		Class III	Evidence and/or expert opinion suggest that a given drug treatment for a specific indication is ineffective

rATG or daclizumab, and found no difference in acute rejection rates, renal function, or patient or graft survival [29]. The best evidence supporting off-label use of alemtuzumab in transplantation derives from the multicenter randomized INTAC trial in which alemtuzumab was compared to either basiliximab (in low immunologic risk patients) or rATG (in high immunologic risk patients). In this study, alemtuzumab was found to have similar efficacy to rATG and potential superiority to basiliximab in low-risk patients [24]. Additionally, there have been several other non-randomized published trials of alemtuzumab for induction. Despite this use of alemtuzumab as induction therapy, Genzyme-Sanofi, has not sought FDA approval for alemtuzumab in kidney transplantation.

In 2009, approximately 13% of transplant centers utilize alemtuzumab in kidney transplant recipients [10]. Although the use of alemtuzumab has been mostly in kidney transplant, alemtuzumab has been used in other solid organ transplant recipients. According to the SRTR alemtuzumab was used in 12% of intestinal transplants, 8% of lung transplants, and 11–12.6% of pancreas transplant (simultaneous pancreas-kidney, pancreas after kidney, and pancreas alone) [10]. Alemtuzumab has also been used in a more limited respect as induction therapy in liver transplantation and in pediatric transplant recipients.

Unfortunately, it appears that alemtuzumab is unlikely to receive FDA approval for use in transplantation. In September 2012, it was announced that alemtuzumab (under the proprietary name Campath) was no longer going to be made available through usual drug distribution mechanisms, and would only be available through the US Campath Distribution Program [30]. It is widely believed that this move was preparatory for Sanofi's efforts to gain FDA approval for alemtuzumab use in multiple sclerosis. This decision by Sanofi was likely based on market potential considerations, as inflammatory and autoimmune disorders have substantially greater market potential and therefore profitability margins. Despite the provision of free alemtuzumab via the US Campath Distribution Program for indications outside of multiple sclerosis, the long-term sustainability of such a program is subject to question. Alemtuzumab is an exemplary case of the issues faced by the transplant field in terms of drug development. The relatively smaller market size represented by transplantation provides a smaller potential financial profitability in comparison to autoimmune diseases and oncology indications. These considerations have resulted in a shift in drug development for new immunosuppressive agents away from transplantation and toward oncology or autoimmune diseases.

Rituximab

Rituximab is a monoclonal antibody specific for the CD20 antigen on B-lymphocytes. The exact mechanism of rituximab is complex. However, B cell depletion, the most prominent effect, is mediated via several potential pathways, including complement-dependent cytotoxicity, antibody-dependent cellular cytotoxicity and apoptosis [31]. Rituximab is FDA approved for treatment of: CD20-positive non-Hodgkin's lymphomas, CD20-positive CLL, moderate to severe active rheumatoid arthritis (in combination with methotrexate) in adult patients with inadequate response to tumor necrosis factor (TNF) antagonists, Wegner's granulomatosis, and microscopic polyangiitis. Within solid organ transplant, rituximab has had several off-label uses investigated, including post-transplant lymphoproliferative disease (PTLD), prevention of rejection, ABO incompatible transplantation, treatment of rejection, and desensitization of HLA-sensitized patients [31]. The area with some of the greatest success has been the use of rituximab for PTLD, however this section will focus on rituximab for use in treatment of rejection and desensitization.

Rituximab use for treatment of refractory rejection has been limited to small, non-randomized studies. This use has been based in part on the observation that patients with resistant rejection demonstrate significant numbers of CD20+ staining B cells on renal allograft biopsies [31]. Becker and colleagues described a case series of 27 patients who received rituximab for steroid resistant or

antibody-mediated rejections (AMR). Nearly all of these patients also received steroids (24 of 27) and plasmapheresis and rATG (22 of 27). Only 3 patients experienced graft loss not associated with patient death. Although this case series was too small to evaluate outcomes, it did suggest that rituximab was an effective therapy for patients with resistant rejection episodes [32]. Another case series of 4 patients with chronic AMR described the use of rituximab in combination with intravenous immune globulin (IVIg). These patients showed improved kidney allograft function at 3 and 6 months after therapy, and 2 patients had reduction in donor specific antibodies (DSA) [33]. Other studies suggest benefit of rituximab for AMR when used in combination with plasmapheresis [34].

Tydén and colleagues performed a prospective, randomized, double blind study of rituximab for induction, in combination with tacrolimus, mycophenolate, and steroids. One hundred and forty patients were randomized to receive one dose of rituximab (375 mg/m^2 body surface area) or one dose of placebo within 24 hours of revascularization [35]. Among the 68 patients who received rituximab significant depletion of CD19/CD20 cells was observed. A trend toward fewer rejection episodes was observed at 6 months in the rituximab arm; however this was not statistically significant. In comparison, an open-label randomized study of comparing rituximab and daclizumab for induction was terminated after enrolling only 13 patients due to an 83% rate of acute cellular rejection within 3 months of transplantation in the rituximab group [36].

Rituximab has also been used in desensitization regimens for highly HLA-sensitized patients. In one study of 20 patients, 16 went on to transplantation following administration of two doses of 1 g rituximab (day 7 and 22) and 2 doses of 2 g/kg IVIg (day 0 and 30) [37].

In summary, the evidence base for rituximab is generally, not as robust as that for alemtuzumab. However, data from uncontrolled clinic trials suggest that rituximab may possess efficacy desensitization regimens and antibody-mediated rejection.

Bortezomib

Bortezomib is a small molecule, first in class proteasome inhibitor that is FDA approved for treatment of multiple myeloma and mantle cell lymphoma [38]. The mechanism of action of bortezomib is complex and involves a myriad of effects on cellular signaling pathways. However, few of these effects are thought to contribute to its efficacy in multiple myeloma. Current thinking holds that the predominant mechanism in multiple myeloma is derived from induction of endoplasmic reticulum (ER) stress, and a terminal unfolded protein response that culminates in apoptosis [39]. Bortezomib is also known to be a potent cell cycle inhibitor and inhibitor of nuclear factor κ B (NFκB)-mediated resistance, resulting in apoptosis.

The first report of bortezomib use in transplantation was for the treatment of refractory antibody mediated rejection (AMR) [40]. In this study, 6 patients with documented AMR refractory to standard therapy were treated with bortezomib. This off-label use of bortezomib resulted in AMR reversal in each patient, who had failed standard AMR therapies. Payor coverage for this initial off-label indication was variable, and ongoing inconsistency with payor coverage complicated the expansion of bortezomib therapy investigation. Following this experience, documentation of treatment success and provision of scientific publications, has been a substantial help in gaining payor coverage. In our experience, bortezomib use was detected and monitored by the hospital pharmacy, and due to its considerable cost (about $5000 for 4 doses during an 11 day cycle) the off-label use of bortezomib drew considerable attention. However, the potential allograft-saving effects helped defray resistance from hospital pharmacy and the formulary committee.

Publication of experiences in peer-reviewed scientific literature became the most effective strategy in obtaining coverage for off-label use of bortezomib for treatment of refractory AMR in kidney transplant recipients. However, had bortezomib therapy not been as effective as it was in the original series of patients, such an approach may very well have failed.

The use of off-label bortezomib illustrates important considerations for the future of off-label drug use in transplantation. In general, decisions regarding registration trials are based on several factors, including known mechanism of action, and also the size of the potential market. Although a drug may have several potential disease states that are amenable to further drug development, the exorbitant costs of clinical registration trials limits investigations to a single indication. The restriction to a single indication, results in off-label drug development the only viable option for other most other potential therapeutic indications. An active phase IV development program may provide substantial support for off-label evaluation in new therapeutic areas. However, when these funds are not available, off-label use becomes challenging. In the case of bortezomib, at the University of Cincinnati, the authors were fortunate secure funding for three clinical trials, including two small, randomized trials — one in induction therapy and another for acute mixed rejection in renal transplantation. The third trial was conducted as a desensitization trial in highly sensitized kidney transplant recipients.

A number of reports followed the initial report of bortezomib for refractory AMR. Unfortunately, results from these published reports had varying success rates. However, bortezomib demonstrated potential efficacy in reversal of AMR in heart and lung recipients, as well as pediatric transplant recipients [41,42]. A large collaborative effort has confirmed the original observations in kidney transplant recipients with refractory AMR [43]. More recently, a large desensitization study confirmed the effects of bortezomib in highly sensitized renal transplant candidates, thereby offering a potential alternative to IVIG-based regimens.

To summarize, off-label development of bortezomib was hindered by its high cost, resistance to coverage by payors, cost containment concerns from hospital pharmacy and formulary committees, and limited funding for phase IV studies by the sponsor. Scientific publication of clinical results, efficacy in preventing graft loss in patients with treatment refractory AMR, and lack of alternative FDA approved AMR therapies helped to improve coverage for off-label use of bortezomib.

French statutory framework for redefining off-label drug use

A recently passed French law and an associated "decree" have created a process for regulating off-label use of approved drugs. This novel regulatory framework intends to provide a means for supporting and assessing the use of newly approved drugs for off-label indications, while assuring public safety [44]. The major effect of the law is to require the sponsor (i.e. drug manufacturing company) to monitor off-label use, and determine if the following actions must be taken:

1 Inform the national regulatory agency (Agence Nationale de Securite du Medicament et des Produits de Sante (ANSM) of unconventional prescribing.

2 To take measures to educate health care professionals and prevent off-label use.

The decree ("Temporary Recommendations for Use" [TRU]) provides for authorization of a one-time TRU designation for a drug that requires reimbursement by payors if no other medications are available for the designated use. The regulatory agency (ANSM) may be notified of the need for a TRU by any of several groups with vested interests such as the national Ministry of Health, the national cancer institute or patient advocacy groups. ANSM may then decide to take the proposal for a TRU under consideration, whereby it will consider data submitted by the sponsor or from the published literature [44].

For a TRU to be granted, there must be no other approved drugs for the indication. Factors to be considered in approving a TRU include:

- the quality of the evidence base supporting the proposed TRU;
- the safety profile of the drug;
- the prognosis of the disease; and,
- the frequency of the disease/condition.

Although the French regulatory framework may enhance safety some factors create considerable concern. Most concerning is the fact that a TRU may be granted only once for each drug. Therefore, if a drug has several potential off-label uses (e.g. several different cancer types) the sponsor is given the decisions of which indication deserves a TRU application. What if a drug has two (or more) potential off-label uses, both of which are for potentially lethal conditions? What is the ethical framework by which such decisions will be made? Clearly, additional consideration is required before such a system would be acceptable to the medical community in the US and the US general public.

Off-label use, standard of care, and investigational use of drugs

Off-label use of drugs has been defined earlier in this chapter. However, off-label use may be further defined in terms of standard of care, or alternatively, may constitute investigational use. As discussed previously, off-label use may become such common practice that it becomes the standard of care (e.g. tacrolimus/MMF regimens for prophylaxis of rejection in renal transplantation), but determining the transition point of off-label use to standard of care is more difficult to define. Similarly, off-label use may or may not be investigational, and this definition raises important concerns regarding human subjects' protection and regulatory issues. Therefore, consideration of providing definitions for standard of care and investigational use are important in the context of off-label use of drugs.

Standard of care has been reasonably well defined from a legal perspective. Legal dictionaries define "standard of care" as "the watchfulness, attention, caution and prudence that a reasonable person in the circumstances would exercise [45]." The definition of standard of care is critical in legal malpractice actions, as the plaintiff is required to establish the standard of care for a physician practicing in a defined specialty or general practice of medicine.

In comparison, standard of care does not have a clearly established medical definition. Moreover, standard of care for medical practitioners may vary significantly based on location of a physician's practice. Even within the US, significant regional or even local differences may exist with respect to the standard of care. As an example, within the state of Ohio, marked differences exist amongst the six adult kidney transplant programs. Even between individual programs within the same city have significant differences in standard of care immunosuppressive regimens despite the physical proximity. There are a number of larger cities in the US that have multiple transplant programs, where the immunosuppressive regimens differ substantially from other programs within that same city.

Given these differences, it is important to understand how a program develops its standards of care. CMS and the Organ Procurement and Transplantation Network (OPTN) regulate the transplant field through program certification and establishing standards for certification. These standards require a team approach toward operating protocols, and also require that standards be developed for immunosuppression and prophylaxis of infection. CMS and OPTN do not dictate which drugs are used for immunosuppression or infection prophylaxis, only that policies for such are developed by a multidisciplinary group, led by certified transplant physicians and surgeons. In this local, program-specific, consensus approach physician leadership must consider the evidence base, prior experience, ongoing experience, financial cost, payor coverage, and individual patient populations in deciding on immunosuppressive protocols.

Electronically derived prescribing data is readily available for the most commonly prescribed immunosuppressive agents and immunosuppressive regimens, which may represent an alternative approach toward defining the standard of care. If a given regimen represents the most commonly prescribed treatment, such data can present a strong argument for the particular combination representing a standard of care. However, for smaller patient populations, such as a high-risk population, prescribing volume would be a more difficult approach to apply toward defining standard of care, unless such high-risk populations can be reliably defined by the prescribing database.

As another consideration, the most commonly prescribed immunosuppressive regimens are tracked in the US on a national, regional, and local basis from the electronic prescribing databases currently in existence. There are cases where local standards of care may differ substantially from those defined on a national basis by prescribing frequency data. In these cases, the local programs should be able to justify the basis used for their selection of a given regimen as their local standard of care.

Evidence based medicine approaches, and patient care guidelines represent another approach for defining a standard of care. However the Kidney Disease: Improving Global Outcomes (KDIGO) guidelines, established by the National Kidney Foundation KDIGO group, present an example of the difficulties inherent in establishing practice guidelines. The immunosuppression recommendations in KDIGO in particular, have been controversial; as some practitioners believed that they did not achieve an appropriate degree of objectivity and were unduly biased by the responsible authors (Dr. E. Steve Woodle, unpublished observation). Therefore, in cases where there are no clear superior approaches established by multicenter double blinded trials, issues of standard of care definitions are inherently and necessarily subjective in nature.

The issue of when off-label use constitutes investigational use is easier to define when an Institutional Review Board (IRB) sponsored protocol is in effect. However, an argument could be made that off-label use may be investigational in the absence of an IRB-approved protocol. As an example, a practitioner or group of practitioners may choose to treat patients with off-label drug use and collect data for purposes of evaluation on the effects of therapy. When such data is published, it begins to approximate

investigational use. An example of this can be provided by the issues and experiences that we encountered in our initial experience with the use of bortezomib to treat refractory antibody-mediated rejection (AMR) [40]. Prior to treating patients with AMR refractory to known therapeutic agents, including IVIg and rituximab (interestingly, also used off-label to treat AMR) internal programmatic discussions were held by faculty nephrologists, transplant surgeons, and transplant pharmacists as to whether patients with ongoing AMR that had failed IVIG and rituximab should be allowed to progress and lose their renal allograft (and return to dialysis) without additional attempts at rejection reversal. Because the return to dialysis and loss of the renal allograft is associated with major decreases in life expectancy for patients, we elected to consider use of bortezomib for this condition. Prior to employing bortezomib, its effects and toxicities and safety profile were carefully researched from scientific literature; we also engaged oncologists and oncology-specialty trained pharmacists. The safety and toxicity profile was judged reasonable to assume in the patient population being considered for treatment. The transplant team discussed these observations and a proactive decision was made to treat the next appropriate patient with refractory AMR, who was judged to be at high risk for renal allograft loss, with off-label bortezomib as rescue therapy. When patients were identified, the prognosis without further therapy was discussed with the patient, the lack of alternative options was discussed, and the potential off-label use of bortezomib was discussed, including potential costs, safety and toxicity. The first six patients treated all demonstrated substantial responses to bortezomib treatment, and experienced AMR reversal [40]. After two patients had been treated, we engaged the head of our local IRB in a discussion of this off label use, specifically addressing whether such treatment represented research that should be conducted under an IRB-approved protocol. It was agreed that at some point, the preferred approach would be to conduct an IRB sponsored trial; however, it was clear that such off-label use was clearly a prerogative of the treating physicians. To date, we have submitted research proposals to study bortezomib AMR therapy, but have been unsuccessful in obtaining funding for such a trial. In the history of transplantation, only a few trials have been funded for the study of AMR. To date, the collective experience with bortezomib therapy for AMR provides results similar to those provided historically achieved with IVIG [43].

In a perfect world, funding would be available for the study of all conditions, no matter how rare, to provide a proper evidence base for off-label drug therapy. However, the reality of modern day medicine is such that many new medications are quite expensive, and the cost of conducting these clinical trials is increasingly substantial. These considerations have largely precluded the potential of industry funding for such trials, leaving the NIH and other entities as the only potential alternatives for such studies.

Summary

Solid organ transplantation is well known for off-label drug use, in part because the field does not experience the same level and extent of new drug development as other fields such as autoimmune disease and oncology. Off-label ISA use and drug development are complicated by refusal of insurance carriers to provide reimbursement, which could result in costs of several thousands of dollars to patients and time-consuming prior authorizations to be completed by providers. Despite these considerable barriers, off-label drug use and development has been possible up to the present. However, the future does not appear to be robust, and with increasing cost of new drugs, it is likely that local and federal scrutiny of off-label drug use will increase, and greater restrictions will result. Historically, off-label drug use has progressively become standard of care for transplant recipients. However, this practice may change in the future. Statutory limitations, such as those created in France, are redefining this area of drug development and it is likely that other countries may soon follow.

