYs can be calculated as follows:

$$\text{Current State: QALYs} = (75-50)*(.75) = 18.75$$

$$\text{TTO State: QALYs} = [(75-50)-(75-70)]*(1) = 20$$

The patient is willing to trade five years of life to gain 1.25 QALYs ($\Delta_{\text{QALYs}} = 20 - 18.75$).

The TTO technique assumes a property called constant proportional time tradeoffs (CPTO) which is that utilities elicited are unaffected by the time the respondent imagines they are in that health state. For example, if I am willing to trade two years for ten years of perfect health, then I should be willing to trade two months for ten months of perfect health. Attema, and Brouwer reviewed the TTO literature and found that CPTO was commonly violated, such that with shorter durations there was less willingness-to-trade for perfect health state [60]. In other words, a person's preferences for health are influenced by the time they obtain in that health state. In a follow-up study by Attema and Brouwer [61] the authors utilized the TTO risk free (direct method) technique using a health state questionnaire based on full health and less than perfect health exhibited by chronic back pain to capture discounted weights. The authors distinguish ordinary CPTO (oCPTO) from generalized CPTO (gCPTO): the former — the years a person is willing to trade to get a full health state — is not influenced by the absolute years of remaining life; the latter posits that a person's remaining utility of life years that they are willing to trade for perfect health are not affected by the absolute number of remaining utility years. This distinction is important, because a violation of gCPTO indicates that the general QALY model is proven false, while violation of the oCPTO means that only a special subset of the QALY model is

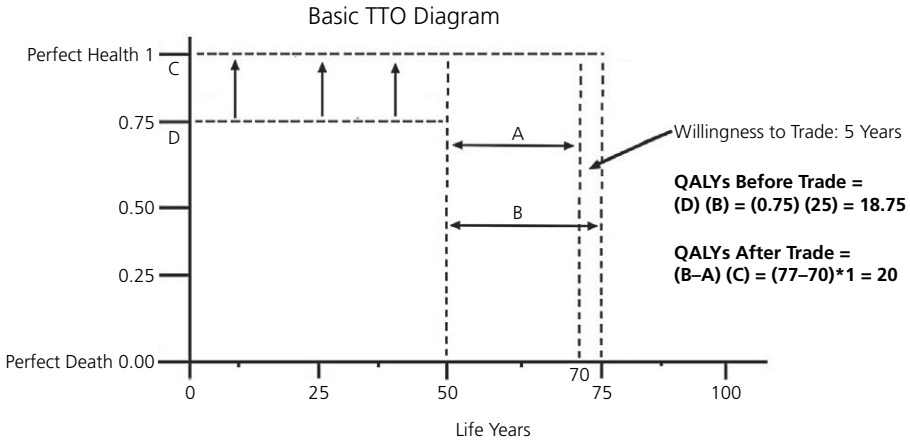

Figure 135.4. Basic TTO: The vertical axis displays the range of utilities from zero of death to +1 of perfect health, with expected life-years on the horizontal axis from birth to death. The patient is willing to trade 5 (B − A) years to return to perfect health (C) from less than perfect health (D) .75. The QALYs before tradeoff is: D * B = .75 * 25 = 18.75, and the QALYs after tradeoff is B − A * C, or 75 − 70 * 1 = 20. Hence, the increase in QALYs for trading five years was 1.25 (20 − 18.75).

proven false, that of the power family. Their results provided evidence for violation of both gCPTO and oCPTO assumptions, casting doubt on the TTO deriving of QALYs. Hence, it appears as though humans link the quality of life and the expected duration of their life.

The SG technique involves respondents having to make a choice between a certain health state and two possible outcomes: Perfect health versus death, and is based directly upon the axioms of von Neumann-Morgenstern utility theory (i.e. expected utility theory) (Figure 135.5). The von Neumann-Morgenstern utility model is $U(Q,T) = p^*$, where Q represents present health state, for a period of T years, and p^* is the indifference probability between choosing to gamble or not gamble [62]. Each alternative choice presented to the respondent has a prescribed probability of occurring, and the probabilities are varied until the respondent does not favor one over the other; called the point of indifference [63,64]. Bala et al. give an example involving chronic pain in which respondents imagined a current health condition of severe pain for the next 20 years, and they could choose to gamble on a therapy that manifested normal (pain free) life for 20 years with a probability of 95%, and a 5% chance that therapy would incur immediate death [65]. Thus, SG gives us the respondent's preferred score for an improved health state over time.

Recently there has been considerable debate regarding the generation of health states. TTO, SG, and EQ-VAS are considered direct valuation measures of health, while a variety of indirect questionnaire-based methods have gained new prominence both in the USA and in Europe. These include the HUI-3 Health Utilities Index, the EQ-5D five-dimensional questionnaire, the 15-D measure, and the six-dimensional health state SF-6d [66]. Given all these different methods of generating health-state utilities, the question looms as to how comparable their results are. Not too surprisingly, a recent comparative analysis of HUI-3, EQ-5D, TTO, and EQ-VAS by Hientz et al. [66] for the generation of QALY weights for diabetic retinopathy found significant differences among the four techniques in the derived utility weights. They demonstrated that the measurement instruments did not follow the course of the disease worsening, except for HUI-3, which was able to detect changes is the severity of the diabetic retinopathy

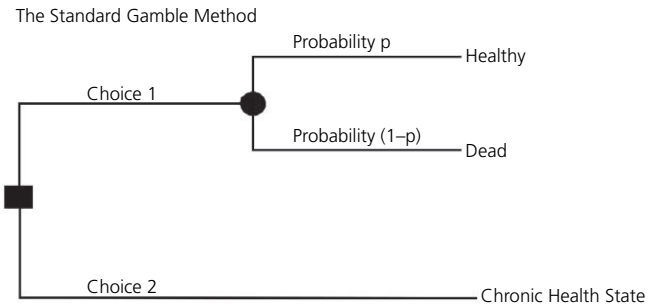

Figure 135.5. Standard Gamble: The decision tree plot displays the choices a person makes: Choice 1 takes on the gamble of some form of therapy with subsequent probability of returning to healthy state or death. *P* is the probability from 0 to 1, and 1-*P* is the remaining probability of death.

(the decrement for blindness was actually two times larger than the other methods). Their conclusion is inescapable: the quality-adjusted life year technique that is chosen will affect the assessment of cost-effectiveness of a treatment or intervention [66]. HUI-3 also demonstrated construct, convergent, and discriminative validity in a study of indexing health utilities in lung transplantation patients [67].

One of the basic concerns is who should be scaling health values: patients involved in the health condition, non-patients in the general population or people with expertise in health? Some economists have argued that patients and non-patients in general would render very diverse utilities because they start from a divergent perspective: that the non-patients will tend to over-estimate the losses attributable to a given health state, while patients will underestimate adaptation to the non-perfect health state [68,69]. However, recent research found no significant difference in health-state values comparing patients to healthy people using the VAS technique [70]. In that study TTO technique did manifest considerable differences between patients and healthy people; this may be due to that fact that TTO method contradicts measurement theory as a one-dimensional measurement since it is trying to measure health

state and temporal longevity at the same time. Thus, the differences observed in health-state utilities may be more a function of the measurement instrument tool employed than a reference bias.

In addition, there is a basic economic presumption that humans value present health higher than future health. When we make this assumption and apply a high discount rate (promoted by advocates of opportunity-cost theory) the result favors a therapy that augments quality of life over longevity (in contrast to a therapy that adds to survival but bears little fruit for quality of life) [71]. Others question the whole business of health states, that is as non-temporal measures, that are valued without taking into consideration the time spent in the health period or the health states before and after the measured health state is captured [68]. The notion that individuals calculate their health-state utilities as risk-neutral and are valued the same over time seems excessive [72].

A more complex, and perhaps more critical, concern is how the scaling of utilities by these quality of health-state techniques is undertaken. Most economists and policy analysts still maintain that SG and TTO methods are the most defensible techniques for obtaining health-related quality of life preferences. The typical TTO approach involves making a choice between a set number of years in a particular health state that is better than being dead, against a lessor chunk of time in perfect health. When the participant becomes stuck, offers no further trading of bad health years to get good health times, this is referred to as the indifference point, and a utility ratio is calculated x/y. With SG good health certainty is compared to uncertain gamble between demise and perfect health, and when the indifference point is reached it is taken to be the utility of the preferred health state. There are two major concerns with this technique (1) it does not capture the utility of bad-health states that are worse than death, and (2) the scaling of utility between 0 and +1, or −1 to +1 is not a statistical distribution that permits valid use of means, medians, modes, and ratio statistical analysis. These two concerns are different dimensions of the same problem: scaling of the utilities as is currently done is essentially arbitrary and in need of complete revision. Lamers [73] initiated the need for refinement by arguing that health states can be assessed as better, equal to, or even worse than death; and the scaling of utility from 0 (= death) to +1 (perfect health) fails to capture the reality of human health preferences. If the utility of death is zero, what about health states that are worst than death? When a health state is assessed to be worse than death, utility can be less than 0, going from 0 to negative infinity. There is considerable debate as to whether to terminate a negative utility at −1, and even discussion on how to unbound a +1 utility [74].

Pullenayegum et al.[75]. acknowledged that there are health states that are worse than death, and as such utilities need to go below 0 and be measured on a negative scale, and Sullivan [74] contends that utilities should not be bounded by +1 since there are utility states that are far above full health as designated by one. The obvious rationale for bounding utilities between 0 and 1 is that they are used as the weights to derive QALYs, and if a utility weight is less than 0, how are negative QALYs to be interpreted? This is particularly troubling when doing an incremental cost-effective utility analysis (ICUR) as follows:

$$\text{ICUR} = \mu_{\text{cost(new Rx)}} - \mu_{\text{cost(standard Rx)}} / \mu_{\text{outcomeQALY(newRx)}} - \mu_{\text{outcomeQALY(standard Rx)}}.$$

It becomes obvious that whenever we have negative outcome interpreting a negative dollars per QALY it is problematic and may

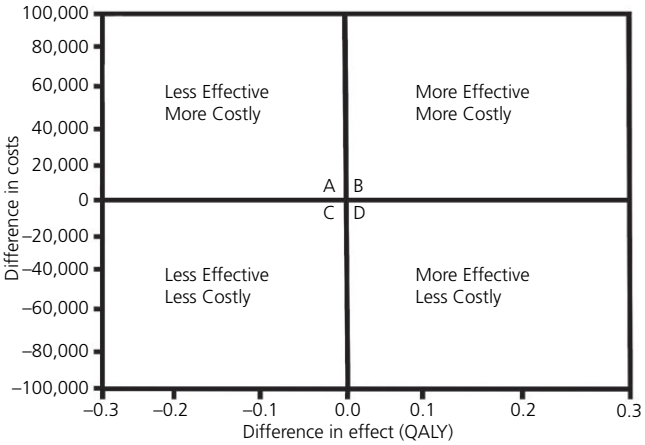

Figure 135.6. ICUR possible results: The diagram has the difference in costs between two competing therapies on the vertical axis, and the difference in QALYs between the same two competing therapies on the horizontal axis, with the possible results of the ICUR displayed in four quadrants. Quadrant A is ICUR that is more costly and less effective, Quadrant B is more costly and more effective, Quadrant C is less costly and less effective, and Quadrant D is less costly and more effective. Reproduced from [113] Kontodimopoulos N, Niakas D. An estimate of lifelong costs and QALYs in renal replacement therapy based on patients' life expectancy. Health Policy. 2008; 86(1):85–96. Copyright © 2008, with permission from Elsevier.

lack a fruitful interpretation [76]. What exactly are we supposed to make of an ICUR of — $80 000 per QALY? Larsen and colleagues have proposed a solution. If we divide the four possible results of an ICUR into quadrants, by plotting the difference in incremental costs by the difference in incremental gains, the ICUR can be interpreted as indicated in Figure 135.6 [77].

In Figure 135.6 Quadrant A, the new therapy costs exceed existing therapy, yet the new therapy's QALYs are less than the existing therapy and hence renders a negative effectiveness. The best ICUR is in Quadrant D, where new therapy costs are less than existing, and new therapy QALYs exceed existing therapy QALYs, hence the new therapy is less costly and more effective.

A plethora of more technical solutions have been proposed: such as rescaling quality of life values into discrete (binominal) measures [78], using negative scores in the health-state questionnaire and simply converting them all to zero [79], converting all scores below −1 to a negative one [80], using monotonic transformation by arbitrarily dividing WTD (worse than death) TTO responses by 39 to increase QALY estimates [73,81,82], or by converting to a scale ranging from −1 to +1 [83,84]. In an elegant mathematical proof, Flyn et al. demonstrated that utilities from 0 to +1 were impossible; the idea being that the probability of at least one person with a quality of life score below 0 cannot be zero [78]. As such, the health value must extend to a negative infinity below zero and positive infinity above zero. Edlin and collegues have proposed distinguishing theoretical from empirical health quality values, suggesting that health values below zero represent "pits" and above +1 are "supra-states" that capture the latent quality of life measures [85]. This is critical, since there can be instances when the majority of cases may register quality of life values that are latent rather than empirical. Perhaps the most intriguing solution to the health-value scaling problem has been put forward by Craig et al.[86]. The problem is

that all the health-value measures use ratio statistics, which are not appropriate because x and y are not interchangeable, for example $\mu(x, y)$ is not equal to the inverse of $\mu(x, y)$.

The ratio of y/x, where y = x — years willing to trade, and x is the expected number of years to live — thus if someone is willing to trade ten years to live two years in perfect health; $\mu = 8 - 10 - 8 = -.2500$. What Craig proposed is to use directional statistics in the use of utilities by converting every y and x into Euclidian space and map them as a set of polar coordinates, delineated by an angle and radius [87]. Each y/x ratio is the tangent of angle Θ ($\Theta_i = \arctan(y/x) + \varepsilon_i$, and the radius is equal to the size of the participant's trade off time [87]. Thus, Craig proposes substituting the estimated tangent of the mean angle for the ratio statistic as the value estimator, referred to as aRUM (angular random utility model) [87]. Angular means are more robust, and as such would be less distorted by large negative ratios than arithmetic means. Finally, Craig and Busschbach propose their own random utility model which is based on probit modeling, called eRUM (episodic random utility modeling) [88]. The eRUM method derives the health-state estimator as:

$$\beta_h = \Sigma x_i y_i / (\Sigma x_i^2), \text{and then a QALY}_i = (\beta_h)(\text{years}) + \varepsilon_i$$

The β_h is a coefficient that approximates the ratio of means [84].

In their comparative analysis of EQ-5D state in the USA, Craig and Busschbach conclude that either eRUM or aRUM are better models and less subjective than simply dividing the lower values of TTO ratios by 39. eRUM has itself come under increased scrutiny and appears to lack monotonicity. Non-monotonicity is a bad property because it means that as some respondents increase their health valuation for a specific state, the aggregated values many actually decrease [89]. Supposing an individual values WTD infinitely, resulting in a negative infinity ($-\infty$), in the eRUM approach that value would exercise no downward pull on the least squares fitted regression line [89].

The validity of the QALY model — which has become pervasive in medical decision-making, health policy and, in the context of CER, useful for patient-centered decision-making — has always been employed with the presumption that in the simple linear model we get the QALY as the product of derived utility of health state and time (in years) that the person is in that health state. In other words utility and time are independent of each other. This independence has been brought into serious question recently, and its violation has implications for all the recommendations made using the linear QALY model, since it may not necessarily be representative of a person's true desires. A recent study by Atemma and Brouwer [90] found evidence in support of this independence property for health state that were better-than-death, yet not for health states that were worse-than-death (WTD). WTD states exist because there are health states that exceed the maximum endurable time a person can tolerate such a state. Attema and Brouwer's [90] results indicate that utility may then depend upon how much time a person is in a health state that is WTD and, as such, additional modifications to QALY modeling need to be considered to better capture human preferences.

As we have reviewed, health-related utilities can be derived from a variety of methods, both direct and indirect. Advanced methodological models are attempts to resolve problems and limitations that have been identified in determining the utility of a given health state; of particular vexation is the boundary scaling of utility matter. Although there are many enticing techniques currently available, such as competing models with various assets and liabilities, there is yet to be a final consensus as to which approach constitutes the ideal rendering of utilities and, hence, QALYs.

CER in renal organ transplantation

The renal organ transplant literature is littered with a plethora of high quality RCTs that primarily focus on the post-transplant immunosuppression therapies to establish superiority or equivalency among competing drug regimens [77,91–95]. There has also been a considerable amount of quality of life research in ESRD patients and related utilization of dialysis [96–104].

Morel and colleagues at University of Minnesota Hospital and Clinic published one of the first studies addressing long-term quality of life after renal transplantation [105]. The study population consisted of 51 pediatric patients who were contacted to participate in the study, who were between 11 and 27 years post-transplantation. Their results found that 90% viewed their life-as-a-whole satisfied or completely satisfied, 91% rated their health as good to excellent, and 65% rated their life as normal with no complaints. Russel [106]and colleagues at the Saint Joseph's Hospital in Ontario undertook a more sophisticated design capturing prospective TTO utilities pre and post-transplantation (n = 27). With TTO technique patients were queried as to how much time they would be willing to trade for perfect health. Patient baseline utility score was a mean of .41, and post-transplant was .74, representing a 33% increase in quality of life.

Laupacis and colleagues undertook the first formal cost-utility analysis study to assess the quality of life and the cost-utility of renal transplantation in Canada [107]. Laupacis used several instruments to capture quality of life: the Hemodialysis Questionnaire (KDQ), the Kidney Transplant Questionnaire (KTQ)-25, the Sickness Impact Profile (SIP), and TTO, with death scored at zero and perfect health scored at 1. Follow-up took place at the following months: 1 (n = 146), 3 (n = 131), 6 (n = 137), 12 (n = 132), 18 (n = 107), and 24 (n = 76). All the health questionnaires demonstrated substantial improvement, as did the TTO utilities. The authors calculated the ICUR at one year and at two years as follows:

$$\begin{aligned}\text{ICUR}_{1\text{year}} &= \$66\,540 - \$73\,659/.65\text{QALY} - .53\text{QALY} \\ &= -\$59\,325/\text{QALY}\end{aligned}$$

$$\begin{aligned}\text{ICUR}_{2\text{year}} &= \$27\,474 - \$70\,869/.62\text{QALY} - .51\text{QALY} \\ &= -\$394\,500/\text{QALY}\end{aligned}$$

These negative costs per QALY were interpreted as meaning that at both one year and two years the renal transplantation rendered more quality of life years and was substantially less expensive compared to dialysis. Not all patients made it to their visits to record the TTO utilities, and the study estimated 224 utilities (24%) of the total potential patient visits (note that all patients too sick to complete the TTO measure were given a score of .20). The Laupacis study (whatever its limitations), at the Vancouver General Hospital, does represent pioneering work to try to empirically quantify the cost associated with quality of life gained for renal transplant patients.

The Franke et al. [108]. study at the University of Essen (Germany) marks a milestone by the development of the ESRD-SCL (End Stage Renal Disease Symptom Check List) that was specifically designed to assess the physical and psychological quality of life among renal transplant patients. The ESRD-SCL consists of

79 quality-of-life measures that are measured by a five point Likert scaling. Construct validity was assessed by correlational analysis with the SF-36, and hierarchical multiple regression revealed six reliable subscales with Cronbach's alpha of .76 to .85. Ziegelman et al. [109]. developed the TxEQ (transplant effects questionnaire) for assessing multiple dimensions related to the outcomes of transplantation in patients with ESRD. The specific domains in TxEQ were as follows:

- worry about transplant
- guilt regarding donor
- disclosure of transplantation
- adherence to anti-rejection medications
- taking responsibility to value the transplant.

The TxEQ proved to have good psychometric properties, and may be useful for a variety of organ transplant studies. Recently Chisholm-Burns and colleagues undertook an analysis of the concurrent validity of the KTQ-25 among USA renal transplant recipients [110]. Concurrent validity is comparing a new measurement instrument with a supposed "gold standard" measurement instrument to see how well the results of the new tool concur with the older and validated tool [111]. In this study, KTQ-25 should have results similar to the SF-12v2 when administered simultaneously if KTQ-25 is measuring the same underlying construct that the SF-12v2 is. KTQ-25 is a 25-item questionnaire, with five domains: physical signs, fatigue or tiredness, uncertainty and fear, appearance, and emotional content. The SF-12 is a much-used shorter version of the well-established SF-36 general health survey instrument, with eight domains. Chisholm-Burns et al. found supportive evidence of concurrent validity; with Cronbach's alpha exceeding .75 for most domains, and thus KTQ-25 can be an important addition to the health quality of life instrumentations used in renal transplantation [110].

Although there is currently a paucity of formal CER studies in renal transplantation given the newness of its emphasis, there are a few studies that approximate some of the key components of CER. One of the very first renal transplant studies to be undertaken using a decision analysis methodology in the elderly patient population was done by Jassal and colleagues in Toronto [112]. They used previously published utilities of .49 for dialysis and .78 for transplantation. For patients age 65 obtaining a cadaveric donor with a two year wait-list baseline the transplant ICUR was $67 779.00, with a gain of 1.1 QALY years, while for those with no wait-list the transplant ICUR was $14 910.00, with a gain of 2.0 QALY years. When wait listing periods were expanded to four years the ICUR at age 60 was $175 107.00, and at age 85 the ICUR plummeted to $14 585 442. The authors conclude that ICURs remain reasonable for patients aged $\leq$70 with baseline wait times not exceeding two years.

Kontodimopoulos and Niakas, at the Hellenic Open University, undertook the first cost-effective and quality of life study comparing hemodialysis (HD), peritoneal dialysis (PD), and renal transplantation (RT) in Europe [113]. Utilities were estimated using the SF-6D, a subset of the SF-36 General Health Survey, and QALYs were calculated assuming the linear QALY model based on projected individual life expectancy, with zero and five percentage present value discounting assumed. SF-6D derived utilities were .639 for HD, .599 for PD, and .716 for RT. QALYs by treatment modality were as follows: HD 5% discounted 3.67, and 4.37 0% discounted; PD 5% discounted 3.38, and 3.94 0% discounted; and RT 5% discounted 9.58, and 16.11 0% discounted. ICURs were calculated for each treatment, with renal transplantation demonstrating the lowest rate of cost per quality of life-year gained particularly at the three year and life-time projections (Figure 135.7). Since their cost estimates were gathered in Greece, caution must be exercised in extrapolating them to a for-profit health care context (e.g. USA).

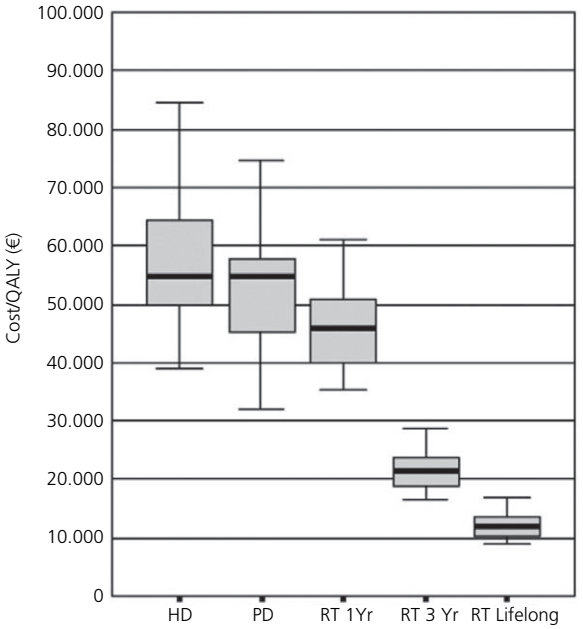

Figure 135.7. Cost per QALYs: The cost/QALY in euros (€) is plotted on the vertical axis, and the specific ESRD therapy is plotted on the horizontal axis. HD is hemodialysis, PD is peritoneal dialysis, and RT is renal transplant. The median cost/QALY is similar for one year RT to HD and PD, and the cost/QALY decreases substantially at RT three years, and RT lifelong.

The Kontodimopoulos and Niakas study raises an important point in cost-utility analysis, that of whether or not to discount future health gains along with future costs [54,113]. The authors disclose that they chose to discount QALYs at 5% rate to achieve a net present value, and used discount rates of 3% to 10% for costs. Some economists contend that since the value of health effects increases over time (presumably because good health causes income to increase) then they should be discounted but at a lower rate than costs [114]. This is referred to as differential discounting of costs and health where different rates of discounting are applied to health values and costs [115]. Equivalent versus differential discounting is a contentious issue among economists, and both approaches are severely criticized. The assumption for both approaches that a QALY is stable or constant over time is itself questionable. Van Hout has argued in favor of hybrid differential discounting adjusted by the economic growth rate and by modeling the growth of health [116].

Recently, Haller and colleagues undertook a cost-effectiveness analysis of kidney transplantation at the Medical Center of Vienna [117]. Quality of life utilities were measured using the EQ-5D, SD, and TTO techniques, while costs and QALYs were equivalently discounted at 3%. Results favored renal transplant and peritoneal dialysis over hemodialysis with a gain of 839 QALYs when 20% of patients received PD, and a gain of 2242 QALYs with 10% of patients receiving transplantation over a projected ten-year period of time.

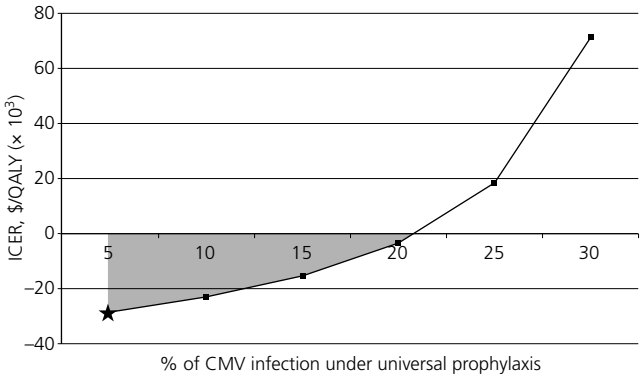

Figure 135.8. CMV infection rates and ICER: the ICER (incremental cost-effectiveness ratio) is plotted on the vertical axis, and the percentage of CMV infection under universal prophylaxis is on the horizontal axis. The figure represents the effect on ICER at various levels of universal CMV prophylaxis. The figure shows that at CMV universal prophylaxis less than 20% the ICER has greater cost-effectiveness ($ per QALY) in the shaded area over the preemptive strategy.

Figure 135.9. Utilities for lung transplantation: utilities are plotted on the vertical axis, and bar graphs are plotted along the horizontal axis for wait-listed versus years after transplantation. All year durations from one year out to five years show greater utility for lung transplantation versus being wait-listed.

In another recent study they utilized data from the Dutch End-Stage Renal Disease Registry (n = 15435), and took previously published utilities (HD .5560, PD .5817, and RT .8077) to simulate the benefit in terms of life-years and QALYs based on a living donor assumption. Early RT manifested improved quality of life-year gains of 6.7 to 8.8 QALYs for patients 40 years old, and a gain of 4.3 to 6.0 QALYs for patients 70 years old [118].

Recently Luan and colleagues completed an interesting quality-effectiveness study comparing the ICUR of universal versus pre-emptive treatments for cytomegalovirus in renal transplant patients [119]. Universal prophylaxis involved treatment with valganciclovir for 90 days for all CMV positive kidney recipients. The study used a pre-existing renal transplant utility of .73, and .57 for dialysis maintenance. The ICUR was −$27967/QALY with universal prophylaxis, indicating a cost savings of $27967 for each QALY gained over a ten year period. Their one-way sensitivity analysis showed a favorable cost saving ICER by implementing universal prophylaxis up to the point of approximately a 22% CMV infection rate (Figure 135.8).

The two-way sensitivity analysis demonstrated a less than $100000 per QALY gained with universal prophylaxis when varying the universal prophylaxis CMV infection rate 5% to 30%, and varying preemptive therapy CMV infection rate between 35% and 60%. Finally, a quality of adjusted-life study was done in Chile recently comparing renal cadaveric transplant with dialysis using established utilities of .80 for transplantation and .50 for dialysis. The study found a positive cost savings began at two years post-transplant, with dialysis costs approximating $134000, and the expected transplant costs of $106000 and a gain in QALYs of 7.30 [120].

Applying CER to organ transplantation

Transplantation is a unique subspecialty of medical practice in that its primary intervention, the organ transplant, is not readily available and is dependent on a national procurement system with donor organs supplying substantially less than patient's demand. CER seeks to determine the most effective therapy, and to derive the lowest risks, lowest costs per gain, and highest gain in quality of life per adjusted years. Clinicians and researchers in the domain of organ transplantation need to incorporate the analytic methodology of CER as we have articulated. For new fields of transplantation, such as CTA (composite tissue allograft), CER may prove useful in the process of advancing CTA as a standard of care. Liver, lung, and heart solid organ transplantation is essentially life-saving and, as such, comparisons can be done for wait listing versus organ recipient. In a Canadian study by Vasiliadis and colleague they compared lung transplant versus patient wait-listing and found a significant variability in derived utilities using standard gamble methodology [121]. The QALYs gained was a modest .62 for the full cohort, and only by making a ten-year projection did the QALYs gained reach 2.19. Figure 135.9 shows the mean utility registered at each time interval following lung transplantation.

How is a lung transplant patient wait-listing able to use these results in their decision making? We can conjecture the following: they should expect, overall, a good improvement in perceived usefulness of their life, yet over the years there is considerable variability to these gains, and the overall quality of life is modest and improves gradually over time.

In a CER study in Finland investigating the quality-adjusted life years following liver transplant, the researchers found a median increase in one year QALYs of .895, and at five years of 3.960. Median cost per QALYs gained (expressed in €) was: (141769/.895 =) 158400/QALY at one year, and at five years post- transplant (177618/3.96 =), 44854/QALY [122]. This study demonstrates two dimensions of informative use; for the patient-centered perspective the increase in quality-adjusted life-years gained, and for medical policy decision-makers the costs associated with each QALY gained. The latter obviously has use for determining society's willingness to pay assessments.

Grauhan and colleagues investigated the effect of the degree of coronary atherosclerosis (CA) on quality of life adjusted-life years (QALYs) for patients undergoing heart transplantation in Germany [123]. They used the SF-36 to measure health status for deriving QALY's among three comparison groups: single artery CA, multiple-artery CA, and those hearts with no discernible CA.

The mean SF-36 scores were very similar across the three groups: single CA 64.6, multiple CA 61.5, and no discernible CA 62.4; however the QALYs were significantly different, with single CA 8.5 QALYs, multiple CA 2.2 QALYs, and no discernible CA 8.0 QALYs. Thus, undertaking a program of pretransplant screening angiography is indicated as a reasonable investment given the gain in QALYs (5.8 to 6.3).

Methodological concerns of CER

CER is not without limitations and challenges as it undertakes the principal goals of demonstrating effectiveness, cost-utility, and favorable incremental utility, all while focusing more on the realities of clinical practice and patient-centered care. The initial broadly stated concern is that comparative effectiveness that focuses exclusively on gain in QALYs comparing new treatment to an established treatment does little to control costs and can actually lead to allocation inefficiencies if strictly adhered to. Secondly, cost-benefit or incremental cost utility analysis — both of which incorporate a comparison to costs and quality of adjusted-life years gained — renders comparison inclusive of their relative merits; this could lead third-party payers to simply adjust their costs to meet the derived standard (which could result in increased costs) [124]. A more fundamental concern with CER is the issue of differential or heterogeneous patient benefits resulting from broadly applying recommended therapies. For example, a meta-analysis of CER-based studies may establish the best practices therapy for the typical patient yet some will no doubt benefit more or less than others. This concern should be tempered by the relaxation of inclusion criteria for entry into the study, such as greater patient heterogeneity, which may dilute the efficacy while increasing broader effectiveness. The problem manifests when benefits are difficult to quantify exactly; such as reducing pain, anxiety, improving sleep quality, or reducing gastritis. Likewise, differences in drug effects are typically small and as such require large recruitments of patients to study arms to find small effect sizes [125]. Establishing equivalency or superiority of drug therapies is not easy with small effect sizes, often needing a placebo arm, which is a salient impediment to patient consenting when drugs for successful treatment have already been established. However, the CER emphasis goes beyond the traditional RCT efficacy ideal, to investigate the comparison of established therapies to enable enlightening the patient and physician decision-making process as to the most favorable course [126]. Hung et al. provide a recent example comparing metformin, sulfonylurea, and rosiglitazone in a retrospective study of 93 577 patients treated for DM on the composite endpoint of persistent decline in eGFR or ESRD [127]. After four years of treatment, sulfonylurea use compared to metformin revealed a 1.2 greater (HR) (CI: 1.13 to 1.28) risk for the composite endpoint. Critics might question the small effect size (<2.0), yet the 20% increased risk may be quite clinically meaningful given the large sample size involved.

Another related issue is non-ignorable physician skill set variance, which is particularly evident in surgical procedures when comparing low versus high-value organ transplantation programs. The intervention resulting in the greatest patient medical outcome and quality of life benefits may be highly dependent on technical skills and thus create wide variance in measurable outcomes and benefits. Albeit, a stated goal of CER is to advance the public's knowledge of what is effective and what is not, CER intentionality is not to produce a "one size fits all" medical decision-making matrix. There will inevitably be conflicts between the patients-favored outcome, such as quality of life, versus the physicans' biophysical outcomes. Recently Fried and colleagues investigated health outcome priorities in an elderly population and found that staying alive was ranked as top priority by only 11%, with pain management being ranked the top by 13%, and staying independent was number one by 76% of respondents [128]. Obviously when faced with the reality of finitude or chronic pain these priorities may alter substantially, but the study does highlight the need to include quality of life perceptions and needs reported by patients in the medical decision-making process such that a greater individualization of care is the result [129].

Recently a modified RCT design has been proposed as a bridge between RCT and CER to better achieve a balance between efficacy (internal validity) and effectiveness (external validity) called pragmatic randomized trials (PRT) [130]. The design is similar to RCT, with randomization to experimental and control study arms, yet the intervention and the outcome are grounded in meaningful and medical practice-focused research questions. Emphasis is upon external validity, thus a more inclusive patient recruitment strategy is employed in an attempt to generate real-life applied results [15]. PRT design differs in focus from RCT: the aim is investigating patient benefits under usual conditions (versus ideal), maintaining intervention flexibility, focusing on usual care practices, and finding answers to a broad set of outcomes that are of clinical importance to patients [16].

When CER studies are not randomized there is always the potential that observed treatment differences are due not to the intervention (or therapy) but to the preselection conditions that the self-selected patients bring to their respective study groups. Since epidemiologists primarily conduct their research with non-randomized designs, they could be considered a natural fit to assist with CER projects. Epidemiology has a long historical use and sophisticated analysis techniques to manage overt bias, such as matching and stratification analysis. Case-control designs frequently use one of two matching techniques. The first is called individual matching, where cases and control are selected to be similar based on some a priori criteria of deemed importance (e.g. age, gender, blood type, inflammatory markers) [131]. The second technique is termed frequency matching, and involves drawing the control sample in such a manner as to approximate the experiment patient characteristics (e.g. all wait listed patients from transplant center xyz that have similar creatinine levels). Note that in matching designs the test statistic is quite different since we are testing the observed probability of a discordant pair and we use the conditional maximum likelihood estimate of the odds ratio: OR = b/c, tested with McNemar's test, $\chi^2 = (B - C)^2/(B + C)$ [132]. Stratification is another pervasive technique to create balance between the experimental and control groups by segmenting the groups by one or more covariates of interest while making the groups otherwise as similar as possible [133]. Other newly popularized techniques that attempt to manage for selection bias in non-randomized studies include propensity score analysis (based on pretherapy variables, determining the conditional probability of each patient receiving a particular therapy) [134–137] and sensitivity analysis (i.e. determining the effect on an outcome variable by varying input variable or variables, such as changing the discount rate to impact the ICUR).

Summary and future directions

CER began in the USA in earnest with passage of the American Recovery and Reinvestment Act of 2009, which provided funding

and catapulted CER into mainstream research efforts. The principal objective of CER is to reform medical research such that it will enhance the patient-centered reality of clinical practice. Modern medicine has functioned for some time with a certain misalignment with clinical research and its emphasis on "one size fits all" generic focused efficacy versus the day-to-day practice needs of a heterogeneous patient population that presents with their chief complaint and a plethora of comorbidities. EBM was Europe's imperfect attempt at heightening research relevancy and legitimacy in the clinician's utilization of medical research in daily practice. EBM seeks to compliment the pathophysiological knowledge base that clinicians rely on with cutting-edge research evidence. CER seeks to expand the domain of EBM with its emphasis on assessing not only efficacy in the heterogeneous patient context, but quality of patient life vis-à-vis the medical intervention and the efficiency of such interventions. CER emerges partly due to the new found relevancy and successes of personalized medicine in pharmacogenomics, which represents a fundamental shift from generic patient pharmacology to a utilization of drugs in a tailored manner based on the patient's own genetic profile [138]. This genomic relevancy was most dramaticly illustrated by finding that the colon cancer drug cetuximab (Erbitux) was not effective in treatment of metastatic colorectal cancer in patients whose tumor had K-ras mutations on codon 12 or 13 oncogene. Thus, patients screened for K-ras mutation can potentially avoid a futile therapy and clinicians can shift to other therapeutics. Even for effective drugs, genomic information can be used in a dosage-tailored manner; for example a genetic test can reveal patients who are at high complication risk when using normal dosage of mercaptopurine for treatment of leukemia. In solid organ transplantation of liver, heart, and kidneys, it has been shown that patients who are carriers of CYP3A5*1 allele have an adverse impact on the pharmacokinetics of tacrolimus, and need a longer time period to achieve desired blood levels [139]. Recently, Provenzani and colleagues demonstrated that renal transplant patients with the 2677T/A allele needed much higher daily dosing of tacrolimus to achieved targeted therapeutic levels compared to patients who were homozygous for wild-type allele [140]. Finally, Einecke et al. developed a molecular classifier to predict renal graft loss, which demonstrated a RR of 2.70 (CI: 95%, 1.82–4.00) for graft loss with the molecular risk score [141]. The researchers conclude that the gene-based molecular risk score successfully identified active renal injury that can eventuate into graft loss.

A philosophical and economic concern with CER is that results, even from genomic biomarkers, are still frequentist averages, although subgroup based. When CER reveals the individual-level heterogeneity of the treatment effects, how will this affect health consumers and health care providers? Medical information will always have an element of uncertainty in its realized successes; as such patients can over or under estimate the treatment benefits. Simply put, when benefits exceed harms of a new therapy versus control (the mission of CER) and the information is uncertain, patients will jump to get the new therapy manifesting a large moral hazard and a demand upon third-party payers [142]. Some have thus advocated for a greater emphasis on individualization in CER, termed iCER, which will improve patient treatment decision-making [133,143]. The iCER can be brought about by n-of-1 trials, pragmatic randomization trials, use of local instrumental variable analysis to better allow for unobserved confounders, investigation of epigenetic factors, cross-over designs, and by using adaptive randomization techniques, the so called "play the winner" approach to patient allocation to the treatment arms that are demonstrating the largest effect size [144].

There has also been some debate as to whether personalized medicine was in conflict with stated objectives of CER, since the former's emphasis is explicitly patient-centric or individualistic, while the latter professes to investigate effectiveness of competing medical therapies among heterogeneous subgroups of patients. These concerns may be overstated since the very legislation creating the PCORI mandates accommodation between the principles of personalized medicine and CER. Both seek to shift the research emphasis from so called "average group effects" that tends to hide important subgroup effects and move research in the direction of improving patient care in an efficacious and efficient manner. The responsibility of CER researchers is to ensure it is undertaken to capture the relevant issues and nuances germane to the course of the illness being investigated. Patients do not respond to therapies monolithically, there is considerable response variation. It is this fact within medicine that will make it continue as an ongoing mix of clinical judgment (both the art and the practice) and necessitates the continuation of high-quality and relevant research that will inform and develop better clinical predictions [145].

CER in transplantation research will play an important role as it seeks to advance knowledge of effectiveness and patient-centered results. The emphasis needs to shift to complement efficacy with expanded external validity and relevancy for patient care and patient decision-making. Adding the utilities, quality of life measures and quality of adjusted-life assessments, all will help augment the decisional pathway within the complicated maze of transplantation decision-making.

SECTION 11

Transplant Policy

CHAPTER 136

Transplant Ethics for Clinicians

Richard N. Formica Jr[1] and Francis L. Delmonico[2]

[1] Yale University School of Medicine, New Haven, CT, USA

[2] Harvard Medical School, Massachusetts General Hospital; New England Organ Bank, Waltham, MA, USA

Introduction

Transplant professionals are entrusted with a unique position in the practice of medicine, the stewardship of a scarce societal resource: the organ donor. This stewardship entails two major responsibilities for which society holds transplant professionals accountable: the equitable allocation of deceased donor organs to medically suitable recipients; and the evaluation and care for the living organ donor. Both of these issues are addressed in additional detail in Chapters 137 and 138 respectively. This chapter focuses on the amalgamation of these from the perspective of the clinician. The decision to pursue organ transplantation as a therapeutic option entails a complex decision by the physician and patient regarding the risks of the procedure and the expected benefits. Ultimately, the treatment recommended for each patient should be based upon appropriate data and the experience of the transplant physician. Transplant professionals face an avoidable conflict in their stewardship of donor organs when balancing advocacy for an individual patient against the societal responsibility of conserving this precious resource. Data, experience and ethical principles relevant to organ transplantation become invaluable in balancing these competing interests. This chapter "Transplant Ethics for the Clinician" attempts to reconcile the competing interest of the patient and society in organ transplantation. Although the focus will be on kidney transplantation, the principles apply to decisions made for all transplantable organs. This chapter is not intended to convey opinion; on the contrary, it is a review of the application of data and experience that results in a normative course of treatment aligned with principles of bioethics.

The final rule

The Department of Health and Human Services has issued a "Final Rule" [1] as a framework for the structure and operation of the Organ Procurement Transplant Network (OPTN) to oversee the practice of organ donation and transplantation in the US. Section 121.8 of the Final Rule addresses the allocation of organs and states that allocation policies:

- Shall be based upon sound medical judgment;
- Shall seek to achieve the best use of donated organs;
- Shall preserve the ability of a transplant program to decline an offer for a specific potential recipient;
- Shall be designed to avoid wasting organs, avoid futile transplants and promote patient access to transplantation and efficient management of organ placement;
- Shall not be based upon the candidate's place of residence or place of listing.

Thus, the OPTN was directed to set priorities for rankings candidates on the wait-list based upon measurable medical criteria and ordered by medical need. In this setting of the Final Rule, the classic ethical principles of justice, utility, beneficence, and non-maleficence, and autonomy become evident [2]. The Final Rule accounts for the *Justice* principle by requiring allocation policy to be based upon sound medical judgment. Justice calls for the distribution of kidneys to patients with the longest waiting time. Ultimately, all patients with the same medical condition should be treated the same when placed on the wait-list. For extra-renal organs, the Justice principle now mandates medical need or the severity of the patient's illness as the foremost criterion of allocation:

- **Utility** as an ethical principle of the Final Rule, seeks the best use of the donated organ in achieving the best allograft survival; the best outcome.
- **Beneficence** promotes the interest of the patient to undergo transplantation. The Final Rule sustains *non-maleficence*, "to do no harm", by enabling a transplant center to decline a specific organ for a specific patient.
- Finally, **Autonomy** preserves the ultimate decision of the patient to undergo transplantation.

Decision-making in the current system

Beneficence, non-maleficence, and autonomy influence the doctor patient relationship at the time of accepting a kidney for transplantation. The patient trusts the physician's intention to make a recommendation regarding transplantation as a treatment option that is in his/her best interest. This decision is formulated with clinical judgment, knowledge of the data and clinical experience. Recent data suggest that patients and surgeons judge the same factors to

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

be important when deciding to accept a kidney for transplantation [3]. These include the quality of the kidney by donor age, risk of transmissible infectious disease or malignancy, the anatomy and function of the kidney, and the degree of HLA match (also accounting for potential recipient sensitization). These data provide essential considerations but the ethical principles elaborated by the Final Rule are important aspects as well.

The application of ethical principles

Addressing the overall quality of the kidney

Justice and beneficence are currently prioritized over utility to enable the allocation of an excellent donor kidney to an elderly patient. Conversely, non-maleficence would reject an older age kidney for a younger recipient. Importantly, the Final Rule enables a transplant center or patient to decline a kidney offer with autonomy as the key ethical component of the decision.

Function of the donor kidney at the time of death

Beneficence compels the acceptance of a kidney with a higher risk of delayed graft function for recipients that are highly sensitized or who reside in regions with longer waiting times and can tolerate the stress of delayed graft function and dialysis. A donor kidney with the same characteristics may be declined for recipients with medical co-morbidities that could not tolerate delayed graft function.

The HLA match of the donor kidney and recipient sensitization

This is a criterion of acceptance or refusal that depends upon the degree of the HLA match, the quality of the donor kidney and sensitization of the recipient. Current practice prioritizes quality over matching especially for the younger recipient. Highly sensitized patients are also afforded a priority for deceased donor kidneys irrespective of donor age and quality.

The risk of transmissible disease

Beneficence supports accepting a kidney at risk for infectious disease transmission for a highly sensitized patient who might otherwise never receive a kidney offer or a patient with failing dialysis access that is in life threatening need of a kidney transplant. However, non-maleficence requires declining such kidneys for recipients with low PRA and those without urgent medical need for transplantation. As the quality of the kidney is improved and recipient factors increase the urgency: such as longer waiting times, higher PRA, and older recipient age, the autonomy of the patient to accept a kidney balances the decision accepting an ill-defined but real risk.

Predicting the survival of the allograft

The expanded criteria donor kidney may be suitable for an elderly patient greater than 65 years of age, because the anticipated mortality on dialysis exceeds the rate of ECD failure. Again, the consideration of non-maleficence would result in the refusal of an ECD kidney for a younger patient. With each occurrence of a kidney offer, the transplant physician must balance beneficence with non-maleficence and determine whether the kidney should be accepted for that specific recipient, based upon sound clinical judgment, current data and guided by ethical principles.

The inadequacy of the current system

The transplantation of a 25 year old deceased donor kidney to a 75-year-old recipient, mandated by current allocation rule exposes the inadequacy of the current system in achieving the best utility of the donated organ. The wait-list has been expanded to accommodate an older age population and patients with more co-morbidities. A system of allocation based mainly upon time waiting overlooks the utility demand of the final rule.

In the past decade, UNOS has attempted to revise kidney allocation policy providing justice to all patients, while exercising utility to maximize the societal benefit of scarce donor organs. However, the potential shift of donor kidneys away from the older age population in the interest of improving the life years gained from a transplanted kidney has not been well received by those who serve the interests of the elderly. To address those concerns, UNOS has proposed a new approach assessing donor kidney and recipient longevity so that the survival of every transplanted organ "can be realized within biological reason and acceptable levels of access for those on the waiting list". The objective is to enhance graft survival for patients with the longest anticipated post-transplantation survival and to minimize the loss of a functioning kidney through an improved matching of the recipient and graft survival.