CHAPTER 102

Drug Interactions in Organ Transplantation

William D. Simmons,[1] Pamala A. Jacobson,[2] and Karen L. Hardinger[3]

Introduction

A drug–drug interaction occurs when one drug alters or interferes with the action of another drug resulting in unintended or unexpected effects. Drug interactions may have potentially life-threatening consequences in transplant recipients, who have several risk factors for drug-drug interactions including multiple concomitant diseases and the use of narrow therapeutic index drugs. The potential for adverse interactions also increases with increasing age. The frequency of drug interactions is not well-known in transplant recipients, although in the general population the incidence of emergency department visits, hospital admissions and re-hospitalization due to drug-drug interactions is 0–7.6% [1]. The incidence of actual drug–drug interactions during hospital stays is 5.3–14.3% [1]. The incidence in transplant patients could be easily envisioned as being higher given the high number of drugs introduced simultaneously at the time of transplantation, the common deployment of drugs in off-label indications, and the rapidly changing function of organs critical to drug metabolism, particularly in liver and kidney transplantation. Drug interactions can be divided into two general categories: pharmacokinetic and pharmacodynamic.

Pharmacokinetics

Pharmacokinetics is the study of drug absorption, distribution, metabolism, and excretion within and from the body. Pharmacokinetic drug interactions occur when one drug affects the absorption, distribution, metabolism, or excretion of another. See Table 102.1 for examples of selected drug-drug interactions.

Pharmacodynamics

Pharmacodynamics is the study of the relationship between drug exposure and its target tissue effects or clinical outcome. Pharmacodynamic drug-drug interactions may result in additive, synergistic or antagonistic pharmacologic effects. Either type of drug interaction can result in undesirable outcomes in patients. Evidence is now accumulating that genetic variation or pharmacogenetics may affect drug interactions.

The purpose of this chapter is to describe pharmacokinetic and pharmacodynamic drug-drug interactions with a focus on the immune suppressants, to explore the influence of pharmacogenomics in transplant recipients, and to present approaches for managing drug interactions. An overview of the common mechanisms for transplant immunosuppressants can be found in Chapter 17, and detailed descriptions of medications commonly used in transplantation can be found in Chapters 98–101.

Pharmacokinetic drug-drug interactions

Pharmacokinetic interactions may result in changes to the drug's pharmacokinetic parameters such as area under the time versus concentration curve (AUC), half-life ($t_{1/2}$), time to peak blood concentration (T_{max}), maximum blood concentration (C_{max}) or minimum blood concentration (C_{min}).

Absorption

Absorption is the process by which a drug reaches the systemic circulation. After a drug is ingested, the dosage form dissolves or disintegrates and then is absorbed. Absorption is dependent on several factors including drug formulation, the presence of food or bile at site of absorption, concomitant drugs, the gastrointestinal physical environment, and transporters.

The presence, composition and timing of food may affect the absorption of many of the immunosuppressive drugs [2–9] (Table 102.2). Because avoidance of food at time of medication administration is not always clinically practical, many clinicians recommend that patients be consistent and that they always take their medication in the same manner whether it is with or without food.

Another factor that may influence the absorption of transplant medications is concomitant administration of commonly used divalent cations. In a single-dose, crossover study in healthy volunteers, co-administration of tacrolimus and magnesium/aluminum hydroxide resulted in a 21% increase in the mean tacrolimus AUC and a 10% decrease in the mean tacrolimus C_{max} relative to tacrolimus administration alone [2]. In a clinical study, patients did not require tacrolimus dose adjustment when magnesium/aluminum was prescribed with tacrolimus therapy [10]. When tested with mycophenolate mofetil (MMF), aluminum/magnesium hydroxide decreased the AUC of mycophenolic acid (MPA) by 17% and the C_{max} by 33% [4, 9]. When given with enteric-coated mycophenolate sodium (EC-MPS), aluminum/magnesium hydroxide decreased the MPA AUC by 25% and the C_{max} by 37% [4] (Package insert). The effect of calcium on MPA absorption has also been studied. In a study of six healthy male volunteers, who received

Table 102.1. Selected drug interactions with immunosuppressants

Immunosuppressant	Interacting agent	Study conditions (if reported)	Results	Reference
Azathioprine	Allopurinol	Not reported	Requires azathioprine dose reduction by approximately 1/3 to 1/4 the usual dose	[6]
Cyclosporine	Acetazolamide	3 men studied before and 72 hours after the co-administration of acetazolamide	Increased mean trough cyclosporine levels, 170 ng/mL (range 54–270 ng/mL) to 1130 ng/mL (range 517–1827 ng/mL)	[76]
Cyclosporine	Aliskerin	14 healthy subjects in an open-label, single-sequence, parallel-group, single-dose study received aliskiren 75 mg orally (period 1), followed by aliskiren 75 mg + cyclosporine 200 mg (period 2) after a 7-day washout period, and aliskiren 75 mg + cyclosporine 600 mg (period 3) after a 14-day washout period.)	Increased aliskerin AUC 4 to 5 fold, C_{max} 2.5 fold, increased mean $t_{1/2}$ from 25 to 45 hours. Did not alter the pharmacokinetics of cyclosporine	[77]
Cyclosporine	Ambrisentan	28 healthy subjects received ambrisentan 5 mg daily either alone or with cyclosporine 100–150 mg 2 times/day, and 24 other subjects received cyclosporine alone or with ambrisentan	Increased ambrisentan Cmax 1.5 fold, AUC 2 fold; CsA Cmax and AUC only increased slightly (906 vs. 1,014 ng/mL) and (3.05 vs. 3.37 μg h/mL) respectively. The recommended maximum dose of ambrisentan is 5 mg if co-administered with CsA.	[42]
Cyclosporine	Fluconazole	16 stable renal transplant recipients in a randomized, double-blind, placebo-controlled study received a constant cyclosporine dose and fluconazole 200 mg daily for 14 days or placebo	Increased cyclosporine concentrations slowly over two weeks of therapy, approximately doubling the cyclosporine trough concentrations	[78]
Cyclosporine	Fluconazole	Pharmacokinetics compared with those 2, 4 and 7 days after starting fluconazole orally in a dose of 200 mg/day	Increased CsA AUC from 2887 +/− 1729 ng h/mL on day 0 to 3842 +/− 1975 ng h/mL on day 2 ($P < 0.05$), 4750 +/− 1718 ng h/mL on day 4 ($P < 0.01$) and then decreased to 4052 +/− 1687 ng h/mL on day 7 ($P < 0.01$)	[79]
Cyclosporine	Indinavir and Nelfinavir	Kidney transplant patients concomitantly administered CsA , indinavir and nelfinavir	Required 85% dose reduction of CsA	[80]
Cyclosporine	Ketoconazole	Not reported	Increased AUC of CsA by almost three-fold, requiring up to 80% CsA dose reduction	[81]
Cyclosporine	Lopinavir/Ritonavir	Liver transplant patients receiving lopinavir/ritonativir and CsA	Required 5%–20% CsA dose reduction	[82]
Cyclosporine	Methotrexate	20 rheumatoid arthritis patients	Increased methotrexate concentrations AUCs approximately 30%, CsA concentrations did not appear to have been altered	[7]
Cyclosporine	Metoclopramide	14 kidney transplant patients with stable renal function, total dose of metoclopramide was 20 mg	Increased CsA AUC by 29%	[22]
Cyclosporine	Nefazodone	Case report of a cardiac transplant recipient maintained on CsA and started nefazodone	Increased CsA trough levels 10 fold after initiation of nefazodone	[83]
Cyclosporine	Posaconazole	3 heart transplant recipients on cyclosporine dosed 3 times/day for 6 weeks or longer were given posaconazole 200 mg/day for 10 days	Increased cyclosporine exposure and necessitated dosage reductions of 14–29%	[84]
Cyclosporine	Quinupristin/Dalfopristin	Concurrent administration of quinupristin/dalfopristin with CsA	Increase CsA trough concentrations by more than 2.5 fold, CsA AUC by 1.6 fold and CsA C_{max} by 1.3 fold within 2 to 3 days	[85]
Cyclosporine	Repaglinide	12 healthy males received two doses of 100 mg CsA capsule orally 12 hours apart with a single dose of repaglinide 0.25 mg orally 13 hours after the CsA initial dose	Increased repaglinide mean C_{max} 1.8 fold (range: 0.6–3.7 fold) and AUC 2.4 fold (range 1.2–5.3 fold)	[7]
Cyclosporine	Rifampin	Single dose of rifampin	Decreased CsA trough concentration by 73%	[86]
Cyclosporine	Rifampin	Kidney transplant recipients on CsA before and after the administration of rifampin	Required a CsA dose increase of 2.5 to 3 times to maintain optimal trough concentrations.	[87]
Cyclosporine	Telaprevir	10 healthy volunteers were administered CsA alone as a single 100 mg oral dose, followed by a minimum 8-day washout period, and subsequent co-administration of a single 10 mg oral dose of cyclosporine with either a single dose of telaprevir 750 mg or with steady-state telaprevir 750 mg every 8 hours	Increased CsA dose normalized AUC approximately 4.6 fold and increased the terminal elimination $t_{1/2}$ of cyclosporine from a mean (standard deviation [SD]) of 12 (1.67) hours to 42.1 (11.3) hours	[88]
Cyclosporine	Voriconazole	7 kidney transplant recipients in a randomized, double-blind, crossover study with the addition of voriconazole to CsA	Increased mean CsA AUC 1.7 fold	[89]
Everolimus	Atorvastatin	24 healthy subjects given a single oral dose administration of atorvastatin 20 mg and everolimus 2 mg	Decreased everolimus AUC 5%, and C_{max} 9%. No change in atorvastatin AUC, therefore no dosage adjustment needed	[90]
Everolimus	Cyclosporine	Single-dose study in healthy subjects which administered neoral 175 mg with everolimus 2 mg compared with administration of everolimus alone	Increased everolimus AUC by 2.7 fold (168% range, 46–365%) and C_{max} by 82% (range, 25–158%)	[91]
Everolimus	Erythromycin	16 healthy subjects given erythromycin 500 mg 3 times/day for a total of 9 days and a single 2 mg dose of everolimus coadministered on the fifth day	Increased everolimus AUC 4.4 fold (90% CI, 3.5–5.4) from 116+/− 37 ng h/mL to 524+/− 225 ng h/mL. Everolimus $t_{1/2}$ was prolonged by 39% from 32+/− 6 h to 44+/− 6 h	[92]

(*Continued*)

Table 102.1. (*Continued*)

Immunosuppressant	Interacting agent	Study conditions (if reported)	Results	Reference
Everolimus	Itraconazole	Renal transplant recipient case report	Decreased itraconazole clearance by 74%	[93]
Everolimus	Ketoconazole	12 healthy volunteers given ketoconazole 200 mg 2 times/day for a total of 8 days and a single 2 mg dose of everolimus coadministered on the fourth day of ketoconazole therapy	Increased everolimus AUC 15.0 fold (90% CI, 13.6–16.6), Increased C_{max} 3.9 fold (90% CI, 3.4–4.6), prolonged $t_{1/2}$ by 1.9 fold; everolimus did not appear to alter ketoconazole concentrations	[94]
Everolimus	Posaconazole	Renal transplant recipient case report who received posaconazole treatment in combination with everolimus	Increased everolimus blood trough concentrations.3.8 fold	[95]
Everolimus	Pravastatin	24 healthy subjects given a single oral dose of pravastatin 20 mg and everolimus 2 mg	Decreased everolimus C_{max} 10% and AUC 6%, decreased pravastatin AUC 5%, therefore no dosage adjustments are needed	[90]
Everolimus	Rifampin	12 healthy subjects given rifampin 600 mg once daily for 8 days followed by a single dose of 4 mg everolimus	Increased everolimus clearance 172%, decreased AUC by 63% and reduced the $t_{1/2}$ from 32 to 24 hours	[96]
Everolimus	Verapamil	16 healthy volunteers given verapamil 80 mg 3 times/day for 5 days with a single dose 2 mg everolimus on second day	Increased everolimus C_{max} 2.3 fold and AUC 3.5 fold	[97]
Everolimus	Voriconazole	Renal transplant patient case report who received voriconazole treatment in combination with everolimus.	Increased everolimus blood trough concentrations 7.5 fold	[95]
Mycophenolate mofetil	Ciprofloxacin or amoxicillin plus clavulanic acid	Kidney transplant recipients on MMF received either oral ciprofloxacin 500 mg bid or amoxicillin plus clavulanic acid 375 mg 3 times/day for 7–14 days	Reduced median trough MPA concentrations approximately 50% in 3 days	[3]
Mycophenolate mofetil	Levonorgestrel	18 women with psoriasis followed over 3 consecutive menstrual cycles were co-administered MMF (1 g bid) and combined oral contraceptives containing ethinylestradiol (0.02 mg to 0.04 mg) and levonorgestrel (0.05 mg to 0.20 mg), desogestrel (0.15 mg) or gestodene (0.05 mg to 0.10 mg)	Decreased mean levonorgestrel AUC(0–24h) by about 15%, mean AUC(0–24h) was similar for ethinylestradiol and 3-keto desogestrel	[3]
Mycophenolate mofetil	Magnesium Aluminum Suspension	10 rheumatoid arthritis patients given a single dose of MMF(2 g) and also taking Maalox® TC 10 mL four times/day	Reduced MPA C_{max} by 37% and AUC (0–24h) by 15%	[3]
Mycophenolate mofetil	Norfloxacin and Metronidazole	11 healthy volunteers administered a single-dose of MMF(1 g) on day 4 of a 5 day course of a combination of norfloxacin and metronidazole,	Reduced mean MPA AUC0-48 by 33% compared to the administration of MMF alone	[9]
Mycophenolate mofetil	Pantoprazole	36 patients with autoimmune diseases under stable MMF maintenance therapy; 23 patients received co-medication with pantoprazole and 13 patients received no treatment with PPIs or antacids	Decreased MPA AUC by 37% in pantoprazole treated patients ($P < 0.01$); MPA exposure correlated with the inhibition of IMPDH activity and the area of enzyme activity curve was 42% higher in the pantoprazole treated patients ($P < 0.01$)	[28]
Mycophenolate mofetil	Probenecid	Monkeys	Increased plasma MPAG AUC 3 fold in and plasma MPA AUC 2 fold.	[3]
Mycophenolate mofetil	Rifampin	Heart-lung transplant recipient case report	Decreased MPA exposure AUC (0–12) 67%	[3]
Mycophenolate mofetil	Rifampin	Heart–lung transplant recipient case report	Decreased MMF exposure by more than 2 fold	[73]
Mycophenolate mofetil	Sevelamer	Adult and pediatric patients	Decreased mean MPA C_{max} 36% and AUC(0–12h) by 26%	[3]
Mycophenolate mofetil	Sevelamer	Kidney transplant recipients with single and repeated concomitant dosing with sevelamer and MMF	Decreased MPA by an average of 25%	[20]
Mycophenolate mofetil/ Mycophenolate sodium	Omeprazole	12 healthy volunteers (6 male/6 female) received a single oral dose of MMF 1000 mg or an equimolar dose of EC-MPS 720 mg while fasting with and without co-administered omeprazole 20 mg 2 times/day	Decreased MPA AUC by 20% and the peak concentrations were halved with MMF but no change with EC MPS	[29]
Mycophenolate mofetil/ Mycophenolate sodium	Pantoprazole	12 healthy volunteers (6 male/6 female) received a single oral dose of MMF 1000 mg or an equimolar dose of EC-MPS 720 mg while fasting with and without coadministered pantoprazole 40 mg 2 times/day	Decreased MPA AUC (0-12) by 27% and C_{max} by 57% with MMF but pantoprazole does not change the pharmacokinetics of enteric-coated mycophenolate sodium	[25]
Mycophenolate sodium	Magnesium Aluminum Suspension	12 stable renal transplant patients taking magnesium-aluminum-containing antacids 30 mL and MMF	Decreased MPA mean C_{max} 25% and AUC 37%	[4]
Mycophenolate sodium	Pantoprazole	21 heart or lung transplant recipients treated with pantoprazole 40 mg once daily and EC-MPS 2 times/day at a mean dose of 960 mg	No significant difference in MPA AUC, C_{max}, T_{max} or IMPDH activity AUC	[98]

Table 102.1. (*Continued*)