Living donor organ transplantation

Live donor transplantation has emerged as the predominant practice of organ transplantation throughout the world. This development was anticipated by a pioneer of transplantation, Dr. Francis Moore, who noted 40 years ago, that the live donor kidney would provide "the best tissue in comparison to an organ from a deceased donor. Today, the live donor affords the recipient the best opportunity for successful transplantation and the longest survival. The ethical principle of *beneficence* enables a healthy individual to donate an organ for transplantation. However, the ethical underpinnings of live donor kidney transplantation are not only built upon its success but by a requirement that there be a minimal risk to be a living kidney donor. The ethical principle of *non-maleficence* calls upon clinicians to avoid doing harm by ensuring medical appropriateness of the recipient. Risk to the donor should not be deemed acceptable unless there is a high probability of benefit to the recipient. This ethical axiom is well described by the consensus statement on living donation:

> the person who gives consent to be a live organ donor should be competent, willing to donate, free from coercion, medically and psychosocially suitable, fully informed of the risks and benefits as a donor, and fully informed of the risks, benefits, and alternative treatment available to the recipient. The benefits to both donor and recipient must outweigh the risks associated with the donation and transplantation of the living donor organ [4].

Non-maleficence or medical appropriateness in balancing risks versus benefits is exercised by clear guidelines established for donor protection. These guidelines include donor evaluation and screening and the monitoring of donor outcomes, all codified initially by the Amsterdam and Vancouver Forums. The Amsterdam Forum focused upon consent of the living kidney donor and the Vancouver Forum addressed extra renal living organ donation. These two forums help define core responsibilities of transplant programs (Box 136.1) and the essential elements of informed consent for all

Box 136.1. Responsibilities of the transplant center performing live organ donor transplantation. Data from [9,10]

- Provide information about organ donation and transplantation.
- Educate about the treatment alternatives available to the recipient.
- Provide an independent donor advocate.
- Assess medical, psychological and social suitability for organ donation.
- Ensure the decision to donate is voluntary and free from coercion.
- Implement procedural safe guards to enhance donor safety, understanding and autonomy.
- Provide medical and surgical staff skilled in the evaluation and care of the live organ donor.
- Provide referral and treatment for any medical conditions identified during evaluation.
- Provide psychosocial support throughout the evaluation and donation process.
- Provide medical care until recovery from donation process is complete.
- Facilitate long term follow up of the living organ donor.
- Perform quality assurance and process improvement to decrease risk of organ donation.

Box 136.2. Essential elements of informed consent in live organ donation

- Must be an adult, 18 years of age or greater.
- Must have the cognitive capacity to make the decision to donate.
- Must be a voluntary decision free from coercion.
- Must include assurances to protect the donor's privacy.
- Must include all relevant information inclusive of but not restricted to:
  - risk of death
  - risk of short and long term surgical complications
  - risk of potential long term medical and psychosocial complications
  - risk of being diagnosed with a pre-existing medical condition
  - risk to future insurability; health, disability, life
  - risk that the recipient may not have the hoped for outcome.
- Must include a cooling off period prior to the final decision.
- Must include the right with withdrawn from the process at any point.

living organ donors (Box 136.2). In certain parts of the world, patients with liver intestine or lung failure may not have the option of receiving an organ from a deceased donor so the availability of living organ donors becomes critical. However, the risks to the living donor of liver or lung allografts are significantly greater than that of a living kidney donor. Thus, these donors must especially be able to assimilate accurate information regarding their risks, with information presented at a level of medical sophistication suitable for that individual. With respect to informed consent, the donor should be able to verbalize his/her comprehension of risks and benefits.

Donors are patients

Donors become special "patients" beginning with the testing to determine whether they can donate [5]. In the practice of live donor organ transplantation, the doctor-patient relationship is one of mutual responsibility, which should not be abrogated by the claim of donor autonomy nor the obligation fostered by the recipient's needs. The physician has a responsibility to promote the interest and well-being of the living donor irrespective of the recipient need. The potential living donor has a responsibility to be forthright as to medical history and social encounters that may compromise the opportunity for donation or influence the ultimate well-being of both the donor and the recipient. The donor cannot demand to undergo a nephrectomy or partial hepatectomy without the support of the physician; and thus, the donor is not autonomous in such a decision. Clearly, there are certain instances in which the donor as a parent will present a compelling basis to be a donor despite an isolated medical condition such as hypertension. Nevertheless, if equipoise is not affirmatively achieved in the risk-benefit calculation for the donor and the recipient, then sound medical judgment should override all other concerns and prevent the transplant from going forward. A familial relationship does not impose on the donor (or the recipient) the necessity to take on additional medical risk to accomplish donation but it may influence the ultimate decision to permit donation to go forward (see further on in this chapter).

The psychosocial assessment

Biologically unrelated donors constitute more than 40% of living kidney donors in the US [6]. Most of these donors are spouses or friends with a long-standing emotional relationship to the recipient. Nevertheless, there are an increasing number of living donations that are occurring through relationships established by the Internet or church bulletins that link a recipient to a potential donor. Unrelated anonymous individuals also come forward today with a genuine altruistic intention to provide for another and in the absence of personal appeals. The potential donors that respond to Internet solicitation must receive a thorough psychosocial evaluation to confirm that there is no underlying financial need or expectation. Furthermore, organ donation should not serve as a remedy for a potential donor's psychological malady. Guidelines for the psychosocial evaluation of the unrelated donor were published following a consensus conference on this topic [7]. Risk factors for an anticipated unfavorable psychological outcome following donation were developed to include a history of psychiatric symptoms or disorders or a history of substance abuse or dependence. A motivation reflecting an interest for personal or public recognition or the desire to use the potential donation as a way of fostering a new personal relationship was considered a high risk. Subordinate relationships such as employee/employer in which coercion may be the basis upon which an individual has come forward must be assessed and fully vetted prior to proceeding.

Autonomy versus paternalism

Autonomy is the capacity for self-determination to act intentionally and voluntarily, with comprehension, and without controlling influences coercing the patient. With organ donation, a persons' autonomy is exercised through the process of obtaining informed consent. Respect for autonomy however, does not imply that physicians are obligated to co-operate with someone to enable them to be a donor if medical judgment is not supportive. Clinicians should not be coerced into recommending or participating in a nephrectomy or partial hepatectomy if the medical evaluation renders the potential donor medically or psychosocially unsuitable. It is also important to recall that autonomy is not a principal exercised in a vacuum; it requires a comprehensive assessment of the role of beneficence and non-maleficence in the decision to go forward with organ donation. The responsibility of the physician to uphold non-maleficence is not paternalism but rather the proper exercise of medical judgment. The Amsterdam Forum recommends procedural safeguards such as a cooling off period prior to final approval to proceed with donation in an effort to minimize coercion and yet support autonomous decision-making.

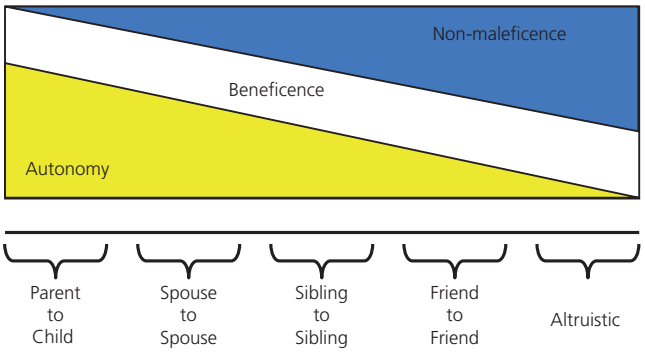

Figure 136.1. Relationship of the donor to the recipient influencing the decision to donate.

The relationship of the donor to the recipient influencing the decision to donate

The relationship between the donor and recipient may be consequential to the ultimate decision for donation. As the relationship becomes more biologically distant, from blood relative — to an acquaintance — to an anonymous stranger, autonomy becomes less influential and non-maleficence becomes the most weighted consideration for the altruistic unrelated or anonymous donor (Figure 136.1). The clinician's concern regarding risk to the donor is not changed by the relationship; however, the exercise of donor autonomy permitting risk is more appropriately sanctioned when there is a strong familial or emotional relationship between the donor and recipient. Isolated medical abnormalities such as hypertension, proteinuria, marginal renal function, or anatomical issues such as renal artery stenosis are not summarily dismissed when the relationship between the donor and recipient is well-established emotionally but rather the good derived from a successful transplant may mitigate such isolated medical conditions. For example, transplant physicians have become more accepting of an older spouse with hypertension to be a donor, because there is a predictable lifespan not adversely affected with successful medical treatment of hypertension and there is a tangible benefit for the donor spouse. Furthermore, the opportunity for donor follow-up simultaneously with care of the recipient helps to mitigate the risk and allows the donation to proceed.

Assessment of outcomes

The transplant community has a responsibility to track and report the outcomes of live organ donors as an integral part of a societal stewardship. Sentinel events such as donor deaths and organ failure should be reported transparently and indemnified from litigation. Similarly, if physician malpractice was not involved, participation in reporting these sentinel events should not place the physician at risk of liability.

The limitations of existing data regarding outcomes of living kidney donors and a defined need for follow-up of donors has been highlighted by a recent consensus conference on these topics [8]. Major reasons to continue the systematic collection and reporting of living donor outcomes were developed:

1 living donors must have accurate outcome information to give informed consent;
2 program specific feedback is necessary for quality assurance and performance improvement;
3 donation is a public trust and the transplantation community has an obligation to continue to collect information on living donor outcomes;
4 ongoing information is necessary to improve the evaluation process and provide a reliable counseling for nontraditional living donor candidates;
5 surveillance may identify individual donor problems at a time when intervention is possible.

The transplant profession must be proactive in ensuring that the donation process is safe both perioperatively as well as long-term. Live organ donation works because the public believes that transplant physicians and surgeons are working for the best interests of donors and recipients.

Summary

The practice of organ transplantation requires the physician to have an understanding of bioethics, and an awareness of current medical information and data that can result in the best outcome for a specific patient. To accomplish those goals, society entrusts the physician to be a steward of the deceased donor organ and to act in the interest of the living donor by providing donor care and assuring safety for the donor's well-being.

CHAPTER 137

The Ethics of Organ Allocation

Richard S. Luskin and Alexandra K. Glazier
New England Organ Bank, Waltham, MA, USA

Introduction

This chapter will examine the general ethical principles applied to the development of deceased donor organ allocation policy, as well as other factors that influence patient prioritization; review issues affecting patient access to the waiting list; discuss the relationship between organ allocation policy and organ donation; and review legal and regulatory factors influencing organ allocation policy.

Organ transplantation is unique

Rationing of scarce resources is certainly not uncommon in health care. Due to limited funding some therapies are rationed overtly as a matter of policy to control spending, especially in nations where the government is the primary or exclusive payer. In these cases, expert panels make choices about which available therapies meet an acceptable cost-to-benefit ratio. Insurers may limit access to certain therapies that are considered less "efficient" through higher co-pays, deductibles or even non-coverage or by requiring use of a generic drug or a particular manufacturer's product. In other examples, therapies may be indirectly rationed in a *de facto* manner through unequal access to medical care as determined by such factors as race, educational level, employment or insurance status, or geography.

However, organ transplantation is the only area of medical practice that must be rationed both explicitly and independently of financial concerns. This is due to the severe imbalance between the demand for this therapy and the available supply of organs. Until there are significant research breakthroughs in preventing end-stage organ failure or a dramatic increase in the supply of transplantable organs, this supply-demand imbalance will continue.

The successful development and expansion of hemodialysis in the 1960s provided a life saving therapy to patients with end-stage renal disease (ESRD). However the lack of available dialysis machinery and trained staff forced decisions about who would have access. The so called "death committee" in Seattle created to assess patient "worthiness" for access to hemodialysis was chronicled in *Life* magazine [1]. The public revulsion to this situation led, in part, to the enactment of the US ESRD program, which provided Medicare benefits to all patients in need [2]. This massive infusion of financial resources partially solved the problem of access to kidney transplantation, but could not overcome the inherent shortage of organs. The situation with other transplantable organs that are in short supply (e.g. livers, lungs) is complicated even further by the lack of any widely available, effective alternative therapy other than transplantation. This hard reality forces the medical community, public policy makers, insurers and the public to face difficult ethical and societal choices about who shall live and who shall die.

Ethical principles in the allocation of organs

Given the scarcity of the resource, each national or multinational organ recovery and transplantation system establishes policies for the allocation of organs. In development of these policies, there are certain foundational ethical principles that are commonly considered, although the weight given to each varies according to history, culture and politics. The three primary ethical principles are: utility, equity (or justice) and autonomy (Figure 137.1) [3].

Utility

In the context of organ allocation, the principle of utility requires the maximization of "the expected net overall good, while minimizing harm." [3] Utility can further be subdivided into social and medical aspects. Social utility seeks to rank potential recipients by estimating their potential future contributions to society were they to receive a transplant. In democratic societies, such assessments of "worth" inevitably are controversial and therefore generally not considered in the development of organ allocation systems. As noted by the Organ Procurement and Transplantation Network/United Network for Organ Sharing (OPTN/UNOS) Ethics Committee: "Considering one person more useful to society than another, based on prevailing social values, may be a matter of opinion or good fortune in the random distribution of natural and socially cultivated talents and abilities. We add insult to injury when we withhold the benefits of transplantation from those who may not be as likely to benefit society as those more fortunately endowed." [3]

Medical utility seeks to assess how much medical "good" a transplant will do for one recipient as compared to another. There are at least five factors that commonly are taken into account under the umbrella of medical utility:

- **Patient survival —** Simply stated, this criterion asks: what is the likelihood, relative to other patients awaiting a transplant of the same organ, that the potential recipient will die if a transplant is not received? This criterion assumes that one can fairly accurately predict the likelihood of death without a transplant given certain clinical criteria and within a specific timeframe. It also begs the

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

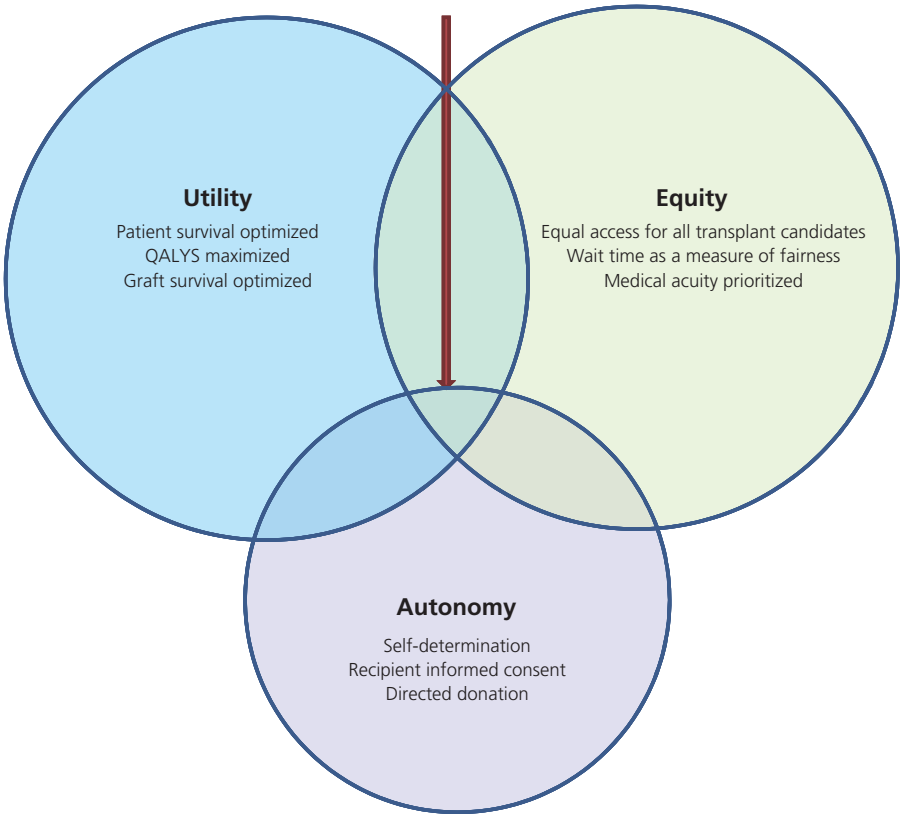

Figure 137.1. Allocation systems are designed to strive for a balance of all three principles.

further question: Is the goal to save a life; or is the goal to maximize the number of years the recipient is expected to live post-transplant? For example, if two potential recipients have the same odds of not surviving without a transplant, but one is expected to live 3–5 years post-transplant and the other 8–10 years, should the second patient receive priority in order to maximize the utility of the transplanted kidney as measured by "life years" added? Specific organ allocation systems often seek to find a balance between these two aspects by providing a "score" that reflects both the likelihood of dying without transplant and the likelihood of surviving for a specified interval post-transplant [4].

- **Graft survival —** Beyond the survival of the recipient, allocation systems also must consider the survival of the graft. An assessment of expected graft survival must take into account both the medical condition of the recipient, and the characteristics of the donor: age, cause of death, process of death (donor after brain death [DBD] or donor after cardiac determination of death [DCDD]) and presence of infectious diseases and/or other medical conditions. Graft survival factors into utility concepts as a measure of how long the transplant is expected to provide medical benefit.
- **Quality of life — I**n recent years, policy makers and clinicians have attempted to assess the usefulness of clinical interventions using the concept of "Quality Adjusted Life Years" (QALY). As its name implies, QALY assesses not only the probability of patient (and graft) survival, but also the quality of life. Although quality of life can be a very subjective assessment, scales have been developed which assume that 0 = death and perfect health = 1, with various states in between along a continuum [5]. Thus comparisons theoretically can be made among potential transplant recipients. For example, a transplant that is expected to keep a patient alive for an additional six years rather than dying within one year, but where quality of life is to varying degrees less than ideal both during the year awaiting transplant and post-transplant, would lead to a calculation as follows:
  - 6 years extra life @ 0.7 quality of life = 4.2
  - less 1 year @ reduced quality of life (1 − 0.6) = 0.4
  - QALYs generated by the intervention = 3.8.

  In the case of kidney transplantation, QALY often is calculated by comparing patients' perception of psychological and physical wellbeing for a year on dialysis, versus a year with a functioning transplant. Various studies have suggested a ratio of 0.8, with transplant the preferred option [6].
- **Availability of alternative treatments —** In establishing priority rankings for transplant candidates a utilitarian approach also considers the availability of alternatives to transplant. The most obvious example is hemodialysis versus kidney transplant although, as noted above, these two therapies generally are not considered equivalent by patients. Similarly, in recent years the increased use of cardiac assist devices (CAD) has complicated the assignment of heart transplant candidate priority. In some cases, CADs have become not just a bridge to transplantation, but a destination therapy.
- **Age —** Age seemingly is the most objective variable as it can be determined precisely without subjective judgments or calculation of statistical probabilities. However, physiologic age is not necessarily equivalent to chronologic age, thus complicating the use of age as a proxy for more subjective variables such as expected

patient survival, expected graft survival and QALY. The application of age as a utility factor in allocation policy may include a comparison of expected graft survival to expected recipient survival. If the graft is expected to survive for more years than the recipient is expected to survive post-transplant, perhaps the graft should be allocated differently to maximize the utility of that graft. For example, a kidney becomes available from an excellent donor and has an expected half-life of 20 years. Should that kidney be prioritized for a younger recipient whose life expectancy with a transplant is at least 20 years? Or should an older transplant candidate with a life expectancy of only ten years have equal priority? In other examples, the choices are clearer. Young children in renal failure will not grow and develop normally on dialysis. Thus most allocation systems provide a priority for children for kidney transplant. For example, in the US, kidneys from standard criteria donors $\leq$35 years old are preferentially allocated to patients listed before their 18th birthday. This policy has effectively reduced the waiting time for a kidney among pediatric patients. However, in a demonstration of the complexity of allocation policy, there has been a concomitant decline in the number of living donor kidneys for the first transplant of a pediatric patient. It is suspected that some parents who are medically suitable donors now choose to save their kidney for the time when their child may need a retransplant [7].

Intuitively, a utilitarian analysis of organ allocation would seek to create a situation where "every allograft is transplanted into a recipient the allograft would outlive, but only by a few days." [8]

On the opposite end of the age spectrum is the Eurotransplant Senior Program (ESP) commonly referred to as the "old-for old" plan. Established in 1999, ESP sought to:

- Find a more effective way to use the increasing number the number of kidneys recovered from donors >65 years old; and
- Reduce the wait time of kidney transplant candidates >65 years old.

A retrospective analysis after ESP's initial five years of implementation demonstrated that these utility goals were achieved with an increase in the total number of kidneys available for transplant for patients of all ages [9].

As we will see further on, the use of age in allocation must be carefully considered in the context of legal prohibitions against age discrimination.

Equity

Counterbalancing the concept of utility is the concept of equity. Sometimes described as fairness or justice, equity in organ allocation acknowledges that there are other criteria, important to most societies, which must be taken into consideration. In general, an allocation system that prioritizes utility above all else probably would not be perceived as the fairest or most equitable by society. If one were to focus solely on utility, then priority might go to: younger patients; patients with stable, intact families able to support them through the surgery and recovery; and patients with insurance (or personal means) to cover the cost of a lifelong regimen of immunosuppressive drugs. Maximizing utility without regard to equity may result in prioritizing shorter waiting times and lower acuity of illness because of anticipated better transplant outcomes (for some diseases). Such an allocation scheme likely would result in de facto discrimination against the poor, the less educated, the underemployed or unemployed, and possibly others with diminished access to health care such as racial minorities.

Because donated organs are considered a public resource to be used for the common good, most societies seek to provide some balance to pure utility factors in order to satisfy a basic sense of fairness. It is relatively easy to reach consensus on some aspects of equity. For example, all other things being equal — expected patient survival, expected graft survival, etc. — generally it is agreed that the patient who has waited the longest should have priority over those who have not waited as long. But waiting time also can be controversial. First, one must agree on a common "time zero" — the moment when a patient is clinically ready for a transplant. Even if that were possible, wait time is heavily dependent on what point in time after time zero a patient is referred to a transplant program, evaluated, accepted for transplant and actually listed. Numerous studies have demonstrated that there is wide variation in patient referral timing, and the timing of transplant center listing [10].

Other factors relevant to assessing patient wait times include:

- Has the patient been offered and previously refused a kidney or liver because they were waiting for one perceived to be from a more ideal donor?
- Has the patient's wait time been extended by periods of wait list inactivity for failure to follow the clinical regimens designed to make them suitable for transplant? (Wait time generally continues to accrue even while the patient is "inactive" on the list.)

Another, more complicated example involves patients awaiting kidney transplantation who are "sensitized" to a large percentage of the population. These transplant candidates may have become sensitized though a blood transfusion, child birth or a previous transplant making it much harder to find an acceptable donor. Thus most allocation systems have provided some priority for kidney transplant patients with increased panel reactive antibodies (PRA). However, even with extra points in an allocation system, high PRA patients still may not have "equal" access to transplant and their graft survival is likely not to equal those not so sensitized [11].

Age can be a factor in equity as well as utility when one considers the concept that everyone should have an opportunity to live a complete life, to marry, to have children and make a contribution to society. This has been termed the "fair innings argument"; that all other factors being equal, younger candidates should be prioritized since they have not had the same number of life opportunities as older candidates [12]. Under this theory, a 20-year-old transplant candidate would be given priority over a 70-year-old transplant candidate. Various proposals have been made to provide some extra access to transplant using a point score that is high for the very young and that diminishes fairly rapidly, but continues to provide some small relative priority to a younger candidate as compared to older candidates at all ages [3].

Autonomy

The principle of autonomy is simply the concept that individuals should be able to exercise self-determination [3]. Although autonomy is the dominant ethical principle in many medical treatment decisions, it plays a less direct role in organ allocation than do the principles of utility and equity. The autonomy principle is most often considered in organ allocation as supporting the potential recipient's right to refuse transplantation or refuse a particular organ being offered for transplant, for example based on medical factors of the donor. This application of autonomy is an essential component of the recipient's informed consent for the transplantation procedure. Note, however, that this only influences allocation indirectly. The initial allocation of a particular organ would be made in accordance with policy and only if the prioritized recipient

declines by exercise of autonomy would the organ then be offered to the next potential recipient in conformity with the allocation scheme.

Another autonomy factor to be considered in organ allocation that is infrequent but has a more direct impact is the ability of a donor to make a directed donation to a specific recipient. In the US, both the state laws governing consent for organ donation (the Uniform Anatomical Gift Act) and the federal law that established the national system (the National Organ Transplant Act) expressly permit organ donors (or their authorized surrogates) to direct a donation to a particular recipient if the organ is compatible and can be transplanted into that individual [13]. If such a directed donation is made, then the organ goes to the intended recipient regardless of the allocation priority such individual would have received. Because a directed donation of organs from a deceased donor will only be facilitated if the intended recipient is in fact listed for transplantation and biologically compatible, it is an infrequent event. Nonetheless, it highlights the importance that the ethical principle of autonomy is accorded given that a direct donation bypasses the allocation scheme entirely.

Legal and regulatory factors influencing organ allocation policy

It is generally agreed that organs are a societal resource, meant to be used judiciously for the "common good." In most nations there are laws and regulations that provide guidance in the development of organ allocation policies.

United States

In 1984 the US adopted P.L.98-507, the National Organ Transplant Act (NOTA), which established the basis for the US Organ Procurement and Transplantation Network (OPTN). NOTA included the creation of a task force to provide recommendations for the development and operation of the OPTN. Included in the charge of the Task Force on Organ Transplantation was a mandate to make:

> "recommendations for assuring equitable access by patients to organ transplantation and for assuring the equitable allocation of donated organs among transplant centers and among patients medically qualified for an organ transplant."

The Task Force report [14] made numerous recommendations concerning the principles that should be applied in developing policy for the allocation of organs. These included:

- . . . donated organs [should] be considered a national resource to be used for the public good; the public must participate in the decisions of how this resource can be used to best serve the public interest [14].
- . . . selection of patients both for waiting lists and for allocation of organs [must] be based on medical criteria . . . [to] be developed by a broadly representative group [and] take into account both need and probability of success. Selection of patients otherwise equally medically qualified should be based on length of time on the waiting list [14].
- . . . the preferential assignment of an organ to a recipient based on objective medical criteria such as HLA matching, a compatible presensitized recipient, or length of time on the waiting list, is well recognized and widely accepted. Other criteria such as urgency of need, age, lifestyle, the presence of social support, or the need for retransplantation must be individualized and carefully applied so that medical judgments are reflected rather than judgments of social worth [14].
- . . . organ-sharing programs . . . [must] be implemented in the interests of the effective and efficient use of organs and justice, and the effect of mandated organ sharing [must] be constantly assessed to identify and rectify imbalances that might reduce access of any group [14].

Although organ allocation policies were developed by the OPTN once it began operating in 1988, the official federal regulatory framework for US policy on organ allocation was not established until 2000 with the adoption of "The Final Rule" [15]. Key sections of the Final Rule call for the establishment of "policies for the equitable allocation of cadaveric organs among potential recipients" to:

- be based on sound medical judgment
- seek to achieve the best use of donated organs
- be designed to avoid wasting organs, to avoid futile transplants, to promote patient access to transplantation , and to promote the efficient management of organ placement
- not be based on the candidate's place of residence or place of listing, except [to] the extent required by [the preceding]
- Distribute organs over as broad a geographic area as feasible [given above] . . . and in order of decreasing medical urgency.

Oversight of the US system is carried out by the OPTN. NOTA requires the US government to contract with a private, not-for-profit organization to carry out the day-to-day management of the OPTN. This includes maintaining a list of all patients waiting for a transplant at all US transplant centers. Since its establishment, the OPTN contract has been held by the United Network for Organ Sharing (UNOS). In addition to prescribing the basis upon which allocation policies are to be developed, the OPTN Final Rule also specifies that the OPTN will seek input from the transplant centers, organ procurement organizations (OPO), histocompatibility laboratories and the public.

Allocation policies are complex and have been subject to change in response to the regulatory requirements and general ethical principles described above, as well as increased understanding of the impact of allocation on various patient groups. Kidney transplant candidates generally are rank-ordered by waiting time, with special consideration for pediatric patients, highly sensitized patients, patients with high degrees of HLA match with the donor and previous living donors. Extra-renal organ transplant candidates are prioritized by acuity of illness, likelihood of dying without a transplant and/or likelihood of surviving with a transplant for at least one year. Allocation policies are designed to attempt a balance between equity and utility and have been slowly evolving to broader areas of sharing.

Although limited by the Final Rule, in practice geography does influence organ allocation. This is a function of historical allocation patterns, the practical limitations on organ transport and preservation given the area of the US and the nature of the US political structure with 50 state governments and a federal government. The US system is three-tiered. There are 58 local OPO service areas, 11 regions and a national list. In general, organs are first offered to medically suitable patients at transplant centers within the service area of the OPO coordinating the recovery. If no suitable recipient is available within the OPO service area, then the available organ is offered to recipients in the OPO's region and then nationally. Thoracic organs not used locally are offered to expanding concentric circles of 500 miles from the hospital where the organ was recovered. Some exceptions to these rules are made to provide improved access to the most acutely ill patients.

Eurotransplant

Eurotransplant (ET) is responsible for the allocation of donor organs in Austria, Belgium, Croatia, Germany, Hungary, Luxembourg, the Netherlands and Slovenia. Its position statement [16] on allocation includes:

- Eurotransplant shall ensure that the allocation of organs under its responsibility be guided by clinical and ethical criteria, and allocation rules that are defined by appropriately constituted committees, based on principles of fairness, equity and transparency, and in accordance with domestic regulations of the member countries.
- Eurotransplant will accept patients on its waiting list for transplantation according to accepted and transparent medical criteria (indication, need, urgency). Allocation of available organs will be based primarily on clinical criteria (need, urgency, and match, other aspects related to both the donor organ and the recipient) and accrued waiting time, taking into account ethical principles, and without regard for personal, social or financial background.
- As Eurotransplant operates on the basis of international cross-border collaboration and exchange of organs, its procedures for allocation across participating countries must take into account the principle of solidarity within each country (to be implemented through a mutually agreed balancing system).

In practice, allocation is based upon two general principles:

1 Expected outcome.
2 Urgency (as determined by experts in an objective and transparent way).

It also takes into account:

1 A reasonable balance among the participating nations and
2 Waiting time of the transplant candidate.

Allocation priorities are developed by panels of professional experts.

Spain

National coordination of the transplantation system in Spain [17] is carried out by the Organización Nacional de Trasplantes (ONT), an arm of the Spanish Ministry of Health and Consumer Affairs. Similar to the US, a three-tiered system of allocation exists. The primary unit of allocation is at the hospital/transplant center level, then to other transplant centers within the region of recovery (there are six) and then nationally. If no recipient is identified, the organ is then offered to other transplant centers within Europe. Unlike the US, each transplant center develops its own medical criteria for prioritizing organ allocation among its waiting patients.

Great Britain

The National Health Service branch for Blood and Transplant (NHSBT) is responsible for matching and allocating donated organs [18]. Rules for allocating organs are determined by the medical profession in consultation with other health professionals, the Department of Health and specialist advisory groups:

"All kidneys from deceased heart beating donors are allocated according to a national system. This is based on five tiers:

1 complete matches for children — difficult to match patients
2 complete matches for children — others
3 complete matches for adults — difficult to match patients
4 complete matches for adults — others and well-matched children
5 All other eligible patients (adults and children).

Within Tiers A and B, children are prioritized according to their waiting time. In the remaining Tiers, patients are prioritised according to a point score, whereby organs are allocated to the patients with the highest number of points. The score for an individual patient is based on a number of factors:

1 Time on the waiting list (favouring patients who have waited longest).
2 Tissue match and age combined (favouring well-matched transplants for younger patients).
3 The age difference between donor and patient (favouring closer age matches).
4 Location of patient relative to the donor (favouring patients who are closer in order to minimise the transportation time of the kidney).
5 Three other factors relating to blood group match and rareness of the patient's tissue type".

Extra-renal organs are allocated by a combination of patient acuity, location of the recovery, waiting time, and a balancing of transplants among the transplant centers.

Access to the waiting list

There exists another key factor that significantly influences how scarce organs will be allocated: access to transplantation. All potential recipients must be carefully evaluated by a transplant center team in order to assess the medical necessity for, and appropriateness of, a transplant. In general, the patient cannot independently make the assessment that the transplant should be considered. Thus patients must rely on their primary care providers to make a referral to a transplant program. Without such a referral and positive assessment, there is no ability to access the deceased donor waiting list. In addition to the medical evaluation of the prospective transplant candidate, transplant centers also assess other factors such as the likelihood that the patient will comply with post-transplant care including taking the necessary immunosuppressive drugs and avoiding other behaviors detrimental to the patient and the transplanted organ. Several of these factors are discussed here.

Organ failure caused by "self-destructive" behaviors

It is well documented that certain behaviors are associated with the likelihood of acquiring certain diseases. For example: smoking is associated with cancer and heart disease; obesity with diabetes; sedentary life style with heart disease; alcohol and drug abuse with liver disease. Health professionals certainly attempt to modify their patients' self-destructive behaviors to minimize the risk of disease. There is rarely a question of whether or not all appropriate treatments should be offered even if the patient's behaviors lead to a diseased state. However, when there is an apparent cause/effect relationship between self-destructive behavior and the need for a transplant, questions arise about the appropriateness of listing these patients.

Because of the organ shortage clinicians and ethicists have debated how best to handle patients in this circumstance. Inevitably part of the debate relates to the "worthiness" of the patient to have access to transplantation as a scarce resource. Liver transplantation for alcoholics is a frequently cited example. Part of the discussion involves whether or not the patient is responsible for their alcoholism, or if it is a disease much like any other disease. In general, the transplant community has focused not on whether the patient is at fault, but rather on determining the likelihood that the transplant will be successful.

Clinicians must take into account the patient's current behavior and the likelihood that the patient will change their lifestyle post-transplant to avoid behaviors that will reduce graft and patient survival. As a result, most transplant programs require the patient to demonstrate their compliance through such things as smoking cessation, weight loss, etc. For patients with a history of alcohol or drug abuse, most transplant centers require a minimum of a six-month abstinence as an indication of the patient's ability to be compliant with post-transplant procedures. Recently, some have suggested that the six-month "rule" should be relaxed in certain circumstances [19]. However, others have noted that "because of the scarcity of organs, we cannot afford to choose candidates in an arbitrary way that cannot be defended in the public eye." [20]

Retransplantation

In the US in 2009, 14% of the kidney transplants, 7.6% of the liver transplants and 4.0% of the heart transplants were into a patient who had received a previous transplant of the same organ [21]. Access to more than one transplant and the priority of access to retransplant has been a source of some contention since the earliest discussions of organ allocation. The 1984 US Task Force on Organ Transplantation noted the debate between those who would limit a patient to a single transplant and those who believed that such a policy would constitute "abandonment" of a patient [14]. The Task Force concluded that medical judgments, not simply the fact of a previous transplant should be the determining factors. Subsequent debates and policy decisions have continued this line of thought.

From a utilitarian perspective, the organ being transplanted saves a life and it is not relevant which life it saves. Except in cases of a recipient deliberately causing the failure of a transplant (e.g. failing to take immunosuppressive drugs) the graft failure is not the patient's "fault." Grafts fail primarily for immunologic reasons or occasionally a surgical technical error, events beyond the patient's control. In certain circumstances, repeat transplant candidates are actually given priority rather than being downgraded. For example, a liver transplant recipient suffering primary graft failure within seven days of transplant is among the highest priority candidates [22].

Others have suggested that the ability to retransplant a patient actually increases organ availability for all. If transplant centers knew that — should it become necessary — they were unable to obtain a second organ for their patient, they would be less likely to use organs from "marginal" or "expanded" donors.

Geography and multiple listing

The location of a patient's residence influences access to being listed at a transplant center and the likelihood that he/she will receive an organ once listed. Factors include:

- the presence of a transplant center close to his place of residence
- the practices of local physicians in referring patients for transplant evaluation
- the medical and social screening criteria used by a transplant center in deciding whether or not to list a patient
- the number of organs recovered by the local organ procurement organization, which is a function of the underlying potential for donation in the region and the efficiency of the OPO [23]
- allocation policy.

In some nations — typically those with a single national payer system (e.g. Spain) — patients are assigned to a particular transplant center, except under special circumstances. However, in the US patients are not only free to list at any center but also are permitted to list simultaneously at multiple centers. Waiting times by organ are publicly available and vary considerably. Patients who are better educated, more resourceful and have better insurance coverage and/or greater financial resources sometimes choose to list at multiple centers, seeking one with a shorter waiting time. In fact, transplant centers in areas with longer waiting times sometimes encourage patients to multiple list if they believe they will not be able to receive an organ in time to meet their needs.

Such practices inevitably raise questions of equity, especially when high profile individuals are transplanted relatively quickly at a transplant center far from home [24]. The ability to multiple list has been challenged as unfair and the US OPTN has proposed banning it. However, significant public opposition to eliminating the practice has maintained the status quo [25].

International patients travelling for transplantation

Travel of patients across borders for the purpose of transplantation may play a role in wait-listing practices and potentially in allocation schemes. The travel of patients for transplant should be considered in the context of the widespread international efforts by transplant professionals, national legislative authorities, and the World Health Organization to counter transplant tourism [26]. Central to this effort has been the widespread endorsement of the Declaration of Istanbul on Organ Trafficking and Transplant Tourism [27]. The concept of "transplant tourism" is defined in the Declaration as follows:

> "Travel for transplantation is the movement of organs, donors, recipients or transplant professionals across jurisdictional borders for transplantation purposes. Travel for transplantation becomes *transplant tourism* if it involves organ trafficking and/or transplant commercialism or *if the resources (organs, professionals and transplant centers) devoted to providing transplants to patients from outside a country undermine the country's ability to provide transplant services for its own population.*" (Emphasis added)

The distinction of "transplant tourism" that is of relevance is whether additional non-citizen transplant candidates undermine the ability of the host country to serve the transplantation needs of its own population. National self-sufficiency is a core principle of the Declaration of Istanbul. Specifically, "jurisdictions, countries and regions should strive to achieve self-sufficiency in organ donation and transplantation by providing a sufficient number of organs for residents in need from within the country or through regional co-operation." The call for self-sufficiency includes the concept that "treatment of patients from outside the country or jurisdiction is only acceptable if it does not undermine a country's ability to provide transplant services for its own population" [28].

The issue of transplantation of foreign nationals traveling to the US for transplant was controversial even in 1986 when the shortage of deceased organs in the US was of a different and lesser order of magnitude than it is today. After vigorous debate the Task Force recommended that "non-immigrant aliens should not comprise more than 10% of the total number of kidney transplant recipients at each center" [14]. A substantial minority of the Task Force members entered a statement of exception to the effect that a kidney should not be offered to a non-resident alien unless another suitable US citizen recipient could not be found [14]. The issue of transplantation of "life-saving" organs such as hearts and livers into non-resident aliens was also addressed by the Task Force recommending

that "extra renal organs should not be offered for transplantation to a non-immigrant alien unless it has been determined that no other suitable recipient can be found" [14].

After UNOS was awarded the OPTN contract, it adopted policies taking into consideration the Task Force recommendations and delegated to an Ad Hoc International Committee the task of reviewing the activities of transplant programs whose proportion of non-resident alien recipients for *any* organ exceeded 10%. In 1994, the threshold percentage was changed to 5%. Given that NOTA requires that only medical criteria be used in organ allocation, the "5% rule" did not prohibit a transplant center from waitlisting or transplanting more than 5% non-resident aliens. Rather, the "5% rule" functioned as a threshold that triggered an audit. In June, 2012 the OPTN/UNOS Board voted to eliminate the "5% rule" in favor of a new policy that requires the collection and public reporting of information on all transplant candidates and recipients who are non-residents and non-citizens of the US [29]. The goal of this new policy is to provide the US public, who are the source of all available deceased donor organs in the US, with a measure of transparency regarding how deceased organs are allocated to foreigners.

Despite the clear legal restriction in the US on utilizing citizenship or residency status as an allocation factor, the transplantation of international patients has caused public outcry on a number of occasions, calling into question the fairness of allowing such patients access to the deceased donor list when so many in the country die waiting [30]. Transplant professionals have also noted that patients who travel to the US for transplant may have shorter waiting times although the severity of sickness when such patients arrive may account for the difference [31]. Ultimately, the issue of international patients travelling for transplant may not have a direct role in allocation but rather exemplify why transparency regarding allocation policy and practice is an essential component to an effective organ donation and transplantation system that preserves the public trust.

Relationship between organ allocation policy and the decision to donate

Does local allocation priority encourage donation?

The 1984 Task Force Report described donated organs as a "national resource." The "Final Rule" implemented in 2000 in the US requires that allocation "not be based on the candidate's place of residence or listing, except to the extent required . . .":

- to support sound medical judgment
- to achieve the best use of donated organs
- to avoid the wastage of organs or futile transplants
- to promote patient access to transplantation
- to promote the efficient management of organ placement [32].

However, the current allocation systems still provide a high degree of preference to recipients at transplants centers affiliated with the local organ procurement organization, much as was the case in the initial development of transplantation. Similar arrangements exist in some European nations even though the geographic area is substantially smaller. There are notable exceptions such as broader sharing for the most acutely ill patients and for highly sensitized kidney patients.

The initial justification for local allocation priority was based on several themes:

- keeping organs local reduced cold ischemic time following recovery and improved transplant outcomes
- transplant professionals would be less willing to recover organs if they were less likely to actually have the opportunity to transplant the organs they recovered
- organ donation would be reduced because people would be less willing to donate if organs did not get used in their own community or nearby
- broader sharing would reduce the volume of transplants at smaller centers, ultimately making them non-viable and thus reducing patient access to transplantation

Proposals to dramatically increase the range of sharing have on occasion led to fierce policy debates. One such proposal concerning liver allocation in 1998 following issuance of the Final Rule resulted in US congressional and state legislative action to preserve local priority. The Institute of Medicine (IOM) was commissioned to study the impact. Its report [33]:

- recommended larger local sharing areas
- found insufficient data to draw a conclusion on the impact on transplant outcomes
- found no data to suggest reduced donation rates
- found indications that costs would increase but not so significantly as to outweigh the benefits
- found no conclusive evidence that smaller centers would be closed or, if they were, that there would be a significant negative impact on patient access.

A 1998 Gallup Poll on Organ Donation included this question — Question 4:

> Thinking as if you were going to be an organ donor, if you learned that your organs would go to sick persons within your local region before they were offered to sicker persons elsewhere in the US would you be more likely to want to donate, less likely to want to donate, or would it not matter in your decision?

In response, the report states:

> . . . most adults say it would not affect their decision. However, 32% say if they knew the organ recipient was the sickest person, regardless of location, they would be more likely to donate an organ. In contrast, 10% would be more likely to donate if they knew their organ was going to a sick person in their local region. It may also be noted that those who have signed an organ donor card, are recipients or candidates for an organ, or have donated an organ or bone marrow are most inclined to say the location of a potential organ recipient would not affect their decision to donate [33].

Accordingly, it does not appear that there is empirical support for the concept that local allocation increases donation rates.

Should registered donors receive allocation priority?

Although social worth generally is rejected as a basis for organ allocation priority, there is one notable exception. In the US, a patient who previously has been the living donor of a vital organ or segment of a vital organ is given a higher priority should they themselves subsequently become a candidate for a transplant [34]. Some have suggested that this relative allocation priority concept should be extended to give priority access to organs to those who have previously registered to be deceased organ donors.

In 2006, when the IOM [35] was asked by the US Department of Health and Human Services/Health Resources and Service Administration to examine possible ways of increasing organ donation, one idea considered in depth was priority access to donors. The primary arguments in favor are:

- It would be consistent with the principle of justice (equity). As there is a shortage of organs, it is necessary to ration organs in some way. There is a simple ethical parity in giving some preference to those who have shown a willingness to give as well as receive.
- Presumably it would increase the number of organs available for transplant by increasing the number of donors. By promoting a sense of community and shared responsibility, such a policy could theoretically increase the available supply of organs sufficiently to come closer to meeting the demand.
- Unlike other possible incentive plans aimed at increasing donation (e.g. paying for funerals, a tax credit, etc.) there is a direct relationship between the agreement to be a donor and the "reward." Transplantation is a community endeavor that cannot be accomplished without organ donation.

The primary arguments against such a system are:

- A massive public education program would be required to assure that all were aware of the option to register as a donor and the advantages that would accrue in return. As with all such public education programs there is a fear that those already disadvantaged in access to medical care (the very poor, the uneducated, those whose primary language is different) would be less likely to learn of, and take advantage of, the opportunity to register as a donor.
- Those most likely to potentially need an organ may disproportionately sign up as donors. If this phenomenon of "adverse selection" were to occur, the number of organs available for transplant might not actually increase very much as such individuals are less likely to have transplantable organs to donate. As the committee noted, "any significant degree of adverse selection erodes one of the strong moral arguments for reciprocity-driven approaches: the emphasis on mutuality of interest and the effort to prevent 'free-riding'" [35].
- A reciprocity system raises "slippery-slope" considerations that it would be the start of a system in which moral worth assumed a role in determining access to transplant.
- Although all major religions support organ donation, some individuals have a strong personal, religious belief that donation is inappropriate. Thus a reciprocity system might not withstand legal prohibitions against discrimination on religious and other grounds.

In the end, the IOM Committee recommended against creating a preferential access system, although noting that their recommendation might need to be revisited if the practical problems could be overcome and if better data on the potential for success becomes available [35].

The majority of the arguments against prioritizing donors are operational. Although some are quite significant, others might be less difficult to overcome. For example, one of the practical requirements cited by the Committee has been met now with the development of a system of state-by-state first person consent donor registries. Also, data on the effectiveness of an allocation priority system should become available in the coming years with the adoption of such a system in Israel in 2010. Although still based primarily on medical criteria, the Israeli system gives preference to a registered donor if the medical need is the same. Accompanied by a significant public education campaign, the law already has stimulated a dramatic increase in the number of registered donors in a nation that traditionally has had a very low donation rate [36].

The future/summary

It is likely that the debate over allocation will continue until there are clinical breakthroughs that either:

- dramatically increase the supply of organs from deceased donors; or
- dramatically reduce the demand for organ replacement; and/or
- Provide alternative therapies such as growth of artificial replacement organs.

Some believe that "it is not possible to simultaneously maximize utility, efficiency, equity and predictability, and it is unlikely that any of these can be maximized without the potential cost to autonomy, controversy, trust or live donation" [8]. However, each national or multinational organ allocation system continues to struggle to balance these factors in the context of its political system, its national values and its history.