Immunosuppressant	Interacting agent	Study conditions (if reported)	Results	Reference
Sirolimus	Cyclosporine	24 healthy volunteers in a single dose study were administered sirolimus tablets 10 mg either simultaneously or 4 hours after a dose of Neoral 300 mg	Simultaneous administration: Increased sirolimus mean C_{max} by 512% and AUC by148%, compared to sirolimus alone. Dosed 4 hours after CsA administration: increased sirolimus C_{max} and AUC by 33% compared to sirolimus alone	[5]
Sirolimus	Cyclosporine	24 healthy volunteers single dose study were administered sirolimus oral solution 10 mg either simultaneously or 4 hours after a dose of Neoral 300 mg	Simultaneous administration: Increased the sirolimus mean C_{max} by 116% and AUC of by 230%, compared to sirolimus alone. Dosed 4 hours after CsA: increased sirolimus C_{max} by 37% and AUC by 80%, compared to sirolimus alone	[5]
Sirolimus	Cyclosporine	33 healthy volunteers in a single dose cross-over study received sirolimus oral solution 5 mg alone, 2 hours before, and 2 hours after a dose of Neoral 300 mg	When dosed 2 hours before CsA: sirolimus C_{max} and AUC were comparable to those with administration of sirolimus alone. When given 2 hours after CsA: Increased sirolimus mean C_{max} by 126% and AUC by 141%, compared to administration of sirolimus alone.	[5]
Sirolimus	Diltiazem	18 healthy volunteers with simultaneous oral administration of sirolimus oral solution 10 mg and diltiazem 120 mg	Significantly increased sirolimus C_{max} 1.4 fold, T_{max} 1.3 fold, and AUC 1.6 fold ; sirolimus did not affect the pharmacokinetics of diltiazem	[5]
Sirolimus	Erythromycin	24 healthy volunteers administered sirolimus oral solution 2 mg daily and erythromycin ethylsuccinate tablets 800 mg every 8 hours at steady state	Increased sirolimus C_{max} 4.4 fold, AUC 4.2 fold , increased T_{max} by 0.4 hours; Increased erythromycin C_{max} 1.6 and AUC 1.7 fold, and increased by T_{max} 0.3 hours.	[5]
Sirolimus	Ketoconazole	Multiple dose ketoconazole administration with administration of Rapamune oral solution	Increased in sirolimus C_{max} 4.3 fold, T_{max} 38%, AUC 10.9 fold and the terminal t½ of sirolimus was not changed; single dose sirolimus did not affect steady state 12-hour plasma ketoconazole concentration	[5]
Siroilmus	Rifampin	14 healthy volunteers administered rifampin 600 mg daily for 14 days, followed by a single dose of sirolimus oral solution 20 mg	Decreased sirolimus AUC by 82% and C_{max} by 71%	[5]
Sirolimus	Verapamil	26 healthy volunteers given simultaneous sirolimus oral solution 2 mg daily and verapamil 180 mg every 12 hours at steady state	Increased sirolimus C_{max} 2.3 fold and AUC 2.2 fold without substantial change in T_{max}.	[5]
Sirolimus	Voriconazole	Healthy males given repeat doses of oral voriconazole 400 mg every 12 hours for 1 day then 200 mg every 12 hours for 8 days and a single dose sirolimus 2 mg	Increased sirolimus C_{max} 7 fold and AUC 11 fold	[99]
Tacrolimus	Darunavir	Kidney transplant recipient case report	Increased tacrolimus trough concentrations requiring a dose reduction corresponding to 3.5% of the usual dose	[100]
Tacrolimus	Lopinavir/Ritonavir	3 liver transplant recipients case reports in co-administered lopinavir/ritonavir in combination with tacrolimus	Increased tacrolimus exposure and $t_{1/2}$ approxiamately 10 fold	[101]
Tacrolimus	Nefazodone	2 renal transplant recipients case reports on stable tacrolimus and added nefazodone	Increased tacrolimus trough levels >3–5 fold	[102,103]
Tacrolimus	Nelfinavir	5 liver transplant recipients compared to historical controls and a case report in a liver transplant patient after addition of nelfinavir to a tacrolimus-based regimen	Required a 38–70 fold decrease in tacrolimus dose in order to maintain similar trough concentrations	[104,105]
Tacrolimus	Omeprazole and esomeprazole but not lansoprazole	Renal transplant recipient with stable blood concentrations maintained between 5–8 ng/mL while on lansoprazole (30 mg/day) was switched to esomeprazole (40 mg/day)	Presented one month later with tacrolimus blood concentrations elevated to 27.4 ng/mL. patient switched back to lansoprazole and tacrolimus conc normalized to target range of 5–8 ng/mL	[106]
Tacrolimus	Posaconazole	36 healthy volunteers received tacrolimus 0.05 mg/kg/day on days 1 and 14 and posaconazole 400 mg 2 times/day on days 7–14.	Increased tacrolimus C_{max} by 121% and AUC by 358%, did not affect posaconazole pharmacokinetics	[84]
Tacrolimus	Telaprevir	Single tacrolimus 2 mg oral dose, followed by a minimum 14-day washout period, and subsequent coadministration of a single 0.5 mg dose of tacrolimus with steady-state telaprevir 750 mg every 8 hours	Increased tacrolimus AUC 70-fold and increased $t_{1/2}$ of tacrolimus from a mean (SD) of 40.7 (5.85) hours to 196 (159) hours.	[88]
Tacrolimus	Voriconazole	A primary renal allograft recipient case report	Increased tacrolimus trough concentrations ≥5 fold after 3 days and 10 fold after 5 to 7 days	[107]
Tacrolimus	Voriconazole	Healthy volunteers with repeat oral dose administration of voriconazole 400 mg every 12 hours × 1 day, then 200 mg every 12 hours × 6 days and tacrolimus 0.1 mg/kg single dose	Increased AUC of tacrolimus 3 fold (90% CI, 2.7–3.8) and increased C_{max} by an average of 2 fold (90% CI, 1.9–2.5)	[99]

MMF, mycophenolate mofetil; CsA — cyclosporine; AUC, area under the time versus concentration curve; C_{max}, maximum blood concentration; $C_{min,}$ minimum blood concentration or trough; EC MPS, enteric coated mycophenolate acid sodium; $t_{1/2}$, half-life; $T_{max,}$ time to peak blood concentration

Table 102.2. Common immunosuppressant and food interactions, and their common metabolic and transport pathways [3–8]

Drug Class	Drug	Effect of food on absorption	Metabolism and transport	
			Effect on CYP P450 3A4/5	Effect on P-glycoprotein
Corticosteroids	Prednisone	No effect	Substrate	Substrate
Calcineurin inhibitors	Cyclosporine	Variable	Substrate, inhibitor	Substrate, inhibitor
	Tacrolimus	High fat meal — $\downarrow C_{max}$ by 77% and $\downarrow$AUC by 37% High carbohydrate meal — $\downarrow C_{max}$ by 65% and $\downarrow$AUC by 28%	Substrate, inhibitor	None
mTOR inhibitors	Sirolimus	High fat meal — $\downarrow$AUC by 23–35%	Substrate	Substrate
	Everolimus	High fat meal — $\downarrow C_{max}$ by 60% and $\downarrow$AUC by 16%	Substrate	Substrate
Anti-proliferative	Azathioprine	No effect	None	None
	Mycophenolate mofetil	$\downarrow C_{max}$ by 40%, no change in AUC	None	None
	Enteric coated mycophenolic acid	High fat meal — $\downarrow C_{max}$ by 33%, no change in AUC	None	None
Anti-T cell therapy	Antithymocyte globulin — horse	No effect	None	None
	Antithymocyte globulin — rabbit	No effect	None	None
IL-2 receptor blockers	Basiliximab	No effect	None	None
Costimulation blockade	Belatacept	No effect	None	None

AUC, area under the time versus concentration curve; C_{max}, maximum blood concentration or peak.

MMF and calcium polycarbophil there was a 50% decrease in MPA exposure [11]. This was thought to be due to chelation between MMF and calcium ions in the gastrointestinal tract [11]. A similar interaction was reported between MMF and iron ions. Sustained-release ferrous sulfate tablets given with MMF resulted in a 90% decrease in MPA exposure in seven healthy volunteers [12]. However, other studies found no reduction in MPA absorption in renal transplant recipients [13–16], therefore the importance of this interaction remains controversial. Monitoring of MPA and calcineurin inhibitor (CNI) concentrations and appropriate dosage adjustments are recommended when these drugs are used with divalent cations. To minimize these potential interactions, magnesium and aluminum containing products should not be administered within 2 hours of tacrolimus or the mycophenolate products.

Cholestyramine also reduces the absorption of many medications [17]. Although there are little data in transplant recipients, cholestyramine is typically reserved as the last choice to treat dyslipidemias [18,19]. Other medications including lanthanum and sevelamer may also inhibit the absorption of immunosuppressants. Sevelamer decreases the C_{max} and AUC of MPA and, if needed, the oral doses should be separated by at least 2 hours [3,20]. Lanthanum has the potential to interact with compounds that bind to cationic antacids [21] and thus has the potential to bind MPA.

Changes to the gastrointestinal tract may influence absorption of immunosuppressants. Gastrointestinal effects such as slowing of gastrointestinal motility (common following intra-abdominal operations) and delayed emptying (common in patients with type 1 diabetes-associated gastroparesis), changes in pH, low blood flow, and reduced surface area adversely affect absorption. Laxatives can reduce absorption of other drugs by accelerating their passage through the intestine, and drugs that decrease peristalsis (e.g. narcotics, atropine) prolong transit time in the intestine, increasing the time for absorption. In contrast, fluid intake such as an 250 mL glass of water can increase absorption of medications by improving dissolution. Likewise, prokinetic agents such as metoclopramide [22] and erythromycin may increase drug concentrations by increasing gastrointestinal motility, gastric emptying and absorption in the small bowel.

Interactions may be mediated through transporters and enzymes present in the gastrointestinal tract. It is thought that the potent interaction between sirolimus and cyclosporine is mediated through these mechanisms. Cyclosporine and sirolimus are both substrates for CYP3A4 and p-glycoprotein. In addition, cyclosporine is a potent inhibitor of CYP3A4 and p-glycoprotein Table 102.3 [23,24] When cyclosporine and sirolimus are simultaneously administered, cyclosporine is thought to inhibit sirolimus metabolism in the gut thereby enhancing sirolimus bioavailability. Cyclosporine inhibition of p-glycoprotein also likely reduces efflux of sirolimus back into the gut therefore also enhancing sirolimus bioavailability. The combination of both of these mechanisms leads to a large increase in sirolimus C_{max} and AUC when administered with cyclosporine. Spacing the administration of cyclosporine and sirolimus by 4 hours reduces the potency of this interaction but the interaction still remains of high significance (Table 102.4). Interestingly, this interaction has little effect on cyclosporine blood levels. Patients should be aware of the interactions and take their medications consistently. Clinicians should closely monitor sirolimus because cyclosporine dose requirements and blood concentrations may decrease with time.

Drug interactions also may occur with concurrent use of proton pump inhibitors (PPI) and MPA. Proton pump inhibitors suppress gastric acid secretion and increase the gastric pH. Studies suggest that the combination of MMF with pantoprazole, lansoprazole, rabeprazole and omeprazole results in reduced dissolution of MMF in the stomach at the higher pH, leading to reduced bioavailability and lower systemic MPA exposure [25–31]. Proton pump inhibitor co-medication reduces MPA exposure in heart transplant recipients receiving MMF [26,27]. However, a retrospective study did not demonstrate a reduction in MPA AUC when MMF was administered with PPIs [32].Therefore, the effect of PPI treatment on MMF absorption remains controversial. Patients receiving this combination should have MPA plasma concentrations obtained, although this is distressingly atypical in clinical practiced. The enteric-coated formulation of MPA, EC-MPS, passes the acidic environment of the stomach and dissolves after reaching the neutral pH environment

Table 102.3. Drugs that induce, inhibit, or act as a substrate for CYP3A4/5 by drug class [3–8,43,74,75]

Drug Class	Substrate for CYP450 3A4/5
Anti-convulsants	Carbamazepine, ethosuximide
Anti-infectives	Clarithromycin, dapsone, erythromycin, ketoconazole
Anti-retrovirals	Etravirine, indinavir, lopinavir, nelfinavir, ritonavir, saquinavir, telaprevir
Anti-neoplastic agents	Crizotinib, docetaxel, etoposide, flutamide, imatinib, irinotecan, sorafenib, sunitinib, tamoxifen, taxol, vincristine
Cardiovascular agents	Amiodarone, amlodipine, atorvastatin, diltiazem, drodarone, eplerenone, felodipine, isradipine, lovastatin, nicardipine, nifedipine, nimodipine, nisoldipine, quinidine, simvastatin, verapamil
Immunosuppressants	Cyclosporine, everolimus, dexamethasone, prednisone, sirolimus, tacrolimus
Pain medicines	Fentanyl, methadone
Psychiatric drugs	Sertraline
Miscellaneous	Aprepitant, armodafinil, budesonide, bromocriptine, cannabinoids, cisapride, conivaptan, dasatinib, dexamethasone, ethinyl estradiol, fexofenadine, hydrocortisone, imatinib, lansoprazole, modafinil, ondansetron, progesterone, rifabutin, zolpidem
Drug Class	**Inducers of CYP450 3A4/5**
Anti-infectives	Isoniazid, naficillin, rifampin, rifapentine, rifabutin
Anti-convulsants	Carbamazepine, fosphenytoin, oxcarbazepine, phenobarbital, phenytoin, primidone
Anti-retrovirals	Efavirenz*, etravirine, nevirapine
Immunosuppressants	Dexamethasone, prednisone , prednisolone
Others	Armodafinil, bosentan, bromocriptine, deferasirox, griseofulvin, modafinil, octreotide#, pioglitazone, St. John's wort
Drug Class	**Inhibitors of CYP450 3A4/5**
Antibiotics	Chloramphenicol, ciprofloxacin, norfloxacin (reported with cyclosporine only), quinopristin-dalfopristin
Anti-emetics	Aprepitant
Anti-neoplastics	Crizotinib, dasatinib, etoposide, imatinib, nilotinib, sunitinib, tamoxifen, vemurafenib
Anti-retrovirals	Amprenavir, atazanavir, boceprevir, darunavir, delavirdine, efavirenz*, fosamprenavir, indinavir (strong), nelfinavir (strong), ritonavir (strong), saquinavir (strong), telaprevir, tipranavir
Azole anti-fungals	Clotrimazole, fluconazole , itraconazole (strong), ketoconazole (strong), miconazole, posaconazole, voriconazole
Calcium channel blockers	Diltiazem, felodipine, nicardipine, verapamil
Cardiovascular agents	Amiodarone, dronedarone
Immunosuppressants	Cyclosporine (3A4 inhibitor only), everolimus, tacrolimus
Macrolides	Clarithromycin (strong), erythromycin, telithromycin (strong)
Psychiatric drugs	Fluoxetine, fluvoxamine, nefazodone (strong), sertraline
Others	Bromocriptine, cimetidine, cisapride, conivaptan, danazol, ethinyl estradiol, grapefruit juice, glyburide, methylprednisolone, modafinil, pimozide, propofol , quinine, star fruit, zafirlukast

*May induce or inhibit; #octreotide suppresses growth hormone secretion, which may decrease the metabolic clearance of drugs metabolized by CYP3A4.

Table 102.4. Calcineurin inhibitors, mTOR inhibitors and mycophenolic acid interactions [2,3,5,8,23,24]

	Sirolimus		Everolimus	Mycophenolic acid

C_{max}, Maximum blood concentration; CsA, cyclosporine, MPA, mycophenolic acid.

of the small intestine [33]. Therefore, PPIs when combined with EC–MPS have limited effect on MPA bioavailability and systemic exposure. This has been demonstrated for pantoprazole and omeprazole [25,29].

Distribution

Distribution is the process by which a drug is transferred from the intravascular to extravascular space, both compartments that are in dynamic flux after a transplant. Many processes may affect distribution of drugs including ability of drug to bind to plasma proteins, drug transporters, lipid solubility, tissue permeability and blood flow. However, many drug interactions occurring by distribution mechanisms occur by protein or drug-induced changes in transport.

Many drugs are *protein bound*; however the extent of protein binding varies widely. In general, drugs that are highly protein are at risk for potential drug interactions that are mediated through changes in binding. Proteins such as α-1-acid glycoprotein, lipoprotein, or albumin can bind to drugs in the blood or tissue and decrease the rate and/or amount of drug that reaches the target site. Only unbound drug is pharmacologically active; therefore changes in protein binding are of importance to drugs that are highly bound to one of more of these proteins. Many drugs are bound to proteins; however, only a few drug-drug interactions that occur as a result of

protein binding are clinically relevant. Concomitant use of highly protein bound drugs can displace each from their common proteins thus increasing the unbound drug fraction. Weak acids primarily bind to albumin and basic drugs bind to α-acid glycoprotein. The most significant protein involved in the binding of drugs is albumin. Thus, certain acidic drugs that bind avidly to albumin (e.g. MPA, furosemide, non-steroidal anti-inflammatory drugs, penicillin, phenytoin, salicylates, and sulfonamides) may lead to an increase in unbound drug concentrations when combined with another drug bound to albumin. Likewise, basic drugs bound to α-1-acid glycoprotein (e.g. lidocaine, phenothiazines, propranolol, quinidine, and tricyclic antidepressants) may display an increased amount of available unbound drug when combined with another drug bound to α-1-acid glycoprotein.

Mycophenolic acid and its primary metabolite, mycophenolic acid glucuronide (MPAG), are highly protein bound (>98% and 82%, respectively) to albumin [3]. As MPAG accumulates (as it does with individuals with poor kidney function) it may displace MPA from albumin binding sites, causing an increase in MPA free fraction and potentially a greater pharmacologic effect [34]. Concomitant mycophenolate and phenytoin or theophylline therapy may result in a decrease in the protein binding of theophylline from 53% to 45% and phenytoin from 90% to 87% [3]. Therefore, in patients who require tightly controlled phenytoin or theophylline concentrations additional monitoring (unbound phenytoin, if available) may be required when given with mycophenolate. These types of interactions are difficult to detect and may be noted only through measurement of unbound drug concentrations. Patients at risk for these interactions should be monitored closely for adverse effects and excessive immunosuppression.

Active drug transporter proteins

Active drug transporter proteins control drug movement in and out of cells and can affect the bioavailability, concentration at target tissue and elimination of many agents. Common active drug transport systems include P-glycoprotein and human organic anion-transporting polypeptides (OATPs). These are regulated by genetic factors but can be influenced by food and drugs. Drugs can up or down regulate these proteins thereby altering intestinal absorption, proximal renal-tubular excretion, or biliary excretion. Drug-drug interactions can be mediated through transporter proteins although they are generally clinically difficult to detect. Drug interactions of this type are more likely if one drug is an inhibitor and the other is a substrate of the same transporter. Many of the drugs and foods that affect CYP450 also affect active drug transport systems, greatly confounding the underlying mechanisms by which these interactions occur [35].

P-glycoproteins

P-glycoproteins are part of a large superfamily of efflux transporters distributed to or expressed in many cells including intestinal epithelium, hepatocytes, renal proximal tubular cells, adrenal glands and the blood-brain barrier. P-glycoproteins also are known as multidrug resistance protein 1 (MDR1) or ATP binding cassette sub-family B member 1 (ABCB1) protein. P-glycoprotein is an efflux transporter involved in the movement of substrates across the cell membrane and plays a large role in the distribution and elimination of many clinically important therapeutic substances. Drugs, foods and substances made by the body may be inhibitors and/or inducers of these transporters. Cyclosporine, everolimus, sirolimus and prednisone are substrates of p-glycoprotein (Table 102.2). In vitro data suggest that tacrolimus is neither a substrate nor an inhibitor of P-glycoprotein [36]. Cyclosporine is an inhibitor of P-glycoprotein [37,38]. In an example of this type of interaction, cyclosporine can enhance the efficacy of daunorubicin, docetaxel, doxorubicin, epirubicin, etopisode, mitoxantrone, paclitaxel, vinca alkaloids by inhibiting P-glycoprotein and reducing the efflux of drug out of the tumor cell. Carvedilol inhibits P-glycoprotein and therefore may increase blood concentrations of cyclosporine [39].

Organic anion transporting polypeptides

Organic anion transporting polypeptides also play a role in drug-drug interactions. For example, cyclosporine inhibits the metabolism of repaglinide [40,41]. Cyclosporine appears to reduce the uptake of repaglinide into the liver by inhibiting OATP1B1, which is an active hepatic uptake transporter. In a randomized, crossover study of healthy volunteers, cyclosporine raised plasma concentrations of repaglinide by 175% and AUC by 244% compared to placebo [40]. Complex drug interactions involving CYP450, P-glycoproteins and OATP can occur. For example, cyclosporine is an inhibitor of CYP3A4, P-glycoprotein, and OATP. Ambrisentan is an ET(A)-selective endothelin receptor antagonist, a potential substrate for CYP3A4, OATPs and P-glycoprotein. Twenty-eight healthy subjects received ambrisentan 5 mg daily alone or with steady-state cyclosporine 100–150 mg twice daily, and 24 other subjects received cyclosporine alone at steady-state or with steady-state ambrisentan [42]. With the combination of cyclosporine and ambrisentan, ambrisentan C_{max} increased 1.5-fold, and AUC increased 2-fold. Cyclosporine C_{max} and AUC increased only slightly (906 vs. 1014 ng/mL and 3.05 vs. 3.37 μg h/mL, respectively). Therefore, the recommended maximum dose of ambrisentan is 5 mg if co-administered with cyclosporine.

Metabolism

Even as drug absorption and distribution are taking place, drug elimination begins. Before reaching the systemic circulation, orally administered medications pass through the liver via the portal circulation. The gastrointestinal tract and liver contain enzymes that can metabolize certain drugs before they reach the systemic circulation. Most drugs are metabolized to inactive or less active metabolites by these enzymes. In transplant recipients the most common type of pharmacokinetic drug interaction involves the cytochrome P 450 enzyme system. A summary of the immune suppressants metabolized through CYP3A enzymes is shown in Table 102.2.

Although there are many sites of metabolism, the liver is the most important location of oxidation, reduction, hydrolysis, and conjugation of drugs. Many lipophilic drugs undergo biotransformation to hydrophilic compounds to be excreted. Drug biotransformation reactions consist of Phase I (e.g. oxidation, reduction) or Phase 2 (e.g. conjugation) reactions that occur primarily in the liver. The CYP450 enzyme system is the key pathway of oxidative biotransformation reactions involved in drug metabolism. CYP450 is a superfamily of hemoproteins which can be divided into families, subfamilies and/or single enzymes. The CYP450 enzymes are designated by the letters CYP (representing CYP), followed by an Arabic numeral denoting the family, a letter representing the subfamily (when 2 or more exist) and another Arabic numeral designating the individual gene within the subfamily (e.g., CYP2D6). Of the different isoforms of CYP450, CYP3A4 and 5 are the prevalent

in humans and very important towards drug metabolism of drugs used in transplantation.

Drugs may be substrates for one or more of the CYP450 enzymes and/or also be an inhibitor or inducer of the same or different enzymes (Table 102.3) [43]. In humans, these commonly include CYP450 3A4, 3A5, 2C9, 2C19, 2D6, 2A6, 2E1, and 1A2. By definition, a substrate is a drug acted upon or affected by an enzyme. An inhibitor decreases the metabolic capacity of an enzyme and may therefore decrease the metabolism of specific substrates, generally leading to an increased drug effect. In contrast, inducers can increase the metabolism of specific substrates, generally leading to a decreased drug effect. Drug interactions of this type are more likely if one drug is an inhibitor or inducer and the other is a substrate of the same enzyme. Although many drugs are CYP inhibitors and inducers, their potency varies widely. The potency of the inhibitor or inducer greatly influences the clinical relevance of these interactions. Everolimus, sirolimus, cyclosporine, and tacrolimus are substrates for CYP3A4/5. The active metabolite of prednisone, prednisolone, is also a substrate of CYP3A4, although clinically significant interactions rarely occur. Cyclosporine is a CYP3A4/5 inhibitor and substrate; everolimus is a competitive inhibitor of CYP3A4/5 and a mixed inhibitor of CYP2D6.

Inhibitors and inducers of CYP3A4/5 are listed in Table 102.3. Patients should avoid these medications if receiving a CYP3A4/5 substrate. If a patient cannot avoid a strong inhibitor or inducer of CYP3A4/5, then drug concentrations and toxicities must be monitored closely. Limited data are available regarding precise dose adjustments when inhibitors are co-administered with cyclosporine and tacrolimus. When initiating therapy with voriconazole or posaconazole in patients receiving tacrolimus, the tacrolimus dose should be initially reduced to one-third of the current dose and the subsequent doses should be adjusted based on the tacrolimus whole blood concentrations [2].

Although most metabolism interactions occur via CYP450, especially in the case of CNIs and mammalian target of rapamycin (mTOR) inhibitors, other types of interactions occur with immunosuppressants that are not metabolized by the CYP450 enzyme system. Allopurinol inhibits xanthine oxidase resulting in reduced metabolism of azathioprine and severe bone marrow suppression and pancytopenia [44]. This combination is a potentially serious interaction and should be avoided. If not possible, this combination can be used with significant reductions in the azathioprine dose by 67–75% [6] along with close monitoring.

Mycophenolic acid is extensively metabolized by uridine-diphosphate glucuronosyl transferase (UGT) enzymes. However, no clinically relevant interactions have yet been identified with MPA through this pathway.

Excretion

Excretion is the last process involved in pharmacokinetics and involves drug elimination from the body. The kidneys are the principal site of excretion for water-soluble drugs. The urinary pH may affect drug reabsorption and excretion. Acidification of urine increases reabsorption and decreases excretion of weak acids and decreases reabsorption of weak bases. Alkalinization of urine has the opposite effect.

For some drugs, active secretion into the renal tubules is an important route of elimination. Drugs may also be excreted by the kidney through glomerular filtration, the passive process by which the kidney filters molecules. When drug concentration is high, secretory transport can become saturated. Mycophenolic acid and antivirals including acyclovir, ganciclovir, valacyclovir, valganciclovir undergo tubular secretion. Concomitant use of MPA and these antivirals may result in competition for tubular secretion and an increase in MPA and/or antiviral exposure. Mycophenolate mofetil (1 g) and acyclovir (800 mg) administered to 12 healthy volunteers resulted in no significant change in MPA AUC and C_{max}. However, MPAG and acyclovir plasma AUCs were increased 10.6% and 21.9%, respectively [3]. Following single-dose administration to 12 stable renal transplant patients, no pharmacokinetic interaction was observed between MMF (1.5 g) and intravenous ganciclovir (5 mg/kg). Although in the presence of renal impairment, MPAG and ganciclovir compete for tubular secretion and plasma concentrations of both are increased. In patients with renal impairment in which MPA and ganciclovir, valganciclovir, acyclovir or valacyclovir are coadministered, careful monitoring for hematologic toxicity and signs of over immunosuppression is warranted [3].

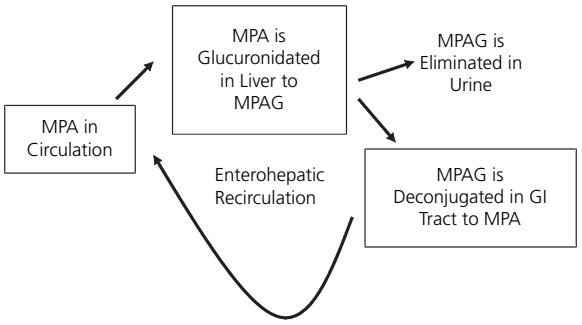

Figure 102.1. Mycophenolate enterohepatic recirulation. Mycophenolate undergoes enterohepatic recirculation and some MPA drug interactions are mediated through this mechanism. In enterohepatic recirculation, a drug secreted in the bile is reabsorbed into the circulation from the intestine.
MPA, mycophenolic acid; MPAG, mycophenolic acid glucuronide.

Other minor sites of excretion are the biliary system, saliva, sweat, and lung. Polar, lipophilic drugs with high molecular weights are excreted in the bile, via active secretory transport. Mycophenolic acid and MPAG biliary excretion, distal absorption and reabsorption may utilize several transport mechanisms including OATPs, and multidrug resistance-associated protein (MRP-2) [45].

Mycophenolate undergoes enterohepatic recirculation and some MPA drug interactions are mediated by interfering with this process. In enterohepatic recirculation, drug secreted in the bile is reabsorbed into the circulation from the intestine (Figure 102.1). In the case of mycophenolate, MPA is glucuronidated by UGT enzymes in the intestine and liver to form the primary glucuronide metabolite, MPAG, which is excreted into the bile. There, MPAG undergoes deconjugation back to MPA and is reabsorbed in the gastrointestinal tract into the systemic circulation, thus increasing plasma concentrations of MPA. Bile acid sequestrants, such as cholestyramine, reduce MPA AUC by inhibiting enterohepatic recirculation resulting in a decrease in MPA AUC by approximately 40% [3]. Cyclosporine also interrupts enterohepatic recirculation of MPA by inhibiting the MRP-2 transporter, thus reducing the amount of MPAG excreted into the bile and less available for conversion to MPA and reabsorption. Mycophenolic acid plasma concentrations are 30%–40% lower when given concomitantly with

cyclosporine than when the drug is given alone or co-administered with tacrolimus or sirolimus [13]. In kidney transplant patients, mean MPA $AUC_{0\text{-}12}$ was increased 30–50% when MMF was administered without cyclosporine compared with when MMF was co-administered with cyclosporine [3,33].

Antibiotics also may interact with mycophenolate. Mycophenolic acid glucuronide is converted to MPA in the gastrointestinal tract by glucuronidases. Glucuronidases are produced by bacteria, and in the presence of antibiotics less glucuronidase is available. In patients and healthy volunteers the use of antibiotics which diminish the gastrointestinal flora, reduce MPAG deconjugation and enterohepatic recirculation of MPA [46,47].

Pharmacodynamic interactions

Pharmacodynamics is the study of the relationship between drug exposure and the drug's pharmacologic effect or clinical response (efficacy or toxicity).

Factors that may contribute to a drug's pharmacodynamic effects include the relationship between a drug and its receptor, age, tolerance, and physiologic factors. Several terms are used to describe the interaction between a drug and its receptor. A synergistic drug effect is when the combination of two or more agents results in an effect that is greater than the sum of their individual effects. For instance, if furosemide and metolazone are given together they have a greater diuretic response than if given alone. Additive drug effects occur when the effects of two drugs combined form a sum effect. In transplant recipients, pharmacodynamics drug interactions generally result in enhanced toxicity or changes in efficacy.

Drug-drug interactions — CNIs

Common side effects of CNIs include neurotoxicity, nephrotoxicity, hypertension, diabetes mellitus, dyslipidemia, electrolytes disturbances. Drugs that also cause the same side effects should be avoided, if possible, in transplant recipients. Hyperkalemia is common after transplantation and therefore drugs that also are associated with hyperkalemia (e.g. potassium-sparing diuretics, ACE inhibitors, angiotension II receptor blockers, amiloride, spironolactone, triamterene) should be closely monitored when given concurrently with CNIs. Transplant recipients treated with cyclosporine and sirolimus had higher serum creatinine levels and lower glomerular filtration rates compared with cyclosporine and placebo or azathioprine controls [5]. Everolimus given with standard dose cyclosporine increases the risk of nephrotoxicity resulting in a lower glomerular filtration rate. Reduced doses of cyclosporine are required for use in combination with everolimus in order to reduce renal dysfunction [8].

Drug-drug interactions — antimetabolites

Bone marrow suppression (including anemia, leukopenia, and thrombocytopenia) is a common adverse event associated with mycophenolate and azathioprine therapy. Given that azathioprine and mycophenolate both inhibit purine metabolism, the combination is not recommended [3,4].

Drugs that increase the risk of bleeding (e.g. anticoagulants, platelet inhibitors and thrombotic agents) should be closely monitored when given with antimetabolites. Additive bone marrow suppression may occur when antimetabolites are given with antivirals such as acyclovir, ganciclovir, valacyclovir, and valganciclovir [3,4,48–50]. Therefore, complete blood counts should be obtained more frequently when these drugs are co-administered. Mycophenolate dose reductions or granulocyte colony stimulating factors are options for treating bone marrow suppression in patients receiving mycophenolate and antiviral agents.

Azathioprine and leflunomide are both associated with hepatoxicity. Regular liver function testing is necessary when these medications are given together. Administration of azathioprine and angiotensin converting enzyme (ACE) inhibitors may result in an increased risk of anemia.

Drug-organ interactions

Table 102.5 provides a list of potential pharmacodynamic interactions relevant to transplantation. The combination of two or more nephrotoxic agents is an example of a pharmacodynamic interaction that results in additive nephrotoxicity. For example, the use of a combination of an aminoglycoside and diuretic should be avoided especially in kidney transplant recipients who have underlying diminished kidney function and are receiving CNIs. Depending on the transplanted organ, certain pharmacodynamic drug-organ interactions may be quite significant. Table 102.6 gives drug-organ interactions that should be avoided or minimized due to the high risk of toxicity to the transplant graft. Herbal or natural products, although sometimes not considered drugs, can have significant toxic effects on the liver, particularly when combined with other hepatotoxins. Table 102.7 is a list of hepatotoxins that should be avoided in liver transplant recipients. Likewise pancreas, heart or lung transplant recipients should avoid drugs that may increase the risk of pancreatitis, hyperglycemia, or compromise cardiac or pulmonary function.

Drug–disease interaction

CNIs, which are known to cause hyperglycemia, have been associated with a worsening of hyperglycemia in those with pre-existing diabetes, or frank development of new onset diabetes, particularly in recipients of African descent [51–53]. To minimize this pharmacodynamic interaction, post-transplant patients should be monitored regularly for hyperglycemia and weight gain.

In general, transplant recipients should not receive live viral vaccines due to their impaired ability to mount an immune response and, therefore, high risk of viral replication. Transplant recipients may require higher doses or more frequent boosters of inactivated vaccines. Likewise, the risks and benefits of co-administration of any medication that may compromise the immune system, for example, antineoplastics, autoimmune disease therapies, natural products with immunosuppressive properties (i.e. Echinacea) should be carefully considered in transplant recipients [54].

Many other drug-disease state interactions might occur. A rare adverse event associated with CNIs and mTOR inhibitors is thrombotic microangiopathy. Concurrent administration of these immunosuppressant's has been associated with an increased risk of thrombotic microangiopathy [55]. Concurrent administration of tacrolimus and quinidine, dronedarone or amiodarone has been associated with prolongation of the QT interval and torsades de pointes [56–58]. Close monitoring with an EKG should occur if the medications are given concomitantly. The administration of sirolimus and everolimus with ACE inhibitors, nonsteroidal anti-inflammatory drugs, salicylates, cephalosporins or penicillins may increase the risk of angioedema [5,8,59]. Prednisone and bupropion combination may increase the risk of seizures [60].