CHAPTER 138

The Ethics of Living Donation

Alice Peng and Andrew Klein
Cedars-Sinai Medical Center, Los Angeles, CA, USA

Introduction

The widening gap between the number of individuals in need of organ transplantation and the number of available organs derived from deceased donors has encouraged the growth of living organ donation. The most common living donor organ is the kidney, but liver and lung donors are also increasing in number. Cultural differences and public policies strongly influence donation rates in various countries. In the US, the scarcity of available deceased donor organs, increasing recipient wait times, widespread acceptance of living unrelated donors, and the influence of media and the internet have increased the complexity of ethical considerations. Many policies and practices in living donor transplantation are heavily debated and are still evolving. Here we will review some ethical considerations in living donation. While many specific issues relevant to donation in the US are discussed, the guiding ethical principles are generally applicable. Additional treatment of these principles can also be found in Chapter 136.

Procedural risks and benefits

In the US, healthy living donors accept the risks and discomforts of surgery and loss of an organ to help another individual. It is considered ethically acceptable to allow living kidney donation if the anticipated benefit outweighs the harm. In this case, the living kidney donor may derive psychological and moral benefits that outweigh the short and long-term risks of organ donation. From the inception of living donation, there have been concerns and questions. As Dr. Frances Moore [1], an early pioneer of living donor kidney transplantation, once said:

> [Living donor] tissue transplantation is a unique field of surgery. It flaunts the ancient principles upon which medical and surgical care are based: do no harm and help the patient to help himself. The welfare of a healthy person, heretofore never sacrificed in human medicine, is now jeopardized when tissue is obtained from the healthy donor.

Because of these concerns, and the perception that the risks associated with donation would be more tolerable if the donor and recipient were bonded by family relationships, early living donors were genetically related. Unrelated donors were initially discouraged due to concerns regarding outcomes and fear of commercialization. As outcomes of kidney transplantation improved and criteria for accepting transplant candidates were expanded, the number of patients placed on the waiting list grew and the duration of waiting time lengthened. Numerous studies demonstrated similar recipient outcomes in living related and unrelated kidney transplantation [2]. As a result, living kidney donation and specifically living unrelated kidney donation has grown considerably. In 2009, 38% of kidneys transplanted in the US came from living donors, 23% of whom were unrelated donors [3]. Donor surveys have demonstrated that almost all donors would make the same decision if asked to donate again, and some actually derive the benefit of enhanced self-esteem and satisfaction with the act [4–6].

In living organ donation, one of the guiding ethical principles is non-maleficence. The decision to donate must be voluntary, and donors must have full autonomy, with the freedom to withdraw from the donation process at any time without consequence and with a supportive environment. All reasons for not proceeding with donation, medical or otherwise, must be kept confidential. Donor consent and autonomy are essential to proceed with donation but they are not sufficient. A donor's desire should never trump medical judgment and decision-making.

The major medical risks associated with living organ donation are directly related to the operative procedure. Surveys show a perioperative mortality risk of three deaths per 10 000 living kidney donors [7,8]. However, advances in kidney donor operative techniques, specifically the development of minimally invasive surgery as the preferred method of donor nephrectomy, have reduced hospital length of stay and permitted an earlier return to a normal lifestyle. Several studies have examined the long-term morbidity after kidney donation. Some have found an increased risk of hypertension and non-progressive mild proteinuria [9–11]. However, death rates (for the white donor) are similar to the general population [12]. End stage renal disease (ESRD) rates following kidney donation are slightly increased, ranging from 0.1–1.1% [12–16]. The higher risk is especially notable in the young black donor [17], although a recent analysis revealed that the increased ESRD rates were similar to the increased rates in the general population [18]. Pre-eclampsia may also be marginally greater [19]. Other problems associated with donation include higher premiums or rejection from health insurance companies and possible long-term financial consequences. However, overall, it can be concluded that living donor nephrectomy is, on the whole, safe, with few perioperative deaths, immediate complications, or long-term consequences.

A unique ethical challenge in living donor kidney transplantation was highlighted by the unexpected transmission of HIV and

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

hepatitis C in 2007 by a living donor [20]. Living donors with known behaviors that are associated with an increased risk of HIV or hepatitis C infection raise specific ethical concerns because donors often have a relationship with the intended recipient. In these situations, the donor's right to privacy may be in direct opposition to the recipient's right to full informed consent. In addition, disclosure of risk behaviors may cause psychosocial harm to both the donor and recipient. Consensus guidelines do not currently exist. Some have suggested disclosure to the recipient of these behavioral risk factors with donor consent or, alternatively, determining that the donor is medically unacceptable. Others question the ethics of such actions [21].

As the demographics of the general population have changed and waiting times have lengthened, acceptance criteria for living donors have expanded at many centers. Donor evaluation and selection criteria do vary [22]. Older age, hypertension, obesity, nephrolithiasis, and impaired glucose tolerance no longer preclude kidney donation at many programs. In 2008, 19.5% of living donors were obese, 2.0% had a history of hypertension, and 3.5% had proteinuria, all known risk factors for cardiovascular or renal disease [16]. A recent review of data provided by the Scientific Registry of Transplant Recipients illustrated the changing characteristics of living kidney donors, with steady increases in the number of older, obese, and hypertensive donors between 1999 and 2009 [23]. Other groups that need more study include donors with borderline acceptable glomerular filtration rates and donors who undergo weight loss to meet acceptance criteria. The long-term impact of these changing criteria on donor outcomes is largely unknown. Thus, current informed consent regarding living donation in these subgroups requires discussion about the current limits of our knowledge and understanding regarding long-term outcomes. Better understanding of the impact of these changes will require ongoing comprehensive long-term follow-up of living donors, especially of non-white donors, to determine the safety of these practices and to better inform living donor candidates.

Donor follow-up

Of note, living donors are not required by all centers to have medical insurance, although this relates particularly to countries such as the US that do not provide universal health coverage. In one survey, 15% of US transplant centers reported that they would exclude uninsured donors, and 42% considered lack of insurance a relative contraindication [24]. In 2008, 12.2% of donors were reported to be uninsured, with 14.9% of black and 17.0% of Hispanic donors lacking insurance [16]. Another survey from 2004 to 2006 found higher uninsured rates in younger donors, male donors, and ethnic minorities [11]. Studies have shown that these groups are at highest risk for long-term complications of kidney donation, particularly male black donors under the age of 35 [17], and lack of health insurance could certainly negatively affect their adherence to recommended long-term follow-up. It seems logical to expect that donors without health insurance face significant financial barriers to preventive screening and monitoring of kidney function and blood pressure, potentially further increasing the risk of many donors at highest risk for complications. Short of a change in government policy regarding universal health care, some have suggested "free" lifetime health insurance. This proposal, however, raises the controversial area of compensated donation which is forbidden under federal law.

As the number of non-directed donors, uninsured donors, and donors with medical conditions such as obesity, hypertension, and impaired glucose tolerance has grown, the importance of long-term donor medical follow-up has become well recognized. This led to a recent report from a Living Kidney Donor Follow-Up Conference, which attempted to review current living donor outcomes data, to define what was needed, to identify requirements to fulfill this need, and to propose practical solutions. Reasons for continued systematic collection and reporting of donor outcomes include: accurate outcomes information for appropriate informed consent, especially in regards to donor ethnicity and medical conditions; program-specific feedback for quality assurance and performance improvement; professional obligation to collect detailed donor outcomes; better information to improve the evaluation process and counseling for non-traditional donor candidates; and surveillance to identify donor problems when intervention may be possible [23]. In response to this, the US Organ Procurement Transplant Network/United Network for Organ Sharing (OPTN/UNOS) expanded the amount of living donor data collected and increased the duration of mandatory donor follow-up to two years post-donation. Review of OPTN reports demonstrates that much of the longer-term data is incomplete, and more than 30% of living donors in 2006 were declared, "lost to follow-up."

Further analysis revealed that many characteristics associated with limited access to healthcare and possible greater long-term health risk, such as non-white race, younger age, non-US citizenship, and lack of health insurance, were also associated with lack of follow-up data reporting. Because of this, the OPTN/UNOS living donor data task force concluded that; "As currently collected, the OPTN/UNOS data are incomplete beyond the point when the discharge form is submitted. . .and therefore useless for research or making conclusions about living donor safety." Thus, despite growing concerns about the impact of living donation on donor health, especially in the setting of expanded criteria, and the critical need to understand the medical outcomes after donation to appropriately evaluate living donor kidney candidates and improve the informed consent process, living donor follow-up in the US remains suboptimal. Currently, there are two ongoing NIH-sponsored studies, Assessing Long-Term Outcomes of Living Kidney Donation (ALTOLD) and Renal and Lung Living Donors Evaluation Study (RELIVE), evaluating living donor outcomes. Both have several limitations, including few minority participants but will help to provide more detailed living donor outcomes analysis [23].

A suggested solution has included a proposal for a living donor registry [25], similar to the EULID project developed by the European Commission which created an e-registry database model on organ living donors in order to have a common European database to monitor living donors. The purpose of the EULID project is to establish a European consensus regarding legal, ethical, protection and registration practices in relation to organ living donors, to guarantee their health and safety [26]. Other long-term living donor follow-up efforts from Switzerland, Pakistan, and Brazil have emphasized that adverse renal outcomes are rare and often potentially preventable. The solution to long-term follow-up in the Swiss long-term living donor registry has been the involvement of the donor primary care physician [23]. A significant difference between the European Union nations and the US is the lack of a national health care system in the US. Thus, the biggest question and concern is in regards to the cost and responsibility for longer-term follow-up,

especially for the follow-up beyond two years. Without additional funding, the consensus is that transplant centers could not maintain longer donor follow-up. Some suggest a system of incentives and penalties to more fully motivate transplant centers to complete the current required OPTN/UNOS donor follow-up data and greater incentives and fewer disincentives to living donors to comply with follow-up visits [25]. The importance of donor follow-up visits should be stressed at the time of donor evaluation, prior to the donation procedure.

Altruism

In the US, only altruistic donations are permitted; monetary compensation for organs is prohibited by the National Organ Transplantation Act [27]. Most living kidney donors are biologically or "emotionally" related and include family, spouses, and friends. However, some living kidney donors have no prior relationship with the recipient. Altruism is the guiding motivation for most living donors. Ideally, donors should be autonomous and free of coercion. Altruism is comprised of several types. "No- or low-cost" altruism entails giving one's own resources to benefit others with little or no incurred risk, an example of which is blood transfusion. A second form of altruism is "dutiful" altruism, which involves a sense of duty. Donors may feel a moral if not legal obligation to donate. Familial donors may serve as examples and are generally widely accepted due to well-recognized relationships between donors and recipients. Traditional living related donors are often felt to derive a greater degree of psychological benefit for donating than unrelated donors, but they often face both subtle and overt coercion based on family dynamics. The third type of altruism is "supererogatory" altruism, which involves giving beyond what is expected or asked. Donors with no defined relationship to the recipient fall into this category [28]. This form of altruism is currently well accepted by the transplant community, with a recent survey demonstrating that 94% of transplant physicians surveyed supported non-directed kidney donation from living volunteers [29]. Motivations for supererogatory altruism include a pure sense of altruism, religious beliefs, a wish to reciprocate to society, and a wish to honor a family member or friend.

Religious beliefs are a common component underlying motivations of an individual to donate. It is not uncommon for church members to volunteer to donate to a fellow church member. In these cases, there is generally a pre-existing acquaintanceship with the potential recipient, and most centers accept such donor candidates readily. Other situations, some well publicized, involve religious sects that strongly encourage living organ donation. One such example was a religious community of Jesus Christians whose leader was motivated to donate a kidney based on his interpretation of New Testament scripture calling for "living sacrifices." He then encouraged other members of his religious community to do likewise. Ultimately, these donors were declined due to concerns regarding financial, spiritual, and social dependence of members on the community, which heightened the probability of coercion [28]. Religious beliefs may be a legitimate motivation for donation, but such donors must be carefully evaluated.

Non-directed donations

The appropriate evaluation and selection of non-directed donors requires the support of a multidisciplinary team that is well versed in the implications of living donation. It is incumbent on each transplant program to screen all donors responsibly to assure that the donation procedure is free of financial remuneration, valued consideration and coercive and exploitative elements. Donors must have autonomy to provide full, voluntary, informed consent. All living donor evaluations include a meeting with a living donor advocate. The role of the living donor advocate is to try to ensure that the donor has a full understanding of the donation process and that no coercion exists. It is recommended by some that that donor advocates have "veto power," so that he/she can exclude a potential organ donor if the advocate determines that the donation is not in the donor's best interest. Reasons for donor exclusion include: an unrealistic expectation or demand by the donor that the transplant be free from rejection and failure; the misperception by the donor that if the transplant is not successful, it is due to personal failure of the donor; monetary compensation for donation as prohibited by federal law; a desire for media attention; a response or remedy for a psychological malady, such as depression, or other underlying mental illness; a desired selection of the recipient by gender, race, or ethnicity; and a desired involvement in the recipient's life after donation, possibly unwanted by the recipient [30]. Medical evaluation of non-directed donors is routinely more stringent since the psychological benefit of the donation is perceived to be less, although a recent report demonstrated encouraging psychological outcomes of altruistic living donors who donated to strangers [6].

Recipients of non-directed living organ donation are identified in a number of ways, through unsolicited inquiries to transplant centers, through the Internet, and through third party organizations. The relationship with the recipient is often tenuous or nonexistent. In the past, non-directed donors that were paired with specific recipients through a process that took place outside the transplant center were frequently rejected. Under these circumstances a major underlying concern has been the possible commercialization of organ donation, and examples of this have been well publicized in the media. It has become the responsibility of transplant centers to try to ferret out any coercive relationship, financial or otherwise, between living unrelated donors and their recipient, but the appropriate method of evaluation remains poorly defined. Most programs require a detailed psychosocial evaluation to rule out any underlying psychiatric disorders, to assess the person's competence to make an informed decision, and to explore the reasons for the offer. Psychosocial evaluations are routinely required in all living donor evaluations but are particularly critical in non-directed donor evaluations. In situations where the relationship between the donor and recipient appears ambiguous, centers often require a more in-depth psychological evaluation. Monetary compensation can be particularly difficult to identify as both the donor and recipient are generally coached to deceive the transplant center. Examples of a black market in human organs have come to light in the press and have prompted some members of the transplant community to advocate for federally regulated paid organ donation. Some have suggested that altruistic-directed living unrelated organ donation is a legal fiction concealing commerce or other forms of coercion, at least occasionally [31]. Unfortunately, tests confirming altruism and tests excluding commerce are weak. More rigorous tests would likely diminish the number of acceptable living donor candidates, and many transplant centers continue to debate how best to evaluate the motivations of such donors.

In selection of a recipient for a non-directed donor, most transplant programs have followed the standard algorithm that applies to the allocation of deceased donor kidneys as the most ethical approach [30]. However, some have diverged from standard practice to maximize the chances for success, such as eliminating retransplants and patients with a history of non-compliance. Thus, both equity and utility are often considered in determining the appropriate recipient. In general, centers have not allowed non-directed donors to place restrictions on the characteristics of the recipient to avoid moral complicity in racism or sexism. Some non-directed donors come with recipients identified through third party organizations or internet websites. Commentators have expressed concern that this unregulated situation unfairly favors potential recipients who have greater media savvy and resources. Nonetheless, many such donors are currently evaluated and accepted.

Paired donation

Several strategies have been developed to increase the living donor kidney supply, including non-directed living donors, extended-criteria living donors, and paired kidney exchanges. Rapaport first proposed the idea of paired kidney exchange in 1986 [32]. His proposal involved two donor-recipient pairs in which the two donors were immunologically incompatible with their paired recipient but were immunologically compatible with the other donor's paired recipient. Rapaport suggested that the two donor nephrectomies could be performed simultaneously with an immediate exchange of the two kidneys to the compatible recipient. Kidney exchange procedures have been used to overcome both blood and tissue type incompatibility barriers and are steadily increasing in frequency. Non-directed living donation has allowed the development of a new kidney exchange strategy to increase living donor kidney transplants, namely closed and open kidney exchange chains. In particular, kidney exchange chains bring unique ethical considerations for both donors and recipients because they generally start with a non-directed donor [33]. Historically, non-directed donors have donated to the deceased donor waiting list. Thus, kidney exchange chains may disadvantage the deceased donor waiting list from their only opportunity for a living donor transplant. In closed kidney exchange chains, the last donor donates back to the deceased donor waiting list, but in open kidney exchange chains (or "never-ending" chains), the donor is permanently diverted from the waiting list. Because paired exchanges and chains provide benefits to recipients who provide a living kidney donor in the exchange, these strategies could be considered a violation of NOTA. To avoid this problem, the Charlie W. Norwood Living Organ Donation Act was passed in 2007 [34]. Proponents of non-directed donor participation in kidney exchange chains argue that the increased number of kidney transplants provides adequate justification. They argue that this strategy allows transplantation across a traditional immunologic barrier and therefore ultimately lessens the number of patients needing placement on the waitlist. However, volume considerations and utility have to be balanced with justice and equity to the deceased donor waiting list, particularly for O blood type recipients. One suggestion is to require a minimum number of transplants when a non-directed donor is involved in a chain [33]. Certainly, as kidney exchange programs develop, data must be prospectively collected to better understand and evaluate the implications of these strategies on the waiting list.

Prior to a kidney exchange procedure, the final kidney donor from the kidney exchange procedure agrees not to donate his/her kidney at the same time as their loved one receives a kidney transplant (i.e. within the same kidney exchange procedure), but rather at a later date, whereby he/she donates a kidney to initiate a second kidney exchange procedure. As such, the bridge donor therefore "bridges" two distinct kidney exchange procedures occurring on different dates within a kidney exchange chain. One of the basic problems in kidney exchange chains is "backing out" by bridge donors, which terminates both open and closed chains [33]. "Honor systems" have been developed as a means for minimizing backing out and involve educating the bridge donor about the effects of backing out on a subsequent recipient within the chain. Honor systems are ethically problematic because they are inherently coercive. Suggested solutions include prompt identification and conduct of kidney exchange procedures and institution of predefined limits (time limits or transplant number limits). The primary benefit for living donors is psychological. Even if the transplant fails, donors know that they did everything possible to help their loved ones. Some have suggested that in kidney paired exchange and kidney exchange chains, the donation is indirect, and the psychological benefit may be more diffuse. After donation, some donors experience depression or conflict with family members. Donors may feel angry or guilty if there is an adverse outcome. In the setting of kidney exchange programs, feelings may be exacerbated by the fact that they do not know the result of their own donation. Further study is needed to identify psychosocial concerns unique to participation in exchange programs.

Recommendations for identification of non-directed donors for initiation of a chain have included a requirement that the interest in donating to a chain originate from the donor and solicitation be avoided [33]. However, the multiple examples of mass media stories focused on kidney exchange creates ethical concerns, as some non-directed donors may be enticed by personal exposure in the mass media. This is particularly concerning as transplant centers may drive the media process as kidney exchange chains often attract considerable publicity for the transplant center.

Privacy and confidentiality must also be assured, both for the non-directed donors and bridge donors [33]. Donors need adequate information about the intended recipients to assure that their donated kidney will be used in a medically reasonable manner. Traditionally, pretransplant meetings are not allowed due to the possible negative effects of the meeting on the donor's decision. It has been recommended that non-directed donors and bridge donors should not be told of the number of individuals involved prior to their procedure as this may subject them to an increased degree of perceived coercion. Thus, the problems of overt and perceived coercion, issues of confidentiality, and patient rights need careful evaluation and oversight. In addition, differences in living donor acceptability criteria add increased ethical complexity to kidney paired exchange programs, where donors may be considered candidates in one center but rejected in another. Responsibility for donor evaluation and consent currently lies in the hands of the originating transplant center.

Liver donation

In living liver donation, the basic guiding ethical principles remain the same. Donors must have full autonomy; they must be fully

informed about the process, the surgery, and the short- and long-term implications of donation; they must have the right to withdraw from the process at any time; and donor safety and risk must be justifiable in the setting of chances of a successful outcome for the recipient [35]. The difference that colors the living liver donor evaluation process relates to the higher risk to the donor and the higher acuity of the recipient. Recipient outcomes following living liver donor transplantation have become equal to or, in some studies superior to deceased donor liver transplantation [36]. However, there remains significant recipient morbidity and mortality, particularly in patients transplanted for fulminant hepatic failure, or those with severe portal hypertension. Much of the challenge in assessing donor risk is the lack of an accepted definition of donor exclusion criteria and lack of long-term outcomes data. The first living liver donor was performed in 1989 [37]. After initial excitement and success, several publicized living liver donor deaths [38] led to a precipitous decline in rates after 2002. Since 2000, over 3000 living donor liver transplants have been performed in the US. Most live liver donations do not lead to permanent long-term consequences, though perioperative morbidity rates in the literature range from 9–67% [39]. Currently, the estimated risk of mortality and morbidity associated with live donor right hepatectomy is 0.4% and 35%, respectively [40]. Left and left lateral hepatectomies are associated with lower rates of complication [41]. Nevertheless, the true morbidity remains poorly understood. Formal reproducible grading systems have been developed to allow for more systematic documentation of living liver donor complications and will help better inform potential candidates [39,42,43]. This will be critical in providing a true informed consent to potential living liver donor candidates.

Significant disagreement exists about living donor liver transplantation in high urgency situations. The recipient result is suboptimal, and time constraints place additional pressure on the donor evaluation and consent. However, some argue that the very ill patients are precisely the ones who would most benefit from a living donor liver transplant [44,45]. A real medical dilemma in this situation is the inverse relationship between the duration of donor evaluation and neurological consequences for the recipient [46]. Whether living donor liver transplantation should be considered relates to the efficiency of transplantation through the deceased donor list. In general, it likely should only be considered in experienced centers. In some cases, living liver donor transplantation may be considered the only option. An example would be for patients who would not receive a deceased donor liver transplant due to advanced liver cancer [41]. Patients with early (stage II) liver cancer are afforded an elevated priority on the waiting list for the allocation of deceased donor organs under the assumption that their post-transplant survival is excellent and the risk of cancer recurrence is low. Individuals with more advanced cancers have a worse prognosis and do not receive such priority, even though the likelihood that they will do well after a liver transplant is better than what would be expected without a transplant. The mandate to achieve the most good for the most patients is the guiding principle that excludes patients with advanced cancer from the elevated priority recipient group. Arguably, the organ shortage and the requirement that the transplant community should be a wise steward of organs from deceased donors do not apply when a volunteer live donor has come forward. In such cases living liver donor transplantation may offer an effective oncological option that is ethically justifiable. A potential problem, however, is defining the lower limit for expected recipient survival in a patient with advanced liver cancer that justifies the risks that accrue to the living liver donor.

The vast majority of living liver donors in the US are related, genetically or emotionally, although a few non-directed liver donors have been reported [47]. A significant ethical debate has focused on the ability of parental liver donors to have free choice. The parent-infant relationship is considered by many to be so inherently coercive that there is no other option for parents than to accept the possibility to donate. Parental donors have emphasized their moral responsibility as parents and the impossibility of living with the guilt of refusing to donate. Thus, many have argued that it is irrelevant to discuss living parental liver donation as a choice [48–50]. In particular, some have recommended that parental living donation in the setting of pediatric fulminant hepatic failure should not be proposed as an option [51]. Nonetheless, parental living liver donation is performed and accepted, primarily due to the procedure's life-saving potential far outweighing many of these ethical concerns. As one mother was quoted when asked if she felt pressured to donate to her infant son, "This was a gift. I had the chance to give life to my child twice." Overall, living liver donation accounted for 12% of pediatric liver transplants performed in 2010 [3].

Lung donation

As of 2011, living donor lobar lung transplantation has been performed in approximately 400 patients worldwide. In the US, no donor deaths have been reported, and rates of perioperative complications vary from 7–49% [52]. An unanswered question remains the long-term outcomes and functional effects of lobar donation, though loss of lung function is an expected consequence. A unique aspect of living donor lobar lung transplantation is that two donors are placed at risk for each recipient surgery. This may be the only procedure that carries with it the potential for 300% mortality. Its use in the US has decreased dramatically in recent years due to a change in the OPTN urgency/benefit allocation systems for deceased donor lungs. Currently, most of the literature in living donor lung transplantation comes from Japan.

Commercialization and remuneration

The organ shortage in the US is reflected in varying degrees around the world, but differences in laws pertaining to organ donation have resulted in international problems with commercialization of organ donation. Internationally, the rates of living donation appear closely linked to deceased donor organ availability. In countries with presumed consent, living donor kidney transplantation rates are lower (2.4 vs. 5.9 per million population) [53]. Most countries have signed a World Health Organization statement condemning the practice of buying and selling organs. Various national and international transplant organizations and international consensus panels have rejected monetary compensation as a solution to the organ gap. Despite the illegality of organ markets throughout most of the world, there is a large international black market. In 2007, the World Health Organization estimated that organ trafficking accounts for 5–10% of kidney transplants performed annually throughout the world [54]. In the face of apparently stagnant donation rates and concerns regarding unregulated organ markets, there have been increased calls within the US, including professionals in the transplant community, for ethically controversial proposals to provide compensation for

organ donation [55]. Debate over incentivized donation has polarized many in the transplant community. The main argument in favor of a regulated system of payment to living kidney sellers is that financial incentives will increase donation, so fewer wait-listed transplant candidates will die on the wait-list. The driving force is the benefit to recipients, in terms of mortality, morbidity, success of the transplant, and quality of life. Proponents argue that regulated payment would aid the international campaign against global transplant commercialism by eliminating transplant tourism and thus protecting sellers in unregulated systems. Suggested payments include fixed sums, term life insurance, lifetime health insurance, reimbursement for travel expenses and time off work, or tax deductions. The proposals generally incorporate allocation through a predefined algorithm, oversight, payment by the government or insurance companies, and long-term follow-up. The last is particularly attractive because it would address the ethical dilemma of long-term medical care in uninsured donors. Most proponents favor a single price per organ that does not vary based on age, health, or lifestyle of the donor. Legalization would also eliminate the current ethical and legal problem of directed altruistic living donation. Some have even argued that the donation process is often a financial burden, and that forcing the donor to shoulder the cost is also unethical. They argue that denying legitimate reimbursement is exploitative of the donor's altruistic motivation. Thus, compensation would be for time and incurred expense, rather than for the organ [56].

Arguments against paid donation include the potential exploitation of the poor, the commodification of the body, the use of financial coercion, the lack of sufficient data to guarantee an increase in donation rates, and the potential long-term harm to the donor. Of greatest concern has been the possible exploitative nature of paid donation as it might create an undue inducement for those who are economically disadvantaged. In unregulated or poorly regulated systems, rich buyers could purchase kidneys with little regard for donor safety and follow-up, thus establishing a two-tiered system in which the wealthy benefit and the underprivileged are coerced by monetary incentives. International data has shown that individuals who sold their kidneys and received cash payments were not financially improved five years later. In fact, many described their health, social situation, and overall wellbeing as worse and 80% would not recommend donation to others [57]. One of the primary concerns has been the fine line between compensation and coercive inducements. Intended compensatory measures may result in irresistible financial pressures that encourage impulse donations and violate donor autonomy. A 2006 telephone survey of American households indicated that lower income groups were more accepting of incentives, suggesting a disproportionate effect of monetary payments on the poor [58]. Similar inequities have been demonstrated in surveys of ESRD patients, with more affluent patients willing and able to pay for a kidney than the poor [59]. Additional concerns include the possibility that inducements might tempt the donor to withhold or lie about their medical history, endangering their own and the recipient's health. Of note, physician opinion was an important criterion in deciding willingness to pay for a kidney. In a survey of transplant physicians, 80% were against or strongly against living donor organ markets for kidney transplantation [29].

Additional concerns include the potential for "crowding out" and "bystander effect" [60]. Crowding out is described as the unintended consequence of decreasing the number of donors by the introduction of extrinsic rewards, thus tarnishing the altruistic motivation of many donors and discouraging potential donors. This was corroborated in a study of Swedish blood donors [61]. Whether such a phenomenon would apply to organ donation is unclear. The bystander effect might result in a decrease in the sense of urgency of donors to volunteer in the setting of paid donation programs. It is felt to have resulted in the decrease in live donors to pediatric recipients when a change in policy prioritizing organ allocation to pediatric recipients occurred [60].

Ethical concerns regarding payment for medical risk extend beyond transplantation [29]. In medical research, monetary payments are not proscribed, but Federal Regulations lack specific guidelines regarding compensation. However, the Office of Human Research Protections (OHRP) approved Institutional Review Board Guidebook instructs IRBs to determine whether payments may constitute undue inducement and to avoid it if it could lead individuals to accept risks they would otherwise not take. However, Menikoff, previous head of OHRP, has argued that failure to compensate for degree of risk taken is inconsistent with recognizing an individual's contribution. But Carl Elliot, a bioethicist currently at the University of Minnesota, states that there is a difference between paying for risks when individuals choose to expose themselves to risks for others and paying for risks when such risks involve the participation of a third party. He argues that there is a difference between allowing a person to risk harm and encouraging it. Many argue that paid donation crosses that line between allowing and encouraging risk.

Currently, the focus of debate in paid donation has been kidney transplantation. However, as the safety and outcomes data for living donors for other organs, such as the liver, improves, the debate may expand to include other organs. Per survey reports, 67% of transplant physicians favor non-directed liver donation, significantly fewer than those in support of kidney donation; and 90% were against or strongly against living donor liver markets [29]. Unlike living kidney donation, in living liver donation, donor risk was the major reason cited for opposition.

Summary

Physicians practice under the basic principle of first to do no harm [62], but donor surgeries pose some risk of harm. It remains a paramount responsibility of the transplant community and transplant centers to ensure the safety of living donation and lack of coercion of living donors. However, the shortage of organs continues to grow, and strategies to increase donor availability have included strategies to expand living donor transplantation. Hypertension, obesity, age, kidney stones, and impaired glucose tolerance are no longer considered absolute contraindications. In addition, non-directed donors, paired exchanges, and donor chain strategies are growing in number. Close follow-up of these subgroups is needed to ensure donor safety and provide better education and informed consent. Currently, only altruistic donors are considered in the US, but proposals to incentivize living donation are receiving increasing attention. These proposals encroach on many basic moral and ethical principles and will continue to challenge our current understanding of living donation for many years to come.

CHAPTER 139

Cultural Variations in Organ Transplantation

Chris J. Callaghan[1] and J. Andrew Bradley[2]
[1] Guy's Hospital, London, UK
[2] University of Cambridge, Cambridge, UK

Introduction

Organ transplantation is a life-saving and life-enhancing treatment for patients with end-stage organ failure. In a fair society, it is self-evident that patients who may benefit from organ transplantation should, so far as is possible, have equitable access to transplantation. Variations in access to transplantation should be identified, the underlying reasons explored, and attempts made to minimize differences in access. Unfortunately, when viewed at a global level, it is apparent that very large inequities exist in organ donation and transplantation rates between countries (Figures 139.1 and 139.2). There are also large variations in access to organ transplantation within many countries, even in countries with well-developed transplant programmes [1].

Organ transplantation is one of the more advanced modes of medical intervention and successful national transplant programmes are undertaken in the context of complex legal, ethical, financial and organizational frameworks. They are also based on a widespread understanding of the benefits and ethical acceptability of donation and transplantation in the societies in which they are embedded. Understanding variations in these societal frameworks enables a better understanding of differences in access to transplantation between and within countries.

The success of organ transplantation has led to a global shortage of donor organs, and this increasing disparity between the demand and supply of organs is in part responsible for inequity of access and has also given rise to the concept of transplant commercialism. Wealthy patients with organ failure, when faced with growing waiting lists and perceived inequities in access to organs, may feel that transplant commercialism offers the best chance of receiving a graft. Transplant commercialization serves as a reminder to the international transplant community that reducing waiting lists and improving access to organs are essential.

This chapter aims to examine selected 'cultural' variations that impact on access to transplantation, and highlights selected strategies that have been developed with the aim of minimizing these variations. Transplant commercialism and the related issues of organ trafficking and transplant tourism are explored, with a global overview of the scope of these issues and current attempts to eradicate them. Finally, the arguments for and against the introduction of financial incentives for organ donation are discussed. Throughout the chapter, renal transplantation is examined most closely, as it is by far the most common type of solid organ transplant worldwide, and one in which both living and deceased donors can be utilized. Renal transplantation is also the type of transplant most closely associated with transplant commercialism.

Cultural variations

Access to organ transplantation should be fair, and not influenced by race, ethnicity, religion, or socioeconomic status, which collectively can be termed cultural factors. The definition of culture is broad, but at a societal level can best be defined as the distinctive ideas, social environments, philosophies, customs, attitudes, and behaviours within that society. Individual patients can be considered to have distinctive cultures, as can the organizations and governments that provide the frameworks within which transplantation takes place. Cultural factors are therefore discussed at these two levels.

Organizations and governments

Kidney transplantation is associated with significant long-term cost savings when compared to dialysis [2]. However, the transplantation of organs where long-term organ replacement therapies are not available (e.g. heart, liver, lungs), is expensive and requires major investment in technical expertise. Costly regulatory and administrative infrastructures are also needed for transplantation to be a viable therapeutic option. The high costs involved mean that initiating or expanding transplant programs may not be feasible for many developing countries where financial resources are severely limited. Additional information on governmental transplant management policies are found in Chapter 128.

It is therefore not surprising that there is a clear relationship between the kidney transplant rate within a country and its human development index (a composite statistic incorporating life expectancy, education, and income) (Figure 139.3). There is also a correlation between a country's wealth and its organ donor rate [3]. Interestingly, it should also be noted that there are significant differences in transplant rates even between countries that have a similar human development index, for example Norway and Australia. This implies that factors in addition to affluence are also likely to impact on access to organ transplantation. Data from the WHO Global Observatory on Donation and Transplantation (www.transplant-observatory.org) also show that rates of live and deceased donor transplantation vary with the level of national development. Highly developed countries have higher rates of transplantation from deceased donors than live

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

donors, whereas this relationship is reversed in countries with low to medium development [4]. This may reflect a lag between the capabilities to perform live donation, and the development of cultural, legal, and economic systems required to provide a source of deceased donors.

Even if sufficient funds are available within a country to perform costly transplants, effective transplant programmes cannot develop unless there are appropriate legal frameworks in which to operate. Asian countries, in comparison to Western nations, have generally had restrictive laws regarding organ donation after brain death (DBD) [5]. However, this pattern is changing, as India passed laws enabling DBD donation in 1994; DBD donation became legal in Japan in 1997, with Korea following in 2000. Despite these changes, deceased donation rates remain low in most Asian countries.

Even countries with similar legal, historical, cultural and religious backgrounds have markedly different approaches to the concept of donation after circulatory death (DCD; covered in depth in Chapter 22). Dominguez-Gil and colleagues have recently documented the wide variation in legislation and acceptance of DCD donors within Europe [6]. DCD donation is forbidden by law in six member states of the Council of Europe (Finland, Germany, Poland, Portugal, and Luxembourg). In contrast, within the UK a third of all kidney transplants come from DCD donors. Within those countries that permit DCD donation, uncontrolled donors (i.e. patients with a cardiac arrest out of hospital) predominate in France and Spain, whilst in the UK the vast majority of DCD donor organs are from controlled DCD donors (patients awaiting cardiac arrest after withdrawal of treatment, or cardiac arrest in a brain dead patient). Transplantation of organs from DCD donors is far more common in the UK than the US [7,8], perhaps due to the much higher rate of donation of brain dead donors in the US.

Many factors influence deceased organ donation rates and these may include the type of consent required. A recent review determined that the introduction of presumed consent, where all members of a society are assumed to be potential organ donors unless they have registered their objection, increased donation by 25–30% [3]. The degree to which legal changes influence donation rates is controversial, as even those countries with presumed consent laws vary in the extent to which they are enforced. Opt-out systems have been described as either 'hard', that is lack of registration on an opt-out register would result in donation regardless of the preferences of the family of the deceased (e.g. Austria), versus 'soft', where family refusal can over-ride lack of registration (e.g. Spain, Belgium). 'Opt-out' legislation may not cause increased organ donation; rather, it may instead be a marker of a highly developed and effective national organ procurement strategy in a society comfortable with discussing end-of-life issues.

While legal frameworks may have an impact on organ donation, healthcare policies appear to have a major influence on outcomes after transplantation. It is instructive to compare post-transplant outcomes in countries with universal healthcare systems and those with personal insurance-based models. The UK has a health system that is free at the point of care and is funded from general taxation. Risk-adjusted mortality within 90 days after liver transplantation is higher in the UK than the US, perhaps due to poorer investment in high-cost intensive care facilities. However, after one year recipient survival is superior in the UK [9]. Patients receiving a kidney transplant in Canada have similar one-year risk-adjusted mortality

to recipients in the US, but after one year, survival in the Canadian cohort is better [10]. Although retrospective analyses of this type must be interpreted with caution, one interpretation of these findings is that countries with universal health care systems such as the UK and Canada may provide better long-term care than the personal insurance-based US model.

Cultural factors in organ donation

Access to transplantation is directly influenced by organ donation rates, which in turn are determined by cultural factors such as donor ethnicity and belief systems [11].

Donor ethnicity has a significant influence on rates of both deceased and live donation. In a national audit of UK intensive care units, families of white potential DBD donors had a consent rate of 65%, whilst for black and Asian families the consent rate was 23–29% [12]. These findings are particularly concerning given that rates of renal failure are 3–4 times higher in black and Asian populations within the UK, and waiting list patients from these ethnic groups are potentially disadvantaged due to difficulties with HLA matching. Ethnicity is an independent risk factor for unfavourable attitudes towards donation and is not confounded by associations with socioeconomic status or educational attainment [13].

Low organ donation consent rates in black and minority ethnic communities may be due to the lack of awareness of the specific needs for organs within these communities, or problems identifying with the society to which a gift of a donated organ would be made. Concerns about wanting to keep the body intact after death, and removing organs for research without consent are also an issue [13,14]. Interviews with families of potential deceased donors in the US showed that higher consent rates were associated with white ethnicity, younger patients, male patients, and death due to trauma [15]. There was no association with family education or income.

Religious factors and belief systems also influence donation rates. A systematic review of qualitative studies on factors influencing the decision to be an organ donor (both live and deceased) identified a number of major themes associated with reduced donation rates. These included religious beliefs, cultural factors (e.g. superstition, difficulties discussing death, death rituals), family/relational ties, the wish to maintain body integrity, dissatisfaction with the healthcare system, and lack of medical knowledge [16]. The impact of religion on organ donation is variable; Catholicism is associated with increased donation rates, possibly because it recognizes transplantation as a service of life [3], whereas Indo-Asian Muslims in West London had negative feelings towards transplantation and cited beliefs that Islam forbids organ donation by way of explanation [14].

Distinguishing between cultural and religious beliefs can be difficult, particularly in Islam, as a formal religious hierarchy is absent, unlike Christian faiths. Local imams, in contrast to their Christian counterparts, have increased influence, and attitudes towards transplantation are varied within Islam [17]. In Saudi Arabia, both living and deceased donation have been endorsed by senior clerics [18,19], while Egyptian Muslim authorities dispute the religious legitimacy of organ donation [20].

Cultural factors in recipient access to transplantation and outcomes

Recipient ethnicity and socioeconomic status are the two cultural characteristics that appear to have the greatest impact on access to transplantation. Unlike heart, lung, or liver transplantation, the existence of an alternative form of long-term organ replacement therapy makes it particularly instructive to examine the impact of social deprivation on access to renal transplantation, as any bias against socially deprived patients may become more apparent.

Recipient ethnicity is known to have a significant influence on access to the waiting list, waiting time, type of organ transplanted, and subsequent post-transplant outcomes. The reasons for these disparities are both immunological and non-immunological, involving a complex interplay between ethnicity, socioeconomic status, associated co-morbidities, the underlying primary disease process, HLA type, and pharmacogenomics. These inequalities have been observed worldwide, with disparities identified in New Zealand Maori and Pacific peoples [21], Canadian aboriginals [22,23], African Americans [24–26], and UK black and minority ethnic populations [1]. The scale of the problem is significant; one study from Georgia found that African-Americans had a 59% lower rate of renal transplantation than whites, even after adjustment for demographic, clinical and socioeconomic factors [26]. Patzer et al. suggest that this finding may be explained by racial bias, differences in referral for transplantation, or lack of access to healthcare.

Recipient socioeconomic status is also a strong determinant of access to transplantation, although the complex interplay between ethnicity and socioeconomic factors can be difficult to dissect. In the US, prolonged time to placement on the deceased donor renal transplant waiting list has been reported for socially deprived patients [27]. Because of the link between race, socioeconomic status, and co-morbidities, adjustment techniques were utilized. Neighbourhood poverty was synergistic with race; black patients in poor neighbourhoods had increased delays when compared to blacks in wealthier neighbourhoods. Many previous American studies have described similar findings [28–30].

Lack of private health insurance might be a factor that limits access to the transplant waiting list in socially deprived patients in the US. Udayaraj and colleagues investigated the link between social deprivation, ethnicity and access to the deceased donor waiting list in the UK [31]. However, even with a universal healthcare system, as in the UK, the most deprived patients have poorer access to the renal transplant waiting list after adjusting for patient age, sex, cause of renal failure, era, and centre. Interestingly, ethnicity does not appear to influence listing for transplantation in the UK; on the contrary, ethnic minority patients aged greater than 50 years had a higher chance of being listed than their white counterparts. Dudley et al. have previously shown that a wide variety of factors influence the likelihood of being placed on a renal transplant waiting list including age, primary diagnosis, ethnicity, social deprivation, previous transplantation, the size of transplant unit, and the size of the unit's live donor programme [32]. A similar link between socioeconomic status and likelihood of receiving a live donor kidney has also been demonstrated in the UK [33].

The conclusion from the above studies is that multiple cultural factors are important in transplantation access, but the relative impact of these factors varies between countries.

Transplant commercialism

Transplantation has been a victim of its own success, with the availability of organs failing to keep pace with demand. This growing disparity, along with inequalities in access to transplantation, has driven the development of transplant commercialism, organ trafficking, and transplant tourism. These issues are particularly relevant to renal transplantation [34], due to the lesser cost of transplantation compared with long-term dialysis, the relatively

low morbidity and mortality of live donation, the lower level of surgical expertise required, and the increasing burden of chronic kidney disease worldwide.

Transplant commercialism has been defined as a policy or practice in which an organ is treated as a commodity, including by being bought or sold or used for material gain [35]. Where transplant commercialism exists, poor or absent regulation provides the opportunity for organ trafficking to occur. The Declaration of Istanbul (discussed in more detail below) has defined organ trafficking as:

- the recruitment, transport, transfer, harbouring or receipt of living or deceased persons or their organs by means of the threat or use of force or other forms of coercion, of abduction, of fraud, of deception, of the abuse of power or of a position of vulnerability;
- the giving to, or the receiving by, a third party of payments or benefits to achieve the transfer of control over the potential donor, for the purpose of exploitation by the removal of organs for transplantation.

When travel is required for transplant commercialism to occur, it is termed transplant tourism. Specifically, transplant tourism is defined as:

1 the movement of organs, donors, recipients, or transplant professionals across jurisdictional borders for transplantation purposes, and involving organ trafficking and/or transplant commercialism; or
2 devoting resources to transplant patients from outside a country which in turn, undermine that country's ability to provide transplant services for its own population [35].

The true scope of the illegal organ trade is difficult to determine due to its clandestine nature, but it has been estimated to generate illegal profits of between $600 million and $1.2 billion per year, ranking number ten in terms of global illegal activities [36]. A recent review estimated that transplant commercialism conservatively accounted for 5% of all transplants performed worldwide in 2005 [37]. India, Pakistan, Philippines, China, Bolivia, Brazil, Iraq, Israel, Moldova, Peru, and Turkey were all identified as kidney 'exporting' countries, while Australia, Canada, Israel, Japan, Korea, Malaysia, Oman, Saudi Arabia, Taiwan, UK, and USA were thought to be kidney 'importing' countries.

It has been estimated that more than 2000 kidneys have been implanted into transplant tourists in Pakistan alone, and that similar numbers have been transplanted in the Philippines [38]. Despite the Philippine government passing an Organ Donation Act in 1981, there was a rise in unregulated organ sales in the late 1990s; in 2007 there were only 29 deceased donor kidney transplants performed, with more than 1000 live donor transplants in the same year. Regulations for generous compensation for live donors were introduced in 2002, but ongoing organ sales to foreigners continued. Kidney transplants to foreign nationals from unrelated local donors were banned in the Philippines in 2008, but given the high level of poverty and corruption, it seems likely that organ trafficking continues [39].

Commercial live donor kidney transplantation has been reported in Egypt, where donation from deceased donors is illegal, and from destitute tsunami survivors in India [38]. In 2007 it was reported that almost 99% of transplants in China came from executed prisoners [40], and reports of transplant tourists from Taiwan paying for these organs have emerged [41]. This appears to be the only example of deceased donor transplant commercialism. Although Iran allows live kidney donors to be paid, there are strict rules preventing the transplantation of foreign nationals, and so transplant tourism in Iran is not thought to occur. As Iran currently has the world's only regulated system of transplant commercialism, this model is explored in more depth below.

The publication of the Declaration of Istanbul in 2008 has raised the awareness of the international community to the existence of organ trafficking [35], and a number of countries have enacted new laws or strengthened existing legislation outlawing transplant commercialism, organ trafficking and transplant tourism. As a result, Shimazono's 2007 study may already be out of date. It is now illegal for a foreign national to undergo transplantation in China. Israel's 2008 Organ Transplant Act condemns organ trafficking and prohibits authorization of insurance benefits to cover the costs of transplantation in a foreign country that does not conform to the provisions of the Act. Previously, it was legal for Israeli citizens to travel abroad and purchase an organ.

Outcomes after commercial live donation

One of the main concerns regarding transplant commercialism is that it leads insidiously to organ trafficking, and exploitation of the destitute and vulnerable donor. Analyses of outcomes after commercial organ donation are highly relevant given these concerns. Again, as expected for an almost globally illegal activity, relatively limited information is obtainable, and selection and publication bias are likely [42]. However, the available data suggests that commercial donors have poor physical, psychological, and financial outcomes.

A landmark paper surveyed 305 individuals in Chennai, India, who had sold their kidney an average of six years before the survey, which was undertaken in 2001 [43]. More than 90% had sold their kidney to pay debts, and the average amount received was US$1070. Average family income declined by a third after donation, and 86% of donors reported deterioration in health status. The majority of donors (80%) stated that they would not recommend commercial donation to others.

Another large report from Pakistan documented similar findings [44]. Some 239 kidney vendors from the Punjab were surveyed a mean of 4.8 years post-donation. Ninety percent of the vendors were illiterate and almost 70% were bonded labourers. Ninety three percent sold a kidney to repay debt; the average received was US$1377 after paying hospital fees and middlemen. Eighty eight percent reported no economic improvement in their lives, and 98% reported deterioration in health status, most likely because of the labour-intensive nature of the occupations of the vendors. Finally, a survey of 50 Egyptian commercial live donors found that 78% reported a health decline, and 94% regretted their donation [38].

It is clear that commercial live donors have poor outcomes after donation and very few attained the expected improvement in their lifestyle. This contrasts with the overwhelmingly favourable experience of non-commercial live donors found in Western reports, with similar long-term survival to that of matched controls [45,46], and equivalent or better quality of life than the general adult population [47–49].

Recipient outcomes after transplant commercialism

As with commercial live donors, there are similar difficulties in reliably identifying the outcomes of recipients of these organs. As expected, most reports have small numbers of patients, and systematic identification of commercial recipients is difficult due to the covert nature of the transplant.

Overall, recipients of commercial live donor kidney transplants have worse outcomes, with higher rates of infection (including hepatitis B, hepatitis C, and HIV), rejection, and graft loss. In addition, documentation from the implanting centre is often inadequate, which may impair effective care [50–52]. One of the largest studies comes from Pakistan, where recipient outcomes of 126 vended and 180 living-related kidney transplants were compared [53]. Recipients were matched for age, sex, and time from transplant. Acute rejection (33% vs.17%), surgical complications (22% vs. 8%), tuberculosis (11% vs. 6%), and acute hepatitis (16% vs. 2%) were all more common in vended recipients. Five-year graft survival (45% vs. 80%) and overall patient mortality (27% vs. 6%) were also dramatically lower.

A systematic review of recipient outcomes after commercial kidney transplant confirmed that higher rates of graft loss and recipient death appear more common than with non-commercial donation, but that this may be dependent on where the surgery took place [42]. Outcomes of 31 Taiwanese recipients of commercial kidney transplants performed in China from executed prisoners found no difference in ten-year graft or patient survival when compared to 44 non-commercial domestic renal transplant recipients [54]. A larger study of Chinese kidney transplants in 389 Malaysian patients replicated these findings, with no difference in patient and graft survival and rates of bacterial, viral, or fungal infection five-years post-transplant when compared to those from non-commercial live donor recipients [55].

These results suggest that there is a significant variation in recipient outcomes between centres that perform commercial kidney transplantation. As increasing numbers of countries tighten transplant regulations in the aftermath of the Declaration of Istanbul, this may have the unforeseen effect of driving illegal commercial transplant centres further underground, paradoxically worsening live donor and recipient outcomes.

The Iranian model of transplant commercialism

Iran is currently the only country that has a semi-regulated system of transplant commercialism and, as a consequence, is of considerable interest to the international transplant community. Although numerous reports from within Iran have described their model, Iran's internal politics are complex, and the veracity of some reports has been questioned. This, combined with the uneasy relationship between Iran and many Western nations, has made it difficult to reliably verify many of the claims made.

Commercial kidney transplantation in Iran was introduced by the Iranian government in 1988 in response to rising waiting lists; deceased donor transplantation was not legal at that time. Details of the scheme have been provided by Ghods et al. [56]. Patients requiring kidney transplantation without a live donor apply to a non-governmental organization (Dialysis and Transplant Patient's Association – DATPA) run by patients with end-stage renal failure. Potential donors who wish to sell a kidney approach the DATPA, who then perform donor-recipient matching. There is no brokerage fee, and no middlemen. Although the government pays approximately US$1200 to the donor, recipients may give more. The potential donor and recipient meet preoperatively and can arrange additional payments. If the recipient is poor, these payments may be met by a charity. Donor medical preassessment is claimed to be rigorous. Surgery takes place in public hospitals, the transplant team is not aware of the financial arrangements, and donors receive health insurance for a limited time afterwards.

Approximately 80% of kidney transplants in Iran are from commercial donors, although legislation enabling a deceased donor program was put in place in 2002 [57]. Approximately 15% of Iranian organ transplants are from deceased donors [58]. The slow growth of this program has been attributed to cultural reasons and infrastructure issues rather than a negative effect of the commercial donor model [59].

Financial and psychological outcomes of Iranian commercial donors appear to be variable, but are more favourable than reports of commercial donors from India or Pakistan. Malakoutian et al. analysed the socioeconomic status of 478 Iranian commercial kidney donors and found that 62% were living below the poverty line, with financial issues the most frequent motive for donation [60]. After donation, 91% were happy with their decision, and 53% would suggest kidney donation to others. In contrast, a study of 300 Iranian commercial live donors found that donation had negative effects on employment in 65%, and that 71% suffered severe de novo depression postoperatively [61,62]. The goals of vending were not achieved by 75% of commercial kidney donors. Nejatisafa et al. examined predonation quality of life of 424 donors and found that 95% had had at least one stressful event six months predonation; most commonly increased life expenses, low income, or household duties [63]. Postdonation quality of life appeared lower in the donors than the general population, although this was not tested statistically, and the control population was not age or sex matched.

In depth analysis of Iranian recipient outcomes is hampered by the lack of a national registry. However, single- and multi-centre reports generally show that renal allograft survival in Iran is similar to that demonstrated in large Western series, with ten-year graft survivals of 46–68% [64,65]. Grafts from live unrelated (commercial) donors had similar or better survival than live-related kidneys in some reports [56,64], but not others [65].

The Iranian program cannot be called fully regulated as payments to the donor are variable, at least partly dependent on the ability of the recipient to pay, and details of additional payments are not kept by the relevant authorities. Nevertheless, the risks of transplant tourism to Iran have been significantly reduced as foreign nationals are not allowed to be either donors or recipients, unless both are foreign and the donation has been authorized by the Iranian Ministry of Health. Although recipient outcomes are far better than those reported in unregulated commercial programs, concerns still exist about exploitation of poor Iranian commercial donors, and the financial and psychosocial outcomes postdonation. Although the Iranian approach has been credited with elimination of the kidney transplant waiting list in that country [56], the true prevalence of renal disease in Iran is unknown. Also, as a developing country, access to dialysis outside of the major cities is believed to be poor, and it is highly unlikely that many patients who would benefit from receiving a graft die of renal failure having never been dialysed. As a result, the potential Iranian renal transplant waiting list may be artificially low. In addition, some reports have questioned the absence of a waiting list [66].

Strategies to decrease global variation and prevent transplant commercialism

Reducing inequities in access to transplantation

While sociocultural and socioeconomic factors that influence access to transplantation have been relatively well researched, particularly in renal transplantation, interventions to reduce disparities

have been comparatively poorly investigated. The Madrid Resolution [67] and others [68] have called for all countries to address the needs of their citizens for transplantation in a sustainable manner. However, when the world's wealthiest nations are unable to reduce the disparity between organ demand and supply, it is unclear how this aim can be achieved in developing countries with more limited resources.

While practical solutions to this dilemma are not readily forthcoming, opinion leaders in transplantation have described possible strategies to increase equity of access to renal replacement therapy [69]. They have called for improvements at international, national, community, and health system levels. International strategies to improve access to renal transplantation include forming productive relationships between professional organizations, and international collaborations and sharing of data and evidence-based best practice. Of note, The Global Alliance for Transplantation was established in 2006 under the auspices of The Transplantation Society to achieve these aims [70]. At the national level, governments should develop a national transplant policy, a register of waiting list and transplant patients, and maintain oversight and regulation of organ procurement and transplantation procedures. Community interventions should include public education on the risk factors of organ failure, and on the benefits of transplantation. Finally, health systems need to improve the education of health professionals, and to develop locally appropriate deceased donor programmes. Such strategies are already in place in a number of Western countries, but are poorly developed in many underdeveloped nations.

While efforts to reduce the disease burden leading to the need for transplantation are important, increasing organ donation is the fundamental means by which access to transplantation can be increased. Spain has the world's highest deceased donor organ donation rate (Figure 139.2), and consequently the Spanish model of organ donation has been studied intensively over the last decade. However, as noted by the architect of the Spanish system, Rafael Matesanz, an adequate legal, economic, ethical, medical, and political background is needed for donation rates to increase [71]. Spain has adopted a systematic, organizational approach to deceased organ donation, with a nationally-led transplant coordinator network. Donor coordinators in Spain are doctors with a background in critical care, working part-time to allow them to continue their work as intensivists. A rolling audit of brain death is undertaken to ensure that all potential DBD donors are identified. Ongoing training of transplant coordinators is a priority. Hospitals in Spain are reimbursed for organ procurement, and the national transplant organization actively engages with the media to publicize transplantation-related issues. Further improvements in organ donation rates have occurred with the introduction of national protocols for the care of DBD donors [72]. Ultimately, Matesanz also recognizes that large numbers of intensive care beds are essential to high organ donation rates [71].

While the evidence base for interventions to improve donation rates is generally weak, more is known about the factors influencing the decision of relatives to consent to the donation of organs from a deceased relative [73]. Consent rates appear to increase if the relatives think the deceased has received high quality medical care, and if they have an understanding of the concept of brain death. A pause between breaking bad news and the subsequent request for organ donation is also beneficial, as is the presence of an in-house donor coordinator. A recent trial has demonstrated that 'collaborative' requesting, that is a joint approach from an intensive care clinician and a donor coordinator, has no effect on organ donation rates from relatives of brain dead patients compared to requests from the clinical team alone [74]. This is a surprising result, and further research on this issue is needed.

Once on the waiting list, one of the most efficient ways to reduce inequalities in access to donor organs is through evidence-based organ allocation strategies. Organ allocation schemes are most effective in this respect when they utilize scoring algorithms that can be readily refined to adjust for ongoing inequities. Due to disparities in the ethnic origin of deceased donors and those patients on the renal transplant waiting list in the UK, it was recognized that ethnic minorities had longer mean times to transplantation than white patients [1]. The algorithm for allocating kidneys from DBD donors has recently been altered to better reflect the HLA diversity of non-white patients on the waiting list, that is rare recipient HLA antigens are defaulted to a more frequent related specificity. This appears to have at least partially addressed these imbalances [75]. The introduction of the deceased donor liver allocation based on the MELD score, a composite score utilizing objective biochemical markers of disease severity, has removed the association between race and receiving a liver transplant in the US [76]. It seems likely that more countries with ethnically diverse populations will follow these examples in order to increase transparency and reduce inequalities.

Prevention of transplant commercialism

The first step in tackling transplant commercialism is to acknowledge the scale of the problem and for the international transplant community to clearly state its opposition. This has been achieved most clearly through the Declaration of Istanbul [35], the first document drawn up by the international transplant community that defines and condemns transplant commercialism, organ trafficking and transplant tourism. Building on the Universal Declaration of Human Rights, and World Health Organization guiding principles on organ transplantation [77], its primary aim is to inform and promote ethical practices in global organ donation and transplantation.

The Declaration is a document published after a summit in Istanbul was convened by The Transplantation Society and the International Society of Nephrology [78]. Six guiding principles are stated for ethical donation and transplantation:

1. governments should implement programs to screen, prevent, and treat organ failure;
2. in every country where organ donation or transplantation takes place, these activities should be covered by legislation to govern the recovery of organs from live donors and deceased donors, and the practice of transplantation;
3. organs should be allocated equitably without regard to gender, ethnicity, religion, social or financial status;
4. the primary objective of transplant policies and programs should be to optimize short -and long-term care of donors and recipients;
5. countries should strive for self-sufficiency in organ donation;
6. organ trafficking and transplant tourism should be prohibited as they violate the principles of equity, justice, and respect for human dignity, and transplant commercialism leads to inequity and injustice through targeting impoverished donors and should be prohibited.

The impact of the Declaration of Istanbul has been considerable, with more than 100 national transplant organizations endorsing it. Although it is difficult to be certain of causality, after the Declaration's publication, China, Israel, the Philippines, and Pakistan all

passed new legislation or strengthened existing laws that ban organ trafficking and organ sales.

However, the Declaration of Istanbul has been criticized by Ambagtsheer and Weimar for failing to recognize the difficulties inherent in enforcing such legislation, and the lack of criminological and legal expertise in those who drafted it [79]. They have argued that the implications of prohibition of organ trade need to be taken into account. Prohibition of trade in any commodity generates black markets, drives up prices, provides illegal incomes, displaces crime to other regions, and drives trade underground. Investigating alleged organ trafficking is unlikely to be a priority with law enforcement agencies due to a lack of knowledge and training. The authors argue that the World Health Organization and the transplantation societies behind the Declaration of Istanbul should support efforts towards boosting organ donation by initiating regulated trials of incentives for donation, while continuing to combat organ trafficking. In addition, they state that these organizations must assist in training police, prosecutors, and judges, and endeavour to increase cross-border co-operation between medical staff and police. Glazier and Delmonico rebutted these suggestions by stating their continued opposition to both transplant commercialism and organ trafficking [80].

Financial incentives for organ donation

Although no responsible commentators have publicly condoned organ trafficking or transplant tourism, as currently defined, many have suggested that regulated financial incentives for organ donation (transplant commercialism) should be trialled, most commonly for live organ donation. In the UK, France, and Sweden, live kidney donors have their expenses and loss of income reimbursed, with the aim of making the donation process cost-neutral [81]. In the US, live donors are not compensated financially as the National Organ Transplant Act 1984 states 'it shall be unlawful for any person to knowingly acquire, receive or otherwise transfer any human organ for valuable consideration for use in human transplantation'. Proposed financial incentive schemes go beyond reimbursement of costs, and would require changes to existing transplant legislation in countries that currently deem transplant commercialism illegal.

The most pressing argument to support the introduction of financial incentive schemes for live donation is the growing number of patients with end-stage organ failure dying on transplant waiting lists, and, paradoxically, the rise in organ trafficking and transplant tourism [58,82]. It has been noted that all participants in the transplant process benefit materially except for the donor: the recipient is often able to return to employment; the hospital and its staff are paid; and the government benefits from the reduction of numbers needing dialysis (in the case of a kidney transplant). However, the family of the deceased donor, and the living donor, do not benefit financially from the donation process. There are many examples of people who receive extra payments for putting their bodies at risk (e.g. soldiers during active service, healthy volunteers in phase I clinical trials); shouldn't this also extend to live donors? Many different putative schemes are possible, ranging from a true market model, where a live donor would decide who to donate to on the basis of the highest offer, to a system whereby live donors are given a modest lump sum in addition to life and/or medical insurance cover [83].

In the US, Matas and colleagues have been the most prominent proponents of a trial of regulated financial incentives for live donors, and have described the moral and organizational requirements necessary for this to proceed [58,84,85]. These include transparency, national standards for the acceptance or rejection of compensated donor candidates, and rigorous legal and regulatory oversight. They describe a scheme whereby live donors could be offered a package of life and medical insurance, free long-term medical follow-up, and a cash lump-sum (e.g. US$5000) [86]. Donor evaluation and informed consent should be separated from the recipient team. There would be no obligation for a donor candidate to accept the offer, and the organ would be donated to the national deceased donor list by a pre-defined algorithm. Total costs of the package up to the value of US$90 000 would still be cost-effective for society [87].

Other opinion leaders in the US have argued that such schemes would disproportionately attract poor people to donate, and while proponents of financial incentives claim that autonomy is paramount, that there is no autonomy in being poor and using any means to resolve destitution [88]. Such schemes could lead to inherent victimization and exploitation, and risk incomplete disclosure of medical conditions by a potential donor/vendor, as demonstrated by paid blood donors [89]. Concerns have also been raised that organ vending would not co-habit well with non-commercial donation systems currently in place for deceased donor organ donation, for example families of potential deceased donors may resent not receiving the financial incentives that live donors might be given and therefore may not consent to donation [90]. This would have particular implications for organs that are difficult/impossible to be donated by live donors (e.g. heart, lung, liver, and pancreas). On an ethical level, incentivized live donation schemes may compromise the dignity of the human body as it becomes a consumer good [83]. Opponents of financial incentives also claim that alternatives to increase organ donation rates have not been fully explored, including an 'opt out' system of consent, organization of procurement agencies, training of paramedics, intensivists and emergency department staff, and use of extended criteria organs [66].

How might the public react to financial incentive schemes? Perhaps as expected, views vary between surveys, and countries. Public opinions on financial incentives for the families of deceased donors have been investigated by Bryce et al., in a telephone survey of 971 Pennsylvania households [91]. Fifty nine percent of respondents agreed that the state should offer financial incentives or benefits, with much more support for funeral benefits and medical expenses than for direct payment (81%, 84%, and 53%, respectively). Interestingly, almost three-quarters of those surveyed said that financial incentives would not make them change their mind about consenting for donation from a family member. In contrast, in a similar survey, when 720 respondents from across the US were asked:'If a person donates their organs after death, do you believe the donor's family should be compensated in some way for the donation?', just 10% answered in the affirmative [92]. Of particular relevance, Rodrigue et al. surveyed 561 next-of-kin in the US who had recently been approached to consent to deceased organ donation from a relative [93]. Overall, just over 90% of all respondents said that financial incentives would have made no difference to their decision. Twelve percent of those who did not consent stated that they would have consented had financial incentives been offered, but 6% of those who did consent would have refused it. Favourable attitudes towards financial incentives were more common in those who did not consent, the young, those with less than a college education, and less favourable organ donation attitudes.

The public's views on financial incentives towards live donation appear to be more positive, at least in the US. More than 80% of a sample of US adults felt that live donors should have their medical costs reimbursed, and should use sick leave or paid leave to enable donation [92]. Only 28% supported direct payment from the government, however. A Dutch internet survey found that 47% of respondents were against the idea of health insurance companies offering compensation to live donors, either life-long health insurance or a €25 000 lump sum [94].

It is apparent that there are strong arguments for and against financial incentives for organ donation. The only way to adequately determine whether such schemes would increase donation rates is a properly designed and regulated clinical trial. The trial design would need to consider whether to limit payments to live or deceased donation, kidney alone or other organs, the type and size of payment, and the necessary regulatory framework and changes to legislation required. Given the many significant bureaucratic hurdles that would need to be cleared before a trial could be initiated, and the administrative costs likely to be associated with it, it seems unlikely that this will occur, especially in the current global economic climate.

Summary

Inequities in access to organ transplantation probably exist in all countries to a varying extent. Inequity varies markedly according to factors that include national wealth, adequacy of legal, ethical, and organizational infrastructures, efficacy of organ allocation schemes, ethnic and cultural diversity, and belief systems. Even in wealthy countries with well-established transplant programmes, the disparity between the supply and demand of organs continues to grow. The global organ shortage and inequities in access to transplantation are the prime drivers behind transplant commercialism, organ trafficking, and transplant tourism. Global strategies have been developed to address these issues, and recognition of the magnitude of organ trafficking and the international transplant community's opposition are important developments. More controversial solutions include financial incentives for organ donation, although public support appears strongest for incentivised live donation rather than deceased organ donation. The Iranian model provides evidence that financial incentives for live donor kidney donation can satisfy demand, but many concerns remain regarding its applicability to Western transplantation systems. Complex ethical, organisational, political, and legal hurdles remain to be overcome before inequities to transplantation and organ trafficking can be abolished worldwide.

CHAPTER 140

Federal and Private Insurance Coverage for Organ Transplantation

Timothy L. Pruett
University of Minnesota, Minneapolis, MN, USA

Introduction

Performing and providing transplant care is not cost-free. A team of individuals with multiple skills; surgeons, physicians, nurses, social workers, pharmacists, dieticians, therapists, administrative support personnel and others, plus immunosuppressive therapies and facility resources are necessary to respond to peculiar needs of the transplant recipient. Moreover, the processes used to assess and procure donor organs require a distinctly different group of individuals and resources than those used for the transplant procedure and post-transplant care. Irrespective of funding or regulation, every healthcare system that performs complex procedures such as organ transplantation must establish a methodology to support and sustain (1) the individuals providing the care, (2) the resources consumed in providing organs, and (3) subsequent transplantation services. Adequate funding determines whether or not a system will remain in existence.

The simple model in which the individual personally purchases the service is not broadly feasible. Alternatively, a common global model is applied in many parts of the world in which government sponsored healthcare incorporates the transplant and organ costs as a component of a wider societal healthcare imperative. In theory, access to care using this model is universal. However, this model makes organ transplantation a cost center within a healthcare delivery system that has significant impact upon resource availability. Within the cost center model, resources are typically allotted by past demand or desired production. By increasing volumes of procedures, premature depletion of resources may result in restriction of service or diversion of resources from other services. However, the funding system in the US is based on the premise that increasing the numbers of transplants results in increased revenues entering into the system and adds to the prestige of the organization. This paradigm is complicated by the fact that the preponderance of the US funding system is a convoluted mix of governmental and private insurance agencies. The following discussion will concentrate upon requirements necessary to perform organ transplants and how the existing system influences and are influenced by these sometimes competing funding sources. The relationship between legal authority, policy, outcome, performance and payment structure has become inextricably linked. Although other healthcare systems may have a different balance of governmental, private insurance or personal funds that support transplantation, all systems must find ways to compensate for the effort, services and products that are necessary for providing donation and transplant care.

While the goal is not to be "US-centric", analyzing the regulatory and performance components within the US transplant system will allow for a better understanding of the diverse, but necessary elements required for the delivery of transplant care throughout the world. The basic elements of a funding system must address:

1. who can be a provider of transplantation services and what services are essential,
2. how does one obtain organs for transplantation,
3. how do patients find centers and organs for their needs, and
4. how to balance conflicting need-based and financially-based goals?

Additional related discussions on national transplant management and oversight, economic impacts of transplantation, and national healthcare policy as it relates to transplantation can be found in Chapters 128, 142, and 143 respectively.

Requirements to be a transplant program or center

Organ transplantation is highly regulated in the US and in most parts of the world. In part, this regulation is the consequence of the limited availability of organs and the need for public assurance that the system functions within legal and moral structures to benefit those in need of life saving organs. The repugnance of preferential access and/or over abuses of the system is an underlying theme of the social regulation. In order to establish an organ donation and transplantation system, a legal infrastructure is necessary that allows the necessary elements in organ transplantation to function within the legal and ethical mores of society (see Chapters 136, 137, and 138). Recognition of neurologic death, that a person can be dead with a beating heart, is fundamental for multi-organ donation. In the US, this was officially recognized in the 1960s, with the broad acceptance by the states that individuals meeting the Harvard criteria were in fact dead. The passage of the Uniform Anatomic Gift

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Act in 1968 (and multiple modifications since) has given legal structure to the process of organ and tissue donation in the US. Additionally, the donation system has been enhanced by a transportation system to move trauma victims and neurologically devastated individuals to facilities with the expertise and the capacity for specialized care. While these elements are not part of the direct payment system for transplantation, they underscore how intertwined organ donation and transplantation have become with respect to the legal, moral and care delivery fabric of society.

The legal authority for organ transplantation in the US was established in 1984 with the enactment of the National Organ Transplant Act (NOTA). NOTA instituted the national Organ Procurement Organization (OPO) network and the Organ Procurement and Transplant Network (OPTN). The OPO system was created to maximize the yield of organs and tissues from deceased donors. All hospitals within the geographic US were assigned to an OPO for the purpose of identifying and managing organ donors, obtaining authorization for organ donation, coordinating organ retrieval and transporting organs to a designated recipient, hospital and community. Funding for the OPO network was assured through Title XVIII of the Social Security Act (42 U.S.C., 1395 et seq.) which established the process whereby monies and financial accountability for organ retrieval practices are overseen and subsequently identified as through Medicare.

The OPTN was established for the purpose of allocating deceased donor organs to individuals on a national wait-list equitably, adopting standards of quality for acquisition and transportation of donated organs, adopting membership criteria to participate in the national transplant system, and acquiring analyzing and publishing transplant information for the benefit of the Secretary and others needing information about organ transplantation. NOTA specified that only members of the OPTN could register patients on the national wait-list and receive organs retrieved through the OPO system. The OPTN mission is carried out by a private, membership organization which provides the specified services through a contract awarded and overseen by the Health Resources and Services Administration (HRSA), a unit of the Public Health Services. Also included within the authorization of the national transplant network was the creation of the Scientific Registry of Transplant Recipients (SRTR). The intent of this information was to report national and transplant center performance to the OPTN for the purpose of general quality assessment and oversight of specific member's performance. The public release and analysis of this information is meant to aid recipients and their doctors better understand their choices for transplantation care.

OPTN membership is a necessary requirement for a center to list patients and to receive and transplant deceased organs. In 1999, the Final Rule defined how NOTA would be implemented. It specified the areas OPTN policy would have jurisdiction, it required that members comply with OPTN policy and that peer review would be utilized to enforce policy. In 2006, OPTN authority was expanded to include oversight of live organ donation and transplantation. At present, a center is not lawfully authorized to perform deceased or live organ transplants in the US without being an OPTN member. Maintaining the status of "member in good standing" has become a minimum standard for the ability to routinely perform organ transplantation.

OPTN bylaws specify the basic membership requirements for transplant programs, which include having key personnel with minimal levels of experience or training and having defined ancillary professional services (such as anesthesia, infectious diseases, radiology, pathology, blood banking, histocompatibility services and others) and specified hospital/institutional services (including sufficient social work, nutrition, financial, physical therapy and other services). OPTN membership comes with a significant institutional commitment of people and resources, along with the accompanying expense. Membership status is subject to performance outcomes and policy compliance (especially as pertains to following organ allocation algorithms and patient safety). Performing specific numbers of transplants is not necessary for either obtaining or maintaining OPTN membership, but failing to meet expected outcomes triggers a peer review by the OPTN. Furthermore, if a member institution is deficient in key personnel or capacity, fails to comply with OPTN policy or jeopardizes the safety of people on the wait-list or transplant recipients, its membership status can be modified. While the OPTN can discipline programs through a variety of means that include an alteration in membership status, the ability to revoke a program's membership with the OPTN resides solely with the Secretary of HHS. At any one time, there are many transplant programs that are being reviewed by the policy compliance arm of the OPTN. Finally, the costs and requirements of OPTN membership must be met if a program is to participate in the US transplant system. All these elements must be supported for a program to be active.

Government and payment for organ transplantation

The payment structure for transplantation has undergone significant transformations over time. When transplantation first got started in the US, the recipient's institution would bill the recipient for each individual component of care following the procedure. If the patient had insurance, the bill would be passed along but third party payments were variable and individuals and families were put at considerable financial risk. The passage of the End Stage Renal Disease (ESRD) Act in 1972 gave all individuals with renal failure access to dialysis and transplant therapy through Medicare. In 1981, the Medicare Secondary Payer provision clarified the role of government ESRD payments for those patients with private insurance that become Medicare eligible on the basis of having ESRD. It was stipulated that in such individuals with a private employer group health insurance; then even though the individual was Medicare eligible, the first 30 months of ESRD payments are the responsibility of the private plan before transferring payment responsibility to Medicare. However, the lack of predictability of coverage for transplant services and the heterogeneous access to care were significant factors leading to the passage of NOTA in 1984. Under this law, the US government not only validated organ transplantation, but also accelerated the process towards uniform acceptance and payment by the private insurers.

The Federal government compensates participating hospitals and physicians that perform organ transplantation for Medicare beneficiaries. The Medicare ESRD Conditions of Participation were first published in 1976 and stipulated resources, personnel and necessary outcomes. These stipulations were initially quite minimal; however, several amendments expanded the conditions prior to the 2007 Final Rule. Other revisions established survival rates for Medicare reimbursement for hearts (1986), liver (1991), and lung (1995). The Medicare reimbursement strategy to the facility was separated into a payment for the organ-associated costs and those for the transplant procedure. The latter was made to the institution under the Diagnostic-Related Group (DRG). Medicare also developed a

proscribed methodology for the institution to recoup some of the outlier costs in the event that a beneficiary had a complicated and prolonged hospitalization. Physician and surgeon payments were made through a separate payment schedule. This basic model continues today. In 2007, the Medicare Conditions of Participation expanded the resources, processes and outcome elements that were necessary for an institution to provide transplant services for Medicare beneficiaries.

The other major government sponsored healthcare assistance is for those with limited incomes. This is accomplished through a jointly funded federal/state program that is administered by the state's Medicaid program. There are clearly defined financial criteria for individuals to qualify for governmental healthcare benefits which are based on income. Because it is jointly funded, but state administered, Medicaid transplantation benefits vary substantially between states. Considerable latitude is given to the states on how the monies should be allocated for the benefit of its citizens. The criteria to qualify for Medicaid benefits are established by the state and the receipt of care is usually required to stay within the state (assuming that it is available).

The private insurers have had an evolving relationship with transplant programs that has been increasingly influenced by government involvement with transplantation. Initially, transplantation was treated as any other approved medical service provided by an institution and the insurers sought professional and institutional discounts on the "fee for service" provided. However, this model was quickly discarded and the process transformed into "group" buying practices and bundled payments to specific institutions. While insured individuals could access any program for transplant services, the insurance company would only pay full/maximal benefits if the insured patient went to a program that was selected as a preferred program; that is "within network." The qualifications necessary for admittance to the provider "networks" have undergone significant evolution. Like Medicare, there is typically an adjustment formula used to compensate the institution for costs occurred in excess of the initially agreed upon amount. As the numbers of transplant programs increased, the relationships between insurer and healthcare providers evolved and it became apparent that membership in "networks" can be formed or broken rapidly. As noted in the beginning of this chapter, the US system is predicated upon the concept that organ transplantation is a revenue center for a healthcare system, so maintenance of network participation and the accompanying access to patients has become a clinical and financial necessity for most programs. Similarly, it is has become critical to understand the resources expended for transplant care and the associated cost structure. When expenses exceed revenues the system falters.

The cost of obtaining organs for transplantation

The cost of an organ is substantial and warrants individual discussion with each patient. It became a federal felony to buy and sell organs with the passage of NOTA; however, organ donation is an expensive, complex activity that must have a funding source. In response to this need, the OPO and transplant center accounting system was established within Medicare. It defines the allowable costs for organ retrieval. Under this system, the costs of retrieving organs for transplantation are allocated to the recipients of the organs. In the US system, the Standard Organ Acquisition Charge (SAC or OAC) is calculated from the costs accrued from the practice of the organization. The center SAC is derived from "allowable" expenses for the beneficiaries' care. This remains the primary mechanism by which an institution recoups the costs for:

1. procuring deceased organs from the OPO,
2. personnel and tests required to assess an individual's suitability for transplantation,
3. evaluation of live donors, and
4. specific additional allowable services that the transplant center must provide that is not directly billable for patient care.

The SAC varies significantly between centers and is partially explicable by differences in staffing and evaluation protocols. Efficiency in managing the SAC is a central component to the financial stability of US programs. This charge is typically the largest single cost component of a kidney transplant procedure and is a significant portion of the extra renal organ transplant cost.

The mechanism for recouping these costs depends upon the payment source. For governmental payers, the SAC/Organ acquisition charge for Medicare beneficiaries is incorporated into the yearly institutional Medicare cost report. Payment for these products and services will be reimbursed to the institution on an annual basis according to the Medicare cost formula. Under this system the ability to recover Medicare associate costs lags for a year, but the funds are reimbursed to the system.

In the case of privately insured individuals, recouping organ acquisition costs is incorporated into the recipient bill. Private insurers typically do not directly pay for potential or actual donor care, but payment for acquisition of an organ is common. The majority of these donor care costs are then recouped after a transplant is performed, although some insurers will make modest "Phase of care" payments for recipient evaluation and wait-list management. Nonetheless, as recipients can stay on the wait-list for years and not be transplanted, the need for resource stewardship is evident. The uncompensated institutional costs can become significant through a variety of means such as large numbers of inactive people remaining on the wait-list, repetitious histocompatibility testing and follow-up, evaluation of potential live donors that do not proceed to donation and inefficient allocation of costs to the charge center. Under such circumstances, as these costs are allocated into the SAC, the resulting high SAC will either decrease the transplant contribution margin from bundled payment agreements with the payer or will make contracting with the insurer difficult because of the high "fixed" costs. The process of understanding and managing this cost center is critical for the financial wellbeing of a transplant program. Furthermore, because a patient's source of transplant payment may change over the time, the processes to gain compensation for institutional transplant expenses demands an intimate understanding of the financial components of the public and private payers.

Government and private insurance and the individual recipient

The payment system for transplant services has been dynamic and continues to evolve. In past times, charges generated from professional and institutional services for organ transplantation were presented to the patient's insurance company for payment. All or a proportion of the charges were then reimbursed to the professionals and to the facility. In the era when transplantation was an uncommon procedure, the centers could demand lucrative payments for their services. But the numbers of transplant programs has proliferated and cost management must be a significant part of a transplant

program's business plan since transplantation reimbursement has evolved away from the charge-reimbursement model. The private and governmental payment systems evolved along somewhat disparate paths and the institutional strategy to remain financially viable has to adapt to the disparate models.

Governmental providers

In most countries, the government pays for a major portion of the population's healthcare. Care is delivered through government owned hospitals (Ministry of Health hospitals, as in many countries) or through military hospital or Veterans' Administration hospitals, as in the US. However, the most common US government payment for healthcare is as a third party payer, with payments directed to independent providers (hospitals and physicians) that qualify to care for Medicare and Medicaid beneficiaries. The potential government beneficiary must qualify for either the federal Medicare or state Medicaid system. Medicare provides healthcare payments for the largest single group of people in the US (over 100 million people). Even with a more limited reimbursement from governmental payers, there are few healthcare systems that can afford to ignore caring for this expanding population.

Volume and outcome requirements are not new for a program or center to qualify as a Medicare provider of transplant care. However in 2007, the Conditions of Participation (COP) to provide transplant care for Medicare beneficiaries went into effect. These conditions placed a new level of process and personnel requirements upon the institution and transplant center. It became necessary to achieve patient and graft survival outcomes defined by the SRTR in addition to specific volumes of transplants. Failure to meet the expected outcomes jeopardized participation in the Medicare system. While there is an opportunity to argue that mitigating factors explain poor outcomes, failure to convince the Medicare panel places the program at risk of losing Medicare affiliation and payments. In addition to performance volume and outcome requirements, the COP requires enhanced processes for quality assessment and process improvement and live organ donation to name a few, which require additional personnel, such as a live donor advocate. While there is some overlap with OPTN membership requirements and policy, there are sufficiently unique requirements that a transplant program or center must take notice of these differences. Medicare assesses compliance with the COP by reviewing the routine volume and outcome reports provided by the SRTR and by on-site CMS audits/inspection every three years. Losing CMS certification is devastating for a program's reputation and patient referrals so all attempts are made to avoid this possibility. In some instances, transplant programs have shut down because the costs of complying with the COP are too high.

Private insurers

The contemporary trend is for the private insurance companies to place increasing financial liability upon the transplant program/center. The fixed bundled payment provides similar amounts for the transplant procedure irrespective of whether the recipient is the "ideal" patient or the one with multiple co-morbidities. The resources required to provide care for these populations is quite disparate, but the trend is for compensation to remain constant. It has become the program or center's responsibility to effectively manage resources, while maintaining satisfactory (SRTR risk adjusted) outcomes. One of the unspoken options is to restrict transplant care for those individuals that consume/cost too much. It may be that an acceptable outcome can be achieved, but that the cost of providing such care exceeds the reimbursement of the private payer. Managing outcome variability within the center's patient population and the resources consumed by those patients has become essential to the financial viability of the program.

As mentioned previously, most large private insurers have established relationships/networks of transplant centers that provide the majority of care for their insured population. The patients are preferentially directed to receive care at the participating institutions. Because a recipient will have more personal financial liability at an "out of network" center, the financial disincentive drives volume to those centers with optimal payment relationships. Criteria to enter into those relationships are typically dependent upon the stipulations of the private insurer, and include reasonable pricing, adequate transplant volume, satisfactory outcomes and available services. Payment to the transplant center is intended to compensate for pre and post-transplant care, the procedure and hospitalization as well as the cost of the organ. It is imperative that the transplant center effectively manages its costs and negotiate effectively for variable compensation when the patient course generates outlier expenses exceeding base payments. The evolving compensation system demands that the transplant center match its resources and processes with the needs of the population that it serves. If appropriate compensation agreements are not made with the companies providing payments for transplantation, a center will find itself in an untenable financial condition.

A recent transformation has occurred within transplant contracting with the incorporation of the publically available "risk adjusted" program specific outcomes (PSR) provided by the SRTR. These outcomes have become widely adopted as a qualification for network participation, despite the fact that they were not originally designed to be used as such a tool. The metric was intended to be used by the OPTN as a system quality assessment tool and a tool to help patients understand a center's experience and transplant outcomes. However, now programs are removed from a payer network when threshold performance criteria are not met, irrespective of the vagaries of how these criteria were derived. The consequence associated with falling out of networks is a reduction of patient flow, loss of revenue and a damaged reputation.

A significant proportion of smaller and self-insured groups cannot afford the variability of risk associated with the delivery of transplant care. Under these circumstances, transplant coverage can be purchased from a large "reinsurer," such as the United Health Group. In this model, the reinsurer typically will develop even more restrictive networks (Centers of Excellence, COE) that contract with a few high-volume, cost-efficient programs. The insured are encouraged to obtain care at a relatively few centers in the country, while the insurer pays transportation and lodging costs so the insured can be treated at the preferred center. The cost of transplant care in this scenario is reduced by the use of "buying" power and the promise of volume to specified transplant centers. A significant percentage of insured patients receiving organ transplants today have their payments coordinated through such a reinsurer. There is some interest in systems where patients and potential donors are transported to other countries to receive transplant care at a reduced financial liability. These relationships have significant moral, procedural and follow-up drawbacks for systems and patients as greater travel distance imposes personal and family hardships (see Chapter 138).

Balancing patient-need, managing outcomes and finance based expectations

In order for any transplant program to continue to supply care, it is essential that there is money to pay for people, resources, organs and services. It is crucial that one understands how resources are allocated and generated. In systems where transplantation is a cost center, for example a national health system, it is necessary that a program have continuous funding to allow for planned numbers of organ transplants. Knowledge of the resources necessary to provide the ongoing services is critical. If the allocated resources are insufficient to provide for all citizens needing care, then some form of resource allocation/rationing must become operative. In this system, there is commonly budgetary sharing with other services, such that when one program is under budget, either services must be curtailed or monies taken from another, better performing, service. The dialogue about resource allocation/rationing of healthcare monies quickly expands past the strict medical needs of a population and into the realm of economics, politics, ethics, and law. Centers in this type of system are franchised by the state and subject to a different set of dynamics than those in a market driven environment.

In systems where transplantation constitutes a revenue center, such as most US programs, a continual volume of transplants is essential for program viability. Increasing transplant volumes generally leads to more revenue, reputation and opportunity. Reduction in the volume of transplants is followed by programmatic revenue reduction and subsequent need for restructuring of program resources. Understanding patient flow and resource consumption has become a critical business metric. Obtaining program access for a broad population of revenue-generating patients is fundamental to the success within the revenue center model. The first hurdle required to assure patient flow is to have access to those systems providing healthcare coverage for large volumes of patients. In the current US system, this requires participation within Medicare and the large private insurer networks. A common prerequisite for all system participation is to meet OPTN membership criteria and volume and outcome standards. The only independent, comparative program metric remains the publically released SRTR generated Program Specific Report (PSR). Transplant centers must be cognizant of the information about performance that is in the public domain. The variables used for risk adjustment are published and transplant programs must use ongoing assessment of their recipients to assure that risk adjustment is appropriate for their population. Being flagged for outcomes less than expected is damaging to a program. In the event that observed outcomes are less than expected outcomes, it becomes essential to modify practice and selection. Risk adjustment is not perfect, so older patients with multiple co-morbidities may be excluded from transplantation or organ acceptance may become more selective to optimize chances for good outcomes. Careful monitoring of public release of transplant outcomes is not only important for public perception, but also for business. Program discipline to align patient risk, organ quality and organ acceptance is required to improve outcomes after being flagged for poor outcomes. While the public release of risk adjusted outcomes remains an imperfect system, its practice has made program quality assessment and process improvement (QAPI) a necessary component of a transplant business plan.

The other major component for a viable transplant program in the revenue center model is effective management of the cost of transplantation. The cost of providing services cannot routinely exceed the revenue generated by giving the service. While one can attempt to negotiate for a higher reimbursement rate with more financial cushion, as transplant centers have proliferated, the insurers have been able to diminish reimbursement and shift risk to the center. Under such circumstances where the financial margin is shrinking, it is essential that a center understand where inefficiencies occur. Without an ongoing QAPI analysis, the most commonly used technique to improve outcomes is to limit care to patients with diminished risk. This technique is typically effective as most transplant professionals can deal effectively with the straight forward patient. However, such constriction of patient selection limits the access of people who would benefit from transplant care and diminishes volumes to the financial detriment of the program.

Summary

Fiscal balance is a necessary prerequisite for a sustainable transplant program, irrespective of whether the funding source is government or private insurer. Revenues entering into the health system must be balanced with an understanding of how they are spent for people, care delivery, organ acquisition and needs of patient flow. This simple relationship has been confounded by the extreme requirements for regulation, performance metrics, network participation and bundled payments. Knowledge of these integrated systems is useful, but implementation of processes to monitor compliance has become necessary to assure sustainability.

Introduction

This chapter will describe the general steps from drug discovery to transplant-specific approval, with an emphasis on late stage (Phases 2 and 3) development and advancement through the health authority approval process. It will focus on development of drugs that are explicitly indicated for use in transplantation and is meant to provide the reader with a satisfactory but non-exhaustive awareness of the processes leading to drug availability for general clinical use. The goal for successful introduction of a new immunosuppressant drug product is to offer physicians and their patients an improvement over existing therapy in such a way that it can be specifically recommended for use in the targeted setting. The key steps from discovery to registration are depicted in Figure 141.1.

During the discovery phase, large collections of chemical compounds are screened using various in vitro assays to identify those with the desired biochemical activity. Active compounds that meet the desired criteria are further screened through more focused cell-based assays and in vivo experimental models, preferably in an accepted non-clinical transplantation model. Compounds which demonstrate the intended activity are advanced for further non-clinical evaluation (see Discovery section further on).

The technical research and development of the drug substance (i.e. active chemical moiety), and the final drug dosage form are conducted in parallel with initial screening and non-clinical testing. Initial laboratory scale production is further optimized and scaled for production as the compound advances through late phase clinical development. As development progresses to clinical testing, candidate compounds must be manufactured into the various commercial forms (tablet, capsule, liquid, etc.) which meet regulatory standards for potency, stability, impurities, etc. (see Product characterization, formulation, delivery, packaging development section further on).

Pharmacokinetic studies are used to determine the absorption, distribution, metabolism, and excretion characteristics of the molecule in vivo to select candidates with an optimal profile (see Pharmacokinetics, drug disposition, bioanalytical testing section). In parallel, various toxicological studies are undertaken in vitro and in vivo to exclude candidate molecules with mutagenic/carcinogenic potential or organ-specific toxicities, for example, hepatic, renal, or cardiac toxicity (see Preclinical toxicology testing from discovery to approval section further on). One or more candidate compounds emerge from this extensive selection process for progression to human (clinical) testing (see Clinical trials further on).

The Clinical Trials section in this chapter describes the different clinical trials performed throughout development. Phase 1 studies assess initial human safety, tolerability, and clinical pharmacokinetics. Changes in a biomarker or other pharmacodynamic measure(s) may also be tested to measure activity or toxicity. The first true assessment of clinical activity in man is often called a Proof of Concept (PoC) study. The purpose of the PoC study is to confirm activity of the compound relative to an established standard of care regimen in the intended patient population. If the PoC is confirmed, larger Phase 2b studies are conducted to further profile and refine the safety, efficacy, and optimal dosing regimens for the compound. Phase 3 or 'confirmatory' trials are usually larger, statistically powered studies of 12 months or longer to confirm efficacy, safety and tolerability from the Phase 2b studies. Upon completion of a Phase 3 program demonstrating efficacy, safety, and tolerability, the data generated from the numerous studies conducted during the research, technical, non-clinical, and clinical programs are compiled into an extensive submission dossier or New Drug Application (NDA).

The drug submission review and approval process is complex, including manufacturing, preclinical, clinical efficacy, and safety information. The process is highly regulated and requires detailed documentation to support health authority requirements. Frequent communication between the submitting company (sometimes called the "sponsor") and the health authority, beginning well before initial studies in humans and continuing throughout the entire clinical trial and submission process, permit the relevant stakeholders to negotiate the complete requirements of the NDA or dossier submission. It is important to reach a common understanding with health authorities regarding any potential concerns and risks. As a drug candidate advances through clinical development, health authorities provide valuable guidance regarding assessment of clinical endpoints that will ultimately lead to labeling the product for prescribing information. Today, new drug submissions are often

electronically transmitted to health authorities with a typical submission size ranging between approximately 4–20 gigabytes and organized into various modules (see Road to registration: drug approval process further on). If the application is accepted, it undergoes simultaneous review by different specialty groups within the relevant agency.

This entire process requires at least a five to ten-year commitment and significant resources to adequately characterize the safety and efficacy and to obtain market authorization. Throughout the development, overall quality and validity of results are ensured by the sponsor's compliance with the various guidelines and regulations issued and audited by the global health authorities.

Discovery

Pharmacological targets for drug-based interventions may come from known biochemical pathways or novel targets, such as components of signaling pathways identified through molecular/genomic approaches. In drug discovery, large arrays of compounds are subjected to successive screens seeking a specific activity; for example, inhibitory activity against a target receptor in an in vitro or cell-based system. Compounds with relevant activity may be further modified chemically and then re-screened to identify candidates with improved activity against the specific target. Similarly, rational approaches may derive directly from a known drug-target interactions or optimization of activity based on structural modification(s).

Candidate molecules with activity in vitro and cell-based assays are then tested, for example, in rodent models of solid organ transplantation. Such models provide preclinical proof of principle and a preliminary assessment of safety and activity based on histology and blood chemistry. Since immunosuppressants are used in combination therapy, it is common to assess the potential for additive or synergistic effects. Due to interspecies differences in pharmacokinetics and pharmacodynamics, non-clinical activity may not always reflect human activity. Consequently, positive studies can provide a solid basis for candidate selection, and discussion with health authorities and investigators. However, a restrained and cautious transition into the clinical setting is absolutely essential.

Product characterization, formulation, delivery, packaging development

During discovery and development, a drug product may require scale-up from milligram-sized laboratory batches to multi-ton production scale manufacturing. When producing clinical batches for use in human studies, this process becomes even more complicated and regulated to ensure safety for human use. The drug sponsor must follow stringent regulations called Good Manufacturing Practice (GMP). The details concerning the physicochemical characteristics, analytical methods, as well as the manufacturing of the drug product and formulation(s), must be submitted to the relevant health authorities prior to use in humans. Detailed guidance is provided by the health authorities (www.ema.europa.eu; www.fda.gov). Additionally, updates must be submitted to health authorities whenever significant changes occur at the manufacturing site, and/or in the process or formulation. This information is referred to as Chemistry, Manufacturing and Controls (CMC), and CMC represents a significant portion of a regulatory submission.

Pharmacokinetics, drug disposition, bioanalytical testing

Understanding the disposition and pharmacokinetics of small molecules and biologics is a central component of the drug development process. Pharmacokinetic data generated during the discovery phase in a non-clinical species allows better prediction and understanding of the compound's pharmacology; this is confirmed in later clinical trials.