Table 102.5. Pharmacodynamic interactions

Immunosuppressant	Interacting medication	Effect
All immunosuppression	Vaccines	Decreased effect of vaccine
All immunosuppression	Antineoplastics, autoimmune disease therapies	Additive immunosuppression and bone marrow suppression
Calcineurin inhibitors	Potassium sparing diuretics, amiloride, spironolactone, traimterene, TMP/SMZ	Additive hyperkalemia
Calcineurin inhibitors	Sirolimus/everolimus	Additive risk of thrombotic microangiopathy/hemolytic uremic syndrome/thrombotic thrombocytopenic purpura,
Calcineurin inhibitors	Hypoglycemics/antidiabetics	Direct beta cell toxicity – hyperglycemia
Calcineurin inhibitors	See Table 102.6 for a list of nephrotoxins	Additive risk of nephrotoxicity
Tacrolimus	Quinidine, dronedarone, amiodarone, alfuzosin, artemether/lumefantrine, chloroquine, ciprofloxacin, crizotinib, nilotinib, quetiapine, quinine, tetrabenazine, thioridazine, vandetanib, toremifene, ziprasidone, ranolazine, cisapride, dasatinib	Additive prolongation of the QT interval/Torsades
Cyclosporine	Minoxidil	Additive hypertrichosis
Cyclosporine	Androgens	Additive hepatotoxicity
Mycophenolate	Azathioprine	Additive bone marrow suppression
Mycophenolate	Anticoagulants, platelet inhibitors, thrombotic agent	Additive risk of bleeding
Mycophenolate	Antibiotics	May alter GI flora and change enterohepatic recirculation
Mycophenolate	Acylovir, ganciclovir, valacyclovir, valganciclovir, TMP-SMZ	Increased risk of neutropenia
Azathioprine	Leflunomide	Additive risk of hepatotoxicity
Azathioprine	ACEi	Additive risk of anemia
Sirolimus/everolimus	ARB/ACEi, cephalosporins, NSAID/salicylates, penicillin	Additive risk of angioedema
Prednisone	Bupropion	Additive risk of seizures

ARB,angiotension receptor blocker; ACEi, angiotensin-converting enzyme inhibitors; GI, gastrointestinal intestinal; TMP-SMZ, trimethoprim/sulfamethazole.

Table 102.6. Selected medications that may harm or counter the beneficial effects of the transplanted organ

Kidney (nephrotoxicity)	Liver (hepatotoxicity)	Lung (pulmonary toxicity)	Pancreas (pancreatitis)	Heart (cardiotoxicity)
Acyclovir	Acetaminophen	Amiodarone	Azathioprine	Doxorubicin
Adefovir	Amoxicillin-clavulante	Beta blockers	Estrogens	Trastuzumab
Aminoglycosides	Azathioprine	Bleomycin	Furosemide	
Amphotericin B	Captopril	Busulfan	Metronidazole	
ARB/ACEi	Carbamazepine	Cyclophosphamide	Pentamidine	
Carboplatin	Erythromycin	Methotrexate	Salicylates	
Cidofovir	HMG-CoA reductase inhibitors	Minoxidil	Sulfasalazine	
Cisplatin	Isoniazid	Mitomycin-C	Tetracycline	
Cyclosporine and tacrolimus	Nafcillin	Nitrosoureas	Thiazide diuretics	
Foscarnet	Nitrofurantoin	Procainamide		
Ganciclovir	Phenytoin	Quinidine		
Immunoglobulin IV	Rosiglitazone			
Pentamidine IV	Tetracycline			
Methotrexate	Trimethoprim-sulfamethoxazole			
NSAIDS				
Pamidronate				
Polymixin				
Trimethoprim-sulfamethoxazole				
Vancomycin				
Zoledronic Acid				

ARB, angiotension receptor blocker; ACEi, angiotensin-converting enzyme inhibitors; IV, intravascular.

Cholesterol medications and drug interactions

Dyslipidemia is common in transplant recipients, and frequently, it requires treatment; therefore, the potential for interactions between cholesterol-lowering drugs and immunosuppressants is high. Many of the HMG-CoA reductase inhibitors (statins) are substrates of CYP3A4 and are associated with rhabdomyolysis and myositis. Drugs that inhibit CYP3A4, such as cyclosporine, may significantly interact with statins, increase statin concentrations and increase the risk of muscle toxicity. To avoid or minimize these interactions, lower doses of statins are recommended when combined with cyclosporine (Table 102.8) [61,62]. Pitavastatin, an HMG-CoA reducatase inhibitor, is contraindicated with cyclosporine. Cyclosporine is also a known inhibitor of OATP transporter and pitavastatin is influxed into human hepatocytes mainly by OATP1B1. This interaction may result in increased pitavastatin concentrations. Rosuvastatin, pravastatin, fluvastatin are less likely than other HMG-CoA reductase inhibitors to interact significantly with cyclosporine since they are poor substrates for CYP3A4.

Other treatment options for dyslipidemias include fibric acid derivatives, ezetimibe and cholestryramine. Often the treatment of choice for hypertriglyceridemia is fibric acid derivatives. However, when gemfibrozil and cyclosporine are combined there is an additive risk of renal dysfunction. Cyclosporine also may increase ezetimibe serum concentrations and ezetimibe may increase the concentrations of cyclosporine. Patients who receive this drug combination should be monitored for the adverse effects of ezetimibe. Cholestyramine impairs the absorption of many medications by

Table 102.7. Herbal products that are potential hepatotoxins [54]

• African remedy	• Germander	• Pennyroyal

Table 102.8. HMG-CoA reductase inhibitor doses when given with cyclosporine [7,61,62]

Drug	Metabolic pathway	Usual starting dose*	Dose with cyclosporine
Rosuvastatin	CYP2C9	10 mg once per day	5 mg once per day
Lovastatin	CYP3A4	10–20 mg once per day	10 mg once per day
Pitavastatin	Minor amounts by CYP2C9	2 mg once per day	contraindicated in patients taking cyclosporine
Pravastatin	No known CYP metabolism	40 mg once per day	cyclosporine 10 mg once per day
Fluvastatin	CYP2C9	20–40 mg once per day	No change
Atorvastatin	CYP3A4	10–20 mg once per day	10 mg per day
Simvastatin*	CYP3A4	10–20 mg once per day	contraindicated in patients taking cyclosporine^

HMG, 3-hydroxy-3-methyl-glutaryl; CoA, coenzyme A; *No more than 20 mg for patients taking amlodipine and ranolazine; and no more than 10 mg for patients on amiodarone, verapamil, and diltiazem; do not start patients on doses greater than 80 mg due to the risk of rhabdomyolitis.

binding to the drug, including immunosuppressive medications when administered simultaneously. Therefore, in transplant recipients cholestyramine is typically reserved as the last line to treat dyslipidemias.

Herbal products and grapefruit and drug interactions

Herbal products may have significant drug pharmacodynamic interactions with immunosuppressive agents leading to adverse immunologic outcomes and unwanted adverse effects such a bleeding. Unfortunately the effect of herbal products in transplant patients is poorly studied. St. John's wort is an example of an herbal product that interacts with immunosuppressive agents. St John's wort induces CYP3A4 and P-glycoprotein. As a result rejection has been reported in kidney, pancreas, liver and heart transplant recipients who took St. John's wort with immunosuppressive agents [63]. Echinacea is an herbal product that also may have adverse effects on the immune system. In vitro studies have shown that it activates phagocytes, T-lymphocyte proliferation and cytokine production [64]. Herbal medications that may harm the native liver or the transplanted liver are listed in Table 102.7 [54]. Several herbal products may also increase the risk of bleeding. Recommendations suggest that herbal products be discontinued at least 2–3 weeks prior to transplant surgery. Clinicians should carefully consider the influence of natural products on the immune system, the potential for interactions with transplant medications and the risk of harm to the transplanted organ. If there are equally efficacious and safe prescription medications available then herbal medications generally should be avoided.

Grapefruit is an excellent source of vitamins and phytochemicals, yet grapefruit has been linked to many significant drug interactions. A group of active chemical compounds in grapefruit, known as the furanocoumarins, are potent inhibitors of CYP3A4 enzyme. Mechanism-based inhibition of CYP3A4 enzymes in the intestine, by furanocoumarins, results in a complete inactivation of the enzyme [63]. This leads to prolonged CYP3A4 inhibitory effects on the intestinal clearance of CYP3A4 substrates, requiring de novo restoration of the isoenzyme for a return to normal metabolic function. With many oral agents undergoing first-pass metabolism by CYP3A4, the effects of enzyme inhibition can be significant and result in an increase in systemic exposure to drugs that are substrates for CYP3A4 (especially cyclosporine). It is important to educate patients about the interaction between grapefruit juice and their immunosuppressive agents. More frequent monitoring of blood CNI blood concentrations may be necessary in patients who regularly consume grapefruit. Star fruit also has similar potential for interaction.

Pharmacogenomics and drug interactions

Genetic variation has an important influence on the pharmacokinetics and pharmacodynamics of drugs. However, pharmacogenomic data are limited in transplantation relative to other therapeutic areas with the exception of tacrolimus where CYP3A5 enzyme variation has a well-established effect on its pharmacokinetics [65–68]. Increasing data suggest that drug interactions arising through inhibition of CYP3A, 2D6, 2C9 and 2C8 enzymes, which generally have limited clinical relevance, may become highly significant in individuals with underlying genetic variation [69–71].

Sixty-one kidney transplant recipients receiving MMF and tacrolimus with or without a PPI were genotyped for CYP2C19*1, *2 and *3 and multidrug resistance (MDR)1 C3435T alleles [31]. Individuals receiving lansoprazole 30 mg who also had the CYP2C19 *1/*2 or *1/*3, or the MDR1 CC genotypes had MPA AUCs and troughs 25–30% lower relative to those without lansoprazole and the same genotypes. These data suggest that individuals with these genotypes who require an acid blocker may be better managed with an alternative acid blocker or higher doses of MMF.

The addition of an azole antifungal to tacrolimus therapy generally requires a substantial tacrolimus dose reduction to maintain similar blood exposure. Kidney recipients (n = 79) receiving tacrolimus and ketoconazole 100 mg/day were genotyped for CYP3A5. Individuals with the CYP3A5*3/*1 or *3/*3 genotype had a 79–112% increase in tacrolimus troughs after starting ketoconazole whereas those with the *1/*1 genotype had only a 30% increase in dose normalized troughs [72]. A genotype effect also has been suggested for the interaction between tacrolimus and fluconazole in 29 kidney recipients [73]. Dose-normalized tacrolimus troughs occurring immediately following the addition of fluconazole increased 73% in those with the CYP3A5*3/*3 genotype and 45% in those with the *1/*3 genotype, relative to prior to fluconazole treatment. More subjects with the *3/*3 genotype than the *1/*3 genotype (73.9% vs. 16.6%) had trough tacrolimus concentrations >25 ng/mL after starting the fluconazole. These data demonstrate that the potency of tacrolimus drug interactions that are mediated through

CYP3A are in part a function of underlying genotype. Preemptive dose reductions may be determined more accurately with knowledge of the CYP3A5 genotype.

Summary

Careful consideration of pharmacokinetics, pharmacodynamics and pharmacogenomics must be taken into account when prescribing medications for transplant recipients, and drug interactions should be anticipated in essentially all patients. Approaches to prevent or minimize drug interactions should be considered. First, it is a general best practice to minimize the number of medications that a patient receives. Conduct a complete drug history at each transplant visit, including prescription, non-prescription, illicit and herbal medications. Pay careful attention to adding or removing an interacting medication to a transplant regimen. It is common that doses of CNIs and mTOR inhibitors require adjustment when CYP3A inhibitors or inducers are added or discontinued. For interactions that relate to absorption, it may be necessary to adjust the timing of medication administration to minimize the interaction. In the case of pharmacodynamics interactions, carefully monitor the patient for early signs of toxicity, infection or rejection. More aggressive monitoring of drug concentrations and chemistries may be necessary in the case of all types of interactions.

SECTION 7

Long-term Transplant Outcomes

CHAPTER 103

Long-term Outcomes after Kidney Transplantation

Sundus A. Lodhi[1] and Neema Stephens[2]

[1] Transplant Nephrology, Emory University, Atlanta, GA, USA

[2] Transplant Nephrology, University of Texas-San Antonio, San Antonio, TX, USA

Introduction

Kidney transplantation has advanced substantially in the past three decades and is now routinely accepted as the treatment of choice for most causes of end stage renal disease (ESRD). With its success, growing numbers of kidney recipients have populated the clinics, and their outcome over time has become a growing concern, supplanting short-term survival as the predominant metric for success. Indeed, the issues influencing long-term outcomes differ in several ways from the factors influencing technical and early phase success, and the data capturing these factors continues to mature. This chapter will cover the long-term results that can be anticipated for patients receiving a kidney transplant, identify the donor- and recipient-specific risk factors influencing death and graft failure, and discuss the causes of late death and graft loss.

Long-term outcomes of renal transplant recipients

Clinical barometers for measuring success after kidney transplantation include traditional end points of acute rejection rates, allograft survival, and overall patient survival. Most data derived from clinical trials is focused on short-term survival. In fact, the majority of landmark studies and pivotal trials that have led to clinical practice changes are designed based on 1-year rejection rates and survival as their primary end points. The major difficulty in attaining accurate assessments of long-term outcomes is two-fold:

- the time required to reach long-term end points, and
- maintaining accurate follow-up during the longer time frame.

One way to navigate around these problems is to make projections using Kaplan-Meier estimates from large registry data as observational or retrospective analyses. One study merged data from the US Renal Data System (USRDS) with data from the Scientific Renal Transplant Registry (SRTR) and subsequently found long-term benefits of deceased donor transplants over maintenance dialysis. These benefits were evident irrespective of genders, ages, and races. These findings re-ignited research emphasis on transplantation as a life saving procedure. Now, kidney transplantation continues to emerge as the treatment of choice for ESRD patients, with well-established benefits in patient survival over dialysis [1,2].

As longer post-transplant follow-up data becomes available, estimation of graft and patient survival after transplantation has become more accurate. Previous predictions on shorter follow-up times are now replaced with actual data based on longer follow-up times. This allows for not only actual survival calculations but also for more accurate forecasting with more available data. Our understanding of long-term graft survival has evolved from a previous overly optimistic state to a realization that improvements in patient and graft survival are driven mostly by improvement of first-year survival [3].

Progress in immunosuppression management has resulted in constant improvement in overall rejection rates and advances in surgical techniques continue to improve graft longevity. This has led to an improvement in unadjusted 1-year graft survival rates from 76% in 1987 to 93% in 2008 (OPTN/SRTR Annual Data Report 2010). Even in the early years of transplantation from 1975 to 1990, a significant increase in 1-year graft survival was seen without a corresponding increase in allograft half-life of those organs that survived past the first year [4].

The most recent analysis of long-term outcomes after transplantation indicates that most advances have resulted in dramatic improvements in first-year survival with smaller advances in longer term survival rates [5].

Acute rejection rates have seen a dramatic decline over the past 20 years, yet graft life over the long run has not been impacted as significantly. This discrepancy may partially lie in the fact that renal allografts with rejections that return to baseline renal function have similar unadjusted 6-year graft survival as those allografts that do not have rejection. However, post rejection renal function that does not return to within at least 15% of baseline function is associated with a decrease in graft survival (50.2% 6-year survival compared to 72.7% that returned to baseline function) [6].

When counseling the individual patient in the pretransplant phase, graft half-life can be a clinically useful tool to provide the patient with a reasonable expectation of survival. Yearly graft attrition rates allow assessment of survival in early versus late post-transplant as the factors relating to survival vary over time.