Bioanalytical testing

The first step in understanding the non-clinical and clinical pharmacokinetics is to develop a reliable bioanalytical assay. Depending upon the properties of the compound, route of administration, and site of activity, assays must reliably measure drug concentrations in biologic fluid and/or tissue samples. The most common research platform for compound measurement relies on the sensitivity and selectivity of high performance liquid chromatography (HPLC) paired with mass spectrometry (MS) which allows for precise, dependable measurement of compound concentrations that can be

transferred across laboratories and developed quickly with minimal time and cost. During later phases of clinical development, solid-phase or immunoassays may be developed to provide a platform for use in clinical practice. In transplantation where therapeutic drug monitoring (TDM) is frequently used, a commercial assay must also be validated in the clinical setting prior to drug approval. The approval process for an assay/device is a separate submission from the clinical dossier or NDA and is usually conducted in parallel.

Pharmacokinetics and drug disposition

The four phases of absorption, distribution, metabolism, and excretion are interrelated; alteration of one component may lead to changes in one or more of the others. Collecting blood or other tissue samples allows for quantification of the various pharmacokinetic parameters that describe the timing and extent of each. Using radiolabeled drug allows the definitive assessment of mass balance in non-clinical and clinical subjects. For orally administered drugs, absorption is the first measureable parameter and is described through serial pharmacokinetic measurements. Concentration data from the entire dosing interval can also be used to calculate the extent of absorption, that is, area under the curve (AUC) or exposure. The distribution of small molecules can be quite complex. A non-physiological parameter associated with this phase is the apparent volume of distribution (Vd/F); this provides insight into the extent of the distribution throughout the body. Computer modeling can predict movement of the drug and metabolites between various tissue compartments. This modeling data can aid understanding the pharmacodynamic effects of a compound in order to optimize dosing and route of administration. For most small molecules, from the moment a compound is administered, various metabolic processes are actively modifying and clearing the compound from the body.

The initial assessment of metabolic clearance pathways can be conducted in silico using the structure of the molecule. These models can be further refined with various in vitro models, such as isolated liver microsomes, human hepatocytes, and metabolic cytochrome binding assays. Assessment of the in vivo metabolic fate of drugs is initially conducted in non-clinical studies using ^{14}C-labeled drug and subsequently confirmed in human subjects. By labeling the compound, both parent (administered drug substance) and metabolite structures and PK can be elucidated and compared across species. This latter point is important when selecting the appropriate species for non-clinical toxicology. Finally, the elimination of small molecules can occur via many routes; the two most common are biliary/feces and urine. Most compounds are eliminated as highly transformed, inactive metabolites.

Toxicokinetics

Measuring drug concentrations and calculating the various PK parameters from samples collected during non-clinical toxicology studies is also key to understanding the concentration-response for various single and repeat-dose toxicology findings. These data also allow prediction of possible future human doses, simulation of human pharmacokinetics, and determination of a predicted safety threshold. Therefore, pharmacokinetic data collected during the non-clinical development program drives many decisions during the drug development process and provides the basis for discussing cross-species differences with regulatory authorities.

Pharmacokinetic clinical trials

Across the phases of development, pharmacokinetic data are collected to first understand how humans process the compound and later, to understand how drug concentrations may be driving efficacy, toxicity, or other relevant biological findings. The impact of disease and other drugs on metabolism and elimination of investigational compounds is the principal focus of pharmacokinetic profiling studies. The potential for drug-drug interactions is more of a concern with small molecules since biologic agents are only rarely affected by other co-administered drugs. The most common type of small molecule interaction is metabolic where a co-administered drug or food, for example, grapefruit juice inhibits or induces the metabolism or efflux of the drug of interest. It is important to profile the potential effects of both the investigational drug and the relevant co-administered drug(s) to provide proper guidance for clinicians in the final use guidance (or labeling). The data defining such interactions are typically generated in healthy volunteers using a crossover study methodology. The extent of drug interaction testing required is driven by the metabolic fate of the investigational drug and the potential to have an effect and/or be chemically altered by metabolism. Global health authorities have released a number of guidance documents to help the pharmaceutical industry standardize and focus the drug interaction profiling process (www.fda.gov; www.ema.europa.eu).

Also, pharmacokinetic profiling studies are conducted in pediatric patients and in various disease states, such as renal and hepatic impairment, to understand the effects of age and disease on the pharmacokinetic behavior of a compound. Other demographic factors that may affect pharmacokinetics can be assessed through dedicated trials, or sometimes through a process called population pharmacokinetics. This utilizes a sparse population pharmacokinetic sampling approach during Phases 2 and 3 clinical trials to gather pharmacokinetic data from a population of interest. The data are then analyzed to assess the effect on large population-related factors, such as age, gender, ethnicity, concomitant medications, or various disease states, on the pharmacokinetics of the compound.

Preclinical toxicology testing from discovery to approval

At first glance, the principles of preclinical toxicology testing for a new candidate in drug development appear standardized and highly regulated. A standardized set of test systems (www.oecd.org) are utilized and must adhere to Good Laboratory Process (GLP) guidelines [1].

Tool box for the toxicologist

Toxicology studies typically involve in vitro and in vivo studies and other test systems to examine the relationship between the dose, exposure of an investigational compound and the resultant toxicity(s). When designing an experiment or evaluating the outcome of a study, the toxicologist must be aware of the potential impact of factors, such as route of administration, dosing frequency, duration of administration, pharmacokinetics, or drug interactions with co-medications that may influence the toxicity potential of a drug. This is particularly important in organ transplantation since the standard regimen often includes a combination of drugs.

Regulatory environment and impact on toxicology testing

Animal research in drug development only serves as a surrogate for efficacy, and similarly safety testing in humans has limitations. The use of animals in research and development is governed by considerations of animal welfare and the ethical requirement to replace,

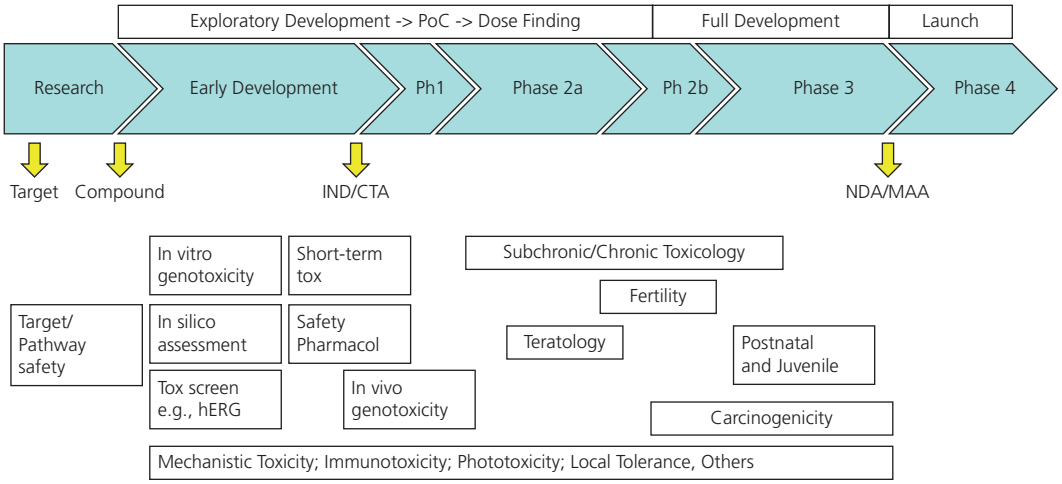

Figure 141.2. Flow chart of toxicity testing in drug development.
Ph, Phase; PoC, proof of concept; IND, investigational new drug application in the US (Europe: CTA, clinical trial authorization); NDA, new drug application in the US (Europe: MAA, marketing authorization application).

reduce and refine (the 3 R's) animal experimentation whenever possible [2]. The most important framework describing guidelines on animal toxicity testing come from the International Conference on Harmonization (ICH) on the technical requirements for registration of human medicinal products (www.ich.org/products/guidelines). Specific guidance is also issued by the US Food and Drug Administration (FDA; www.fda.gov/drugs/), and the European Medicines Agency (EMA; www.ema.europa.eu/).

Based on the experience of limited predictability of drug-induced adverse events in animals with respect to humans [3,4], evaluation is usually required in two or more species (one rodent, one non-rodent). Traditionally, and in line with the ease of animal husbandry and handling, the rat and the dog are the preferred species for toxicity testing. This paradigm was especially useful in developing early transplantation drugs, such as azathioprine and cyclosporine. The introduction of monoclonal antibodies in the late 1990s, however, highlighted the need for an alternative approach; testing was not relevant in a species where the antibody did not cause the pharmacological reaction being studied [5]. Accordingly, the non-human primate was introduced for toxicity testing of therapeutic monoclonal antibodies and other biologics.

In principle, non-clinical safety testing of biologics follows the same considerations as outlined in ICH M3(R2) (www.ich.org/products). Specific aspects and deviations on safety testing for small molecules are described in ICH S6(R1). Additionally, the dog as a non-rodent species for toxicity testing proved extremely difficult for second generation transplant drugs due to the exaggerated toxicity on the gastrointestinal tract [6,7]. Specifically, the (mini) pig has become an alternative non-rodent species which has a high potential for safety assessment [8].

Designing a toxicology program to support drug development

The non-clinical safety assessment strategy in drug development focuses on two major goals; namely, to provide the necessary information for safely testing a drug candidate in man for the first time so that the necessary preclinical safety information is available to extend clinical studies into Phases 2 and 3 and also to support registration. Therefore, deliverables from toxicology are often planned as "study packages", and the execution is triggered by milestones achieved in clinical development. A typical flow chart for a toxicology program is depicted in Figure 141.2.

The IND stage

The safety information needed to support the first dosing of a novel agent in humans is supported exclusively by animal data, placing the burden of proof in decision making, upon the expertise of the pharmacologist, pharmacokineticist, and toxicologist. The majority of adverse drug reactions in man are dose-dependent and predictable from primary or secondary pharmacology [9]. Therefore, a prerequisite for proper safety testing is that the therapeutic agent must trigger a similar pharmacological response in animals being tested and humans. If this is not the case, the differences across species must be elucidated, and these results also become part of the risk assessment strategy and algorithms. Additionally, molecules that exhibit their effects chemically have the potential to cause chemically-mediated toxicity; these toxicities are usually unrelated to the intended pharmacological interactions with enzymes or receptors; they are often called "off-target" effects. An example is the interaction of proteins accumulated in a cardiac potassium channel, which is responsible for repolarization (hERG); blockage can precipitate arrhythmia and even sudden cardiac death. This type of effect has been the reason for a number of drug withdrawals from the market [10] and accordingly, evaluation of this potential effect has become a major focus during development. It is well known that some drugs show fundamental differences in their pharmacokinetic behavior between animal species and humans [11]; similarly, gender differences in absorption, distribution, metabolism, and excretion [12] may influence the safety profile of a compound. Therefore, the preclinical safety strategy must examine and consider species differences in a drug's pharmacokinetic parameters, such as absorption, protein binding or tissue distribution, and elimination before testing in man is undertaken [13]. The basic prerequisite package consists of appropriate pharmacology and pharmacokinetic experiments, plus a number

of toxicology studies covering safety pharmacology, genotoxicity, and acute and repeated-dose toxicity. As needed, exploratory mechanistic toxicity studies are also conducted to provide a good prediction of human safety risk [14] and help to reduce the late-stage attrition rate [15].

The safe starting dose for humans in Phase 1 testing is based on safety margins derived from these extensive toxicity studies. The approach is similar for small molecular weight compounds and biologicals [16], but special considerations are given to immunomodulating compounds [17] or highly pharmacologically active compounds [18,19]. The safety margin (also called therapeutic index) is based on a comparison of systemic exposure from animal efficacy models and results from toxicity studies. Other calculations, such as body surface area, allow a comparison between animals and humans and are sometimes used (FDA guidance on MRSD, www.fda.gov/Drugs/). The key criteria for a Go/No-Go decision for a first-in-man (FIM) study is based on the overall evaluation of the non-clinical safety data relating to the risks identified, as well as a prediction of the likelihood that any observations would occur in man. The benefit-risk assessment is driven by a number of considerations, including the ability to monitor and reverse off-target or adverse events. Following a comprehensive evaluation of these non-clinical safety data, an Investigative New Drug (IND) application is prepared.

Support of clinical development and marketing authorization

If a drug candidate demonstrates promising results in early clinical studies, this triggers initiation of a non-clinical safety program to support continued development in Phases 2 and 3 and eventually, to support registration. Based on international conference guidelines accepted by most health authorities ICH M3(R2), the full development toxicology program centers around covering the duration of expected human exposure. Toxicity studies are conducted in two species (one rodent and one non-rodent) of at least similar duration to that expected in clinical trials. Guidelines dictate a maximum duration of treatment of six months for rodents and up to nine months for non-rodents, even if lifetime treatment is intended in patients. The purpose of these sub-chronic and chronic studies in animals is to refine the dose-response characteristics and to establish the threshold exposure for inducing adverse events upon prolonged drug administration. These studies may additionally identify any new and/or unexpected toxicity upon longer term use. Beyond the standard toxicology studies, two special types of toxicity studies may also be initiated to assess additional hazards or risks; namely, reproductive toxicity and carcinogenicity studies. Since ethical considerations preclude direct investigation, results from such studies serve as a surrogate for the risk assessment in humans. These studies may not be required if treatment in patients is for a short period of time, is life-saving, meets a high unmet medical need (HIV, oncology), or certain groups of patients (women of childbearing potential) will not receive the drug. Results from reproductive toxicity and carcinogenicity studies are presented in the package insert of a compound, together with guidance on the presumed relevance and significance for the intended patients.

For drugs used in pediatric patients, European regulatory requirements on the Pediatric Investigational Plan (www.ema.europa.eu/ema) request toxicity studies in juvenile animals to support clinical trials and registration in some cases. Therefore, careful consideration of juvenile animal studies [20] and an upfront discussion with health authorities would be useful [21].

Reproductive toxicity studies

Reproductive toxicity studies assess the effects of a compound on fertility, embryo-fetal toxicity (e.g. risk of spontaneous abortion or fetal malformations), or pre and postnatal development (e.g. risk of late fetal death, retarded development or functional deficits in early postnatal life). Again, data from animal toxicity studies serve as a surrogate since human data will usually not become available for many years after approval and introduction into general use; low incidence events may take considerable time before relevance is appreciated directly from the human experience. Some drugs have a patient registry program for pregnancy, or preclinical flags have triggered more intense clinical surveillance [22]. In addition, results from preclinical studies help guide the potential nature of effects seen, for example, on fertility. Such results may trigger clinical investigations, which may corroborate preclinical data, as was seen with potential effects on male fertility caused by sirolimus [23].

Carcinogenicity studies

The most time and resource-intensive toxicity studies are those evaluating potential carcinogenicity. These are required for all pharmaceuticals whose intended clinical duration of use exceeds three to six months. This affects all small molecule drugs for transplant patients. Drugs intended for certain oncological indications, biologics, and drugs used for induction therapy (e.g. anti-IL-2 monoclonal antibodies) may not require carcinogenicity studies [24]. Additional studies may be mandated when the chemical is related structurally to other products with known carcinogenic potential, or the biological action, long-term toxicity, or mutagenic study results may indicate a potential for carcinogenicity. In such cases, health authorities may ask for the results before Phase 3 studies may be started. When needed, this type of guidance can significantly extend development program timelines. The association between cancer risk and immunosuppressive therapy was noted well before the cyclosporine era when allograft recipients were treated with azathioprine and prednisone [25]. The increased risk of malignancies associated with immunosuppressants in transplantation is mainly concerned with virus-associated malignancies, such as lymphomas associated with Epstein-Barr virus, human herpes virus 8 (also known as Kaposi's sarcoma-associated herpes virus), and skin and genital cancers associated with papillomaviruses [26]. Aggressive immunosuppression in children with the monoclonal antibody OKT3 or with tacrolimus has been associated with an increased incidence of malignancies, such as lymphoproliferative disorders) [27,28]. Accumulated evidence from clinical experience indicates that the risk of developing certain malignancies in transplantation is associated more with the level of immunosuppression than with a specific drug.

Supplementary studies

Lastly, depending upon the specific intended use of a therapeutic agent, the toxicologist may design and conduct additional studies in vitro or in animals to support the conduct of clinical trials or registration. For drugs being developed in organ transplantation, assays could be required, for example, to elucidate phototoxicity [29], immunotoxicity [30], local tolerability, mechanistic aspects of toxicities seen in animals or man, or combination toxicities of a new drug regimen.

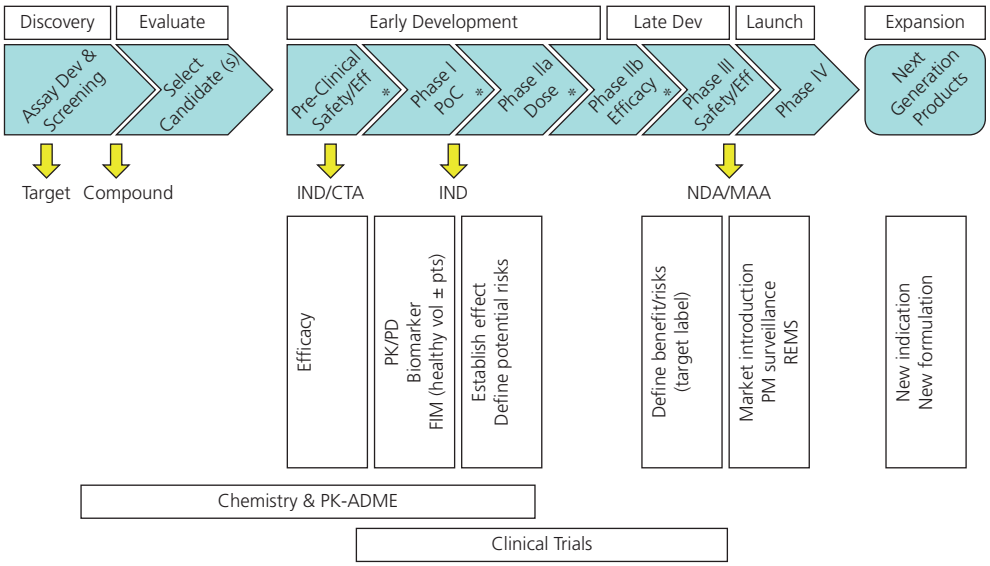

Figure 141.3. Phases of drug development.
Dev, development; Eff, efficacy; PoC, proof of concept; IND, investigational new drug application in the US (Europe: CTA = clinical trial authorization); NDA, new drug application in the US (Europe: MAA = marketing authorization application); FIM, first-in-man; vol, volunteers; PM, post marketing; REMS, risk evaluation and mitigation strategy; ADME, absorption, distribution, metabolism, and excretion.

Clinical trials

To gain health authority approval for novel drug candidates, both safety and efficacy must be demonstrated in the intended patient population. Some approved compounds do not require a full development program as depicted in Figure 141.3; for example, demonstrating bioequivalence is acceptable for generic compounds.

Phase 1 — Clinical development

Phase 1, also referred to as clinical pharmacology, covers the initial clinical profiling of a compound in humans. These studies include the initial assessment of the safety, tolerability, pharmacokinetics and pharmacodynamics of single and multiple doses, and mechanistic profiling of the compound in humans. Depending upon the molecule, five to 40 individual studies may be needed to describe the relevant clinical pharmacology of a given compound. These studies serve as the foundation upon which later phases of development (and eventually labeling) are built, including expected drug-drug interactions and dosing recommendations for special populations.

First in man study

After the biologic activity has been established, biopharmaceutical properties characterized, and potential toxicities identified in non-clinical studies, the compound transitions from research to Phase 1 clinical development for evaluation in human subjects. The human pharmacokinetics, tolerability, and toxicity thresholds (see Pharmacokinetic clinical trials section) are determined from the first-in-man (FIM) study. If the compound is poorly tolerated, exhibits poor biopharmaceutical properties, or subjects demonstrate previously unidentified toxicities, the results may terminate further development.

In general, the FIM study is a randomized (usually 1:1), blinded, placebo-controlled, parallel group, single ascending dose (SAD) design. The initial dose selection and upper boundary of dosing for the FIM study is based on results from non-clinical toxicology studies and the established no observed adverse effect level (NOAEL) using allometric scaling (see The IND stage). Dose escalation is typically time-lagged; that is, one dose-level at a time is assessed prior to proceeding to the next dose. The decision to escalate is based on the overall safety, tolerability profile, and guided by toxicities observed in preclinical studies. Dose escalation typically occurs in half-log or one-log steps, but this may be constrained to a simple doubling of dose depending on the preclinical dose response. This rapid log-based escalation allows profiling of a large dosing range, for example 0.1 to 1000 mg, which minimizes pharmacokinetic overlap between doses. Such a design usually results in a rich dataset, allowing adequate characterization of human pharmacokinetic parameters, as well as dose- or concentration-dependent toxicities.

Depending upon the pharmacodynamic activity and the type of compound (e.g. small molecule or biologic), the FIM study may be conducted in a healthy volunteer or patient population. In the case of first-in-class novel immunosuppressant's, where the extent of pharmacodynamic activity and immunosuppression may be considered too high of a risk for healthy subjects, the FIM study may be conducted in a population where there is a potential benefit. This population might, for example, include stable transplant patients or patients with autoimmune disease.

Proof of concept design

A formal PoC study may be conducted once the tolerability profile has been established and single and multiple dose human pharmacokinetics have been characterized; this signifies the start of Phase 2a. The purpose is to rapidly establish the biological activity of the compound in patients with the disease, or in the case of transplant immunosuppression, as part of an immunosuppressant regimen to determine if the compound warrants further development in the intended indication. Depending upon the primary endpoint being evaluated, there may be two to three dosing cohorts of six to 24 subjects each. An established "gold standard" clinical endpoint is

usually used as the primary PoC endpoint, although a relevant biomarker might be used for decision making in certain settings. Since the primary goal of the study is to assess the potential for clinical activity with a small sample size, innovative statistical approaches may be used to predict success or failure, such as Bayesian methods.

Post PoC activity

When a compound moves into later phases of development, the Phase 1 profiling activities focus on establishing the detailed clinical pharmacokinetics, and pharmacodynamics of the compound. This includes drug-drug and drug-disease interactions, as well as consideration of special populations, such as effects on clearance in patients with renal and hepatic impairment. Additional mechanistic studies to better elucidate the biological activity of the compound in man or the mechanisms behind toxicity may also be conducted at this time. During recent years, depending on preclinical signals (e.g. hERG inhibition; see The IND Stage) a thorough QT study (ICH E14, www.ich.org) has become an industry standard to profile effects on cardiac repolarization, specifically QT interval prolongation.

The scope of the clinical pharmacology package (regulatory studies required to characterize the clinical pharmacology of the molecule) is dependent upon the specific pharmacology. For example, the package for a monoclonal antibody can be quite straight forward since drug interactions and QT prolongation are not expected, and non-specific activity is unlikely. On the other hand, a small molecule, metabolized by the liver which binds to a number of "off-target" receptors, may require 30 or more clinical pharmacology studies to profile the compound under various clinical treatment conditions. The knowledge collected from these studies is essential for both the design of subsequent clinical trials as well as providing labeling regarding the safe use of the investigational drug.

Phase 2 — Dose finding, and the assessment of preliminary efficacy and safety

In solid organ transplantation, the most common study design in Phase 2 and beyond is an open-label, randomized controlled trial against an active comparator. The choice of active comparator is usually the contemporary, approved standard of care in the indication under investigation. If practical, some level of blinding is preferred to minimize potential bias. A Phase 2 development program may include only one study, but the more often utilized 'learn and confirm' construct includes two or more studies prior to Phase 3.

The primary objective of most Phase 2 transplant studies is to demonstrate efficacy of the investigational regimen compared to the standard of care. Study endpoints can be as short as three months post-transplantation, but usually 6 or 12 months are needed to ensure adequate exposure to therapy and to demonstrate that the treatment response is durable. Global health authorities may also require longer-term data for approval; hence, following a primary analysis at 12 months, studies are usually continued for 24 months or longer. A key goal during Phase 2 is to establish the dose (or exposure) that provides optimal efficacy within the context of the planned treatment regimen. Depending upon the size of the study, the scope of pharmacokinetic assessments needed, efficacy, and the task of establishing an exposure-response during the Phase 2 program can be straightforward; at other times, this can be impractical. Results from the single and multiple doses Phase 1 and PoC studies will support the determination of initial dose(s) to be evaluated in Phase 2. It is typical to test two or more doses of the investigational drug against the standard of care regimen to build the exposure-response data set. Sometimes, it is not possible to establish optimal dose and/or exposure data until the end of Phase 3.

Phase 3 — Confirmatory efficacy and safety/registration

Design and endpoints

Phase 3 trials are often referred to as "pivotal" or "confirmatory" because they provide the basis upon which a health authority will make a final determination of the safety, effectiveness, and labeling for the population of interest. With appropriate statistical power, the results need to confirm the correct dose (or concentration range) and demonstrate a clear risk-benefit based on the overall safety and efficacy. The topic of clinical trial design and the specific statistical challenges involved are covered in depth in Chapters 134 and 135 respectively. For transplantation, the duration of a Phase 3 program may span three to five years at a cost of $50–100 million. A common Phase 3 study design tests one or two treatment arms versus control, using a randomized, blinded (when possible) study design with a 12-month study endpoint. The sample size for a Phase 3 program is based upon the effect size and study endpoints (e.g. superiority or non-inferiority) when compared to active, standard of care as control. Acute rejection rates have decreased to the point where it is often difficult to show a significant difference between standard of care treatments and investigational drugs. Consequently, a study demonstrating superior outcome may require thousand(s) of patients per treatment arm, and this is impractical given the limited number of transplants performed each year. Therefore, many sponsors default to a "non-inferiority" approach with the intention of developing new agents that provide a secondary benefit, such as less toxicity or better tolerability.

For drugs intended to prevent post-transplant acute rejection, the traditional FDA endpoint for assessment of primary efficacy failure is a composite of efficacy criteria, including acute rejection, graft loss, and death and "patients lost to follow-up" (see later). Due to the limited potential sample size in Phase 3 transplant development programs, the FDA requires a more rigorous assessment. Therefore, the composite index is comprised of several outcome measures to provide confidence regarding efficacy. Combined (or composite) endpoints may allow better differentiation of the efficacy rate to help delineate non-inferiority between arms. Regardless, the individual efficacy components are also reported. The EMA requires a similar composite efficacy approach, in addition to a functional outcome measure for the transplanted organ. For example, in renal transplantation, this might include a comparison of renal function by estimated glomerular filtration rate (eGFR) as a component of the primary composite or as a co-primary endpoint. The FDA usually requires adequate justification to accept co-primary endpoints.

Since the FDA has tended to also include "patients lost to follow-up" as a component of the composite efficacy endpoint, missing data from discontinued patients represents a potentially significant confounder. This has, in fact, been a major concern for some Phase 3 trials. Understandably, the FDA typically adopts a statistically conservative approach and considers patients who are non-evaluable for the primary endpoint (including those who withdraw consent or are lost to follow-up) as efficacy failures. Therefore, it is also extremely important to ensure study completion for as many enrolled patients as possible. This continued follow-up

within the study, even when patients have discontinued the assigned treatment regimen, allows the efficacy endpoint to be fully evaluated for all patients and also provides valuable follow-up safety information. Differences exist among health authorities; for example, current EMA guidelines do not recommend inclusion of non-evaluable subjects as part of the primary composite endpoint to assess efficacy failure.

Patients and demographics

Health authorities also have an interest in regional demographics, usually requesting that Phase 3 trials include a study population representative of the intended population for use. In Europe, the EMA requests representation from a broad European population. In the US, given the known ethnic differences in response rates to transplant immunosuppression [31], the FDA also recommends that the drug sponsor consider enrollment of a meaningful percentage of African American and Hispanic patients.

Novel endpoints and biomarkers

Biomarkers offer the potential for new insights into transplant biology with potential clinical relevance, but validation using clinical outcome measures is required to gain broad acceptance by the scientific community and regulatory authorities. Standardization of the clinical protocol across regions and centers, as well as strict adherence to prespecified data endpoints and rigorous data collection, are critical components in validating a biomarker for use. Such standardization and clinical correlation provide confidence that results will accurately assess efficacy and safety, thereby helping to inform the overall benefit-risk decision.

Statistical considerations for Phase 3

A comprehensive statistical analysis plan addressing study objectives is prespecified and submitted to health authorities in advance of study completion, preferably during the design phase in order to confirm agreement. Included are measures of study quality (by examination of protocol deviations) and consistency of effect within important subgroups, such as regional and ethnic populations. Statistical concerns are also considered in depth in Chapter 134.

Placebo controls remain the "gold standard" for comparison in clinical research. However, this is not feasible for transplantation since graft survival requires immunosuppression, and it is unethical to withhold immunosuppression. Patients usually receive a combination of drugs to maximize efficacy and safety; the incidence of acute rejection in contemporary kidney transplantation approximates 15% in most recent trials. As described earlier, since increased immunosuppression usually brings improved efficacy (fewer rejections), but more safety issues (e.g. infection), it is difficult to achieve significantly better efficacy versus standard of care regimens without negatively influencing the benefit-risk profile. Therefore, as described earlier, clinical trials in transplantation are usually designed to show non-inferiority (NI) (demonstrating that the test regimen is not worse than standard of care) as the primary efficacy endpoint. With a non-inferiority design, the test agent shows differentiation by secondary measures, such as improved renal function, increased duration of benefit, decreased health care utilization, or perhaps an improved safety profile. Potential areas of differentiation or unmet medical need could also include areas, such as a lower incidence of infection, malignancy or diabetes mellitus or a better side effect profile with respect to gastrointestinal, hematological or neurological systems.

A well-designed NI study, in the setting of combination drug regimens, is based on estimating the effect of the test compound relative to a "putative placebo;" that is, the effect of the test compound must provide an effect over and above that expected from other elements in the combination. This can be challenging to demonstrate if historical data using the drug combination, excluding the test drug, are unavailable or are very sparsely reported in the literature [32]. Sometimes, information can also derive from disease area guidelines, previous trials, discussions with the regulatory agency, and knowledge of historical data on the comparator treatment. Also, the effects seen in the literature should be relevant, for example, in similar populations that are likely to respond similarly to the proposed study population.

According to FDA guidance, a successful NI justification should demonstrate constancy of effect over time. This might be challenging if the characteristics of the "current" transplant population differ significantly from historical data with respect to certain key risk factors. For example, the expanded donor and recipient criteria used in contemporary clinical practice are arguably different from those used previously in the literature. Often the NI margin proposed for Phase 2 transplant trials is more lenient based on operational feasibility, compared to the more stringent NI margin required in Phase 3 pivotal trials for drug approval.

Regardless of the design (non-inferiority or superiority), sample sizes are calculated with the goal to either provide reasonable confidence to estimate a difference in event rates between regimens (Phase 2 trials) or to have higher power to demonstrate the primary objective(s) (non-inferiority or superiority) in Phase 3 trials. Sample size calculation is a function of the expected event rates, estimates of variability, and the level of confidence desired. Typically, for Phase 3 confirmatory NI studies, a power of 90% is desirable, which is a 90% probability of demonstrating that the regimen is non-inferior to control.

Road to registration: drug approval process

Interactions with health authorities

In the US, prior to the first study of a new drug candidate in humans, an investigational new drug (IND) application is submitted to request authorization from the US Food and Drug Administration (FDA) to administer an investigational drug or biological product to humans in a clinical study. In Europe, a Clinical Trial Authorization (CTA) must be submitted and granted from each participating country's health authority and each study center's Ethics Committee. Some FDA divisions, such as the Center for Drug Evaluation and Research (CDER), recommend a pre IND meeting prior to filing an application. This provides early feedback on preclinical information to establish if there is agreement that a particular product has adequate supporting data to meet the requirements for an IND submission and to support early clinical development. It is also an opportunity to assess the overall preliminary clinical proposals and to discuss whether innovative approaches (biomarkers, diagnostics, etc.) will be included.

These early interactions are also important to establish if the product might qualify for special designation or a special review and approval pathway, for example, "orphan drug status" which is intended for rare disease populations (prevalence defined as $<$200 000 cases in the US). Another designation, "Fast Track" can provide a shorter development timeline and review period. This approach can result in conditional/accelerated approval, such as when there is no alternative therapy or there is significant improve-

ment over existing therapy and the investigation compound could treat that specific life-threatening or debilitating condition. All applications to health authorities require adequate documentation to support proposals for clinical study. Also included in a typical application is an Investigator Brochure (IB), which provides a comprehensive understanding of the drug characteristics (chemistry, non-clinical pharmacology and toxicity studies, and any past human experience), a proposed study protocol, and qualification of the investigators being proposed to conduct the planned studies. Full supporting information is also provided for the health authority review, including preclinical reports, manufacturing controls documentation, and any reports of prior experience in humans. Once an IND or CTA is accepted by the responsible health authority, it remains active as long as the drug sponsor intends to maintain an active development program. An annual report is submitted on the progress of the human trial(s), including safety updates, and IB revisions. Depending upon the assigned FDA Division, separate new applications may be required for new formulations or indications. Ongoing opportunities to discuss with the FDA, in person and by telephone, may be requested at each drug development stage and sooner, by specific request (ad-hoc discussions).

Once Phase 2 data are available and a sponsor intends to progress to Phase 3, the sponsor may request an End of Phase 2 (EoP2) meeting with the FDA. At this meeting, the FDA will review non-clinical and toxicology data, as well as clinical data generated during Phases 1 and 2. The purpose of this review is to establish, in consultation with the health authority, that the risk-benefit ratio is justified by the data collected, and that the compound is sufficiently safe for use in larger confirmatory Phase 3 trials. Acceptable clinical endpoints, optimizing the protocol design and appropriate patient types are discussed, as is the justification for the proposed dosing in Phase 3. Any agreements with the responsible health authority at EoP2 are non-binding; they do not guarantee acceptance, for example, if the medical/scientific knowledge and/or standard practice evolve during the Phase 3 development. Although not required, the sponsor may also request a Special Protocol Assessment review meeting with the FDA to discuss and approve the Phase 3 study protocol.

All clinical trial conduct and management must adhere to Good Clinical Practice (GCP) guidelines as a prerequisite to acceptability of trial results for drug registration (approval); this includes local requirements wherever the drug is evaluated, such as the FDA, European Medicines Agency (EMEA) of the European Union or Member states, Japan's Ministry of Health, Labor and Welfare (MHLW), and other local health authorities as appropriate. Some countries have different requirements for conducting clinical research. Guidance for the conduct of most clinical trials are based on: FDA 21 CFR Parts §50, 56, and 312 (http://www.accessdata.fda.gov/) and also the International Conference on Harmonization Harmonized Tripartite Guideline for Good Clinical Practice (http://www.ich.org/) based on the ethical principles described in the Declaration of Helsinki.

Application for market authorization

Before submission of the NDA, the company may request a pre-NDA meeting with the responsible health authority to obtain feedback on the format and content of the proposed review package and to identify potential major interests with the content (efficacy or safety database, chemistry, preclinical, or other administrative requirements). The purpose of this early discussion is to understand any known risks that may cause the health authority to "refuse to file" (FDA) or to validate (EMA) the application (e.g. proceed to substantive). Typically, an original drug application for a new chemical entity contains clinical study reports from a minimum of two adequate and well-controlled Phase 3 trials, a Risk Management evaluation, and submission plans for a pediatric study. All health authorities now require fees for drug applications. For example, in the US, since the adoption of the 1992 Prescription Drug User Fee Act (PDUFA) regulations, the "user fee" funds the NDA review process over a designated target completion timeline: up to six months for a Priority review, and ten months for a Standard review period. Additional review time may be added if necessary and is dependent on the complexities of the documentation.

The FDA review is coordinated by a lead project manager and involves multiple disciplines, including medical, statistical, and/or the clinical pharmacology of the compound, preclinical, and chemistry. The FDA will communicate a filing decision and potential issues concerning the application within a defined time period after submission: 30 days for a Priority NDA review and 60 days for a Standard NDA review. The FDA will also send a formal 74 Day Letter, also known as the Filing Review Notification that communicates preliminary comments on potential issues that could impact approval and also the timeline on providing feedback on labeling, the REMS proposal, post marketing commitments; and an action date that the review will be completed.

In parallel with the NDA review, the Division of Scientific Investigations may conduct a preapproval inspection of the full-scale production facilities to ensure that the infrastructure can produce the quality product. Also, an FDA investigator(s) may conduct a site audit to evaluate the overall integrity of data adherence, compliance, and investigator reporting to confirm the reliability of data submitted by the company. Foreign site audits are becoming more common with the participation of non US investigators to support global clinical trials.

Sponsors of NDAs are required to submit follow-up safety information (typically a 120 day Safety Update) after the initial application; the content and actual timing can be negotiated with the FDA. In the last 45 days of the review cycle, the FDA will also communicate its decision on acceptance of the proposed trade name. It is common that a company will submit alternative names due to the potential for product confusion with respect to sound-alike or look-alike names.

Upon completion of the NDA review, if the benefit does not outweigh the risk, the FDA will issue a "Complete Response" letter listing identified deficiencies. Type 1 letters list minor issues that must be addressed within two months and resubmitted to the FDA for a timely review. Type 2 letters may require additional data, including full study reports or major statistical analysis, within six months. Even if the Action Letter deficiencies are adequately addressed, an approval decision is not guaranteed. The FDA may also require mandatory post marketing requirements or commitments to confirm the clinical benefit and to answer additional safety questions. Termed post approval commitments, these studies are conducted by the sponsor after the FDA has approved the product for commercial marketing. Product approval is posted on the FDA website shortly after the drug sponsor is notified. The FDA may also provide access through the Freedom of Information, which contains summary reviews by the director, including documents and decisions by the assigned review team by discipline, and the REMS document reviews, if applicable. Drug reviews and approval decisions in Europe are also made available to the interested public and are known as European Public Assessment Reports.

FDA advisory committee

As part of the agency's regulatory decision-making process, an Advisory Committee (AC) may be requested approximately two to three months before the NDA action date for drug applications containing a New Molecular Entity. Otherwise, an approval letter may provide a summary of why consultation with the advisory panel was not needed to make a final determination of approval. AC meetings can provide expert advice and are intended to help guide the FDA with discussions and recommendations on any topic related to the drug application itself. The advice of the expert advisory panel is considered useful when data issues are difficult, or of significant public interest, or controversial, or if a special type of expertise is needed, or the division wants confirmation of their own findings. The panel of independent experts is considered knowledgeable in specific areas related to the drug and biologic product and may consist of representatives from academia, the community, patient advocacy, industry, or special governmental agencies.

Benefit/risk analyses

The benefit/risk evaluation is the cornerstone upon which a drug application is approved. In Phases 2 and 3 clinical studies, adverse events and efficacy are analyzed in a fixed population. Following approval, a more diverse and greater number of patients will be exposed to the drug. Health authorities take this increase in exposure, plus additional factors such as the indication, medical need, other available treatment options, prognosis of the untreated disease, mechanism of action (MOA), safety profile, robustness of efficacy data, and likelihood of appropriate use, into consideration as part of the benefit/risk equation. This is considered against alternative treatment options, as well as the prognosis of the disease if left untreated, to arrive at a final assessment. A novel MOA with a better clinical outcome has a clear advantage. However, if less is known about the MOA, the novel setting may become a disadvantage, as there may be unknown long-term risks. Drugs of the same class can be approved providing the drug meets acceptable predefined efficacy endpoints, and safety data are provided to support labeling requirements. A drug with a unique defined characteristic, in addition to the baseline expected demonstration of efficacy and safety, will further improve the benefit/risk profile. The presence of a safety signal, especially if it is not adequately characterized in Phase 3 trials, may require additional post marketing studies to evaluate the safety profile or verify the clinical benefit longer term. A Risk Management Plan (RMP) is being required by an increasing number of countries. In the US, the FDA prefers more succinct documentation known as the Risk Evaluation and Mitigation Strategy (REMS). These documents identify known or potential safety risks, and define specific actions to minimize risks. The REMS may provide additional confidence in labeling the drug to communicate the appropriate use, have a system in place to assure the likelihood of appropriate use, and, under certain circumstances, restrict availability of product use through a controlled distribution system.

Other regulations and compliance

Clinical, non-clinical, laboratory, and manufacturing processes supporting the generation of key data for regulatory submissions and commercialization of investigational drugs must follow specific guidelines often referred to as GxP. Good Laboratory Practice (GLP) describes how non-clinical studies should be planned, performed, monitored, recorded, reported, and archived. Good Manufacturing Practice (GMP) ensures that products are consistently produced and controlled to quality standards (bioavailability, safety, and stability) appropriate to the intended use, as per the product specification. Good Clinical Practice (GCP) is an international ethical and scientific quality standard, dictated by the International Conference on Harmonization (ICH) (www.ich.org/) and FDA E6 Good Clinical Practice Consolidated Guidance (1996) (www.fda.gov/ScienceResearch/SpecialTopics) to protect the rights of human subjects and provide guidance for the design, conduct, recording, and reporting of clinical studies. It also defines the roles and responsibilities of clinical trial sponsors, clinical research investigators, and monitors.

Biologic approval process

The approval process for a biological product in Europe and USA is similar to that for a small molecule. Biologic applications for well-characterized compounds are reviewed by the same CDER divisions as that of drug applications. Applications for novel or more complex biologics are known as a Biologics License Application (BLA) and are reviewed by the FDA's Center for Biologics Evaluation and Research (CBER). In any regulatory environment, there are additional complexities associated with manufacturing and characterization of the biologic; stringent process controls and inspections of manufacturing facilities are pre-approval requirements.

Different health authority approval processes

In general, global health authorities are reasonably aligned with the acceptance of study design, outcome measures, and analyses using data from multi-national studies. The traditional endpoint of composite efficacy failure criteria of acute rejection, graft loss, and death is generally accepted. Based on the number of new drugs under development in transplantation in 2009, EMA introduced comprehensive guidelines and recommendations for the development of transplant drugs in solid organ transplantation (www.ema.europa.eu/docs/). Health authorities in certain areas, such as Asia-Pacific countries, have region-specific interests in evaluating the drug experience from local clinical trial data in order to better assess any potential ethnic sensitivities. This is in addition to reviewing justifications in support of comparable evidence from the global trial database. Each potential new drug candidate, whether a biologic or drug, continues to be developed, with applications reviewed and approved by health authorities on a case-by-case basis, to establish the merits for use in organ transplantation.

Summary

The path from discovering a compound that exhibits biological activity toward a desired pathway/target, to health authority approval of a new drug requires multi-disciplinary teams to translate fundamental science into clinical treatment. Research and development activities are integrated through a complex and lengthy process, to fully characterize and optimize the candidate compound, resulting in a final drug product with demonstrated safety, efficacy, and an adequate benefit-risk profile. After one or more candidates are identified with relevant chemical properties and biological activity, initial safety and toxicology studies are undertaken. When a favorable profile is demonstrated, a clinical PoC study is undertaken to confirm mechanism of action and establish preliminary safety. A positive PoC result leads to full development of the compound, including Phase 2 trials to establish dosing, safety, and efficacy followed by robust, statistically powered Phase 3 confirmatory trials. Health Authorities in countries where

regulatory approval is being sought (e.g. FDA, EMA) interact closely with the Sponsor, using both verbal and written feedback, throughout the process to guide clinical development. Phase 1 establishes the molecule's clinical pharmacology, including the PK, PD, drug-drug and drug-disease interactions; Phase 2 demonstrates the clinical efficacy and preliminary safety of the candidate. After receiving Health Authorities' agreements to proceed, larger Phase 3 trials are conducted to provide enough data to confirm efficacy, safety, and establish the benefit/risk profile needed by them to decide on the adequacy of a product to treat patients. Upon completing Phase 3, the Sponsor submits a detailed dossier to Health Authorities for their review and decision-making. The US FDA process ranges from six months (priority review) to ten months (standard review) and usually includes a public Advisory Committee Meeting in advance of the final FDA decision on a NDA. Even after approval, ongoing pharmacovigilance monitoring programs may be volunteered by the sponsor, or mandated by health authorities, to confirm the ongoing clinical benefit and address drug safety in the intended patient population.

CHAPTER 142

Organ Specific Benefits of Transplantation: Outcomes and Economics

David A. Axelrod,[1] Mark Schnitzler,[2] and Richard Freeman[1]

Introduction

Organ transplantation is widely cited as one of the key scientific contributions of the twentieth century [1–3]. The Nobel prizes awarded to the landmark contributions of Alexis Carrel, Peter Medawar, and Joseph Murray are a testament to the innovations that have advanced the field from fiction to reality. Beginning with the first successful kidney transplant in 1954, the standard of care for end organ failure changed from symptomatic treatment to functional replacement. Thomas Starzl [4], Norman Shumway and Christian Bernard [5], and Richard Lillehei [6], extended the benefits of organ transplantation from renal failure, to end stage liver, heart, and beta-cell failure, providing millions of years of quality life to recipients around the world. Details of transplantation's rich history are outlined in Chapter 1.

Currently, organ transplantation has been established as the standard of care for advanced organ failure in modern medical systems with sufficient resources to support this complex clinical enterprise. Unfortunately, widespread distribution of transplant services remains constrained by two primary factors; donor organ supply and economic resources. For example, in the US, the waiting list for deceased donor kidneys eclipses the potential supply by more than six fold, resulting in waiting times of greater than 7 years in some locations [7]. As a result, patients experience high rates of waiting list death and prolonged requirements for mechanical organ support with its attendant inferior quality of life and complications. The international community continues to debate key questions regarding the design of the optimal allocation system for the available organs. This debate focuses on the important tradeoffs between equality of access and maximizing the efficacy of the procedure (e.g. benefit of the organ to a specific recipient) [8].

While US domestic variation in access to transplantation is generally a function of organ supply and insurance coverage, variation in care internationally reflects the degree of industrialization and economic infrastructure [9]. Populations with the greatest access to renal transplantation are clustered in Western Europe, North America, and Australia with rates of greater than 30 kidney transplants per million people. By comparison, there is no African nation above ten transplants per million people. Expansion of transplant services to developing nations has been established as the most effective way to address end stage renal disease (ESRD) in countries, as dialysis is not a viable solution given limited health care resources. However, the vast majority of the world's population still lives without access to these life saving procedures [10]. Additional consideration of cultural practice variations, insurance coverage for transplantation and national transplant administrative policy, can be found in Chapters 139, 140 and 143 respectively.

Transplantation is not immune from discussions of about its high cost. Heart transplantation remains the most expensive procedure covered by the Medicare system in the US [11].The substantial resources expended in the care of the relatively few transplant patients prior to and following transplant procedures compared with the total health care enterprise are likely to be increasingly scrutinized in light of an international effort to scale back spending on health care services. Even within the US, transplant care for certain conditions (e.g. liver transplantation for Hepatitis C) was initially removed from the benefits package for Medicaid patients in the state of Arizona [12]. While this decision was eventually overturned, this is likely to be the first of many efforts to restrict access based on cost.