In analyzing cumulative half-lives based on Kaplan-Meier estimates from 1989–2005, we find that the actual half-life of deceased donor transplants has improved from 6.6 years in 1989 to 8.2 years in 2000 and is forecasted to increase to 8.8 years in 2005. Among deceased donor transplants, standard criteria half-lives improved from 6.7 years in 1989 to 8.8 years in 2000, and forecasts to 9.5 years in 2005.A more dramatic improvement is noted with expanded criteria kidney half-life with an increase from 3 years in 1989 to 5.6 years in 2000 and forecasts to 6.4 years in 2005. Living donor transplants fare better, but have seen less of an improvement over time

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

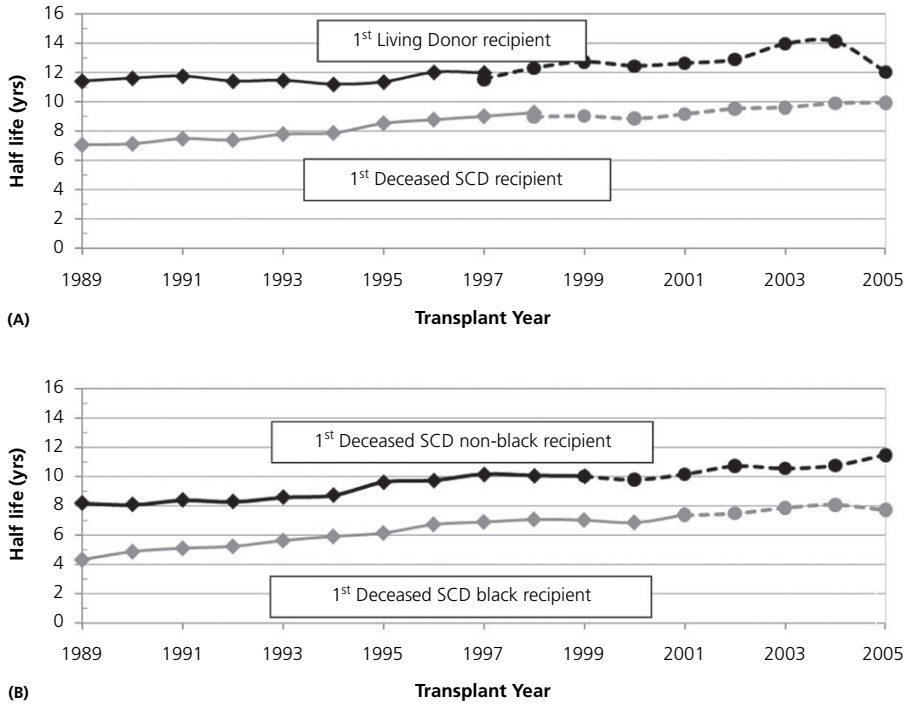

Figure 103.1. Actuarial (diamond marker, solid line) and projected (round marker, dotted line) cumulative half-lives. (A) First living donor versus standard criteria recipients. (B) First standard criteria in non-black versus black recipients. (Reproduced from [5] Lamb et al. Am J Transplant. 2011, with permission from Wiley-Blackwell).

with half-lives of 11.4 years in 1989 to a forecasted half-life to 11.9 years in 2005.

Racial disparities are known to exist with multiple studies showing black recipients having lower graft survival than non-black recipients [7,8]. In comparing half-lives of black versus non-black recipients, a similar absolute increase has been observed (4.1 to 7.4 years for black and 7.8 to 10.9 years for non-black), but not a major narrowing in the gap among black and non-black recipients (Figure 103.1).

The factors that contribute to long-term graft survival are different from short-term survival. Allograft-specific factors include chronic rejection, infections, and risks associated with long-term immunosuppression such as post-transplant lymphoproliferative disease. As an individual graft and patient life increases, more complex factors such as cardiovascular disease, weight gain, and access to care become more predominant. Indeed we are now beginning to see issues related to the aging transplant recipient that are resulting in increasing rates of death with a functioning graft.

Clinicians have struggled to find the best way to describe chronic allograft injury leading to graft loss. The term chronic rejection was initially used to describe the histologic changes of the failing allograft. The term was overly simplistic, since rejection is not the only mediator of chronic damage leading to graft loss. The term chronic allograft nephropathy (CAN) was adopted in the early 1990s as a means of emphasizing the multi-faceted etiology of progressive graft dysfunction. The characteristic lesions of CAN encompass tubular atrophy, interstitial fibrosis, glomerulosclerosis and arteriolar hyalinosis. In 2005, the 8th Banff Conference decided to eliminate the term CAN and focus on the more descriptive term chronic allograft injury. This term illustrates that a number of processes often contribute to chronic graft dysfunction. Hypertension, diabetes, infections such as BK virus, calcineurin inhibitor (CNI) toxicity, recurrent or de novo glomerular diseases, and chronic rejection can all cause chronic allograft injury and ultimately graft loss.

Organ quality and donor factors

Organ type and size

Risk factors for graft failure vary depending on the type of renal transplant. Organ quality plays a major role in outcomes [9]. Living donor transplants have minimal cold ischemia time and superior outcomes to include lower rates of acute rejection, lower incidence of delayed graft function, and longer graft life. Deceased donor transplants, regardless of the degree of HLA matching, have overall worse long-term survival when compared to living donor transplants. To illustrate this point, a living donor kidney transplant with 0 HLA matches has better graft survival than a 6 antigen match deceased donor kidney.

The quantity of functioning nephron mass in the renal allograft plays an important role in graft performance and survival. A large multi-center study of first time kidney transplant recipients determined that the ratio of kidney weight to recipient weight of less than 2.3 g/kg was an independent risk factor for graft loss at 2 years follow-up [10]. It is proposed that the same concept is relevant for kidneys from extremely young or older donors due to the smaller quantity of functioning nephrons relative to recipient need.

Donor risk index

The kidney donor risk index is an equation designed as a practical tool to assist clinicians with decision-making regarding deceased organ acceptance. This assessment takes into account donor factors that impact graft survival: donor age, height, weight, ethnicity, presence of diabetes, hypertension, death from stroke, donation after cardiac death, terminal creatinine, and hepatitis C virus infection

[11]. This calculation assigns a risk of graft failure relative to an "average" 40-year old standard criteria deceased donor kidney. While this score is useful in regards to assessing how well a kidney may do at the time of acceptance, the score does not reflect other factors that play into long-term graft survival and has not been validated prospectively.

When considering factors that predict prognosis, a distinction should be made regarding a risk factor (e.g. diabetes is a risk factor for graft failure) versus a prognostic factor, in which case the factor should reliably and predictably separate outcomes. The kidney donor risk index (KDRI) is reasonable to separate outcomes of kidneys from very high or very low risk donors, however it is not as robust in distinguishing outcomes of the majority of the "middle-range" kidneys. A risk index to reliably predict long-term graft survival that has been prospectively validated has not yet been identified.

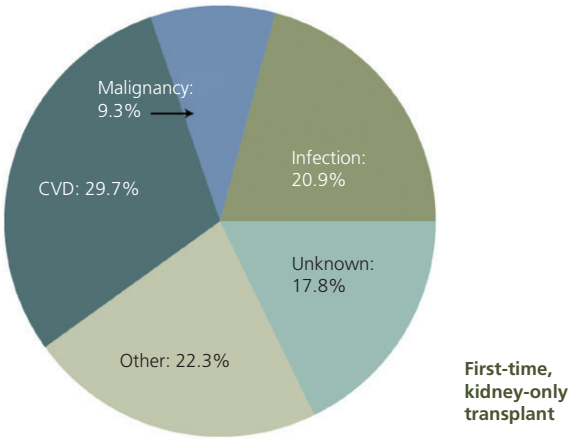

Figure 103.2. Cardiovascular disease accounts for most death with functioning renal allograft. Data from USRDS.
US Renal Data System, USRDS 2011 Annual Data Report: Atlas of Chronic Kidney Disease and End-Stage Renal Disease in the United States, National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases, Bethesda, MD, 2011. The data reported here have been supplied by the United States Renal Data System (USRDS). The interpretation and reporting of these data are the responsibility of the author(s) and in no way should be seen as an official policy or interpretation of the U.S. government.

Recipient factors

Timing of transplantation

The duration of time on dialysis is a known negative factor of allograft survival. Pre-emptive transplantation before dialysis initiation or minimal time on dialysis (<6 months) have been shown to have superior patient and death-censored allograft survival compared to and increasing time on dialysis [12]. Pre-emptive transplantation specifically is shown to significantly decrease patient mortality (relative risk [RR] 0.84 and 0.69) and graft failure (RR 0.75 and 0.73) in both living and deceased donor transplant recipients respectively. However, pre-emptive transplantation is also more likely to happen in younger, privately insured, and higher education recipients [13]. The studies showing benefit of early transplantation are mainly retrospective, and they inherently cannot avoid the preselection bias of healthier individuals with better access to medical resources receiving early transplants. Nonetheless, statistical adjustments to account for donor factors and preselection biases seem to uniformly indicate that earlier transplantation results in improved long-term outcomes. While the reasons have not been entirely elucidated, the early introduction of transplantation may reduce dialysis-related infectious and cardiovascular morbidity subsequently resulting in better long-term survival.

Death with a functioning allograft

While transplantation confers a survival advantage and net gain in life compared to dialysis, transplant recipients still have a shorter life expectancy than the general population. Cardiovascular disease is the leading cause of premature death in this patient population (Figure 103.2).

The annual incidence of death from cardiovascular causes is estimated to be 5%. Patients with advanced chronic kidney disease accumulate a significant burden of cardiovascular disease prior to transplant that further contributes to outcomes after transplant. The renal transplant recipient often has a combination of traditional and non-traditional risk factors for cardiovascular disease. The traditional Framingham risk factors include the presence of hypertension, hyperlipidemia, diabetes mellitus, tobacco use, obesity, and physical inactivity. Additional non-traditional risk factors affecting the transplant recipient are immunosuppression related side effects. Managing recipient risk factors for cardiovascular disease is of prime importance since it is the most common cause of death with a functioning allograft. This section will review each risk factor in detail.

Hypertension

Hypertension is an independent risk factor for late allograft loss. Blood pressure at one year is predictive of graft survival. There is a statistically significant reduction in graft survival for each 10 mmHg increase in systolic, diastolic and mean arterial blood pressure [14]. While there have been no prospective randomized controlled trials on blood pressure therapies and targets in the transplant population, Kidney Disease: Improving Global Outcomes (KDIGO) guidelines recommend maintaining blood pressure <130/80 mmHg.

Hypertension, defined as a blood pressure exceeding 140/90, is prevalent in the majority of renal transplant recipients. It can be a consequence of pre-existing hypertension, obesity, or other transplant related factors. Graft dysfunction from acute or chronic causes is also associated with the development of hypertension.

Immunosuppressive therapy itself directly causes hypertension. Corticosteroids have been used for immunosuppression since the early years of transplantation and contribute to hypertension through mechanisms of salt and water retention. In the early 1980s, 50–60% of transplant recipients had hypertension. This prevalence has increased to 75–90% in the modern era of CNI use [15]. Many transplant programs are now employing steroid sparing and CNI avoidance protocols in attempt to minimize this adverse effect, as it is a major contributor cardiovascular disease and death with a functioning allograft.

Hyperlipidemia

In the first transplant year at least half of patients will have lipid abnormalities. Hyperlipidemia, especially elevated low-density lipoprotein (LDL), is an independent risk factor for cardiovascular disease. KDIGO guidelines recommend checking a lipid panel within the first three months post-transplant and annually thereafter. Certain immunosuppressive agents such as corticosteroids, CNIs and mammalian target of rapamycin (mTOR) inhibitors can exacerbate or cause de novo hyperlipidemia. Therefore, one may

consider modifying immunosuppression to help improve the lipid profile. Sirolimus is most associated with elevations in both total cholesterol and triglyceride levels. Among the CNIs, cyclosporine has the greatest impact on worsening of total cholesterol and LDL. The Assessment of Lescol in Renal Transplantation (ALERT) trial was a prospective, randomized control trial investigating the impact of statin therapy on cardiovascular outcomes of renal transplant patients. Over 2000 patients were randomized to fluvastatin or placebo. The statin group had a statistically significant reduction in the secondary endpoint of non-fatal myocardial infarction and cardiac death and a non-statistically significant trend toward reduction of cardiac events [16]. Based on this evidence, it is recommended that statins are the first-line pharmacologic therapy for hyperlipidemia in renal transplant patients. While attempts at lifestyle modification may be helpful, most patients will require pharmacologic therapy. When selecting a statin, one must be aware of the potential for drug interactions with the CNIs. Since both classes of drugs are metabolized via the cytochrome P450 system, some statins will need to be dose reduced when used in combination with CNIs. In general, fluvastatin, atorvastatin and pravastatin have the better safety profile for use in transplant patients. Due to the higher risk of cardiovascular disease in transplant recipients, KDIGO recommends LDL goals of less than 100 mg/dL. For diabetic transplant recipients or those with a known history of cardiovascular disease, some clinicians favor more aggressive target of less than 70 mg/dL.

Tobacco use

Up to one-third of kidney transplant patients smoke tobacco products on a regular basis Smoking at the time of transplant is an independent risk factor for all-cause mortality, ischemic heart disease, stroke, congestive heart failure and peripheral vascular disease. In a single center study, active tobacco use was associated with a two-fold increase in cardiovascular death compared to non-smokers. Additionally, data from the USRDS system indicates that incident smoking *after* transplantation increases the risk of death-censored graft loss and overall patient death. This is independent of pre-existing lung disease prior to transplantation [17]. Since patients have a forced abstinence during the transplant hospital admission, this represents an opportunity for interventions and counseling. Counseling should include the "5 A's":

1 ask about tobacco use,
2 advise to quit through clear and personalized messages,
3 assess willingness to quit,
4 assist in quitting, and
5 arrange follow-up and support.

There are a number of pharmacotherapy options available including nicotine replacement gum, lozenges and patches, the nicotinic receptor partial agonists, and anti-depressants.

Diabetes mellitus

As one of the leading causes of ESRD in the US, diabetes mellitus is present in one out of every five patients at the time of renal transplant. Among renal transplant recipients without pre-existing diabetes, 24% will develop new onset diabetes by 3 years after transplant. As in native kidney disease, diabetic nephropathy can affect the renal allograft and lead to graft dysfunction, although it is rarely the sole cause for graft loss. A retrospective study of renal transplant patients in the USRDS demonstrated that new-onset diabetes after transplantation (NODAT) was associated with increased graft failure and patient mortality. They identified a number of key risk factors for NODAT including age, African American and Hispanic ethnicity, obesity, and hepatitis C [18]. Transplant providers are encouraged to use the American Diabetes Association criteria to identify patients with impaired fasting glucose and diabetes. Impaired fasting glucose defined as a fasting glucose between 100–125 mg/dL without diabetes is also associated with higher rates of cardiovascular events in the renal transplant population. Education about lifestyle modification with diet and exercise should be included, especially in patients with obesity. Pharmacologic therapy should be prescribed with the goal of achieving HbA1c 7–7.5% per KDIGO guidelines. Low dose aspirin therapy is recommended for primary prevention of cardiovascular disease events in all renal transplant patients with diabetes.

Modern-day immunosuppressive therapy again can directly contribute to the development of NODAT. CNIs, especially tacrolimus, impair insulin secretion from pancreatic beta cells while corticosteroids contribute to insulin resistance. Therefore, providers should consider customizing immunosuppression based on the presence of or risk factor for diabetes.

Obesity

As in the general population, a large number of renal transplant recipients are affected by obesity. In fact, a retrospective review of the United Network for Organ Sharing (UNOS) database noted a 50% prevalence of obesity in renal transplant recipients. Utilizing the body mass index calculation (BMI), obesity is defined as a BMI greater than 30 and morbid obesity the BMI is greater than 35. Morbid obesity is independently associated with higher rates of delayed graft function and decreased overall graft survival [19]. In addition to its impact on renal allograft outcomes, obesity is linked to the development of insulin resistance, diabetes mellitus and atherosclerotic heart disease. Since appetite improves after transplant and dietary restrictions are lifted, transplant patients should be counseled on the importance of physical exercise and nutrition. This should be incorporated into each routine clinic visit.

Cardiovascular disease

It is important to realize that cardiovascular disease involves a spectrum of various endpoints including ischemic heart disease, congestive heart failure, peripheral vascular disease and stroke. These are all important outcomes of interest that contribute to premature death in renal transplant patients. The clinician should have a low threshold for screening. Revascularization procedures such as percutaneous angioplasty and coronary artery bypass grafting are available options in kidney transplant patients yielding 2-year patient survival rates of approximately 80% [20]. While there are risks of acute kidney injury related to the procedure, the rates of graft loss as a consequence are low.

CNI nephrotoxicity

CNI, cyclosporine and tacrolimus, have served as the backbone for maintenance immunosuppression for decades. These potent agents are largely responsible for the high rates of early graft survival seen in kidney transplantation. The weakness of CNIs is their associated nephrotoxicity. Thrombotic microangiopathy, arteriolar hyalinosis and tubular injury with isometric vacuolization have been described with CNI-related renal toxicity. Nephrotoxicity can present clinically as an acute azotemia and also as slower, chronic injury occurring with long-term use. Dihydropyridine calcium channel blockers

are believed to have a protective effect against the vasoconstrictive properties of CNIs. In a prospective study of 107 cyclosporin (CsA) treated patients, those receiving nifedipine had lower rates of delayed graft function, higher measured glomerular filtration rate and less interstitial fibrosis on biopsy at 12 months [21]. The hypothesis is that calcium channel blockers not only cause vasodilation of the afferent arteriole, but they also block the influx of intracellular calcium and this may protect the graft from ischemia-reperfusion injury. In addition to the direct effect of CNIs on afferent arteriole constriction, CNI therapy significantly contributes to cardiovascular risk by having higher incidences of hypertension, diabetes, and hyperlipidemia as mentioned above.

CNI-sparing regimens have long-been sought after with very few immunosuppression therapies showing longer allograft survival in the long term. Belatacept is the only recent exception, with better documented renal function at three years post-transplant compared to recipients maintained on cyclosporine [22]. Recipients maintained on belatacept without a CNI also seem to have better metabolic risk profiles with decreased incidence of hypertension, hyperlipidemia, and diabetes compared to cyclosporine treated recipients [23]. Long-term follow-up data is still needed, however the projection of improved renal function in patients treated with belatacept as opposed to cyclosporine appears promising.