While the challenges of transplantation in the first 50 years were primarily focused on overcoming immunologic and technical barriers, it is likely that the next 50 years will be dominated by addressing the allocation and economic constraints on access. Organ transplantation will increasingly exist within an organized system of care responsible for the allocation of fixed resources across a population in need. By necessity, expansion of transplant care is likely to result in the reduction of resources available for other services. Thus, an accurate understanding of factors affecting the cost and efficacy of specific organ transplants is needed to accurately demonstrate the comparative benefit of these life-extending procedures.

The primary goal of this chapter is to consider the organ specific implications of variation in donor quality, recipient severity of illness, and clinical practice patterns on the cost and benefit of organ transplant. This analysis will focus primarily on kidney, liver, and heart transplant procedures and relevant alternative treatments, as they are the most widely performed and the best studied. The intersection of organ allocation policy and transplant access with cost will also be examined as geographic differences between organ supply and recipient demand substantially influence transplant related resource utilization.

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Kidney transplantation

Background

The successful transplant of Ronald Herrick's kidney into his identical twin brother Richard in 1954 marked the beginning of successful clinical kidney transplantation [1]. The procedure extended the life of Richard by 8 years, without the need for immunosuppression. While initially limited to identical twins, the development of increasingly successful immunosuppressive regiments allowed broad application to patients with end stage renal failure, limited only by the ongoing shortage of transplantable kidneys [3].

It is instructive to contrast kidney transplantation with dialysis, which developed concurrently [1,13]. Willem Kolff pioneered mechanical support of patients with dialysis in the 1950s, initially in The Netherlands and subsequently in the US. Access to the Kolff kidney, however, was also very limited as both the machines and the expertise needed were confined to a few centers. Furthermore, there were insufficient resources in the private sector to fund this care. At the University of Washington, an anonymous panel of lawyers, physicians, clergy, and others was appointed to determine who would be placed on dialysis and who would die [14].Soon referred to as the "God Panel," these individuals initiated a system of allocation; limiting care to those over 18 and under age 45 without hypertension, diabetes, vascular disease, and who possessed an appropriate "emotional" character. The panel selected ten of the initial 17 applicants to receive care, leaving the remainder to die. The public outcry over this outcome contributed to the inclusion of support for ESRD care under the Medicare program in 1972. Unlimited by financing or organ supply limitations, dialysis became widely available to all, consuming over $24 billion in Medicare funds alone in 2007 [15].

Clinical and economic benefit of kidney transplantation

The clinical benefits of successful renal transplant have been clearly established. Compared with dialysis, transplantation is associated with prolonged survival and reduced morbidity. In the landmark analysis by Wolfe and colleagues in 1999 comparing waitlisted patients with those successfully transplanted, kidney transplantation was associated with average improvement of 10 years in overall survival [16]. Although the transplant procedure was associated with a brief period of increase risk of mortality, the risk/benefit assessment favored kidney transplantation after 106 days following the transplant. In this analysis, the greatest benefit accrues to the younger patients, who lived on average 17 years longer following transplantation.

Recent analyses have extended Wolfe's original work, through the incorporation of quality of life adjustment and accounting for survival after allograft failure [17]. This work was conducted in support of novel allocation proposals being considered by the United Network for Organ Sharing (UNOS), which are designed to maximize transplant benefit. Benefit was defined as the added survival achieved by patients who underwent transplant (including survival after graft failure) compared with that of patients who remained on dialysis. This measure, termed life years from transplant (LYFT), estimates the contribution of a particular donor and recipient combination to the overall survival impact of kidney transplantation over a ten year time horizon. These estimates were adjusted for quality of life, valuing a dialysis year as 80% of a transplant year. Under the existing kidney allocation system, the average LYFT resulting from kidney transplant varied by age from 9.6 years for candidates less than 17, to 3.5 years for those 65 and older [18]. When aggregated across all patients transplanted under the current allocation system, kidney transplantation adds an estimated 48 850 quality adjusted life years annually. Improved matching of donor and recipient characteristics, for example by placing kidneys from younger donors into younger recipients, has the potential to further improve the benefit of kidney transplant. One proposal examined by the UNOS kidney committee resulted in an annual benefit of kidney transplant that could increase the quality adjusted life years resulting from transplantation by over 3000 annually, although this was achieved at the expense of transplanting fewer older recipients [19].

The increasing benefit of kidney transplantation reflects, in part, the slowly improving rate of long-term allograft survival. Previous analyses have documented that improved immunosuppression has reduced early graft loss from immunologic causes; while, long-term kidney graft survival had remained generally static. However, recent analysis of Scientific Registry of Transplant Recipients (SRTR) data suggests a modest improvement in long-term graft survival for some disease categories [20]. Meier-Kriesche and colleagues reported that that graft half-life for deceased donor transplants increased from 6.6 year in 1989 to 8.8 years in 2005. For ECD transplant recipients, the half live has increased from 3 years in 1989 to 6.4 years in 2005. This improvement demonstrates the benefits of more recent strategies to reduce the impact of chronic calcineurin inhibitor toxicity and corticosteroid side effects, identify and treat both early and late antibody mediated rejection, and, perhaps, better address medical co-morbidities including post-transplant diabetes and cardiovascular disease. Living donor transplant continues to have the best survival, with a half-life that now exceeds 11.5 years.

Similar to the assessment of the clinical benefits of kidney transplantation, the economic outcomes for kidney transplantation must be considered in relationship to the principal alternative treatment, hemodialysis. Dialysis is a highly resource intensive and morbid treatment associated with repeat hospitalizations. Direct costs of dialysis treatment are greater than $73 000 per year per patient under the Medicare system; while private payments can be nearly double [21]. By comparison, kidney transplant is associated with a cost savings of >$200 000 per transplant over the first five years after transplantation [22]. Examination of Medicare spending, suggests that the breakeven point at which spending is equivalent is 2.3 years for patients who undergo living donor transplantation and 3.6 years for recipients of deceased donor transplant. Organ survival beyond this point results in significant cost savings for payers and improved quality of life for recipients. (Figure 142.1). The economic benefits of living donor transplants far eclipse those of deceased donor transplants as a result of the improved long-term survival [23]. Current estimates based on Medicare spending, indicates that each living donor transplant performed for a Medicare recipient saves at least $94 579 dollars. Given the improved quality of life associated with transplant compared with dialysis, the true value has been estimated as $269 319 per living donor transplant.

Impact of donor characteristics on kidney transplant benefit

The clinical success of kidney transplantation has resulted in a dramatic increase in waitlisted patients and has resulted in a significant donor shortage. The desire to treat the greater than 80 000 individuals currently on the kidney waiting list has led to broader use of donor organs with characteristics associated with reduced graft survival and a shorter LYFT benefit. Available allografts were

initially dichotomized as Standard Criteria Donors (SCD) and Extended Criteria Donors (ECD). The ECD kidney definition was based on donor characteristics that equated to relative risk of graft failure of 1.7 [24]. These higher risk grafts were offered on an expedited basis to candidates who were informed of the added risks and indicated their willing to accept such an offer at the time of listing [25]. Because ECD kidneys are associated with a greater risk of delayed graft function and early allograft loss, the benefit of transplantation with an ECD kidney is confined to waitlisted patients with significantly increased risk of wait list mortality. Through a retrospective analysis of the SRTR database, Merion and colleagues identified a population of patients for whom ECD transplant conveys a significant survival benefit: any adult candidate over 40 years old with diabetes or residence in a donation service area with waiting times greater than 1350 days [26]. Recipients not meeting these criteria did not have a significant benefit from transplantation with an ECD organ. Although this information has been widely disseminated, the proportion of patients who are offered and accept wait listing for ECD kidneys varies widely across US transplant centers [27]. Among the US kidney transplant centers, the percent of candidates meeting Merion's criteria who are listed as willing to accept an ECD kidney ranges from 0–100%. Appropriate candidates willing to accept an ECD kidney appear to have a reduction in waitlist mortality (HR 0.88 [0.85–0.91]) as predicted. However, up to 40% candidates listed for ECD kidneys actually appear to not meet Merion's criteria and may not benefit from the ECD kidney. While patients who did not meet Merion's criteria but were still listed for ECD kidneys were transplanted more quickly, their overall mortality was increased (OR 1.11 [1.05–1.18]) in comparison to similar patients not listed for ECD transplants who remained on dialysis for a longer period.

A continuous measure of kidney graft failure risk offers a more realistic characterization of the continuum of donor risks that can affect graft function and outcome [28]. Unlike the dichotomous ECD versus SCD distinction, the kidney donor profile index (KDPI) compares the relative risk from graft failure of each donor organ to the average kidney risk on a linear scale [29]. The KDPI includes an expanded number of variables, weighted using a regression equation (Table 142.1). There is a significant overlap in KDPI scores across ECD and SCD kidney donors, demonstrating the limitation of a dichotomous classification. The newly approved kidney allocation policy incorporates the KPDI. Using KDPI, the lowest risk kidney donor quintile (the 20% of kidney donors with the lowest KDPI scores) will be preferentially offered to younger, healthier recipients to maximize the number of years with a functioning kidney transplant [30]. Similarly, broader sharing has been proposed for the highest KDPI kidneys. These organs are often harder to place and if offered, are more likely to be used by aggressive centers in regions with longer waiting times. Improved donor risk assessment also offers the opportunity for better informed consent for potential recipients as it may also allow modeling to assess the individual risks and benefit for specific recipients of specific organs. Unfortunately, like other metrics of donor quality, the predictive value of the KDPI remains limited [28,31]. The c-statistic for the full model is 0.62. This value indicates that the KDPI can accurately predict longer survival among any pair of kidneys only 62% of the time, while a model with no information has a c-statistic of 0.5. This lack of predictive ability reflects the fact that significant variation in outcomes occurs because of variation in recipient factors, clinical events, and un-captured variation in donor quality.

An alternative method for effectively utilizing marginal allografts is to explicitly match donor and recipients based on age, as is done in the Eurotransplant Senior program [31]. Under this protocol, kidneys from donors greater than age 65 are offered exclusively to recipients in the same age group. This protocol increases the rate of transplantation in the elderly thereby reducing wait list mortality. Post-transplant patient and allograft survival in older recipients of the older kidneys is similar to that of older patients who received younger donor organs [31]. However, when compared to older recipients receiving younger donor grafts, utilization of the older grafts resulted in increases in the rate of surgical complications (47% vs. 28%, $P = .03$) and reduced rate of primary function (69% vs. 74%, $P = .03$).

Donor characteristics that predict decreased graft survival are also associated with an increased incidence of delayed graft function (DGF), prolonged hospitalization, and increased need for expensive induction treatments with cell depleting antibody [32,33]. A review of 4618 ECD transplants in the UNOS database demonstrated a DGF rate of 36% for ECD kidneys preserved by static cold storage [22,34,35]. This rate can be improved with pulsatile perfusion, which has been shown to reduce the incidence of DGF to 26%. By definition, DGF requires dialysis in the postoperative period resulting in longer hospital stays and higher initial costs. Because DGF is associated with a higher rate of acute rejection, use of induction therapy is believed to be beneficial.

As a result of the increased rate of early complications and decreased allograft survival, ECD kidney transplants are more

expensive to care for in both the perioperative and postoperative period. From a societal viewpoint, ECD kidney transplants remain cost saving, although the time to breakeven in cost is significantly longer than SCD kidneys [22]. Compared with SCD transplants, ECD transplants are associated with a modest increase in the cost per quality adjusted life year ($41 000 vs. $54 000). However, both transplants are markedly less than the cost of maintenance dialysis ($79 000 per QALY). The economic impact of reduced allograft quality reflects both the higher incidence of early graft dysfunction, persistent reduction in the estimated glomerular filtration rate, and early return to dialysis. Compared to kidney recipients with an eGFR >60 mL/min/1.73m^2, the average recipient with an eGFR of <30 mL/min/1.73m^2 incurred over $7000 of increased costs over the first year and more than $10 000 in increased costs between one and 3 years after transplant [36]. Declining renal function increased cost at an accelerating rate based on baseline creatinine and the rate of eGFR change over time.

The economic impact of ECD transplantation on transplant providers is more dramatic. While the outcome and savings benefits of ECD transplant accrue over time, the higher cost associated with the increased complications and early graft dysfunction/primary non-function with ECD grafts is predominantly incurred in the perioperative period. In a recent evaluation of transplant center finances, Englesbe and colleagues demonstrated dramatic erosion in transplant center profitability from 1999–2005 at the University of Michigan [37,38]. While overall reimbursement was static, the cost of transplant rose significantly. ECD donors were associated with a margin reduction of over $8000 per case, resulting a net loss for the institution. Kidney recipients experiencing DGF also resulted in substantial losses for the center ($4947/case) despite an increase in the overall reimbursement from the patients' insurers. One consequence of these financial results is to dis-incentivize the use of higher risk donors, despite their long-term economic benefit. One potential solution is to design risk adjusted payments to transplant centers that reflect the increase initial cost of caring for high-risk patients and transplanting higher risk organs.

Impact of recipient factors on cost and outcome

The clinical success of renal transplant has led to expanded application to older patients with increasing degrees of medical co-morbidities. Segev's data indicates that even patients >65 years of age gain additional life years compared with remaining on dialysis [27,39]. Over the past decade, patients older than 50 are the fasted growing cohort of newly listed recipients, within which those over 65 constitute a proportionally larger share [7]. Additionally, the incidence of diabetes has increased by 17% and hypertension related renal failure by over 30%. These factors have a direct impact on the post-transplant survival. Older patients with diabetes, who do not undergo kidney-pancreas transplant (likely type II), have the lowest expected LYFT post-transplant (approximately 4 years), a 50% decrease compared to young patients without diabetes [17]. Increasing age is also associated with a decrease in expected LYFT, due principally to age related increase risk of death with a functioning graft. Moreover, older patients have a greater incidence of complications, prolonged hospital stays, and re-admissions. However, for all of these higher risk groups, transplantation continues to offer substantial benefits in survival and quality of life compared with remaining on dialysis. Multiple single center studies have documented safe and effective renal transplantation is possible even for octogenarian patients [40].

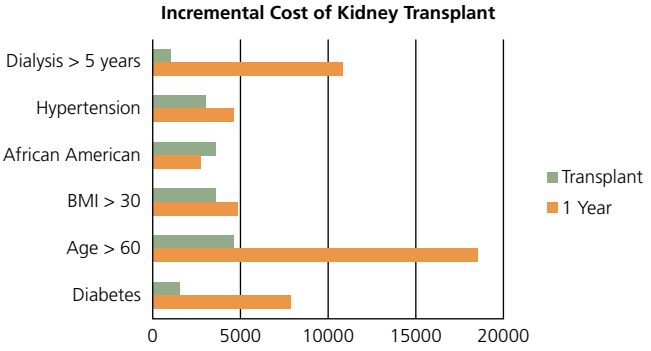

Figure 142.2. Impact of recipient characteristics on kidney transplant cost. Data from [22].

Graft survival outcomes are also closely associated with waiting time, particularly if patients are dialysis dependent [41,42]. Dialysis for greater than 24 months reduced 5 year graft survival to 58% compared with78% for recipients with less than 6 months of dialysis (P <.001) and 10 year graft survival to 29% from 63% (P <.001). Among the factors that predict short waiting times are white race, high socioeconomic status, private insurance, and donation service area of listing [43] (Figure 142.2). Ongoing disparity in organ availability, has led to a marked variability in access to transplant within the US, with median waiting times varying from less than 18 to more than 40 months after listing. Post-transplant patient and graft survival is further impacted by prelisting dialysis time which reduced graft survival markedly. Postlisting time had only a minimal impact on graft survival. Longer prelisting dialysis time reflects late referral and has been associated with lack of private insurance and non-white race. Furthermore, there are marked differences across donation service areas (DSAs) and transplant centers in the amount of prelisting dialysis time reflecting the diversity in local practice patterns and suggesting the need to increase access to early evaluation.

Changing patient demographics have had an equally profound impact on the cost of transplant care both at the initial hospitalization and over the first year after transplant [22] (Figure 142.3). Diabetes increases the cost of the transplant procedure by a mean of $1531 and one-year expenditures by $7884. Similarly, older age, longer time on dialysis, and increased body mass index (BMI) all substantially impact the cost of providing care. High expenditures have also been associated with increased degrees of allosensitization, which requires the use of expensive procedures (plasmaphoresis, intravenous immunoglobulin therapy, and cell depleting antibody therapies) [44]. These techniques, while clinically successful, can add $30 000 or more to the transplant procedure.

Summary

Renal transplantation remains one of the few medical or surgical interventions that has historically proven to be both life and cost saving. This remains true today for young healthy recipients of high quality organs. Reduction in the risk of rejection, improved management of cardiovascular complications, and development of targeted immunosuppression, have all enhanced the benefit of renal transplantation. However, changing demographics of the donor and recipient populations could potentially erode both the clinical and economic benefits of transplantation. Longer waiting times, resulting in a greater burden of co-morbid illness contribute to higher costs and reduced patient survival. Equally significant for

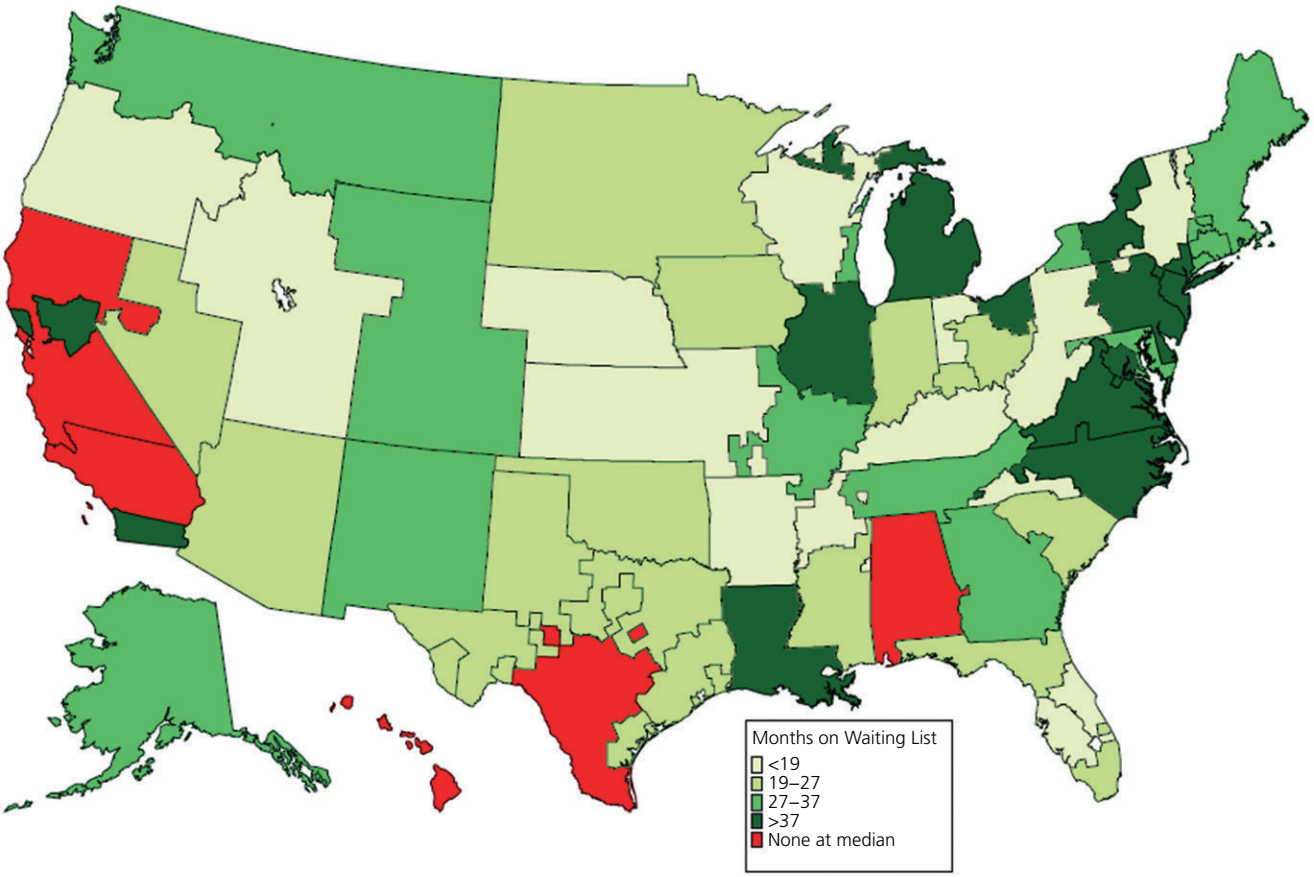

Figure 142.3. Variation in waiting time for kidney transplantation. Reproduced from [7] with permission from Wiley.

transplant centers, these factors interact with donor quality changes to substantially erode transplant center profit margins. Should the proposed kidney allocation system be implemented, there will be an increasing number of more expensive, older, higher risk kidney recipients receiving allografts with a greater risk of delayed graft function. Without adjustment in reimbursement practices to adjust for the risks and these procedures, access to transplantation services for these patients, who would still receive a survival benefit from the procedure, may become more geographically limited as centers with smaller volumes are unable to offset losses with sufficient numbers of higher revenue cases and close.

Liver transplantation

Background

The population of patients with end stage liver disease (ESLD) is rapidly growing throughout the US [45,46]. This growth is fueled by the hepatitis C epidemic, ongoing alcohol abuse, and the consequences of obesity and metabolic syndrome. Although the incidence of new hepatitis C infection appears to have peaked in the mid 1990s, as a result of long standing infection the population of patients with cirrhosis, hepatocellular carcinoma and decompensated liver failure requiring transplantation are expected to grow for at least the next two to three decades. Furthermore, the obesity epidemic has resulted in an unprecedented increase in the incidence of non-alcoholic steatohepatitis (NASH). If untreated, NASH also leads to cirrhosis and ESLD. Current estimates of proportion of the population affected with NASH range from 3–37% [47].

ESLD care is complex and multidisciplinary. Potential liver transplant candidates require a combination of medical interventions to control the manifestations of cirrhosis and portal hypertension [48]. Patients require vaccination, early and repeated radiographic screening for hepatocellular carcinoma to identify lesions that are treatable with liver directed therapy, and treatment of viral hepatitis. While not curative, some patients derive significant health benefits from strategies designed to treat the cause of their cirrhosis including: treatment of hepatitis C infection, abstinence programs to reduce ongoing drug and alcohol abuse, and aggressive weight loss regiments. Progression of ESLD disease is associated with expensive hospitalizations and procedures including therapy for hepatocellular carcinoma or variceal bleeding.

The complexity and severity of clinical care related to progressive chronic liver disease results in significant health care expenditures. Direct health spending for hepatitis C care alone exceeds $5 billion annually and is expected to consume nearly $55 billion over the next decade [49,50]. Similarly, the cost of NASH treatment has risen with the obesity epidemic, adding to the economic burden of ESLD [51]. Severity of liver failure, as measured by the Model for End stage Liver Disease Score (MELD), has been shown to correlate with ESLD mortality as well as spending. Preliminary analysis of charges incurred of pretransplant care of patients transplanted with a MELD score of 25–40 are 14× greater than for patients with a MELD score less than 25 [52] (Table 142.2). Average annual health

* $P < 0.05$.

care charges for a high MELD patient (>25) in the year prior to liver transplant exceed $230 000.

In addition to direct medical expenses, the complications of ESLD, including encephalopathy, impose additional economic burdens on patients and caretakers. Among patients with a history of encephalopathy, 87.5% are unemployed and 85% report that their disease significantly impacts their financial status [53]. Family members also reported high levels of depression, anxiety, and concerns about social support and the burden of caring for their loved ones. These concerns varied by severity of illness, and they accelerate once the patient's MELD score reaches 15 [54].

Survival benefit of liver transplantation

As a result of improved surgical and anesthetic techniques, better immunosuppression, and lower rates of infection, liver transplantation has become a very successful procedure, with 1-year patient survival rates that routinely exceed 80%. This has been accomplished despite a progressive increase in the severity of illness among patients reaching transplantation, as a result of organ allocation changes [55].

Under current allocation systems, US patients waiting for liver transplant are prioritized based on severity of illness as assessed by the MELD score. As a result of increasing waiting lists, the average MELD score at transplant has been increasing across the country albeit at uneven rates in different geographic regions [56–58].

As a result of the complexity of liver transplantation and the potential of operative complications, the benefit of liver transplantation varies significantly by severity of illness. In patients with high MELD score, death without transplantation is nearly universal, justifying the cumulative risks of surgery, immunosuppression, and less than ideal donor organs. However, for patients with well-compensated cirrhosis, the cumulative risks of transplant have been found to exceed the expected benefit. Merion et al. identified a MELD score of 15 points as the point at which the survival benefit of the transplant begins to exceed the risks of transplant and/or continued waiting [59]. As severity of illness (MELD) increases, the hazard ratio (HR) for death with a transplant compared without a transplant diminishes linearly. Comparing transplanted patients with waitlisted patients, the risk of mortality is greater for patients with a MELD score of 6–11 (HR 1.79, $P = .10$) and 11–15 (HR 1.76, $P = .04$) who receive a transplant than it is for patients who remain on the waiting list. In contrast, transplantation reduced the risk of mortality by 94% (HR 0.06, $P < .001$) for patients with a MELD of 30–39.

The benefit of liver transplant has been found to vary by diagnosis [60]. Factors associated with worse survival in multivariate models include age >42 years (relative risk [RR] 3.4), pretransplant hemodialysis (RR 5.1), and diagnosis. In a review of 4000 liver transplants performed at the University of Pittsburgh, diagnoses that predict worse survival include a history of malignancy and fulminant hepatic failure, while biliary atresia, metabolic disease, and autoimmune (PBC, PSC) conditions faired better [61]. The etiology of post-transplant graft failure reflects differences in disease etiology and recipient factors. Older recipients had a high risk of graft failure from PSC and early vascular thrombosis. In younger recipients, graft failure was more likely from recurrent disease including hepatitis C and hepatocellular carcinoma. Chronic rejection was more common among African Americans, patients with PSC, and younger recipients. Finally, graft loss from recipient death due to cardiovascular/cerebrovascular events was most prevalent in older patients and those with a history of diabetes.

Although severity of illness, as measured by MELD at transplant, has been found to correlate with post-transplant survival, it remains a very imprecise measure of post-transplant outcome [62]. Retrospective studies have confirmed that high MELD patients generally have higher rates of post-transplant graft loss than low MELD patients. In a recent analysis of European outcomes, patients with MELD >30 had over 4 times the risk of post-transplant mortality, when compared to low MELD patients. However, the c-statistic for this analysis was only 0.66, suggesting that MELD in isolation did not accurately predict post-transplant survival. Similar estimates have derived from survival models based on US populations [63]. A comprehensive review of studies evaluating MELD based models across the US and Europe, demonstrated that the C-statistic for MELD predicting post-transplant survival was never greater than 0.7. The lack of high levels of correlation between MELD and post-transplant outcome is reassuring in a MELD based organ allocation system. If high MELD patients universally experience decreased survival, allocation based on severity of pretransplant liver failure could result in lower overall utility from transplantation. In fact, increase MELD scores at transplant following the implementation of the MELD system, did not result in reduced post-transplant survival on average [55].

Impact of donor characteristics on liver transplant survival

Given the ongoing shortage of available liver allografts, expansion of the organ supply is vital to decrease waitlist mortality. The impact of donor characteristics on liver transplant outcome has been examined through registry and single center series. Feng et al. utilized the SRTR registry to define a donor risk index that identified six factors that together predicted decreased survival (older age, African American race, reduced donor height, non-traumatic cause of donor death, donation after cardiac death, and partial/split liver) [64]. Using these characteristics and two additional process factors (cold ischemic time, regional or national sharing), these

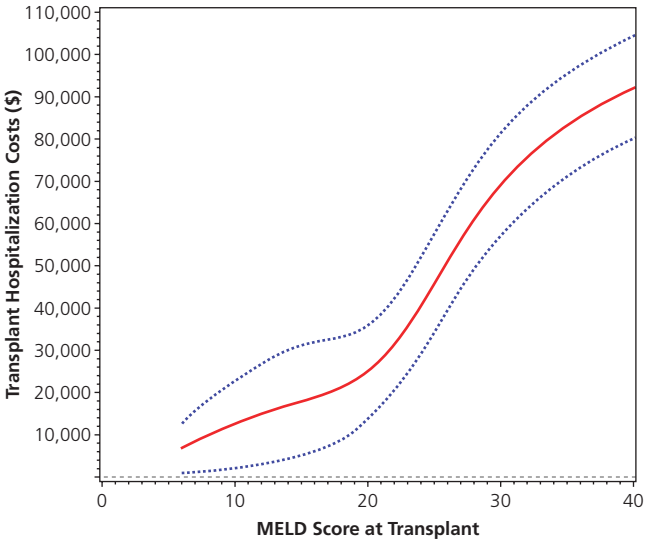

Figure 142.4. Independent associations of MELD score at transplant with transplant hospitalizations costs by multivariate spline regression. Transplant hospitalization costs at each MELD score adjusted for donor and recipient factors including status 1 transplants. Reproduced from [66] with permission from Wiley.

investigators designed a donor risk index (DRI) that can be used to compare the risk of graft failure among deceased donor liver allografts. Additional studies have examined individual factors such as donation after cardiac death to estimate the effects of the duration of warm ischemic time on the risk of non-fatal complications such as biliary strictures. By combining DRI and MELD, Schauble, Merion and colleagues, revised their initial study assessing benefit according to recipient MELD score [65]. They demonstrated that better quality organs (low DRI) conveyed benefit even at MELD scores <15, while riskier organs conferred overall benefit to candidates with higher MELD scores who are exposed to a greater risk of waiting list death.

Liver transplant economics

Liver transplantation remains a resource intensive procedure resulting in inpatient hospital charges that routinely exceed $100 000 per transplant in the US [52,66,67]. The principal cost driver for liver transplantation is patient severity of illness. It follows that the adoption of MELD based organ allocation has resulted in substantial increases in spending for liver transplantation. Retrospective analyses have demonstrated that increasing MELD score is associated with longer length of stay and greater utilization of intensive care units, dialysis, and ventilation [67]. Overall costs increase on average by $4309 per MELD point at the time of transplantation. Similarly, there is a 4% increase in average hospital length of stay per increasing MELD point [68]. The relationship between MELD and cost, however, is not linear. There is a substantial increase in the slope of the cost curve beyond a MELD score of 20 (Figure 142.4) [69].

The increased cost associated with the severity a recipient's liver failure has a direct impact on transplant center profitability. In an early examination of costs and Medicare reimbursement, hospital net income was found to decrease by $1512 per recipient MELD point [67]. These findings were confirmed in Europe, following the adoption of a MELD allocation by Eurotransplant and others [70]. In Switzerland, average transplant costs increased by over 50% following MELD based allocation, driven in part by a marked increase in the use of renal replacement therapy. Once discharged, however, pretransplant MELD is a poor predictor of costs incurred after the initial hospitalization ($P = 0.60$) [52].

The cost of liver transplant care demonstrates marked regional variation in the US, driven principally by differences in organ availability. Currently, average MELD at transplant varies markedly within the US from 21 to 35 across donation service areas [71]. The regions with the highest MELD scores (New York, California, and New England) routinely have higher costs for initial liver transplant care compared with lower MELD regions, largely due to the increased severity illness in the recipients at the time of transplantation. Currently, the UNOS liver-intestine transplant committee is considering proposals to expand organ sharing. One impact of these policies may be a reduction in the rate at which patients with higher MELD scores receive transplants, at least in some regions, as a result of improved access to organs for patients before their liver disease advances to the most severe stages. Without change to the overall organ supply, this proposed broader sharing may result in a corresponding reduction in access to organs for low MELD patients in DSAs that currently have better organ supply. The net economic impact of this shift, would be an increase in the cost of liver transplantation overall because more transplants would be performed at mid to higher range MELD scores; however, given the potential live years saved, the cost of improved access was estimated to be $17 056 per quality adjusted life year saved [66].

Donor selection has also been shown to impact resource utilization for liver transplantation. Multiple studies have demonstrated differential rates of complications and allograft function depending on the type and characteristics of the donor liver transplanted. Use of liver allografts from DCD donors has been extensively studied in single center, registry, and meta-analyses. When compared with DBD donor organs, transplantation of DCD liver grafts increased the need for retransplantation (14.7% vs. 6.8% , P <.001) and reduced 3 year patient survival (71% vs. 77%, P <.001) [72]. The major cause of morbidity in DCD transplants compared with DBD donors is the increased frequency of biliary complications (HR 2.4 [1.8–3.4]), specifically ischemic cholangiopathy (HR 10.8 [4.8–24.2]). These complications increase the need for readmissions, interventional radiology procedures, and retransplantation, raising the overall cost of transplant by as much as 25%, after adjustment for other characteristics [73].

General indexes of organ quality such as the DRI have also been found to correlate with cost, both at the initial admission and over the first year after liver transplant. Compared to low DRI organs, there was a consistent increase in the cost of care associated with the use of higher risk organs [69,74] (Figure 142.5). High DRI organs (>1.8) were associated with $33 627 in additional costs compared to low risk organs. Among the individual components of the DRI, DCD donation ($59 000), Black race ($15 000), Hispanic race ($15 000), nationally shared liver allografts ($30 000), and donor age >40 ($34 000), were associated with an increase in the cost of transplant care.

While the cost of liver transplantation care and quality of life benefits have been relatively well characterized, prior assessment of the overall cost effectiveness of liver transplantation has been limited by the lack of a comprehensive measure of pretransplant costs indexed to severity of illness and by an assessment of

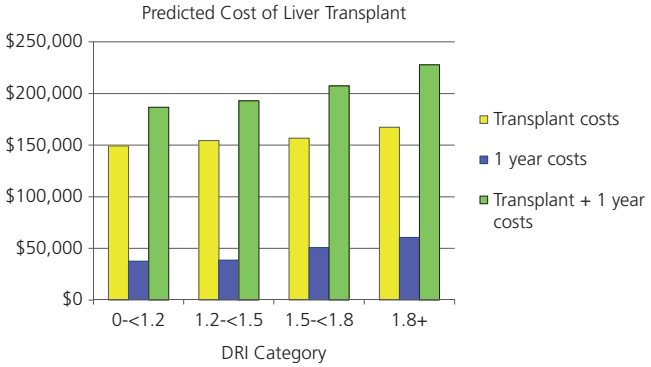

Figure 142.5. Impact of liver donor characteristics on cost of transplant. Data from [52].

the cost of patients who die while waiting of an available liver. Northrup and colleagues recently completed a Markov analysis of liver transplantation cost effectiveness comparing deceased donor liver transplantation, living donor liver transplantation, and medical management [75,76]. In this model, deceased donor LT was associated with an incremental cost of $180 804 compared with medical management. Evaluation for and potential receipt of living donor transplantation added $248 255. Overall, the deceased donor liver transplantation was associated with a cost of $35 976 per quality adjusted life year (QALY), while living donor transplant resulted in costs in excess of $100 000 per QALY. These results are in line with other recent analyses of deceased donor transplants, all of which have been based on Markov models developed from literature review to determine the cost and incidence of complications.

Summary

Continued expansion of the number of patients in need of liver transplantation is likely to result in greater pressure on the organ supply. As a consequence, patients will have greater degrees of decompensating prior to transplant. One likely consequence of increasing disease severity among waiting list patients is an increase in waiting list mortality and perioperative complications. These changes will undoubtedly increase the cost of care for patients with ESLD while waiting and at the time of transplantation. Unfortunately, current efforts to expand the donor supply (e.g. DCD allografts) appear to exacerbate rather than improve these trends. Reallocation of existing livers across a broader area has the potential to decrease wait-list mortality without a dramatic increase in the overall cost of care. As with renal transplant, further use of marginal donors is likely to be limited by financial pressures on transplant centers. Prospective adjustment of payments for complicated patients and donors is needed to ensure that the benefit of all potential organs is realized.

Heart transplant

Background:

While end stage kidney and liver failure represent important sources of morbidity and health care expenditure, their impact is dwarfed by the staggering consequences of chronic heart failure (CHF) worldwide. CHF is the final pathway of a variety of conditions including idiopathic (non-ischemic) cardiomyopathy, ischemic cardiomyopathy resulting from coronary artery disease, chronic hypertension resulting in diastolic dysfunction, acquired or congenital alular disease, and infective myocarditis [77]. Population based estimates predict a 20% lifetime incidence of CHF among individuals greater than 40 years old [76]. Although many patients with CHF can be successfully managed with medical therapy (e.g. ACE inhibitors), others develop refractory arrhythmias requiring implantable cardioverter-defibrillators (ICDs) or progressive ischemic heart disease that benefit from revascularization. Patients failing these treatments are deemed end stage and require consideration for additional interventions including cardiac transplantation.

End stage CHF currently affects between 250 000 and one-half million Americans [78]. End stage CHF is a lethal condition with a very short expected survival. Among patients assigned to the medical treatment arms of recent randomized trials of left ventricular support devices (LVADs), average mortality was 75% at one year and 87% within 2 years [79]. Advanced disease requiring chronic inotrope support, results in an average survival of 3.4 months and a 6–11% 1-year survival rate [80,81]. Currently, between 80 000 and 150 000 US patients would benefit from cardiac replacement therapy with heart transplant if the supply of organs were sufficient [82]. Unfortunately, only 2200 heart transplants are performed annually in the US. While patients who did not undergo transplant were formerly offered palliative care, the development of improved mechanical assist devices provides a growing alternative with the potential for long-term survival, albeit at great cost.

CHF is the most common discharge diagnosis among US Medicare recipients, resulting in over one million hospitalizations annually [78]. Patients are frequently readmitted for ongoing care (25% at 30 days; 50% at 180 days). Among patients with advanced (stage D) heart failure, the overall rate of freedom from hospitalization or death at one year was only 33% [83]. Spending on heart failure appears to be increasing markedly since 2000. Medicare beneficiaries with CHF spend an average of $36 216 during the last 6 months of life in 2007, a 26% increase since 2000 [84]. Despite an increasing use of hospice services, nearly 80% of patients were still hospitalized at some point in this period and 35% died in an acute care setting. Among patients randomized to the medical care arms of the LVAD trials, spending over two years exceeded $200 000, largely driven by inpatient costs [85].

The cost of medical management of CHF is expected to rise further with the deployment of advanced therapies to an aging population. For example, despite population-based analysis that suggest 15–40% of patients with advanced CHF could benefit from ICD therapy, ICD implantation remains limited and demonstrates substantial geographic variation [86]. Comparison of ICD implantation rates, demonstrated a 250% increase in rate between the lowest and high regions, which led to small increases in overall survival (64.8% to 66%). Regions with higher utilization rates had greater numbers of cardiologists and higher per capita income. Expansion of this technology could reduce the incidence of sudden death; however, at a cost of more than $50 000 per device, it is not clear that this approach is cost effective or affordable.

The clinical benefits of heart transplant

Heart transplantation offers patients with end stage heart failure the best opportunity for long-term symptom free survival. The International Society of Heart and Lung Transplantation database estimates that 5000 transplants are performed worldwide [87]. Approximately 50% of the transplants occur in centers that perform

less than 20 transplants per year, and only 5% of centers perform more than 40 transplants.

In the most recent decade, the most common etiology of transplantation for heart failure is non-ischemic cardiomyopathy (53%), followed by ischemic cardiomyopathy (38%), with the remainder composed of varied diagnoses including retransplantation, congenital heart disease, and valvular heart disease. This represents a shift in the dominant etiology leading to transplant. In North America, ischemic cardiomyopathy was the dominant diagnosis from 1997 to 2003.The shift back to non-ischemic cardiomyopathies disease may reflect changes in the management of CHF and the use of mechanical support. Other significant demographic changes comparing patients transplanted in 1992–2001 with patients transplanted 2002–2008 include a greater percentage of heart transplant recipients over the age of 65 (6.6% vs. 10.3%), a higher incidence of diabetes (14.2% vs. 22.4%), and a dramatic rise in the percentage of patients with LVADS (13.4% vs. 20.1%) and RVADS (0.5% to 3.1%).

The median survival of patients following heart transplant has steadily increased from 8.3 years in patients transplanted in the 1980s to 10.4 in the 1990s, and further in the 2000s, though an exact estimate is not possible as greater than 50% of the patients are still alive [87]. Among patients who survive at least 1-year, the median survival has increased from 11.4 to 12.9 years. Multivariate analysis has demonstrated reduced survival among patients who were maintained on preoperative mechanical support devices (RR of mortality: 2.93 for patients with temporary extracorporeal support, 1.33 axial flow LVAD, 1.22 for pulsatile perfusion LVAD). Additional risks for poor outcome include congenital heart disease, use of renal replacement therapy, prior transfusions, and ABO non-identical transplant. Among adult recipients, age has a U-shaped relationship with mortality, with higher mortality from age 18 to 30 and among patients greater than 55. Mortality rates are highest in the 30 days following transplant, largely resulting from graft failure. Long-term mortality is associated with the development of chronic allograft vasculopathy, malignancy, and infection (through the risk declines with time). Acute rejection is now an infrequent cause of graft loss or mortality.

Heart transplant donor selection remains more conservative than that of kidney or liver transplantation [88]. Only 39.2% of Eurotransplant donors were considered for heart donation and only 26% were actually used. However, the pressure to increase access to transplantation has led to limited expansion of "marginal donor" transplants. Registry data comparing transplants performed between 1992–2001 and 2002–2008, demonstrated that mean donor age has increased by 2 years, donor BMI is slightly greater (24.2 to 25.1), and prevalence of hypertension has increased. Interesting, the mean donor age is 6 years greater in Europe than in North America.

The Eurotransplant association has designed a scale to assess donor hearts [88]. Factors associated with an increased risk of graft failure include donor age, cause of death, angiographic results demonstrating CAD, ECHO cardiographic demonstration of left ventricular hypertrophy, high serum sodium, and vasopressor use. This scoring system predicted both donor discard and long-term survival. Additionally, a strong correlation has been noted between donor gender-recipient gender mismatch and outcome. Men receiving female allografts had the greatest risk of long term allograft failure [89].

Economic assessment of cardiac transplant including the impact of donor and recipient characteristics has not been evaluated to the same extent as liver and kidney transplantation. The cost of heart transplant has been compared retrospectively with surgical ventricular restoration (SVR) procedures designed to improve left ventricular function [90]. SVR procedures included coronary artery bypass grafting (CABG), mitral valve repair or replacement, and ventriculotomy with excision of scar and reshaping. A series comparing 69 SVRs with 53 cardiac transplants at Johns Hopkins demonstrated similar survival. Median hospital charges were significantly less for SVR than heart transplant ($45 506 vs. $137 679). However, the recent randomized trial comparing SVR with CABG alone (the Surgical Treatment for Ischemic Heart Failure trial) failed to demonstrate a substantial benefit of SVR over CABG alone which limits the utility of these findings [91]. The single study examining the cost effectiveness of heart transplant was performed in the pediatric population [92]. Published in 2006, the median cost of hospitalization was $221 987 for primary transplant and $285 296 for retransplant. Post-transplant costs were estimated at approximately $18 000 annually. Using survival data drawn from UNOS data, the authors estimated that primary transplant was associated with a cost per QALY of $49 679 ($44 943–$57 628) for primary transplant and $87 883 ($70 834–$103 661) per QALY for retransplantation. These estimates fall marginally under the commonly accepted cost effective threshold of $60 000 per QALY saved for primary pediatric heart transplantation. Corresponding estimates for adults are not available, but may exceed acceptable QALY thresholds given the increased cost and decreased survival potential for older recipients.

Mechanical alternatives to heart transplant:

The development of alternative treatment strategies for end stage heart failure is driven by marked limitation in access to donor allografts. Heart transplantation rates do not exceed 2–3% of the overall need for cardiac replacement therapy. Moreover, expansion of the donor pool to include living donors and donation after cardiac death as has been done for kidney and liver transplantation is not possible for heart transplantation. LVADs are now employed either as a bridge to eventual transplantation (BTT) for waiting list patients with progressive failure or as a permanent treatment for advanced heart failure [82]. Permanent implantation, termed destination therapy (DT), has been prospectively evaluated in several large clinical trials beginning in the late 1990s, leading to FDA and Medicare approval.

The Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH) trial enrolled 129 patients in 20 transplant centers who were randomized to medical management or placement of the HeartMate XV (HM XV) device [79].Entry criteria in the trials were very strict and included only patients with advanced heart failure (New York Heart Association Class IV CHF symptoms, left ventricular ejection fraction $<$25%, and either peak oxygen consumption less than $<$12 mL/kg/min or need for intravenous inotropic infusion). Enrolled patients were deemed not to be transplant candidates. The patients randomized to the LVAD group, had a doubling of their survival (25% to 52% at 1-year, 8% to 23% at 2-years) and improved quality of life. Because the HM XV, is a pulsatile device, patients required long-term anticoagulation which contributed to significant morbidity including bleeding complications, and stroke.

Recent design improvements have reduced the morbidity of LVAD implantation resulting further reduction in CHF related mortality [93]. The HeartMate II (HM II) is an axial, continuous flow pump in which a suspended impeller is used to augment

cardiac output. LVAD placement remains a complicated procedure with a significant risk of operative mortality and morbidity. The majority of the mortality associated with LVAD use occurs during the initial hospitalization for implantation, and has not improved with technology. In the DT trial comparing HM XVE (an improved version of the HM XV) and the HM II, patients had 30 day mortality rates of 28% and 26%. Long-term, however, the HM II design improved the probability of freedom from stroke or device failure resulting in improved 2-year survival compared with the earlier design (58% vs. 24%). In the pivotal trial, only 9% of the HM II recipients required pump replacement compared with 34% of the HM XVE. Based on these results, the HM II was approved by the FDA for BTT in April 2008 and destination therapy in January 2010. Additional devices are currently under development, which utilize magnetic levitation technology to eliminate the need for bearings and improve device life. Also in development are devices without external drivelines and extended battery life.

Despite the complexity of LVAD therapy, many DT patients report a substantial improvement in overall quality of life. The HM II design appears to have limited the duration of rehospitalization and improved patient rated quality of life. Retrospective analysis 30 DT patients treated at Johns Hopkins with either the HM XV or HM II for one year revealed a similar average number of admissions per year (2.9 ± 2.2) but a reduction in average stay (26.3 days for HM XVE to 6.8 days for HM II) [94]. Three patients with HM II were never readmitted after the initial procedure. Patients reported a remarkable reduction of NYHA class (3.9 to 1.4), improved exercise tolerance, and better quality of life scores.

Current indications for DT therapy under Medicare are based on the REMATCH trial criteria. Patients must have advanced heart failure, an appropriate body size to allow implantation, and a contraindication to heart transplant due to age or co-morbidities. However, the choice between DT and BTT may not be clear at the time of original implantation [95]. For instance, in the pivotal trials, approximately 20% of patients who were originally deemed not to be heart transplant candidates due to medical co-morbidities or insufficient period following a malignancy, improved sufficiently to undergo HT. Many of these patients had resolution of severe pulmonary hypertension, improved renal function, or achieved substantial weight loss. Conversely, patients treated with LVAD as a BTT, who are blood group O, highly sensitized, or at the extremes of body size (very small or very large), may never be allocated appropriate allografts.

The overall cost of treatment for the population of patients with advanced heart failure will undoubtedly increase when the constraint of the supply of viable allografts is lifted by further development of mechanical support devices. Like hemodialysis for renal failure, the US is poised to create a large population of patients with end-organ failure who have an indefinite reliance on mechanical support devices. While age was originally viewed as a contraindication to DT, recent studies have demonstrated successful implantation in patients over age 70. A recent retrospective analysis of 2943 patients receiving LVAD within the Medicare program between 2000–2006 assessed the cost and outcome among patients receiving LVAD as a primary procedure compared with those who had undergone a prior cardiac procedure (cardiotomy) in the last 30 days [96]. The mean 1-year payment for inpatient stays alone was $178 714 for patients with primary device implantation and $111 769 in patients who had undergone a previous cardiotomy. Survival in these populations was 73% at one year for the primary implantation and 76% for the postcardiotomy cohort. While the cost of the initial implantation has decreased over the past decade from $210 000 per patient to $126 000 as a result of shorter length of stays and complication rates, reimbursement has continued to climb ($188 000 in 2010 under Medicare). More recently, a Markov model of outcomes was designed using data from recent clinical trials in estimate the cost of complications following LVAD placement compared with medical management [97]. For the continuous flow pumps, they estimated a cost effectiveness ration of $198 184 per QALY. While still expensive, this is a dramatic reduction from the estimates of $802 700 per QALY for pulsatile pumps. Given the clear clinical need and recent Medicare coverage decisions, it is likely that total spending will increase dramatically, if even a fraction of the 80 000–150 000 patients with advanced CHF undergo placement of an LVAD. The return on this health care investment has been questioned given the high cost and relatively short survival of patients following VAD placement. Recent analyses have suggested that while LVAD therapy is not yet cost effective either for DT or BTT given a current standard of $60–100 000 per life year, the cost effectiveness may be improving for the pulsatile perfusion devices [97–99].

Summary

Heart transplantation remains the best alternative for patients with end stage heart failure, but its economic impact is incompletely studied. Confounding aspects of its delivery include an expanding population of elderly potential recipients, and an increasing number of non-transplant alternatives that also have substantial competing expenses. These issues will prompt significant discussions of resource utilization.

Conclusion

Therapy for end stage organ failure has evolved from symptom palliation to functional replacement with the expectation of long-term patient survival. Outcomes following transplant remain far from uniform. Younger, healthier recipients of optimal allografts have achieved levels of success previously unimaginable. This success has led to inclusion of higher risk candidates and expanded waiting lists. As a consequence, transplant professionals are forced to utilize a growing number of marginal organs, and are still unable to meet the demand.

The ability of medical professionals to meet the needs of patients with organ failure is further limited by available resources to invest in high cost services. While challenges of the 20th century were largely proof of scientific principal and technique development, the hurdles of the 21st are questions of scale and sustainability. Expanding indications and further erosion of the quality of the organ supply will increase the cost of care. However, if the constraint of the limited number of organs is removed by the development of mechanical support devices, spending will likely far exceed the capacity of even developed nations. Already, the demand for definitive treatment for end stage organ failure is orders of magnitude greater than we treat today, particularly when considered on a global scale. As we witnessed in the 1970s with dialysis for ESRD, the availability of cardiac mechanical support, unconstrained by the necessity to ration based on a limited organ supply and supported by federal financing through Medicare's approval of LVAD for DT, will far eclipse the cost of organ transplant for CHF. Choosing the appropriate recipient for new technology is crucial to achieving success.

Perhaps the greater challenge both ethically and financially is determining "who is not a candidate" given the limited number of organs and diminishing financial support for health care. Transplantation requires the assignment of a limited resource among a greater number of patients, all of who could potentially benefit to some degree. Absent the barrier of the organ supply, another metric will be needed to restrict access to beneficial treatments based on society's limited resources. In addition, absolute reliance on incremental cost effectiveness as the measure, may limit promising technologies based on today's cost and outcomes. Based on these measures, organ transplantation would never have been approved. However, over decades of perseverance, we have now established a cost effective solution for many patients with end organ failure. Balancing the opportunity to innovate with the necessity to constrain spending may be the greatest challenge facing transplant professionals for the next fifty years.

CHAPTER 143

National Healthcare Policy, Transplant-specific Statutes, and the Future of Organ Transplantation

Keren Ladin,[1] Rui Wang,[2] and Douglas W. Hanto[3]

[1] Tufts University School of Medicine, Boston, MA, USA
[2] Harvard Medical School, Transplant Institute, Beth Israel Deaconess Medical Center, Boston, MA, USA
[3] Washington University School of Medicine in St. Louis, St. Louis, MO, USA

Introduction

During the past century, transplantation and health policy in the US have evolved in ways inconceivable to previous generations. From the first successful kidney transplant performed in Boston, Massachusetts in 1954, to the first successful liver transplant in 1967, to the establishment of the first organ procurement organization (OPO) in 1968, to the 1980 Uniform Determination of Death Act, and to the first successful face transplant in France in 2005, transplantation has changed dramatically. Health policy too has evolved tremendously, from the establishment of Medicare and Medicaid in 1965 and the adoption of employer-based private health insurance, to the current healthcare climate in which healthcare expenditures exceed 17% of the Gross Domestic Product (GDP). Technology has advanced, health insurance coverage has expanded, and delivery systems have improved so that more Americans have access to healthcare than ever before. The Patient Protection and Affordable Care Act passed in 2010 will continue to reshape the healthcare landscape through policies aimed at expanding coverage, implementing market reforms, improving healthcare quality through payment incentives and other demonstrations, and containing costs. These reforms will undoubtedly affect all areas of healthcare, and have important implications for transplantation.

The purpose of most existing transplantation policy is fourfold: to protect the health of recipients and donors, to preserve dignity and protect autonomy throughout the transplantation process, to enhance efficiency in organ allocation, and to ensure equity in availability and allocation of resources. The future of transplantation policy is a broad topic beyond the scope of a single chapter. However, in this chapter, we address a number of key challenges central to the future of transplantation policy, including: implications of health reform for patients and providers, and meeting a growing demand for organs through donation incentives. Given the marked variability of specific laws worldwide, this chapter is presented from a North American perspective, with specific examples from the U.S. legal system. However, the general themes facing transplantation in the U.S. are reflected in similar legal statues in most developed countries. Additional discussions on national oversight in general, and cultural variability as it relates to transplant policy and practice, can be found in Chapters 128 and 139, respectively.

Legal and regulatory structure of transplantation in the U.S.

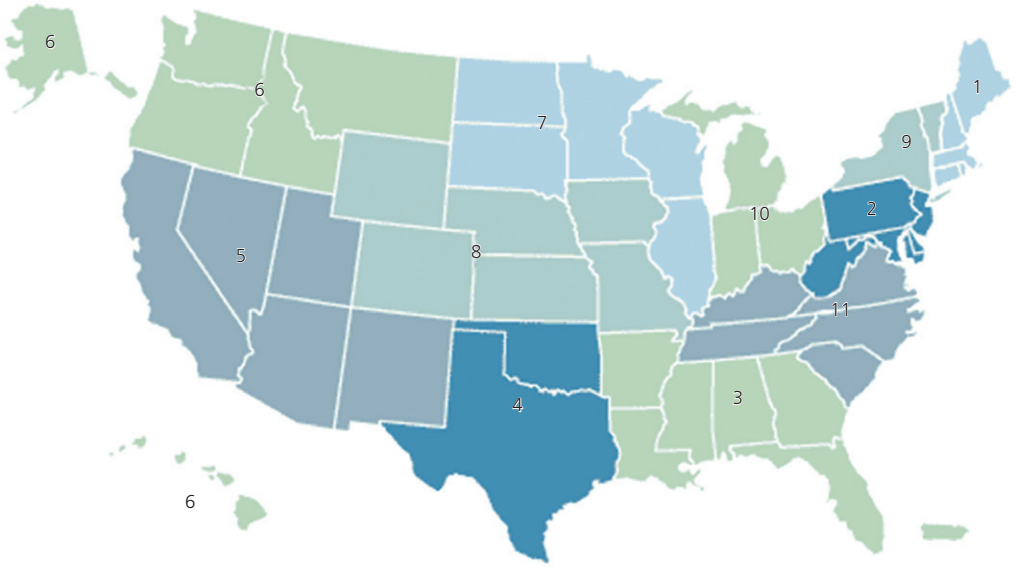
The U.S. transplant system is composed of a network of transplant centers, donor hospitals, OPOs, and ten geographic regions for the purposes of allocation of organs. Each donor hospital is situated within a single geographic region and assigned to a specific OPO (Figures 143.1 and 143.2). Organ donation and transplantation policies are dictated by the Organ Procurement and Transplantation Network (OPTN), which currently contracts with the United Network on Organ Sharing (UNOS) to frame and administer transplantation policies. The Division of Transplantation (DOT) of the Health Services and Resources Administration (HRSA) (a branch of the Department of Health and Human Services (DHHS)), provides federal oversight of the OPTN (Figure 143.3).

Significant changes in transplantation policy have taken place over more than 20 years. For example, the organ allocation algorithms have been devised and revised, criteria for donors and recipients have been expanded, and process, quality and outcomes standards have been established and enforced by the Centers for Medicare and Medicaid Services (CMS). Although some standards have been universally applied, others, such as OPO policy allocation variances, were granted regionally or on an individual basis, creating a patchwork of protocols [1]. Currently, UNOS policy efforts are aimed at reconciling variances and at amending allocation algorithms to better achieve equity and efficiency. Other initiatives involve changes to the kidney allocation rules [2], inclusion of the Kidney Donor Profile Index (KDPI) score in UNet, initiatives to prevent transmission of donor diseases, and for liver transplantation patients, tiered regional sharing to facilitate wider sharing for critically ill patients with MELD/PELD scores above 35 [3].

Despite central oversight for transplantation, laws and rules governing the transplantation process are layered and somewhat fragmented. The legal and regulatory policies that shape transplantation are framed at four levels, in order of most to least granular: UNOS policies, federal regulations, and state and federal laws.

UNOS rules provide detailed instructions and operational protocols for the OPTN, OPOs, and transplant hospitals. UNOS is a private, non-profit organization that is contracted by the OPTN to manage organ transplantation, donation, allocation, and distribution nationally. UNOS rules dictate how transplant data is

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.



The states comprising each region are as follows:

- Region 1: Connecticut, Maine, Massachusetts, New Hampshire, Rhode Island, Eastern Vermont
- Region 2: Delaware, District of Columbia, Maryland, New Jersey, Pennsylvania, West Virginia, Northern Virginia
- Region 3: Alabama, Arkansas, Florida, Georgia, Louisiana, Mississippi, Puerto Rico
- Region 4: Oklahoma, Texas
- Region 5: Arizona, California, Nevada, New Mexico, Utah
- Region 6: Alaska, Hawaii, Idaho, Montana, Oregon, Washington
- Region 7: Illinois, Minnesota, North Dakota, South Dakota, Wisconsin
- Region 8: Colorado, Iowa, Kansas, Missouri, Nebraska, Wyoming
- Region 9: New York, Western Vermont
- Region 10: Indiana, Michigan, Ohio
- Region 11: Kentucky, North Carolina, South Carolina, Tennessee, Virginia

Figure 143.1. Current UNOS Region Map *(Reproduced from http://optn.transplant.hrsa.gov/members/regions.asp)*

transmitted, stored, and disseminated between hospitals, OPOs, and UNOS. UNOS also maintains a national database. UNOS is tasked with managing the national waiting list, running the matching algorithms, and overseeing the public process for continuously monitoring and improving organ allocation. Finally, UNOS is charged with promoting awareness and education related to organ donation and transplantation.

Just as UNOS rules provide practical guidance for transplant providers, federal regulations and CMS requirements also provide concrete direction for the OPTN, OPOs, and transplant programs by clarifying key principles and procedures.

At a higher level, state laws define the donation process. These have been amended to include criteria for declaring death, donor consent requirements, composition of donor registries, the scope of public education programs, and benefits for living donors. In contrast, federal laws govern national processes such as organ procurement, allocation, transplantation, and anatomical gifts. Federal laws outline the principles and constraints at the highest and broadest level; they establish the OPTN and guidelines for OPOs. For example, the federal laws establishing the OPTN stipulate that it is responsible for coordinating, monitoring, and implementing organ transplantation policies and procedures at the national level, while OPOs, which are local or regional organizations are responsible for retrieving organs and notifying potential recipients under the supervision of the OPTN [4]. The sections below discuss in greater detail these types of laws and regulations, as they pertain to organ transplantation.

UNOS

While the federal laws and regulations dictate the framework of the OPTN and its relationship with member OPOs and transplant centers, UNOS is responsible for many of the policies that dictate the action of the OPTN and its members [5]. UNOS has been the organization that administers the OPTN through a contract with DHHS since 1986. While UNOS and the OPTN are legally distinct, they have the same Board of Directors and the same policies.

UNOS is tasked with ensuring that organs are procured and allocated as expeditiously and as fairly as possible through the Organ Center. The Organ Center matches donors with recipients and manages distribution of organs using UNet, a nationwide transplant computer system. UNet maintains information about all wait listed patients. Once the donor organ information is put into UNet, it generates a list of ranked potential recipients for each organ type. Finally, when a match is made and the potential recipient's transplant hospital agrees to receive the organ, the organ is delivered by the corresponding OPO. Importantly, UNOS monitors the matching process and ensures adherence to organ allocation policies. The UNOS Evaluation and Quality Department also

monitors OPTN members, OPOs and hospitals, and ensures that they are compliant with rules and that they can receive CMS benefits. As efforts to promote paired kidney exchange nationally increase, UNOS may play a role in coordinating a united national system.

In addition, UNOS develops policies for the OPTN. Policy proposals are developed by UNOS committees, distributed as initial briefs, and circulated for public comment.

UNOS then incorporates the public comments and submits the final proposal for approval by the Board of Director to become UNOS/OPTN policy. UNOS has 22 committees: Ad Hoc Disease Transmission Advisory, Ad Hoc International Relations, Ethics, Executive, Finance, Histocompatibility, Kidney Transplantation, Liver and Intestinal Organ Transplantation, Living Donor, Membership and Professional Standards, Minority Affairs, Operations and Safety, OPO, Pancreas Transplantation, Patient Affairs, Pediatric Transplantation, Policy Oversight, Thoracic Organ Transplantation, Transplant Administrators, and Transplant Coordinators. The Board of Directors can also submit approved proposals to the Secretary of HHS, and if approved, the policies are incorporated into

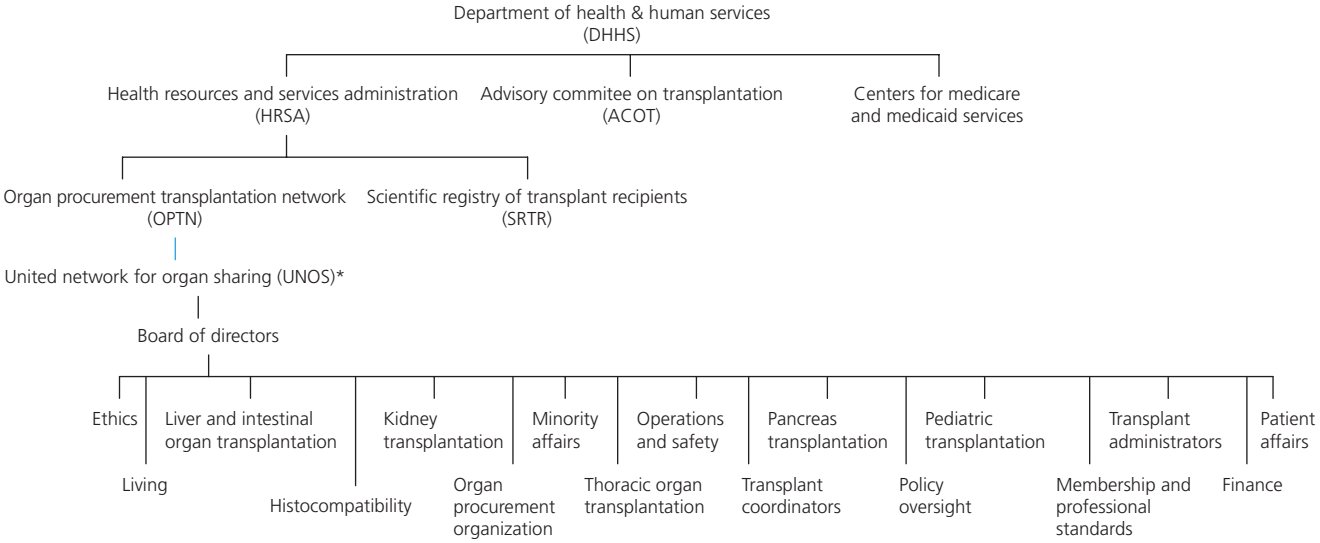

Figure 143.3. Schematic representation of transplantation oversight structure.

official regulations. Most of the committees, including the Board of Directors, are comprised of elected members representing the transplant community. These members include: transplant clinicians and coordinators, histocompatibility experts, OPO representatives, voluntary health organizations, medical or scientific member organizations, and public representatives (including transplant candidates, transplant recipient and families, living donors and families). The Board of Directors is comprised of 41 members and is responsible for overseeing the policy development for UNOS. The diversity of the committees is critical to ensure that all voices and interests present in the transplant community are heard during the policy-making process.

Finally, UNOS has an important role in maintaining public trust and promoting organ donation and transplantation. It provides information and support for patients and their families, as well as for donors. Similar to the Scientific Registry, UNOS collects and distributes information on organ transplantation from UNet. Along with the states, UNOS also promotes the need for organ donation.

Federal regulations and CMS requirements

Federal regulations

These federal laws are supplemented by federal regulations on organ transplantation in Title 42, "Public Health" of the Code of Federal Regulation 42 CFR Part 121 [6]. Effective March 16, 2000, DHHS implemented the "Final Rule", which established the organizational structure and regulatory framework of the OPTN. All OPTN members must comply with the Final Rule, and to future policy amendments added by UNOS, the OPTN, and HHS.

Title 42 Section 121

Describes requirements for transplant programs, guidelines for organ procurement, regulations of the OPTN, and allocation of organs.

Title 42 Section 121.4

Outlines policy guidelines for the OPTN Board of Directors. These include equitable distribution of organs, testing to avoid the spread of infectious diseases, reduction of inequities caused by socioeconomic status, and training of transplant surgeons and physicians.

Title 42 Section 121.5

Establishes listing requirements for an OPTN member. There are three main rules. The member transplant hospital may list a person only for a designated transplant program. The transplant hospital must place individuals on the waiting list as soon as they are deemed eligible to be candidates for transplantation. The OPTN member must pay a registration fee for each transplant candidate placed on the waiting list.

Title 42 Section 121.6

Outlines the determination of suitability of organs donated for transplantation. The OPTN member retrieving the organs must assure that laboratory tests and clinical examinations of potential donors are performed to identify any contraindications for donor acceptance. The OPTN shall have standards to prevent the acquisition of organs from HIV infected individuals. The transplant programs must also establish criteria for organ acceptance and provide them to the OPTN and OPOs.

Title 42 Section 121.7

Explains the identification of an organ recipient, allocation of the organ, and transportation to the recipient. The OPTN member must use the OPTN computer match program, with its organ specific allocation criteria, to identify and rank potential recipients. The OPTN member arranges for the transportation of the organ to the transplant hospital. If the transplant hospital rejects the organ, the OPTN member must offer the organ to the next most eligible recipient.

Title 42 Section 121.8

Establishes guidelines for the allocation of organs and performance goals. The allocation policies must be based on sound medical judgment, preserve the transplant program's right to decline an organ, be organ specific, and avoid wasting organs. Performance goals to ensure equitable allocation include standardizing the criteria for determining the suitable candidates, setting priority rankings

expressed through objective and measurable medical criteria and distributing organs over as large a geographic area as possible.

Title 42 Section 121.11

Requires the OPTN and the Scientific Registry to use a system for managing information about transplant candidates, recipients, and donors. This section establishes rules for rigorous reporting and record keeping through the HHS Secretary, the OPTN, the Scientific Registry, and the OPOs. Information must also be provided to the public on the performance of transplant programs.

Title 42 Section 121.12

Establishes the Advisory Committee on Organ Transplantation (ACOT) for opinions on proposed OPTN policies and any other issue the Secretary deems necessary.

Title 42 Section 482.90

Requires transplant centers to ensure that a prospective living donor receives medical and psychosocial evaluation, to document the living donor's suitability for donation, and to document informed consent.

Title 42 Section 482.92

States that, if a center performs living donor transplants, the transplant surgeon and at least one other licensed healthcare professional at the transplant center must verify that the donor's blood type and other vital information is compatible with transplantation immediately before the removal of the donor organ(s) and prior to the removal of the recipient's organ(s).

Title 42 Section 482.94

Requires transplant centers to write patient management policies including patient care policies for the pretransplant, transplant, and discharge phases of transplantation, and donor management policies for living donor evaluation, donation, and discharge.

Title 42 Section 482.98

Requires transplant centers to identify either an independent living donor advocate or an independent living donor advocate team to ensure protection of the rights of living donors and prospective living donors.

CMS requirements

Requirements fall into three categories: data submission, outcomes measures, and process measures. CMS final regulations (published March 30, 2007) became effective June 28, 2007, establishing conditions of participation (CoPs) for hospital-based transplant programs. These requirements focus on outcomes largely reflecting the clinical experience, quality of care, and resources available at the transplant center. Although CMS did not cede sole jurisdiction over transplant centers to the OPTN, in an effort to fulfill CMS's own role in ensuring patient safety, the additional CoP requirements are meant to complement existing OPTN rules. The data submission requirements largely mirror those of the OPTN (e.g. that 95% of all OPTN-required forms be submitted directly to CMS for all transplants within 90 days of the OPTN's required deadline). Outcome measures are meant to ensure patient and graft survival that is within the appropriate threshold (estimated by Scientific Registry of Transplant Recipient's [SRTR] data). Outcomes falling below the expected threshold will be deemed inadequate and thus may face penalties or sanctions. In addition to these initiatives, CMS instituted process measures, affecting patient and living donor selection and protection of rights, organ recovery and receipt, patient and living donor management requirements, waiting list management, detailed quality assessment and improvement requirements. Important changes include providing potential donors with complete information regarding the short and longer term risks of donation, opportunities for withdrawing from donation, and implications for future insurance coverage [7].

State laws

State laws are fairly uniform and generally govern the donation process, including: education and outreach initiatives, donor consent and donor reimbursement, donor registries, and designation of death. There are numerous state laws that govern donation. The major ones are briefly described below:

Uniform Anatomical Gift Act

The 1968 Act (and its periodic revisions) establishes criteria for donation of organs for the purposes of transplantation and donation of cadavers for medical research and education. The Act describes how the donation process might take place, designating who is eligible to donate the body after death, who has the right to use the body, and the priority list of persons that may donate the body if there is no preference against donation. The Act was revised in 1987, specifying that documentation of a desire to be an organ donor is sufficient for organ procurement (without consent of next of kin), and that witnesses are not required for documentation. The Act also mandated Routine Inquiry (questioning of patients about their organ donation preferences upon admission to a hospital) and Required Request (request from a deceased patient's next of kin in the event that donation preference was not indicated). The Act also prohibits trade of organs, which reiterates the federal ban enacted in 1984 [8]. The National Conference of Commissioners on Uniform State Laws (NCCUSL) has drafted this Act in an attempt to harmonize the law between states.

Recently, all 50 states and the District of Columbia adopted first-person consent laws (also called "First Person Authorization" or "donor designation" to force the honoring of donor intentions. First person consent laws mandate that the indication of an adult's intent to donate on any legally binding document, such as a driver's license, donor card, or online registry be upheld, even against their family's expressed wishes. This legislation frees the OPOs from securing consent from families to donate their loved one's organs, to informing the family of the patient's wishes to become an organ donor and educating the family about the process [9].

Many states have also created computerized donor registries. Revisions of state anatomic death acts allowed people to declare their intention to donate by enrolling in state donor registries, facilitating the identification of potential donors by OPOs. Elements of effective donor registries include: donor designation is considered legally binding consent; consent for tissue donation is included; individuals can enroll through a dedicated website; State Department of Motor Vehicles (DMV) enrolls donors via driver's license and ID card applications and renewals; no follow-up step required for State DMVs or online enrollment; State DMVs export donor records to registry database; organ, eye, and tissue recovery agencies can effectively access donor designations. Other initiatives include the establishment of the National Minority Organ/Tissue Transplant Education Program to increase the rate of donation by minorities, the formation of the Organ Donation Breakthrough Collaborative to raise the rate of recovery of organs in

participating hospitals, efforts to increase retrieval of organs from cardiac death donors as well as brain death donors, and provision of financial subsidies to donor families, such as contributions to funeral expenses in Pennsylvania [10]. All states recognize the driver's license as a document of gift. Finally, most states subscribe to the same ways of determining death. These states base their definitions on the NCCUSL's Uniform Determination of Death Act.

Although there is consensus among states on areas defined above, state laws diverge in some important ways. Some states have anatomical gift funds meant to increase public awareness and encourage organ donation. These initiatives will be discussed below under "Promoting Organ Donation." Some states have laws aimed at removing disincentives to donation, primarily by addressing the financial burden associated with donation. These initiatives may include: paid leave for state employees, a requirement for private employers to provide unpaid leave of absence for organ donation, and tax credits if the donor received paid leave or tax deductions for unpaid donation expenses. The location of donor laws within state codes also varies (Table 143.1).

Federal laws

Federal laws in the U.S. dictate the legal structure of organ transplantation, and are primarily found in Title 42 of the United States Code, which is called "The Public Health and Welfare" [11]. These laws frame the American system of organ transplantation by establishing the OPTN, the SRTR, defining how organs may be transferred between persons, and assisting federal employees who become organ donors. Further on in this chapter details the three sections and several subsections that together comprise the federal framework for transplantation.

Title 5 Section 6327 of the United States Code

Describes provisions for federal employees donating an organ. The Code states that an employee of any executive agency is entitled to a leave from work without a loss of pay to serve as a bone marrow or an organ donor. This supplements state laws to reduce disincentives and costs associated with organ donation.

Title 42 Section 273

Establishes the roles and structures of transplantation organizations. Section 273 requires that the OPO be a non-profit organization under the jurisdiction of the Secretary for Health and Human Services, and ensures equitable allocation and efficient procurement. OPOs must maintain connections with local hospitals and together identify and consent potential donors. Section 273 also describes federal funding for OPOs, the geographic areas that OPOs must serve, and the policies that they must follow to be reimbursed. Title 42 Section 273a outlines evaluations of the long-term effects associated with living organ donations.

Title 42 Section 274

Establishes the OPTN as the main national entity governing the procurement, allocation, and transplantation of organs. The OPTN must first establish membership criteria and medical criteria for the allocation of organs, then establish a national list of individuals requiring organ transplantation and a national system, including a telephone service, to help match organs and individuals on the list. The OPTN must assist OPOs in the nationwide distribution of organs. And finally, it must carry out studies on how to improve organ procurement and allocation. UNOS has had the contract for the operation of the OPTN since its establishment.

Section 274a

Establishes the Scientific Registry as a national database on organ transplantation that includes national transplant statistics, transplant center-specific reports, and transplant research resources.

Section 274b Establishes general provisions for grants and contracts.

Section 274c and 274d Establishes administration and report.

Section 274e

Prohibits the buying and selling of organs. Organs must be given as gifts without payment. While living donors may receive reimbursement for the costs of giving, only those who provide the necessary services involved in transplantation may receive payment. The Charlie W. Norwood Living Organ Donation Act of 2007 clarified that paired donation is not deemed valuable consideration, ensuring that criminal penalties are not applied to human organ paired donation.

Section 274f

Permits grants for the reimbursement of travel, subsistence, and appropriate incidental non-medical expenses incurred by living donors. These grants can be provided to states, transplant centers, and qualified OPOs. Section 274f-1, 274f-2, 274f-3, 274f-4 contain rules regarding public awareness, studies and demonstrations, grants, and studies and reports relating to organ donation and the recovery, preservation, and transportation of organs.

Multiple levels of oversight are needed to ensure that the transplantation system not only functions effectively and efficiently in allocating scarce resources in acute situations, but also that it upholds the ethical principles of fairness, equality, efficiency, and transparency. To this end, the rules and regulations promote organ donation as a public good while protecting individual autonomy in donation decisions. The laws protect the equal rights of citizens and prevent discrimination in organ allocation. Finally, the laws protect the dignity of human life, and prohibit commodification and trade of organs.

Implications of the Patient Protection and Affordable Care Act (PPACA)

Implications for patient care

The passage of the Patient Protection and Affordable Care Act (hereafter PPACA) (P.L. 111-148) presents the single largest piece of healthcare legislation since the passage of Medicare and Medicaid in 1965. A massive piece of legislation with many goals, PPACA has two main aims: expanding access to health insurance and limiting the growth in healthcare costs and reform the delivery system. One of the primary goals of health insurance is to improve access to healthcare for many Americans, including the 50.7 million uninsured and the 25 million underinsured [12]. To this end, the Act aims to increase insurance coverage to 32 million Americans by 2019 (16 million from Medicaid expansions, and 16 million from insurance exchanges and expansions of private insurance). The major provisions affecting transplant patients in the PPACA seek to expand coverage and reduce exorbitant costs associated with receiving needed healthcare. The Act attempts to do this in a number of ways, most notably, through insurance expansions (both private and public) and through reducing the financial burden of healthcare, especially for those who need it most and cannot afford it. Insurance expansions are a vital part of the PPACA and are achieved using a number of mechanisms. For private insurance, the Act institutes an individual mandate to purchase health insurance, establishes a competitive insurance rate for individuals and the small-group market, and requires employers to "play or pay" with respect to provision of health insurance. More important for vulnerable populations, the Act provides significant funding for Medicaid expansions and subsidies for private insurance for those qualifying. Implementation of the law is staggered, with major milestones taking place between 2012 and 2018 (Figure 143.4). We detail provisions of the PPACA that relate to insurance expansions and regulation of the insurance market further on.

Increased access to care and lower cost liability through insurance expansions and insurance regulation

Private market expansions

PPACA mandates that all citizens and legal residents buy and maintain insurance or face a financial penalty that will be gradually

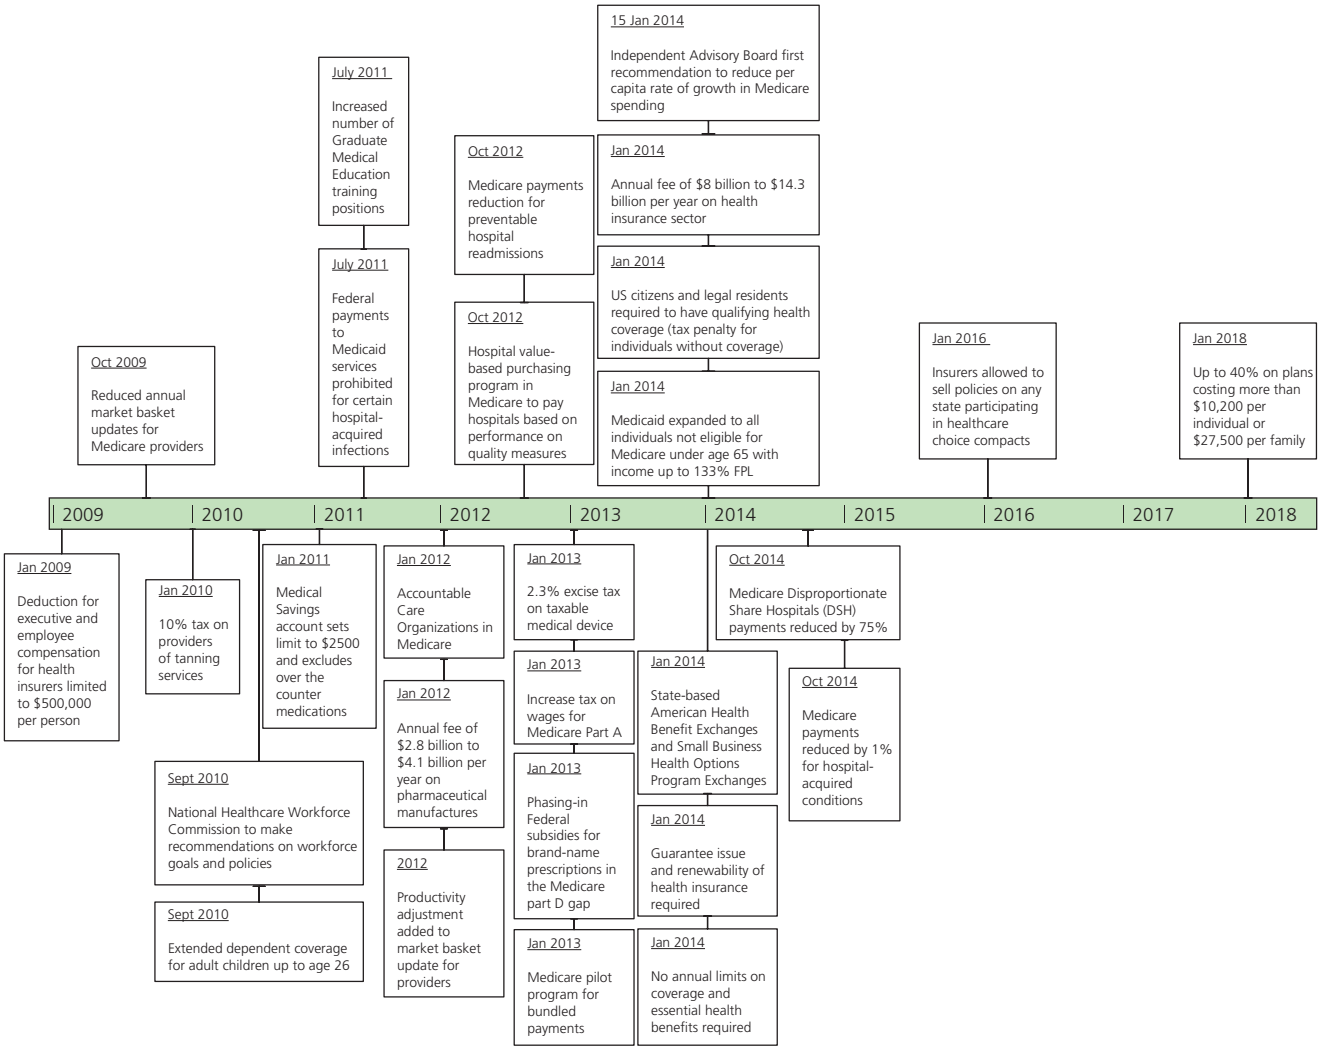

Figure 143.4. Timeline of US health reform implentation.

phased in through 2016. The individual mandate, or "minimum coverage requirement," requires that persons over the age of 18 obtain health insurance, either through their employers or through the state-run health insurance exchanges or public insurance programs if they cannot afford insurance otherwise. Starting in 2016, those who do not have insurance will be assessed at $695 per year, or 2.5% of their income, whichever is higher. Exemptions are available for those who cannot afford insurance.

The rationale for the mandate (and non-discrimination measures) is to reduce moral hazard and adverse selection in the insurance market. Although the goal is to reach universal coverage, persons demonstrating extreme financial hardship, those for whom purchasing insurance would exceed 8% of income, and those with religious objections will be exempt from the mandate. Native Americans would be exempt due to their coverage by the Native American Health Service, and incarcerated persons would be exempted as well. Although PPACA has many implications for healthcare systems and patients beyond the scope of this chapter, we focus our discussion on the potential implications for transplant patients and providers.

Mandating that individuals purchase insurance has been politically and legally controversial. Those opposed to the mandate have stated that it is unconstitutional on the grounds that the federal government oversteps its boundaries by applying undo coercion onto individuals by requiring them to purchase health insurance. In a nearly unprecedented case with three days of Supreme Court arguments, 26 states, the National Federation of Independent Business, and numerous individuals argued that the mandate interferes with personal liberties. The Obama Administration argued that the right to regulate interstate commerce is granted to Congress in the US Constitution, and that this right extends to the case of health insurance. Furthermore, lawyers on behalf of the Administration argued that the individual mandate is a necessary step to achieving universal coverage and preventing discrimination, goals sanctioned by the Constitution and government. In the June 2012, the Supreme Court delivered a final ruling in this case, upholding the individual mandate, leaving much of the law in tact. However, the Court ruled against the right of the federal government to require (or even very strongly incentivize) states to expand Medicaid programs. This may severely impede the likelihood

of achieving universal coverage while keeping the costs of premiums affordable.

On the employer side, consistent with a "pay or play" model, employers with more than 50 employees will be required to provide insurance, and a voucher to employees whose income falls within 400% of the federal poverty level. The exchanges are meant to facilitate affordable health insurance options for those not covered by employers, remedying the problem of unaffordable insurance premiums in the current small-group insurance market. To further ensure affordability for those in need, credits are available based upon income level from 133–400% of the Federal poverty level (FPL). The credits are indexed to keep total premium payment for individuals at a reasonable level (2% of income for <133% of FPL to 9.5% of income for 300–400% of FPL).

Essential benefits package

PPACA establishes an essential health benefits package (termed essential health benefits) that is mandatory for:

1 Health plans offered to individuals and small groups (both in or out of the affordable insurance exchanges);
2 All plans offered in the exchanges; and
3 Medicaid plans.

This benefits package includes ten categories: ambulatory patient services; emergency services; hospitalization; maternity and newborn care; mental health and substance use disorder services, including behavioral health treatment; prescription drugs; rehabilitative services and devices; laboratory services; preventive and wellness services and chronic disease management; and pediatric services, including oral and vision care [13]. This package covers at least 60% of the actuarial value of the benefits, restricts cost sharing to current Health Service Administration limits, and is generally inline with the employer plans. The essential benefits package, which became effective January 1, 2014, also tasks the Secretary of HHS to define and update the benefits package annually through a transparent and public process.

Public insurance expansions

Medicaid expansion is a key feature of PPACA meant to provide coverage for low-income and vulnerable populations and is likely to positively impact transplant and pretransplant patients. The Act extends Medicaid to nearly all individuals under the age of 65 with incomes up to or below 133% of the federal poverty line. For many low-income adults without children, as well as parents at 133% of the poverty line, this expansion marks the first time that insurance coverage is readily available. The federal government will pay 100% of all newly eligible Medicaid patients in financial year (FY) 2014 through FY2016, 95% in FY2017, 94% in 2018, 93% in 2019, and 90% for 2020 and beyond. The federal government also has committed additional transition-making funds to assist states that have expanded Medicaid coverage for adults at least 100% of federal poverty. Although the federal government will pay a very high share of the Medicaid costs in all states, uptake may vary. This is in part due to differences in state policies and their support for the Medicaid program, and partly due to the constrained funding environment and deficits facing many states during difficult economic times. Geographic disparities in Medicaid coverage are likely to augment existing geographic disparities in organ transplantation, and may impede transparency among patients in understanding eligibility and projecting costs associated with care. In particular, lower Medicaid uptake in states with high incidence and prevalence rates of hypertension, diabetes, chronic kidney disease, and substance abuse are likely to exacerbate geographic disparities in organ transplantation.

Relevance to transplantation

Lack of insurance has long been linked to lower rates of transplantation [14–16]. Continued access to care over the life course has the potential to improve health of patients with end-stage renal disease (ESRD) and other chronic conditions that can lead to organ failure by facilitating early diagnosis, and helping patients to better manage their chronic conditions. Furthermore, patients with "pre-existing conditions" can often feel job locked leading to underemployment because they are hesitant to transition to a different job where their insurance coverage may suffer. This is particularly true of patients who have received a transplant and are worried about losing coverage for immunosuppressive drugs. These patients often face a difficult choice between rejoining the workforce and suffering loss of coverage, or applying for disability [17]. For these persons, the promise of insurance is in and of itself, life improving by increasing jobs open to them and reducing anxiety surrounding loss of coverage. Access to insurance and a lower financial burden associated with needed healthcare is likely to solve these problems, resulting in better health and quality of life for transplant (or pretransplant patients).

Expanded Medicaid coverage should increase access to transplantation, offer coverage for uninsured patients in the post-transplant period, and reduce organ loss due to medication non-adherence. Beyond these implications for transplant recipients, expanded coverage will also likely help patients with end-stage organ failure by enhancing their access to transplant services at an earlier stage, leading to better care and more equitable access. This is likely to be particularly important for patients suffering non-kidney organ failure. Unlike patients with ESRD who receive a Medicare entitlement, patients with organ failure, such as those with chronic liver disease, are likely to benefit greatly from this insurance expansion.

Greater access to referrals and chronic care may lead to more patients being listed for transplant. This could lead to proliferation of the waiting list, accompanied by an absolute decline in outcomes for wait-listed patients (e.g. deaths on the waiting list, wait time, etc.). In this sense, increasing access to care will only remedy the situation insofar as there is care to be provided. Without a corresponding increase in the organ supply, longer waiting times and greater use of marginal organs will likely occur and increase the cost of transplant [18]. It is worth noting, however, that while this is a potential outcome, it is unclear whether increased insurance coverage will actually lead to more equitable referral and listing. Some studies suggest that, despite improved coverage, disparities remain [17,19]. Lack of private insurance (in the presence of Medicaid) has been a demonstrated barrier to receipt of quality and timely care for transplant patients [19]. As such, increased access, while alleviating some burdens, is unlikely to solve all of the healthcare difficulties facing transplant patients. Quality and performance measures aimed at providing equitable care are still needed in order to achieve this outcome.

Insurance regulations

Reducing the financial burden and uncertainty associated with paying for care is key to achieving universal coverage. PPACA has been relatively successful at limiting abusive insurance practices, including restricting access, unpredictably increasing costs, and denying claims. Together, these provisions protect the consumer

and aim to reduce the often-ruinous consequences of adverse health shocks.

Private sector reforms such as the elimination of pre-existing condition clauses will likely benefit transplant patients and increase coverage rates among this population. Similar to increasing insurance coverage, defraying the costs of healthcare may result in earlier specialist referral, improved access to transplant evaluation and listing, reduced risk of non-adherence from loss of drug coverage, and improved continuity of care. In particular, elimination of pre-existing condition clauses and annual spending caps may help patients whose immunosuppressive drug Medicare coverage is expiring and those who cannot afford to seek care.

Annual spending caps per enrollee and lifetime limits have also been mechanisms facilitating abusive behavior by insurance companies. These constraints have been particularly injurious for chronically and acutely ill patients, such as those with organ failure, whose annual healthcare costs are substantial. Limits on insurance coverage have transferred the cost burden to the patient, many of whom are forced to liquidate all assets or are driven into bankruptcy in order to pay medical bills [20,21]. For transplant patients in particular, the burden continues even after receiving a transplant. Rodrigue et al. surveyed 333 liver transplant and 318 kidney transplant recipients who were at least one year post-transplant asking whether transplantation caused financial problems, whether income had changed since transplantation, what resources they used to pay for transplant-related expenses, and what their out-of-pocket monthly expenses were. The authors found that 41% of patients reported financial problems after transplantation, and nearly half reported lower monthly income over a year post surgery than in the year preceding transplantation. Average out-of-pocket expenses were estimated to be $47 660 in 2007; this figure has likely increased since. Rodrigue et al. found that patients primarily relied upon savings and credit cards to cover these expenses, however, in the currently constrained lending environment and prolonged recession, patients are likely to face even greater difficulty in paying for care. Provisions to reduce the cost of care, such as elimination of annual spending caps and lifetime limits per enrollee are critical to transplant patients. These patients often experience extended and repeated hospitalizations in addition to requiring expensive medication indefinitely, and as a result, exceed both annual and lifetime limits, resulting in significant financial burden [22].

PPACA also allows for parents to retain their adult children on a family insurance plan up to the age of 26 and limits coverage waiting periods to 90 days. This policy took effect for insurance plan renewals beginning on September 23, 2010. As with the other provisions, this will help transplant patients (and those potentially needing a future transplant) gain and maintain access to care, in particular for younger patients between the ages of 18 and 26 years. Young adults are the age group least likely to have health insurance. This group has benefited tremendously from PPACA, as 18–24 year olds were the only age group to experience a significant increase in the percentage with health insurance, from 70.7% in 2009 to 72.8% in 2010 [23]. Despite the ongoing recession, the two-percentage point increase in coverage for 500,000 young adults aged 18–24 is largely attributable to the PPACA's provision to extend coverage until age 26. Since the fraction of insured adults was stable or decreasing among other age groups, this two-percentage point increase almost certainly reflects the effects of the extension of dependent coverage to age 26.

Effective June 21, 2010, legal immigrants who have resided in the U.S. legally for more than five years or U.S. citizens with pre-existing conditions who have been uninsured for more than six months became eligible to participate in a state managed and underwritten temporary high-risk pool, subsequently replaced by state health insurance exchanges. Premiums will be established based on the standard population and can vary no more than 4 to 1 based on age, geographic area, and family composition. The Act also limits out-of-pocket spending to $5950 for individuals and $11 900 for families, excluding premiums, (on a graduated basis) for families under 400% of the federal poverty level [24]. Up-front deductibles are limited to $2000 for individuals and $4000 per family for plans in the small group and individual market. This will help to assuage the fear of many transplant patients that a 10% or 20% co-payment or high deductibles will exclude them from access to transplantation. Many transplant recipients may be eligible for these plans. However, potentially low reimbursement rates and high costs of organ acquisition may pose a problem for providers, and may pose barriers to access for vulnerable patients [25,26].

PPACA also attempts to reduce administrative costs of healthcare and redirect health insurance costs to pay for healthcare. The Act addresses this partially through instituting a new medical loss ration and premium rate reviews. The Act requires health plans to report the proportion of premium dollars spent on clinical services, quality, and other related healthcare costs, and provide rebates for the amount of premium spent on administrative costs that is over 15% in large group market plans and 20% in individual and small group market plans. Reporting of medical loss ratio was effective in 2010, with the rebate provision effective in January 2011. Additional oversight was included to ensure appropriate increases in premiums. Significant abuses have taken place, with premiums for family coverage having increased by 50% across states, and employee annual share of premiums increased 63% between 2003 and 2010. Were premiums to continue to increase at the rate observed prior to the enactment of PPACA, the average premium for family coverage is estimated to increase by 72% by 2020, to nearly $24 000 [27]. Many insurance regulations in the PPACA are aimed at slowing premium increases, in particular a review process for examining increases in insurance premiums and a requirement for the justification of all increases. Since 2010, all increases in insurance premiums must be approved by the states.