Recurrent or de novo glomerular disease

The risk of graft failure from recurrent glomerulonephritis (GN) is highest in patients whose ESRD was from focal segmental glomerulosclerosis (FSGS), membranoproloferative glomerulonephritis, and IgA nephropathy. Patient at low risk for graft failure from recurrent GN include patients with lupus nephritis and anti-glomerular basement membrane disease. In patients with a history of idiopathic FSGS, an estimated 30–50% of patients will experience disease recurrence in the allograft. A history of rapid progression to ESRD within three years of diagnosis and previous failed transplant due to recurrent FSGS are the strongest predictors of recurrent disease.

One retrospective analysis compared 167 renal allograft recipients with recurrent or de novo glomerular disease to 4746 recipients without glomerular disease.

Patients with GN had a median graft survival of 1360 days compared to 3382 days in recipients without recurrence or de novo disease ($P < 0.0001$). The 5-year survival rate for those with recurrent or de novo disease was 39.8% versus 67.6% without disease [24]. Recurrent disease is covered in additional depth in Chapter 77.

Immunologic injury

Transplant recipients with higher panel reactive antibody (PRA) values at the time of transplant are known to have worse long-term survival. A retrospective analysis of 4000 HLA-identical sibling transplant recipients showed a 72.4% 10-year survival in recipients with no PRA pretransplant as compared to 63.3% with 1–50% PRA, and 55.5% in >50% PRA [25]. Some studies also suggest that patients maintained on lower doses of immunosuppressive therapy develop a higher prevalence of chronic allograft nephropathy as another risk for earlier graft loss. These data indicate that chronic and subclinical immune-mediated injury clearly plays a role in long-term graft survival. Identifying non-HLA immunity continues to pose a challenge in improving chronic allograft injury.

The impact of sensitization and donor specific antibodies

Sensitized patients are those individuals who have detectable HLA antibodies in the serum prior to transplantation. Pregnancy, previous blood transfusion and prior transplants are all sensitizing events, which may lead to HLA antibody formation. When present in sufficient quantity, these donor-specific antibodies (DSAs) will cause positive crossmatch studies. Some transplant centers in the US report successful transplantation of individuals with a positive flow cytometry crossmatch after the use of desensitization protocols. These protocols combine pretransplant plasmapheresis with intravenous Ig to lower the titers of DSA prior to transplant. DSA at the time of transplant has been associated with early antibody mediated rejection and shorter graft half-life. Additional detail regarding DSA and its detection can be found in Chapter 77.

Non-sensitized patients can experience antibody-mediated rejection (AMR) through the development of de novo DSAs. A multi-center, prospective trial by demonstrated that 20% of patients with a functioning renal allograft developed HLA antibodies [26]. These antibodies were associated with significantly higher rates of graft loss one year after detection. This association was true for those sensitized at the time of transplant as well as those who developed de novo DSA post-transplant. DSAs may appear months to years prior to the development of graft dysfunction. A prospective study of 300 first time renal transplant recipients with no detectable HLA antibody at the time of transplant found a 15% prevalence of de novo DSA development after the first six months post-transplant. The two strongest predictors for de novo DSA development were HLA-DR mismatch and medication non-adherence. In ten-year follow-up, graft survival was 57% in the de novo DSA group compared to 96% in the group without DSA [27]. Another single center study of 347 renal transplant patients followed prospectively over a three year period 18% of recipients developed de novo DSA, with DQ antibody being the most prevalent [28]. Patients with DQ antibody in conjunction with other DSA had worse three year graft survival (52%) compared to HLA-DQ alone, other HLA antibodies alone, or no antibodies (92–94%). This supports the pervasive belief that class II HLA antibodies have a dominant role in late graft failure. The following diagram (Figure 103.3) depicts the proposed natural history of de novo DSA and its impact on the allograft.

The spectrum of antibody mediated injury

HLA antibodies are the major players in the development of AMR. The entity of AMR traditionally compromises a wide spectrum of pathology from hyperacute rejection to acute and chronic AMR and ultimately transplant glomerulopathy. Late-onset acute AMR with or without detectable DSA is often a signal of medication non-adherence.

A variety of effective therapies for acute antibody mediated rejection are employed, including plasmapheresis, immunoadsorption, and intravenous immunoglobulin (IVIG), rituximab, bortezomib, and eculizumab. These therapies are discussed in detail elsewhere in this textbook.

While targeted therapy can often reverse the acute AMR episode with improvement in renal function, the occurrence of AMR negatively impacts long-term graft survival. Despite improvement in clinical parameters, patients with AMR may progress to develop transplant glomerulopathy. Transplant glomerulopathy is believed to be a consequence of immune mediated endothelial injury, and is highly associated with inferior graft outcomes.

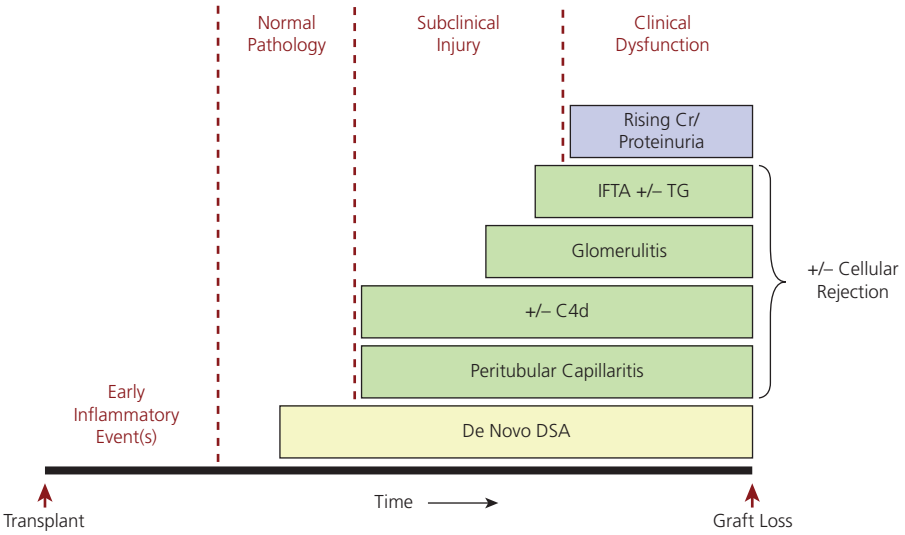

Figure 103.3. Proposed natural history of de novo donor specific antibodies (adapted from [27] Wiebe et al. Am J Transplant. 2012, with permission from Wiley-Blackwell).

Chronic antibody mediated rejection (CAMR) has been a major cause of late graft failure. Histologically, CAMR is associated with the presence of multi-lamination of the glomerular and tubular basement membrane, transplant glomerulopathy, and peritubular capillaritis with or without C4D deposition. CAMR often is accompanied with significant tubular interstitial fibrosis and tubular atrophy as well as microvascular changes. Since antibodies initiate their insult by adhering to the endothelium of the microvasculature, this is common. Despite effective immunosuppression and a variety of strategies to treat acute humoral rejection, there are no effective strategies for the management of CAMR. Clinically, CAMR may manifest as subacute, progressive renal allograft dysfunction and proteinuria. Patients may also have peripheral edema and hypertension. The presence of pretransplant DSAs, highly sensitized state and de novo DSA formation are all associated with the development of CAMR. Non-adherence is a major contributing factor and should be suspected in patients with serial subtherapeutic immunosuppression drug levels.

Infection and post-transplant malignancy

Transplantation continues to be hampered by infectious and malignant morbidity and mortality. While additional detail regarding the general topics of late infectious and malignant disease can be found in Chapters 94 and 95, respectively, the prevailing features of these complications are summarized below.

Cytomegalovirus infection

CMV mismatch (donor positive/recipient negative) status at the time of transplant is associated with decreased graft survival and increased patient mortality. CMV disease post-transplant has also been shown to be of a higher incidence in recipients that received zero match HLA-DR kidneys [29]. This single-center retrospective review of 470 transplanted recipients also found decreased graft survival of recipients with CMV disease and zero matched HLA-DR (5-year survival was 16.2% for zero matches compared to 87.5% for two matches). The predisposition to earlier graft loss may in part be due to direct morbidity from CMV infection, and also may be from the longer-term effect of decreasing maintenance immunosuppression. Although allocation based on CMV sero-status matching along with HLA has been considered in the transplant community, the current organ shortage in the US favors less waiting time over serological matching. After transplant however, most centers continue 6–9 months of extended prophylaxis in recipient CMV-negative transplants with the intent to minimize CMV disease and subsequently improve longer outcomes.

BK polyoma virus

In transplant recipients, increased immunosuppression burden is associated with active BK infection leading to tubular-interstitial nephritis, ureteral stenosis, and cystitis. Diagnosis is usually made by screening and mostly occurs within the first year after transplant, although it can occur much later. Since first-line treatment involves reduction of immunosuppression, adverse effects on the allograft may be three-fold:

- direct viral tissue injury may occur with complications in the renal parenchyma and urinary tract,
- long-term chronic immunological injury can result from immunosuppression reduction, and
- faster decline of renal function after inflammation and fibrosis may be observed.

Actual data on graft loss effects after detection of BK nephropathy are limited to very small studies with a wide variety of immunosuppression reduction strategies, making the actual impact of late BK difficult to assess. In an analysis of 41 renal allograft recipients with BK nephritis, 3- and 5-year survival was significantly reduced from 83% and 76%, respectively in those without BK down to 58% and 47%, respectively. Forty six percent of BK recipients experienced graft loss. Of those that recovered renal function after management of BK, the time to stabilization of renal function was 112 days [30]. BK virus nephropathy presents a significant threat to both short and long term graft survival.

Epstein-Barr and post-transplant lymphoproliferative disease

Post-transplant lymphoproliferative disease (PTLD, covered in detail in Chapter 96) occurs in an estimated 1% of transplanted

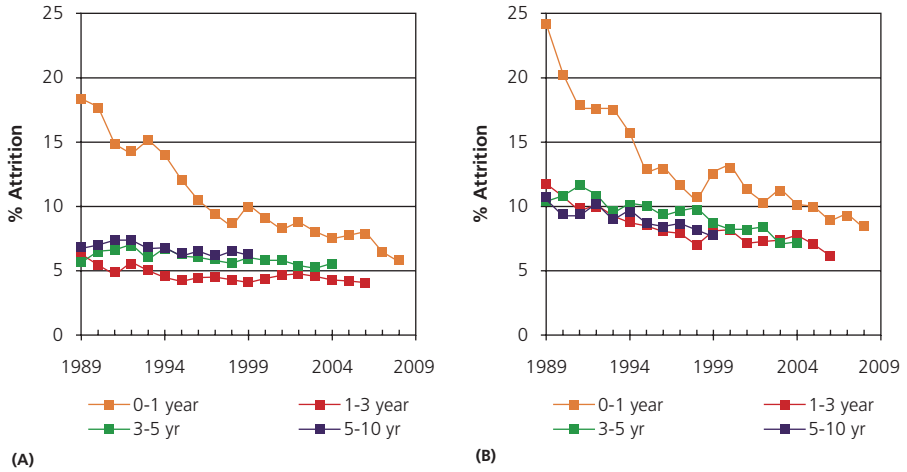

Figure 103.4. Cumulative graft failure yearly attrition rates of first kidney transplants. (A) Non-black deceased SCD donor, and (B) black deceased SCD donor. (Reproduced from [5] Lamb et al. Am J Transplant. 2011, with permission from Wiley-Blackwell.)

patients, but confers a high risk of death. It is classically associated with Epstein-Barr virus (EBV) induced B cell proliferation, although EBV-negative PTLD is well documented. It is the most common malignancy of transplant recipients excluding non-melanoma skin cancers. The traditional thought has been a higher risk of PTLD is conferred by EBV seronegative status at the time of transplant and immunosuppression burden. Recent data showing a higher incidence of PTLD in EBV negative patients on the CLTA-4 inhibitor belatacept suggests that risk of PTLD is more related to T cell suppressive therapy [22].

Most diagnoses of PTLD are made in the first 18 months post-transplant with an estimated 1% incidence over 10 years. Although a relatively rarer complication, patient survival is significantly reduced to 51% at 1-year and 39% at 5-years [31]. An OPTN database analysis of PTLD diagnosis estimated the risk of death with graft function to be 17.5 times higher with diagnosis of PTLD, and the risk of death-censored graft failure to be 5.5 times higher [32].

Social and racial determinants of health

Significant but still poorly characterized effects of socioeconomic factors on long-term outcomes of transplant recipients are becoming increasingly recognized.

Black recipients experience worse graft and patient survival rates than other races. Variations in HLA polymorphisms, immunosuppression requirements, and pharmacokinetic variability have been described as biological factors influencing higher rejection rates and graft [7,33]. In the recent era of immunosuppression advancement, evidence suggests that some biological barriers are giving way to more socioeconomic influences that result in poorer outcomes. Lower graft survival is known to be associated with low income, low education, less insurance coverage, and access to care barriers. However it is also notable that the graft survival racial gap narrows when factors such as income and education are accounted for. Many socioeconomic barriers are found in a higher prevalence and exert a more significant effect in black recipients as compared to non-black recipients.

When analyzing long-term outcomes, graft yearly attrition rates can serve as a valuable tool to distinguish the early versus late post-transplant period. In this way, we note that a greater impact on the reduction of long-term graft attrition rate of black recipients has been made (Figure 103.4). Not only is there a steeper reduction in the first year attrition rate, but the subsequent years appear to have a modest yet perceptible reduction in the 1–3, 3–5, and 5–10 year attrition rates.

The multifactorial nature of chronic allograft loss poses a significant challenge in the current transplant era. Control of the immunological response drives short-term survival, however the interventions that protect the graft early post-transplant ironically contribute to long-term attrition. Eventually, predisposition to cardiovascular disease, infectious complications, and PTLD becomes the predominant threat to both graft and patient survival.

Chronic disease states coupled with socioeconomic burdens make it difficult to pinpoint specific intervention points on a large population-based level. Improving long-term survival now requires a long-term follow-up process on each individual patient level. An emphatic approach of modifying risk factors and preventive health care from even prior to transplant surgery will eventually be necessary. As the transplant recipient is now living longer and little room is left for short-term success improvement, our focus is becoming increasingly directed at modifying chronic disease and social barriers.

Summary

Kidney transplantation remains a highly satisfactory alternative to dialysis. However, it remains a cure for kidney failure in that it imposes a chronic condition of immunosuppressive drug use that adversely influences long-term patient and graft survival. The great successes in early phase survival have now provided an opportunity to tackle the challenges of prolonged immunosuppressive drug therapy, and the chronic co-morbidities that are associated with renal failure. A thorough understanding of these issues will be required for clinicians and researchers hoping to improve transplant care in the future.

CHAPTER 104

Long-term Outcomes after Liver Transplantation

Heidi Yeh, Paulo Martins, and James F. Markmann
Harvard Medical School; Massachusetts General Hospital, Boston, MA, USA

Introduction

Liver transplantation is now the standard of care and only cure for end stage liver disease (ESLD). However, the first human liver transplantation was reported only 50 years ago, in a three patient series whose first recipient died on the operating table, the second died three weeks after transplant, and the third died one week post-transplant [1]. Up until as recently as 1980, less than 40% of patients undergoing liver transplantation survived to 1-year after the transplant [2]. In contrast, the 2009 SRTR annual report lists graft survival as 86% at 1-year, 70% at 5-years, and 53% at 10-years, and patient survival as 90% at 1-year, 75% at 5-years, and 60% at 10-years [3].

Long-term graft and patient survival following deceased donor liver transplantation have been steadily improving over time, and much of the improvement occurred between 1980 and 1995 (Figure 104.1A and B). This has largely been attributed to refinements in surgical, immunosuppressive, and organ preservation techniques during the first three decades of our human liver transplantation experience. These are covered in depth in Chapters 56, 66, and 21, respectively. The argon beam coagulator was invented in 1988 and intraoperative blood salvage devices (cell-saver) came into use in the 1990s, as well, completely changing the magnitude of blood loss in the operating room. The conversion to tacrolimus in the early 1990s also contributed to improving long-term outcomes by decreasing not only the incidence of rejection, but also the side effects associated with high dose steroids and T-cell depleting therapy needed to treat rejection episodes. In the late 1980s, University of Wisconsin solution (Viaspan) was developed originally for pancreas preservation, but soon replaced Eurocollins as the standard for liver preservation, because of better outcomes; it remains the gold standard preservation solution today. Improvements in intensive care have also played a role in decreasing postliver transplant mortality; this is covered in depth in Chapter 43. Since the number of living donor liver transplants was well under 100 per year for most of the 1990s, long-term graft and patient survival statistics are erratic during that decade, but since 1999, when over 200 living donor liver transplants were performed, succeeding years have also shown small gains in survival (Figure 104.2A and B; see also Chapters 24 and 57).

It is interesting to note that the slopes of the survival curves from one era to another are quite similar after the three month time point, with the greatest decrease over time in liver recipient deaths occurring during the first 0–90 days post-transplant (Figure 104.3). Thus, the apparent improvement in long-term outcomes is actually the result of improved short-term outcomes following liver transplantation. Although we have made great strides in the factors that contribute to perioperative mortality, as discussed above, we have made less progress with the long-term challenges of liver transplantation, many of which are the result of underlying patient disease and the side effects of chronic immunosuppression. This chapter outlines some of the late causes of recipient death and graft loss, factors that affect long-term outcomes after liver transplantation, and late complications occurring after liver transplantation.