It is likely that these provisions will reduce the cost of care for transplant patients and will increase access, particularly for young patients who may have been uninsured. It will likely also improve quality of life, as young patients may feel more freedom since they will be able to relocate or pursue a different job without fear of losing insurance. However, quality of care and choice of provider may suffer somewhat. Transplant services are often financed as a "carve-out" from medical/surgical premiums because of their high cost and need for highly specialized services. Given heightened scrutiny of the fraction of premium dollar spent on clinical services and restrictions in increasing premiums, it is possible that transplantation coverage may be somewhat limited. Ultimately, transplantation coverage is largely contingent upon the health insurance market (because carve outs are financed by reinsurance) and regulations that more directly relate to transplantation. Depending on the level of reimbursement, plans offered to individual and small group markets and the high-risk pool may restrict choice, reducing care options for transplant patients.

Immunosuppressive drug coverage:

Although kidney transplantation has proven to be superior to dialysis for improving patient survival rates and quality of life and is

cost-effective, its long-term success depends upon ongoing treatment with immunosuppressive drugs. An initial kidney transplant costs Medicare an average of $110 000. Immunosuppressive medications cost $15 000 to $20 000 annually. This is compared to the annual cost of $75 000 for dialysis treatment in the case of premature transplant failure as well as the cost of repeat transplantation. The Medicare extension of funding for immunosuppressive medication for kidney transplantation from one to three years reduced costs and income-related disparities in outcomes [28]. Economic analyses confirm that providing lifetime funding for immunosuppressive medications would lower overall costs by $200 million annually [17]. In addition, long-term survival rates are higher in countries that provide continued immunosuppression. Furthermore, patients experiencing premature transplant failure due to loss of immunosuppression must revert back to dialysis, thereby experiencing poorer outcomes at greater expense. Premature transplant failure is the fifth leading cause of initiation of dialysis in the US [29]. The 2-year mortality rate for patients whose transplants fail is worse than the mortality rate among patients with a functioning transplant and even that among age-matched patients who have never received a transplant.

Transplant failure can result directly from non-adherence to immunosuppressive drugs, which may be due to inability to pay. This link is difficult to confirm using prospective research since transplant recipients are unlikely to admit to poor adherence [30]. However, in a 2010 survey, more than 70% of US kidney transplantation programs reported that their patients had an "extremely serious" or "very serious" problem paying for immunosuppressive medications, and 68% reported deaths and graft losses attributable to cost-related non-adherence [29]. Ensuring lifetime access to these medications with kidney transplants would save lives and reduce the total cost of treating patients with ESRD [29].

Prior to PPACA, in the US, Medicare rules end immunosuppressive drug coverage three years after kidney transplantation for all Medicare patients below 65 years of age or those with work-related disabilities. Upon returning to work and losing disability status, many transplant recipients also lost coverage of their medications. The Comprehensive Immunosuppressive Drug Coverage for Kidney Transplant Patients Act of 2011 is a proposed amendment to the Social Security Act that would grant lifelong coverage of immunosuppressive medications to all kidney-transplant recipients in the US [29]. Currently, lifetime coverage of immunosuppressive drugs is thought to be afforded largely through various provisions in PPACA. Access to immunosuppressive drugs is provided through the high-risk pool (Pre-Existing Condition Insurance Plan), as well as through private insurers who can no longer exclude enrolled patients or institute annual spending caps or lifetime limits. The Act also prohibits discriminatory practices such as exclusion of pre-existing conditions and the lifetime caps on spending. These practices, in particular, have negatively affected transplant patients because they have impeded their ability to receive care, including vital coverage for immunosuppressive drugs beyond the 3-year period covered by Medicare following transplantation.

PPACA also includes Medicare reforms that will result in better drug coverage by closing the "donut hole." Effective starting in 2010, Part D enrollees with any spending in the "donut hole" (coverage gap) will receive a rebate ($250). Subsequently, in 2011 enrollees with spending in the coverage gap will receive a 50% discount on brand-name drugs (provided by the pharmaceutical industry). Medicare coverage is phased in beginning in 2011 to 2013 for generic and brand name drugs, respectively, purchased in the gap. Part D enrollees will ultimately be responsible for 25% of the cost of drugs (brand-name and generic) purchased in the gap by 2020. PPACA also reduces the catastrophic coverage threshold by 2019. Despite these policies, patients may still have outstanding expenses due to the high costs of immunosuppressive drugs, and as such, a special provision addressing the need for full coverage of immunosuppressive drugs may still be needed.

Coverage for living donors

PPACA may also positively impact the health of living donors post donation, as well as potential donors hoping to donate. High rates of no insurance coverage, the transient nature of insurance, and restrictions on pre-existing conditions may have served as deterrents for donation. Lack of follow-up care for living donors may have also been a deterrent. Lack of coverage for long-term donor follow-up may be particularly important due to the relaxing of certain donation criteria (e.g. mild hypertension and higher BMIs) The long-term consequences of donation is unclear for these donors, and coverage for comprehensive follow-up may be both important to their physical and mental health. Insurance expansions may also help living donors, whose long-term follow-up, at least within the 2-year period following transplantation, will be covered by Medicare and is likely to be covered under private insurance as well. A recent study by Kher et al. examining reimbursement rates for donor follow-up at a single center, suggests that private insurance and Medicare reimburse follow-up for donation at rates similar to reimbursements for recipients [31]. This suggests that insurance coverage for donor follow-up should not pose a significant barrier to care.

Importantly, given that people could become donors at any time, increasing coverage, expanding preventative health services and encouraging healthy behaviors is likely to increase the pool of potential donors. This is especially true for previously uninsured populations, many of whom are young and healthy, who may not have considered donation due to lack of insurance. The Act promotes preventative care by eliminating cost sharing on recommended preventive services delivered by Medicare and all new insurance plans; providing an annual free wellness visit under Medicare, contributing more federal Medicaid matching funds to states that offer evidence-based prevention services and requiring coverage of tobacco cessation services for pregnant women in Medicaid; and promoting community preventative services by supporting grants [32].

The transplant community, including professional societies, have embraced living donation and have advocated for supporting living donors. The American Society of Transplantation (AST) has publicly called for policies providing health insurance to donors to address the short- and long-term effects of living donation [33]. Although the recipient's policy typically covers donor-related expenses for a limited time before and after transplantation, the donor is exposed to significant risk by not being guaranteed his or her own insurance. First, the long-term health consequences of donation are not well understood, and as a result, donors may experience a health event related to donation after the recipient's insurance coverage period has expired. Second, if the recipient dies or loses insurance, the donor will also lose coverage. This could result in substantial medical expenses, often totaling thousands of dollars. Prior to PPACA's provision banning exclusions due to pre-existing conditions, donors suffered a further risk that any future medical need might not be covered if it could be tied in any way to donation. With great uncertainty related to future access to medical

care and potentially high out of pocket expenses, living donors might be dissuaded from undergoing surgery. Universal coverage for donors, granted either through the PPACA or through a separate tailored provision, is likely to help alleviate fears surrounding donation and may encourage donors to come forward.

Implications for transplant providers

Reimbursement

Expanded Medicaid coverage through PPACA is likely to increase the number of individuals with access to transplant services (both pre and post-transplant). Furthermore, if this insurance expansion encourages living donation by making living donors more inclined to donate after being insured, then PPACA may indeed increase the number of transplants. As insurance coverage expands though Medicaid and state-run health exchanges, reimbursements for specialists, in this case transplant centers, will likely decrease. This shift in payer mix may lead to revenue deficits, particularly for centers in large, urban regions with long waiting times and those that use a higher proportion of expanded criteria organs [34].

PPACA establishes an Independent Payment Advisory Board (IPAB) to advise the President and CMS using cost-effectiveness analysis. Although this is in line with PPACA's mission to improve efficiency and decrease waste in healthcare, many specialists and surgical organizations have voiced their concern about the potential of President-appointed IPAB to influence Medicare coverage decisions. It has been widely suggested that the IPAB is likely to increase funding for primary care and decrease reimbursement of specialist care [35]. This means transplant and potential transplant patients may have better management of chronic disease and potentially earlier referral and better screening. However, it likely will reduce access to specialized transplant services at the same time. Although the need for Disproportionate Share Hospital (DSH) payments as offsets is debatable depending on the rate of insurance uptake among the uninsured and underinsured and the reimbursement rates offered by safety net payers, Medicare generally provides DSH for large academic medical centers that treat an indigent patient population. Under health reform, hospitals are likely to lose 75% of DSH. Finally, the complexity of transplant patients, infection and readmission may be more common than in other patient populations. This may be construed as "poor quality care," defined by Medicare as high rates of readmission and infection, resulting in lower reimbursement. One way to help both outcomes and reimbursement is through better risk adjustment and enhanced integrated care (perhaps through Accountable Care Organizations).

Restrictions on insurance premiums may lower reimbursement and limit patient choices. These restrictions may increase the market power of large networks, which may limit access to certain transplant centers and may also reduce reimbursement for transplant providers. Thus, restrictions on the overall cost of insurance plans may potentially increase the patient base, but restrictions on high-cost, high-benefit plans will likely decrease reimbursement and choice [18].

Quality improvement

PPACA also addresses stabilization of the sustainable growth rate, creation of medical homes, shift to episode of care reimbursement (already familiar in transplantation), and development of comparative effectiveness research in an attempt to improve the delivery system and enhance healthcare efficiency. The Act also attempts to improve quality by incorporating pay-for-performance incentive mechanisms. Many studies have demonstrated that physicians and hospitals are responsive to such incentives, and this model has been used successfully across a number of clinical domains [36–38]. In PPACA, two provisions aimed at integrating pay-for-performance became effective in 2012: the first provides incentives for the formation of accountable care organizations (ACOs), and the second links payment to quality outcomes, supplying hospitals with financial incentives to improve quality of care.

Accountable care organizations

ACOs promote care coordination and quality improvement by focusing especially on disease prevention, disease management, reducing redundancy, and ultimately reduction of unnecessary hospital admissions. Cost-saving is achieved if ACOs provide high-quality care at lower costs to the healthcare system, in which case the ACOs receive a fraction of the costs saved.

ACOs encourage a disease management approach to healthcare delivery, by linking providers and provider payment (ambulatory, hospitals, nursing and ancillary care facilities) in a defined way to an episode of care. The expectation is that greater communication and ownership over the patient experience will enhance quality care and decrease costs. In many ways, transplant care is a pioneer in this approach, since many of the services surrounding transplantation are integrated and involve a number of different specialties, centers, and routine follow-up care. Transplant centers have acted essentially as medical homes, integrating a number of medical and surgical subspecialties, and even incorporating emergency department visits for patients under their care. Bundled payments, which often accompany discussions of ACOs, will be familiar to transplant centers that have been reimbursed in this way for some time. Provisions aimed at developing the Medical Home Care Models and expanding the Federally Qualified Health Centers may also serve transplant recipients in providing long-term care [34].

The American Society of Transplant Surgeons (ASTS), although supportive of developments proposed in the ACA, suggests that CMS take special care to ensure that Medicare and ACO patients with expensive healthcare needs, such as transplantation, receive proper information about their care options and are not dissuaded from pursuing transplantation [39]. ACOs may have to overcome disincentives to provide such information, particularly if a transplant center is not included in their network.

Pay for performance

The second main quality-related provision incorporates pay-for-performance (P4P), which entails "linking payment to quality outcomes", and offers hospitals financial incentives to improve quality of care. The provision requires public reporting of hospital performance, beginning with measures related to heart attack, heart failure, pneumonia, surgical care, and nosocomial infections. Public reporting requirements will extend to discharges effective October 1, 2012.

P4P has two main components: the first rewards physicians for outcomes meeting a quality threshold, and also often for demonstrating improvement. The second component involves public reporting of outcomes in an effort to increase transparency and information in the market, and facilitate consumer-driven demand. The provision is structured at the hospital or group level, meaning that for physicians individual returns are not directly linked to individual effort. Instead, physician returns depend on the group or hospital quality improvement. Such a structure is risky in that it creates a "free rider" problem, where certain physicians can experience benefits without improving their own quality.

The structure of the incentives is also important. Rewarding absolute quality thresholds can have negative consequences, such as discouraging physicians with complex patients. Without proper risk adjustment, this could exacerbate disparities and lead to fewer physicians accepting patients with severe medical needs. In such a system based on absolute performance, low performers, even those demonstrating significant improvement, would not receive any rewards. In a system rewarding improvement, high performers would not be incentivized to maintain high performance because they would not be rewarded for that. Risk adjustment is crucial, as are both relative and threshold performance incentives. For transplant physicians, this is of particular importance given the range of patients and geographic variation in availability of standard criteria organs. Furthermore, given the importance of equity to transplantation policy, special attention should be paid to incentives and their potential negative consequences.

PPACA is also focused on process-based measures. Process of care measures are intended to improve how care is being delivered, not simply the outcome. Incorporating process measures somewhat mitigates the gaming problems associated with outcome-based quality measures. The timing of incentives (end of the year versus continuous) as well as the relative size of incentives (at least 5% of the capitated salary) will also be important [40,41]. P4P incentives must be carefully structured and implemented. It is currently unclear with these incentives, as they are included in PPACA, will achieve their desired outcome.

Meeting a growing demand for organs through donation incentives

A third area of developing transplantation policy involves stimulating organ donation through incentives and increased public awareness. The current waiting list for kidney transplants has more than 85 000 people, but donated organs allow only about 17 000 transplants each year. Approximately 4500 people die each year while waiting for a kidney transplant, and an additional 33 000 join the list [10]. The growing number of patients on waiting lists is increasingly disproportionate to the supply of donor organs. While the use of organs from donors dying from cardiac death has increased over the past decade, with such donors now exceeding 10% of the total, UNOS policies intended to facilitate the use of expanded criteria donor kidneys (making a second transplant waiting list available for kidneys recovered from older and sicker donors) have met with mixed success [1]. Currently, about 60% of kidney transplants come from deceased donors. Forty percent of kidney transplants are from living donors, with the proportion of living donors increasing in recent years [42].

Legislative attempts to increase organ donation aim to increase the supply of potential deceased donors, to increase the pool of potential living donors, and to improve donor conversion. The transplant community and the US government overwhelmingly support the notion that organ donation (especially living donation) should rely on volunteerism and altruism. This is deeply rooted in legislation in the Uniform Anatomical Gift Act (UAGA) and in Section 301 of the National Organ Transplant Act (NOTA) of 1984. NOTA states that, "It shall be unlawful for any person to knowingly acquire, receive or otherwise transfer any human organ for valuable consideration for use in human transplantation" [43]. In this context, "valuable consideration" has been interpreted as a conditional transfer of money or valuable assets between the recipient, donor, and potential broker [43]. In particular, the law serves to prohibit coercion of inducements of any kind for donation, and explicitly bans the purchase or sale of organs. Policies related to stimulating organ donation can be categorized by the intended benefactor: either living or deceased donors; and, by mechanism: financial incentives, material compensation, non-material compensation. The structure and size of potential financial incentives also vary significantly, with some favoring significant market regulation and non-material compensation, compared to others that promote an open and unregulated market for organs where the price of an organ would be regulated solely by the law of supply and demand.

Conflicting views exist about whether financial compensation for organ donation would alleviate the organ shortage and increase supply. Some have argued that the presence of financial incentives would decrease the pool of potential donors because people would no longer feel ethically compelled to donate, viewing the exchange instead as a transaction. In his "Open Letter" to Senator Arlen Specter of Pennsylvania asserting his concerns related to his proposal for the Organ Donor Clarification and Anti Trafficking Act to amend NOTA, Gabriel Danovitch details numerous concerns related to providing incentives, integrating ethical concerns of commodification (detailed in the Declaration of Istanbul) as well as practical concerns. Of note, Danovitch suggests that in countries where financial incentives or payment for donation are introduced, funded donation crowds out voluntary donation. Danovitch cites examples of Israel, Pakistan, and Iran, among other countries which demonstrate this effect [44]. This line of opposition is well established. Policy makers, including several senators and professional societies such as the National Kidney Foundation, along with religious organizations vehemently and successfully lobbied to exclude pilot programs examining the financial incentives for organ donation in the Organ Donation and Recovery Improvement Act (S 573), introduced by Senators William Frist and Chris Dodd [45]. Opponents of financial incentives caution that financial incentives could reframe the way the public views organ donation from an altruistic behavior to a normal market transaction. This could lead to (and has in some countries) lower familial and altruistic donation rates.

In contrast, proponents of financial incentives suggest that the distinction is not so stark, and that some level of financial incentives may be both ethical and effective in promoting donation. A common ethical argument supporting financial compensation is that all other stakeholders taking part in the transplant process are compensated and paid for their participation, except for the donor. Other ethical considerations include utilitarian arguments that suggest that everyone would gain from a shorter waiting list and that many lives would be improved by increasing the supply of donors. Some ethicists have gone so far as to argue that restricting the ability to sell one's organ unfairly constrains autonomy, and in particular harms those of low socioeconomic status who have most to gain from such a transaction [46]. Matas, amongst others, has called for a regulated system that would compensate living donors. He suggests that the system would have six key elements to be administered by OPOs:

1. ban on donor-recipient contact;
2. donor compensation that includes a 1-year $1 million term life insurance policy and guaranteed lifetime healthcare;
3. reimbursement of travel for donation;
4. fixed compensation for leave from employment;
5. fixed payment or tax break;
6. a payment of $500 for completing follow-up evaluation 1-year post-transplant [47].

He argues that such a system would not undermine altruistic donation, but rather would fairly and ethically supplement this pool with more donors who would be adequately compensated and incentivized, without being coerced.

More recently, many professional transplant societies have come to adopt the view that a middle ground might be most appropriate, both ethically and practically. In 2002, the ASTS sponsored a panel of ethicists, OPO leaders, and transplant physicians and surgeons to consider financial incentives. The panel supported efforts to promote a pilot project to examine the effects of funeral reimbursements or charitable contributions in the name of the donor, as a means of expressing appreciation to the donor and donor family [48]. Roth found sustained support for a certain level of compensation among the ASTS membership, stating that, "in an informal poll following a debate on the subject at a recent meeting of the ASTS, a majority of those polled expressed a willingness to contemplate a trial or demonstration project involving compensation for organ donors" (personal communication, Arthur Matas, January 27, 2007) [49]. Other professional societies, including the AAKP, the PKD, the AST, have also expressed support for various types of supports for living donors, but the enthusiasm for financial incentives per se varies significantly [50–52]. Importantly, the politically powerful American Medical Association (AMA) also joined the chorus of support, urging Congress to amend the NOTA of 1984 to permit demonstrations incorporating financial compensation for families of deceased donors. The UNOS/OPTN have also recently called for study of potential financial incentives for organ donation [53].

The political and policy debates have become increasing complex as the organ shortage has grown and the number of stakeholders and number of proposed incentives has proliferated (Figure 143.5). The policy debate surrounding financial incentives often conflates both living and deceased donation, intensifying concerns about exploitation and extending them even to discussions of deceased donation where they may not be relevant. Five main approaches have been suggested for increasing donation using incentives: payments, tax benefit, funeral reimbursement, and charitable contributions on behalf of donors, and medals honoring donors.

Federal legislation

In 1999, the Organ Donor Leave Act (PL 106-56) was passed, granting federal employees paid leave to serve as organ donors. The law grants federal employees up to 7 days for serving as bone marrow donors, and up to 30 days for serving as organ donors [54]. Following a spirited debate surrounding financial incentives and potential commodification of organs, federal legislation, originally introduced by Senators William Frist (R-Tenn) and Christopher Dodd (D-Conn) was passed. In 2001, two bills were introduced in Congress, one proposed offering a $10 000 tax credit for deceased donation and another a $2500 tax refund for living or deceased donation [55,56]. The Organ Donation and Recovery Improvement Act ((PL 108-216), signed into law in 2004, promotes organ donation by allowing reimbursement of travel and subsistence expenses for living donors, supports long-term follow-up of living donors by facilitating a registry, and provides grants to states and public entities [57]. Importantly, this legislation did not overturn the 1984 NOTA ban on buying and selling of organs. Efforts to expand incentives for donation without providing additional financial incentives led to the enactment of two laws in 2007 and 2008. The Charlie W. Norwood Organ Donation Act (PL 110-144) in 2007 [58] paved the way for paired donation, clarifying that it is not considered valuable consideration for purposes of Section 301 of NOTA. The Act also calls for an annual report detailing advancements in understanding the long-term health impacts of living donation. The Stephanie Tubbs Jones Gift of Life Medal Act [59] (PL 110-413) grants the DHHS authority to award organ donors a National medal in honor of their donation.

State legislation

Financial incentives for living donation

States have enacted a set of financial incentives as well. Despite the prohibition of financial compensation for donors stated in the NOTA of 1984, many states afford living donors some benefits to offset the costs and physical or emotional burden of donation. Beginning in 2000, Wisconsin, followed shortly by Maryland, introduced a law that instituted policies granting state employees 30 days of paid leave following organ donation. In other states, this law often is extended to local government employees as well as public school teachers. Some states have expanded this initiative, adding a requirement for private employers to provide unpaid leave of absence for organ donation. Many states further incentivized living donation by passing a second law that grants donors up to a $10 000 tax deduction to compensate costs associated with donation. The actual tax deduction depends on the donor's marginal tax rate. This varies between states and also depends on income and filing status. The actual monetary value of this deduction depends on the individual's state marginal tax rate, which depends on the state, as well as one's income and filing status. As Wellington and Sayre note, "a single filer in Wisconsin with an adjusted gross income of $25 000 faces a relatively high state marginal tax rate because as one's income increases, the value of the person's state earned income tax credit decreases. However, Minnesota's tax system results in more wealthy individuals facing a higher marginal tax rate [60]". While these examples demonstrate that the value of this benefit varies substantially, in all cases the benefit is relatively small (less than $1500). The transplant community has also called for lifetime insurance benefits for living donors. The ASTS, the AST, and the Declaration of Istanbul have also proposed legislation to provide federally funded lifetime insurance benefits for living donors [48,61]. Although specific guarantees have not been made for living donors, provisions in the PPACA to expand coverage may be enough to encourage donation, likely achieving much the same result as a discrete provision targeting organ donors.

Financial incentives for deceased donation

Efforts to pass legislation related to financial incentives for deceased donation have been less fruitful. According to a 2005 Gallup poll, 95.4% of Americans reported that they "support" or "strongly support" organ donation [62]. Despite this widespread support, less than half of Americans have registered as organ donors [5]. Proposed financial incentives for deceased donation include payments to the donor's family to defray funeral costs or support designated charities as well as tax credits [63]. In 1999, the Pennsylvania Department of Health proposed offering $300 to families of organ donors to defray funeral costs [60]. However, despite multiple revisions and negotiations, the law was never enacted due to concerns about violating NOTA.

The idea of a "futures market" has also been proposed, whereby individuals would receive payment in exchange for the promise of donating their organs after death [64]. As Howard and others have noted, while the concept of a "futures market" is an interesting thought experiment, it would likely require financing out of general

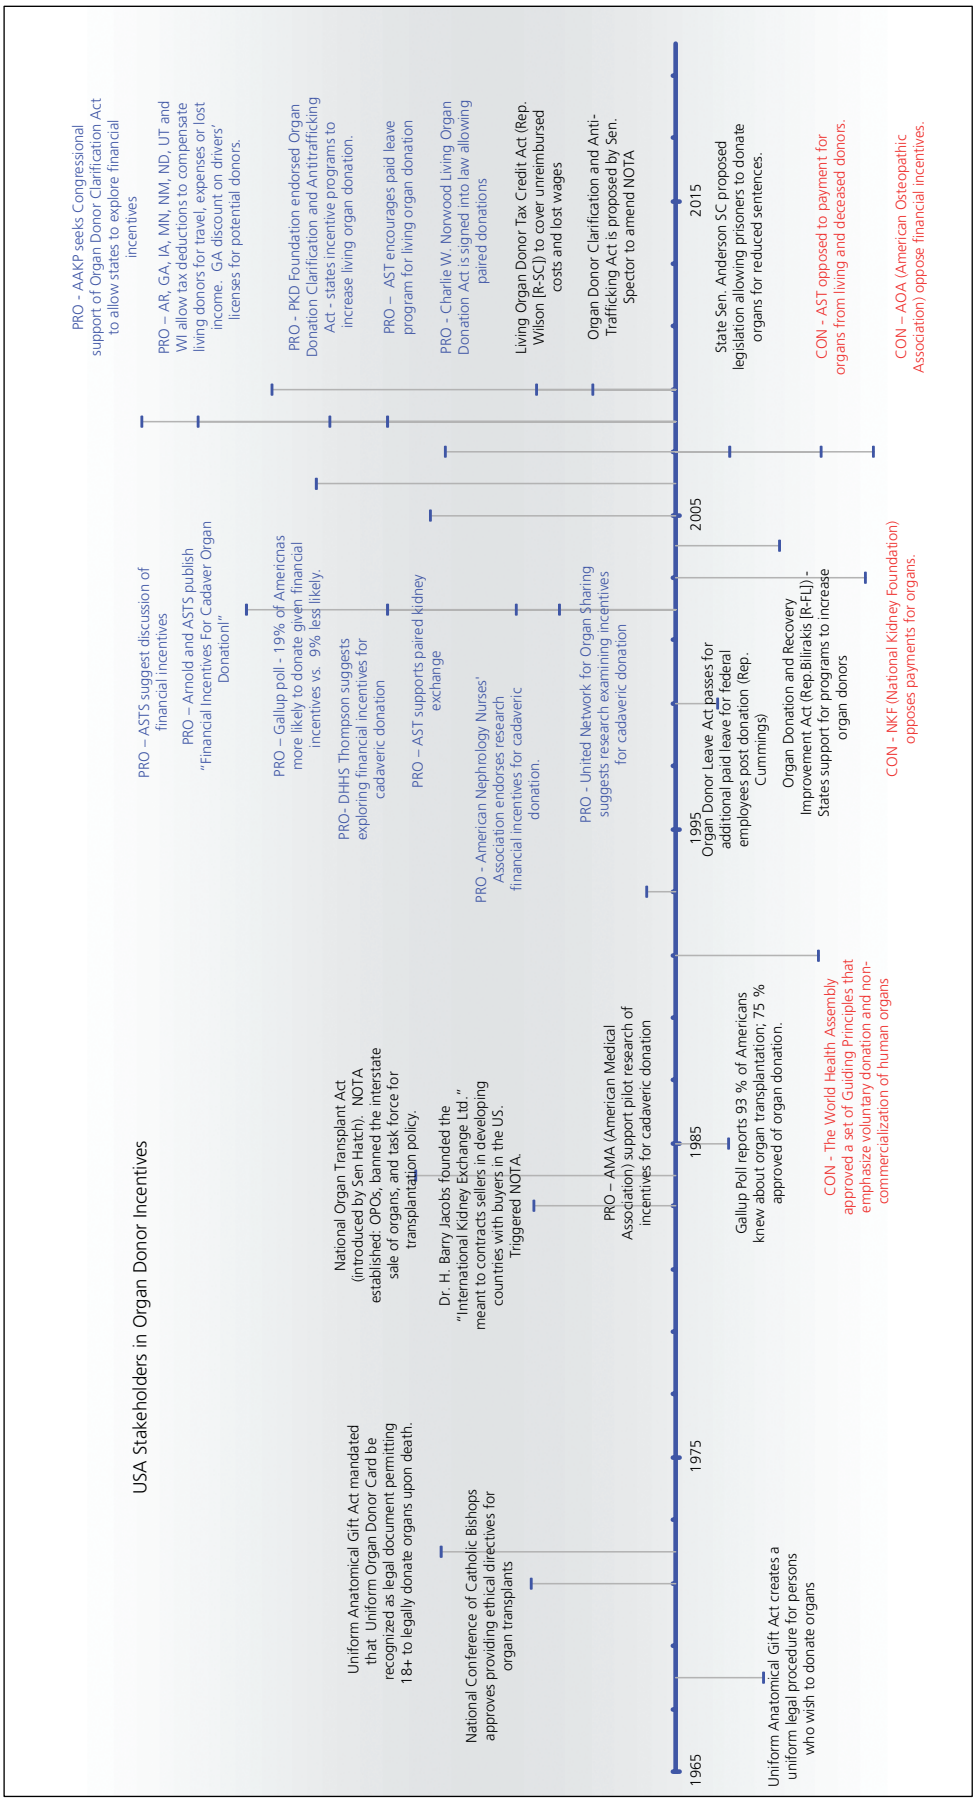

Figure 143.5. Timeline of legislative and policy initiatives related to offering incentives for organ donation in the US.

revenues or tax on hospitals or health insurers [64]. One example of an incentive for a type of futures market can be found in Georgia. Until 2005, Georgia provided a $7 discount on driver's license registration fees to individuals who registered as organ donors. It seems that this small incentive was relatively effective, and in 2005 Georgia boasted one of the highest donor registration rates for organ donation in the US [64]. Although effective, a futures market undermines the validity of the donation designation on the driver's license because the intent of the registrant is unclear with respect to wanting to donate or simply wanting a discount. As a result, Georgia's OPO was reluctant to use the Georgia donor registry data while the driver's license discount was in place. Bryne and Thompson, among others, suggest that such a system may undermine familial consent rates as well [65]. Many in the transplant community suggest that, although financial incentives may increase donation rates, the ethical concerns associated with such measures and potential negative implications public perception, public trust, and living donation render them currently undesirable [66].

Mandated choice

The current practice of requiring family consent at the time of organ procurement is problematic because often families are unsure of the donor's preferences, and even if aware, they may object to donation and refuse efforts by the OPO and clinical team to follow the donor's expressed wishes [67]. Despite the public's strong support for organ donation in public opinion polls [68], suggesting that the stress accompanying the decision-making process may be contributing to the rates of family refusal. Mandated choice would compel all competent adults to decide whether they wish to donate their organs after their deaths. People could document their decision via a number of forums, including: driver's license registration, voter registration, or income tax forms. Donor consent would be indicated on the driver's license or in a state donor register that is accessible at the time of death. For example, in Virginia, three options were available: donor, non-donor, and undecided. In the first six months, 24% were undecided with 31% registering as donors [69]. The main objection to mandated choice is that forcing people to make choices undermines personal autonomy. However, proponents of mandated choice argue that autonomy is actually enhanced because it forces an active decision as opposed to an implied assumption. Mandated choice allows competent adults to make the donation decision for themselves, rather than have it foisted upon them by relatives [70]. Mandated choice may also be beneficial for families too, who often suffer severe stress and internal discord due to donation decisions [71].

Presumed consent

Presumed consent for organ donation attempts to increase organ donation by changing the default option. Changing defaults has been shown to be an extremely effective way to overcome "status quo" bias, where people fail to take action because they are not incentivized to leave the default option. Presumed consent is an opt-out system where, following death, organs can be removed, stored and used in transplant unless a person explicitly refuses to allow such activities. Several European countries such as Spain and Austria have introduced presumed consent. Spain's presumed consent law is considered somewhat soft, because health providers actively check that the next of kin do not object to organ donation, whereas in Austria the organ recovery proceeds unless it is known that the deceased objected before death. Their law actually provides for preservation without consent; the Spanish norm is to use normothermic extracorporeal membrane oxygenation (NECMO) or cardiopulmonary bypass on donors to keep the organs perfused until family located and consent obtained. Still, Spain has relatively high donation rate of 35.5 per million [72]. Abadie and Gay have estimated that donation rates are 25–30% higher in presumed consent countries [73]. Brazil introduced a system of presumed consent in 1998, but returned to a system of informed consent after a year due to systematic failures. In Brazil, the public lacked trust in the organ donation system, stemming largely from misperceptions that organs would be removed before patients were clinically dead. Brazil also failed to institute a system to allow people to object to donation while alive. Evidence from several studies suggests that presumed consent law is associated with increased organ donation rates, but other factors such as availability of potential donors, infrastructure for transplantation, investment in healthcare, and public attitudes may all play a role [74,75].

The Institute of Medicine has recommended that the social climate be changed before any drastic legislative moves aimed at increasing organ donation [76]. The IOM Organ Donation Committee suggested that the long-term goal would be to create a society so committed to organ donation that such presumed-consent or mandated-choice policies would be acceptable. Professional societies seem to be mostly in agreement. A survey of members of the International Society for Heart and Lung Transplantation (ISHLT) in conjunction with the Foundation for the Advancement of Cardiac Therapies (FACT) found that members overwhelmingly favored indirect over direct compensation as a way of increasing organ donation. This is despite the belief among the majority of respondents that presumed consent is the best way to significantly improve organ donation. The majority also favors the wishes of the individual over the family in determining donor status [63].

Promoting organ donation: interventions

Organ donation involves a few components: first, people must volunteer to be organ donors; and second, families must consent to donation once a donation situation arises. This dynamic decision-making process is complex and is influenced by a number of factors and numerous stakeholders. These include: the potential donor, the donor's family, the OPO, the clinical staff taking care of the potential donor, and potentially public figures such as religious or community leaders. This section will review a number policy and clinical efforts aimed at overcoming barriers to organ donation (see Figure 143.5)

Deceased donors: increasing public awareness of organ donation

Organ registries might not be sufficient to expand organ donation rates if awareness among the general public remains low. Public education aims to increase organ donation by improving public awareness of transplantation and the need for organ donation [77]. Approaches include public information campaigns using the media, distribution of donor cards, and providing teaching materials for schools [78]. Increasing the opportunities to register as organ donors, such as during driver's education and licensing, during advance-care planning, and in work, faith, school, and community-based initiatives may help increase the number of potential donors [76].

Changing the social climate would require relieving people of their fears and misconceptions about organ donation and transplantation [79]. Horton and Horton found that lack of religious

support, confusion about the concept of brain death, fragmented healthcare provision by physician teams responsible for the welfare of the donor and recipient, and a mistaken belief that to be valid an organ donor card must be filed with the US Department of Health and Human Services, were associated with organ donor status. The authors found that knowledge of organ donation facts was associated with carrying or requesting an organ donor card, attitudes towards organ donation and willingness to donate their own organs or the organs of a deceased loved one [80].

Willingness to donate also varies by sociodemographic and racial characteristics. Bouleware et al. found that black females were least willing to donate blood (relative to other race and gender groups), whereas black men were least likely to donate organs after death. The authors suggest that mistrust of hospitals and perceived discrimination in hospitals explained much of the racial and gender gap in willingness to donate blood, whereas religious and spiritual beliefs explained the racial gap in willingness to organs after death [81]. Low rates of organ donation among African-Americans has been attributed to: less awareness of transplantation, religious distrust of donation, institutionalized racism and distrust of the medical community, fear of medical abandonment and fear of discrimination [82,83]. Siminoff et al found that, compared to whites, African-Americans reported lower trust in the healthcare system [83] and were more likely to believe that physicians would not try as hard to save lives of donors and that physicians could not be trusted to pronounce death. African-Americans were also more likely to favor compensation for families of donors, such as financial compensation and coverage of funeral expenses. These studies suggest that low levels of trust and lack of awareness and education about the donation process may pose particularly important barriers in minority communities.

Interventions

Despite more research related to identifying barriers to donor registration, few successful interventions have been identified. Given efforts to increase evidence-based policy, HRSA and NIH have committed significant funding to stimulating research promoting organ donation. Future policies may need to incorporate legal and regulatory components of information technology law (specifically internet law), work with various governmental departments, such as the Department of Education and local school committees, and incorporate interdisciplinary teams in order to successfully increase organ donation.

Several studies have highlighted the potential of new media in promoting organ donor registration [84]. Merion et al. studied the effects of an internet-based multimedia intervention (http://www.journey.transweb.org) on donation registration and family notification. The authors found that for the 10 884 participants, knowledge improved after completing the educational module. Furthermore, willingness to donate and join a donor registry increased after the intervention. While increases in knowledge were not associated with changes in attitudes, an increase in pro-donation attitude was a significant predictor of donor registry participation and family notification [85]. Thornton et al. examined the effect of an iPod video intervention on donor registration in DMVs in Ohio. They found that viewing the video was associated with increased rates of donor registration. Importantly, they also found that the video was particularly effective among black participants, although it was also effective for other racial groups. This brief video exposure that took place at the DMV was successful in providing information about organ donation and reducing some of the barriers associated with organ donation, particularly amongst minorities [86]. In a recent unprecedented move, the social networking website, Facebook introduced an "organ donor" option allowing their 161 million members in the US (and over 900 million members worldwide) to advertise their organ donation status. The Facebook option will likely be important for two reasons: first, it will increase awareness and likely lead to high rates (at least initially) of donor registration. Second, declaring one's donation status on Facebook serves as a record documenting consent. Although this may not be legally binding, it will serve as a way for the family to identify the patient's wishes when they are not known. Following this move by Facebook, organ donation registries reported a spike in donation registrations. California alone experienced a 700% increase above the typical number of new registrants [87]. Other states reported a tremendous rise in new registrants following this option, including: Colorado, Connecticut, Maine, Massachusetts, Michigan, Nebraska, Nevada, New Hampshire, Rhode Island, and Wyoming.

School based health education also presents a promising approach for improving organ donation rates, potentially also among ethnically diverse youth. Tailored interventions also hold promise. Piccolil et al. demonstrated that a two hour class and two hour session with patients and experts held in eight schools for 17–18 year old students helped increase interest improve attitudes related to organ donation [88]. Using a randomized-control study design, Cardenas et al. found that in a multicultural high school, following an educational intervention, students in the intervention group demonstrated a significant increase in knowledge scores and improvement in willingness to donate [89]. Positive changes in attitudes and willingness to donate occurred independent of ethnicity and gender, in spite of these both being negative predictors of opinion at baseline. These studies suggest that classroom based interventions may be important in promoting organ donation, particularly among young adults.

Increasing donor conversion

Awareness of a loved ones wishes, and concordance of family members during the decision-making process is also vital to successful donation [90]. Polls have suggested that a key factor in families agreeing to consent to organ donation at the potential donor's death is whether the potential donor had previously discussed organ donation with his or her family [79]. Siminoff et al. found that prior knowledge of the patients' wishes along with discussions of more topics and had more conversations about organ donation were significantly associated with willingness to donate. Families with greater contact with OPO staff and those who experienced an optimal request pattern also were more likely to donate [91]. Rodrigue et al. examined the relative influence of donor and next-of-kin factors, requestor characteristics, communication processes and satisfaction with the healthcare team on the donation decision [92]. Similarly, they found that prior knowledge of preferences, favorable organ donation beliefs were important, satisfaction with the OPO and healthcare team and timing of requests were associated with donation. These studies suggest that there is a need for a sustained commitment to public education interventions aimed at improving beliefs about organ donation, documenting and discussing donation decisions with next-of-kin, and to improving the request process in hospitals.

Even when a patient has a signed organ donation card, the OPO typically seeks family approval to proceed with donation. Although the Uniform Anatomical Gift Act (1968, revised 1987) states that

a signed organ donation card is sufficient to proceed with donation and serves legally as an advanced directive, requesting consent from the next-of-kin remains standard, largely to avoid lawsuits and unfavorable press. This model may be slowly changing, however, with many states passing legislation establishing "first-person consent" laws. These laws establish that the family cannot supersede an individual's expressed wish to be an organ donor. Often times in such states first-person consent registries are maintained, often by the Department of Motor Vehicles (DMV). First-person consent laws support patient autonomy, promoting the ideal that patients should be able to choose what the type of care that they will receive and what should happen to their body after they pass. First-person consent may also alleviate a burden from family members wanting to do the right thing in a stressful and difficult circumstance. In this situation, first-person consent laws relieve the family from making the decision while grieving, and reduces the likelihood of familial conflict related to donation. Given the instability of donation decisions made by families (more than one-third of families who made a decision and declined to donate regretted their decision), avoiding this scenario may provide even greater benefit [90,93].

Laws have been passed that require referral of all potential donors to the OPO or request of the families' permission to obtain organs of potential donors. This requires an effective screening system for identifying potential donors and sharing their information in an expedient way with OPOs. Such systems have required additional hospital development to facilitate donation requests [78]. Demands for organ transplantation may conflict with end-of-life preferences, as organ transplantation may require profusion, receiving or withholding that do not correspond to the patient's end of life treatment plan. Further research is needed to better develop policies that will allow OPOs to intervene efficiently and expeditiously when needed, while maintaining patient autonomy, dignity, and respect during end of life care.

Given that there are such wide range of consent rates from OPOs and transplant centers (from more than 70% to less than 30% of potential donors), the Institute of Medicine has recommended identifying best practices and disseminating them among the institutions. There should also be research identifying new ways to improve the system and increase donation rates. Organ donation could be coordinated with discussions about end-of-life care. Patients and families should be offered the opportunity to donate as standard end-of-life care. There could also be increased efforts to procure organ donations from cardiac-arrest deaths occurring outside of the hospital. According to one estimate, at least 22 000 people each year who die of cardiac arrest outside of a hospital could be potential organ donors.

The refusal of families to grant permission for donation presents a major impediment to organ donation. Three factors that have helped overcome this barrier. First, decoupling the request for donation from the declaration of brain death to allow the family time to cope with the loss of a loved one and fully understand the concept of brain death. Second, a trained OPO representative along with the clinical team should make the request together. Studies suggest that the clinical team should wait for the OPO representative to discuss donation with the family and chart a course of action. Third, the discussion with the family should be discrete, ideally in a quiet and private setting [94]. In 2003, the Secretary of DHHS launched the US Organ Donation Breakthrough Collaborative to formalize national efforts to improve efficiency and outcomes in organ donation. Housed under HRSA's Division of Transplantation, the Collaborative included the national community of OPOs and hospitals. Selecting experts from hospitals and OPOs that had a successful record of achieving and sustaining high organ donation rates to serve as faculty, the Collaborative developed best practices [95]. The intervention yielded positive results, with the number of organ donors in Collaborative hospitals rising 14.1% in the first year compared to merely 8.3% increase experienced by non-Collaborative hospitals. Importantly, sustained increases in organ recovery continued into the post Collaborative periods. Between 2003 and 2006, the number of total US organ donors increased by 22.5%, compared to the 5.5% increase measured over the same duration in the immediate pre Collaborative period. Although perhaps not all of the change is due to the Collaborative, studies suggest that dissemination and implementation of best practices gleaned from the Collaborative were a significant factor in this increase [96].

Living donors

Some have concluded that the waiting list for kidney transplant is too long, growing, and unlikely to be substantially reduced by increases in the recovery of deceased donor kidneys. Of the approximately 2.3 million deaths annually in the US, only between 11 000 and 14 000 produce eligible donors under the standard criteria. Removing barriers for living donors can increase the rate of living donations. These include funding to cover their living expenses, travel, lost wages and the costs of care they provide to other family members, assistance for postoperative care of the living donor, encouraging employers to accommodate employee requests to take time off to donate organs [77]. Minorities are far less likely to be living donors as well. Barriers to minority living donation include: unwillingness to donate, medical co-morbid conditions, trust or fear of medical community, loss to follow-up, poor coping mechanisms, financial concerns, reluctance to ask family members and friends, fear of surgery, and lack of awareness about living donor kidney transplantation [82].

The National Living Donor Assistance Center, administered by the Division of Transplantation of HRSA through a co-operative agreement with the University of Michigan and the American Society of Transplant Surgeons (ASTS), aims to provide greater access to transplantation for persons who want to donate, but cannot otherwise afford the travel and subsistence expenses associated with donation [97]. The program states that, it is "authorized by section 377 of the Public Health Service (PHS) Act, 42 U.S.C. § 274f. The specific authority was authorized by the Organ Donation and Recovery Improvement Act (P.L. 108-216) which provided authority to the Secretary to establish this grant program to assist living donors who need financial assistance to help defray travel and subsistence expenses". In 2006, HRSA awarded the co-operative agreement to the University of Michigan with a subcontract to the American Society of Transplant Surgeons to establish and operate the program, charged with:

1. running a national system to provide reimbursements for "travel, subsistence, and other non-medical expenses that may be authorized by the Secretary, to individuals making living donations of their organs";
2. establishing governing policies together with HRSA and the transplant community;
3. operating the program effectively including efficient payment to living donors;
4. ensuring continued fiscal health; and
5. monitoring and evaluating the quality of the program.

In October 2007, transplant centers were invited to register for the program on the NLDAC website. Between its inception in 2007 and through July 26, 2010, NLDAC received over 1200 applications and funded 86% of them. The expense for travel and lodging has averaged $2900 per application. Payment is granted in the form of an American Express Controlled Value Card (CVC) to purchase airfare, gas, rental cars, hotel rooms, food and other incidental expenses such as parking [98].

In June 2008, the OPTN/UNOS approved a proposal for a national pilot program with interim implementation that began in October 2010 [99]. 77 transplant centers in four regional networks are enrolling patients and potential living donors in the pilot exchange program that includes two- and three-way exchanges.

Current policy and transplant tourism

In 1984, a proposal for kidney sales by a US physician led the National Organ Transplant Act to prohibit monetary compensation for transplantable organs. The prohibition of commodification current policy in the US prevents exploitation. However, data on departures from the US kidney waiting list suggest that from 1987 to 2006, over 335 Americans traveled overseas to obtain kidney transplants. These transplant "tourists" often pay brokers between $15 000 and $150 000 for transplant packages [10]. The current policy thus gives an advantage to those who are wealthy and those with social capital and thus more likely to obtain a live donation. This policy is inefficient due to unrealized willing-but-incompatible donations and losses to potential savings due to these willing-but-incompatible donors. In addition, studies of transplant tourism have found that kidney patients transplanted abroad had a high incidence of serious postoperative infections, although graft survival and function appeared fine [100]. There may also be inadequate communication of information such as immunosuppressive regimens and preoperative information. The extent of commercial transactions and organ theft remains incompletely understood. The WHO estimates that roughly 10% of organ transplants worldwide involve organ trafficking and transplant tourism. Several principles came out of the Declaration of Istanbul World Health Organization Summit on Organ Trafficking and Transplant Tourism. National governments should develop and implement comprehensive programs for the screening, prevention, and treatment of organ failure. Legislation should be implemented to govern the recovery of organs from deceased and living donors, and transplantation, consistent with international standards. Organs for transplantation should be equitably allocated to recipients. The primary objective of transplant policies should be optimal short and long term medical care to promote the health of donors and recipients. Countries and regions should achieve self-sufficiency in organ donation. The World Health Assembly called on countries to prevent the purchase and sale of human organs for transplantation [101].

Summary

Transplantation has evolved from an experimental curiosity to one of the most complex of all human endeavors. This complexity is evident in the exceptional number of statutes and the immense regulatory fabric that covers all aspects of the field, from the formal definition of death, to restrictions on who can give the gift of life. Arguably, no field touches on more of the technical, logistical, social and ethical aspects of human existence, as does transplantation. As such, the study of transplantation will forever uniquely reflect the human condition, and in doing so, make this one of the most satisfying of careers.