Causes of late deaths and graft failure

Over half of liver transplant recipients who die, do so with a functioning graft. Isolated graft failure, as a cause of death, is reported to account for only 9–43% of late deaths (beyond 1–3 years after transplant) in various single and multi-center studies in North America [4–9]. In contrast, early deaths (within three months of transplant) are overwhelmingly the result of infection, graft dysfunction, and technical complications.

Recurrent disease and chronic rejection

Graft failure results primarily from recurrent disease, followed by chronic rejection, the former almost entirely due to recurrent hepatitis C virus (HCV) infection, with a small percentage due to relapses of alcoholic hepatitis. Interestingly, in the UK, graft failure from all causes accounts for barely 10% of post-transplant deaths [10]. Of note, only 21% of liver transplants in England were done for HCV in 2008, up from 10% in 1996 [11]. Over a similar period, liver transplants done for HCV in the US rose from 21% to over 40% [12]. An in depth treatment of recurrent disease can be found in Chapter 78.

Malignancy and infection

Other major causes of death include malignancy and infection. As complications of immunosuppression, they might justifiably be considered graft-related, even if they do not represent actual graft failure. Nine to 24% of deaths are due to de novo malignancy, with an approximately equal percentage due to recurrence of the malignancy that was the indication for transplantation, making malignancy the single largest cause of late death in liver transplant recipients [4,6,7,9,10]. Post-transplant lymphoproliferative disease (PTLD) accounts for a very small proportion of these deaths, since the 15 year cumulative incidence of PTLD is only 4.7% and is

associated with only a 10–15% increase in risk of death [13]. Additional treatments of these topics are found in Chapters 95 and 96.

Infection, the most obvious side-effect of immunosuppression, is listed as the cause of death in 8–20% of cases [4,5,8,9], although as much as an additional 10% of "multi-system organ failure" reports may be related to infection, as well. Not surprisingly, series with a higher rate of death due to infection have a lower rate of death due to chronic rejection and vice versa. General discussions on infections are found in Chapter 94.

Cardiovascular disease

The primary non-graft related cause of death is cardiovascular disease (see also Chapter 88), accounting for approximately 20% of late deaths in most series [4–9,14]. Although cardiovascular disease is sometimes considered a side effect of steroids and calcineurin inhibitors, based on their well-documented association with risk factors associated with cardiovascular disease (hypertension, diabetes, hyperlipidemia), studies suggest that those who die of cardiovascular disease had risk factors or even known coronary artery disease prior to transplant [4]. One series from Canada found that there was no statistical difference in the incidence of cardiovascular disease between liver transplant recipients and the age matched general population [5].

Cardiovascular disease is likely to become the primary cause of death overall as non-alcoholic fatty liver disease (NAFLD) assumes an increasing share of the underlying diagnosis in liver transplant recipients. NAFLD is predicted to become the leading indication for liver transplantation over the next 5–10 years [15], and the risk factors associated with NAFLD are the same as those predisposing to cardiovascular disease: diabetes, hyperlipidemia, hypertension, and obesity. Indeed, deaths from cardiac events occur more frequently in those transplanted for NAFLD than in those transplanted for primary biliary cirrhosis (PBC), primary sclerosing cholangitis (PSC), alcoholic liver disease (ALD), or HCV [16].

Recipient factors that affect long-term patient outcomes

Primary diagnosis

Given the fact that recurrent malignancy is a major cause of death following liver transplantation, it is not surprising that malignancy as a primary diagnosis for transplant is associated with the highest risk of death. Studies estimate that transplantation for hepatocellular carcinoma (HCC) incurs twice the risk of death as transplantation for non-malignant indications [17]. SRTR reports similar or better survival at three months and 1-year after transplantation for malignant neoplasms when compared to other diagnoses, but lower at 5- and 10-years by approximately 10% and 20%, respectively. One single center study reported the gap at their institution to be over 10% at 1-year, and over 40% at 5-years and later [18]. Five and 10-year survivals following transplantation for malignant neoplasms are only 67% and 50%, respectively [3].

Liver transplantation for fulminant hepatic failure also carries higher risk of death than for non-malignant chronic liver disease, with 5- and 10-years survivals of only 71% and 58% [3]. Unlike for malignant disease, lower survival is evident within three months after transplant, after which the drop-off rate is similar to recipients transplanted for non-malignant chronic disease [3]. This is consistent with the high incidence of sepsis/multi-organ failure and neurologic complications as a cause of death post-transplant, much of which were present going into transplant [19]. Pretransplant renal failure is the strongest predictor of post-transplant mortality [19].

Although transplantation for HCV was initially thought to result in similar outcomes to other diagnoses [20], this included patients transplanted in the early 1980s and 1990s, when overall survival after liver transplantation hovered just above 70% after 1-year. In the meantime, survival after transplantation for non-HCV diagnoses has improved, but survival after transplantation for HCV has shown less improvement [21–23], and more recent studies suggest that HCV is associated with a 23% higher risk of death and 30% higher risk of graft failure than non-HCV diagnoses [24]. Part of the failure of long-term outcomes to improve over time as much as short-term outcomes may be related to the increasing percentage of transplants performed for HCC and HCV, both of which are associated with poorer long-term survival than other diagnoses.

On the other end of the spectrum, biliary atresia and metabolic disease are associated with the best long-term survival. Although biliary atresia and metabolic disease are the two leading indications for liver transplantation in children, together they comprise less than 1% of total transplants performed in the US. Pediatric liver transplantation is covered specifically in Chapter 114. Among the more common indications for transplant, transplantation for cholestatic disease, including PBC and PSC, is associated with the best outcomes [3,18].

Hepatopulmonary syndrome and portopulmonary hypertension

Hepatopulmonary syndrome (HPS) is thought to result from intrapulmonary dilation and shunting, returning unoxygenated blood to the left ventricle and causing hypoxemia. Estimated to occur in 8–32% of patients with ESLD [25,26], the only known treatment is liver transplantation. However, patients with HPS tend to fare worse after transplant than patients with normal oxygenation [26,27], with 90-day mortality in some series approaching 30% [26], although select patients may do as well as those without HPS [27]. Death after transplant is associated with a larger shunt fraction, whether measured by room air $PaO2 < 60$ mmHg, A-a gradient, or macroaggregated albumin scan [26]. Reversal of shunting post-transplant can take weeks to months.

In contrast, liver transplantation is not standard treatment for portopulmonary hypertension, not because of any viable alternative therapy, but because outcomes after liver transplantation are so poor in severe cases. Portopulmonary hypertension occurs in 4–16% of cirrhotics, more frequently in those with severe ascites [28], but the mechanism is not clear. High pulmonary vascular

resistance is thought to arise from an imbalance of vascular mediators in ESLD that lead to vasoconstriction, endothelial damage with vascular remodeling due to excessive shear stress in the setting of vasoconstriction, and finally, smooth muscle proliferation, microvascular thrombosis, and right heart failure [28]. Depending on how far remodeling has progressed, the situation may or may not resolve after transplantation.

Overall mortality following liver transplantation in the setting of portopulmonary hypertension approaches 40% during the transplant admission, nearly one-third of which are intraoperative [27]. Studies stratifying recipients by mean pulmonary artery pressure (MPAP) demonstrate perioperative mortality similar to that of recipients without portopulmonary hypertension if MPAP = 25–35 mmHg. For those with MPAP = 35–50 mmHg, perioperative mortality is over 50%, and 100% for those with MPAP >50 mm Hg [29]. Good outcomes have also been demonstrated in patients whose initial MPAP >50 mmHg, but were able to be lowered to <35 mmHg with prostacyclin [30]. The ability to decrease MPAP with vasodilators is considered to be an indicator of reversibility and a good prognostic sign.

Age, gender, and race

Although some groups have reported that patients over the age of 60 have worse outcomes than those who are younger [31–37], in reality, there is not an abrupt change in median survival at age 60. In general, younger patients, especially preadolescent children, do better than older patients after 1-year post-transplant, with three month survivals being fairly close in all age groups (Figure 104.4).

Recent studies of older cohorts suggest recipients over the age of 70 do just as well as recipients less than 60 years of age. However, the older patients tended to have lower MELD scores, creatinine levels, and rates of pretransplant intensive care unit stays, or higher albumin levels than their younger counterparts [38,39], suggesting that use of more stringent selection criteria in older candidates is important in ensuring good post-transplant outcomes. Not surprisingly, both studies found that the risk of cardiovascular complications post-transplant was higher in the septuagenarian population, indicating that screening for cardiovascular risk factors and disease is especially important in older recipients.

Twice as many men as women have received liver transplants, but gender does not appear to influence overall patient survival post-transplant [3,40]. Of note, as a sub-group, female, HCV+ recipients have a 14–15% greater risk of death at 1-, 5- and 10-years post-transplant than male, HCV+ recipients [40].

Older studies found that Asians and African Americans had worse outcomes than Whites and Hispanics [41]. Over time, outcomes among Asians have improved to the point that the group now has the highest survival rates after liver transplant [3,42]. This may be due, in part, to improving treatment for Hepatitis B virus (HBV) associated cirrhosis, which is the leading indication for liver transplantation among Asians, as opposed to HCV, which is the leading indication for liver transplantation in non-Asians [42]. Initially, outcomes after transplantation for HBV were so poor that it was considered a contraindication to liver transplant. With the advent of HBIg and then the nucleoside analogs lamivudine, tenofovir, and entecavir, HBV recurrence can be prevented, and HBV patients who do not recur have some of the best survivals post-transplant [43–46].

However, African Americans continue to suffer from poorer outcomes. It has been noted that African Americans experience higher rates of chronic rejection [47]. At the same time, they have a higher likelihood of HCV recurrence that is less likely to respond to therapy [48]. African Americans are also more likely to develop post-transplant diabetes, which has been associated with increased morbidity and mortality [49].

Body mass index

Approximately 3% of liver transplants are performed in patients with body mass index (BMI) >35 kg/m^2 [50]. Although single center studies did not find any difference in long-term survival

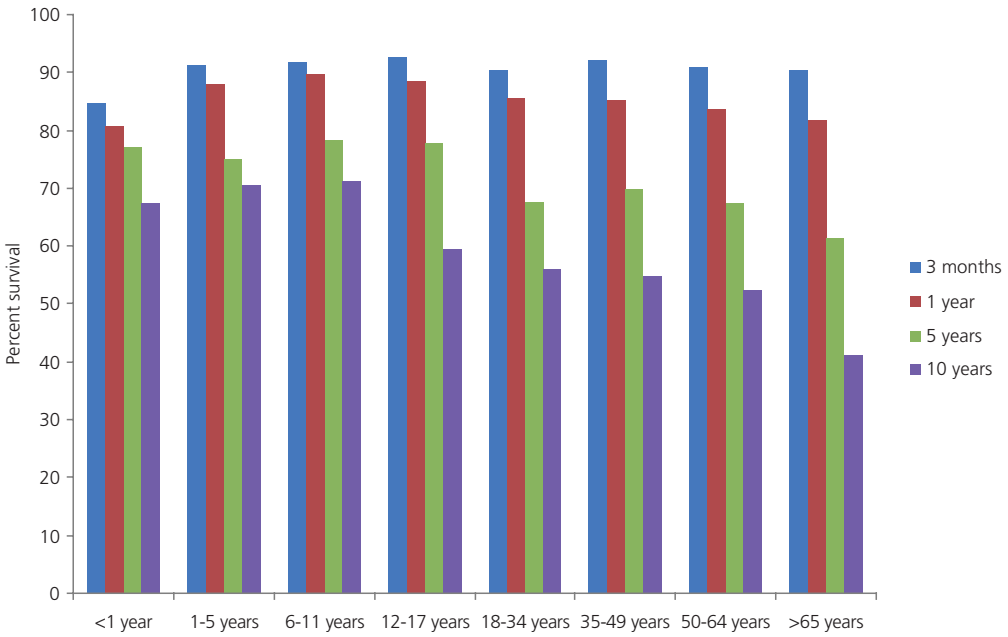

Figure 104.4. Patient survival after liver transplantation by age group.

among the obese (BMI 27–32 kg/m^2) and severely obese (BMI >32 kg/m^2) when compared to normal BMI recipients, they nevertheless found that obese patients had higher rates of postoperative respiratory failure and longer hospital stays and costs [51]. Severely obese recipients are also more likely to experience graft dysfunction, possibly due to longer warm ischemia times resulting from technical issues associated with the obese body habitus [52]. Furthermore, larger studies demonstrate that recipients with BMI >35–40 kg/m^2 experience as much as a 40% higher risk of death, generally due to cardiovascular events and within the first post-transplant year [50,52].

The disparity between the results of large and small studies is generally attributed to statistical issues, with small studies being insufficiently powered to detect survival differences. However, some authors suggest that there is truly no difference in survival if BMI's are corrected for ascites. As many as 20% of patients move into a lower obesity category once their weight is corrected for ascites, and the authors point out that each liter of ascites is associated with a 7% increase in mortality [53]. It is possible that obesity itself is not a strong predictor of post-transplant mortality, but associated co-morbidities that are more common in the morbidly obese, whether occult or recognized, play a role in increasing the risk of death [54].

As an alternate to post-transplant survival as a measure of the value of liver transplantation, some studies look at survival benefit, arguing that long post-transplant survival times are meaningless if survival times without transplant are equally long. When considering survival benefit, as determined by the hazard ratio of death with transplant to death without transplant, there is no difference among BMI categories stratified in intervals of 5 kg/m^2 [55].

On the other end of the spectrum are recipients with BMI <18.5 kg/m^2, who constitute approximately 2% of the transplant population [50]. Although they are generally considered to be high–risk candidates, there are few studies published on outcomes in the severely underweight. Those few indicate that they have a 55–60% higher risk of death after transplant, mostly due to hemorrhagic and cerebrovascular complications [50,51]. Again, most deaths appear to occur during the first year after transplant [50]. Their survival benefit from liver transplantation is slightly lower than for other BMI categories (0.14 vs. 0.14–0.17), but this difference is not statistically significant [55].

Multi-organ transplantation in ESLD

Of the various combinations of multi-organ transplants performed, simultaneous liver-kidney transplants is the most common, numbering over 300, and sometimes over 400, a year since 2005 [56]. This has been substantially influenced by allocation policy in the US, with renal failure increasing a recipient's MELD score substantially. The indications for combined liver-kidney transplant are beyond the scope of this chapter, but studies suggest that there is no penalty in survival for recipients who receive a kidney at the time of primary liver transplantation than for those who receive a liver only [57,58]. In fact, a subset of ESLD patients with renal insufficiency fare better with concomitant renal transplantation than liver transplantation alone, although the severity of renal failure and length of dialysis that defines this subgroup varies among studies [58–60]. At the same time, multiple studies have demonstrated that pretransplant renal failure is a predictor of increased mortality post-transplant [61,62], suggesting that including a kidney with the liver reverses the detrimental effects of renal failure in liver transplantation. Of note, simultaneous liver-kidney transplantation results in better renal allograft survival compared to kidney after liver transplantation [63], due in part to the removal of donor specific antibodies by the liver [63–65], although this protection from humoral rejection of the kidney is not absolute [66].

The need for any other concomitant abdominal organ transplant besides kidney is associated with much poorer outcomes than liver alone. However, this is presumably balanced by an even higher risk of mortality without transplant. Approximately 100 liver-intestine (a handful including pancreas and/or kidney) transplants are performed a year in the US. In spite of significant improvement in survival after intestine transplantation over the last ten years, 1-year patient and graft survival following combined liver-intestine transplantation hovers around 70%, much lower than for either liver alone or intestine alone [67]. Three and 5-year patient and graft survival are just above and just below 60%, and 10-year patient survival is less than 50% [67]. Only a handful of liver-pancreas (with or without kidney) are done a year [56], with 3- and 5-year survival reported to be 71% and 64% [68]. Outcomes after liver-intestinal and multivisceral transplants are covered in Chapter 109.

Combined liver-thoracic organ transplantation is similarly rare. In 2009, a record high of 11 liver-heart transplants (with an additional liver-heart-kidney) and ten liver-lung transplants (with an additional liver-lung-heart) were performed [56]. Although uncommon, outcomes after liver-heart transplantation are only slightly worse than for liver alone and certainly no worse than for heart alone, with patient at 1-, 3- and 5-year survival reported to be 85%, 77%, and 75% [69,70]. This may be due, in part, to the fact that the leading indication for simultaneous liver-heart transplantation is familial amyloidosis, in which the recipients rarely have any pretransplant liver dysfunction except for mutant transthyretin production [69–71]. In addition, the mean age of all reported liver-heart transplant recipients was only 46 years old when last calculated in 2007 [69]. As in simultaneous liver-kidney recipients, combined liver-heart transplantation appears to provide some protection against rejection for the heart allograft over heart transplantation alone [70].

Liver-lung transplantation is done most commonly for cystic fibrosis, followed by alpha-1-anti-trypsin disease [72]. In 2008 1-year patient survival was calculated to be less than 70% [72,73], and there remains a great deal of controversy over when and if a liver, lung, or dual organ transplantation should be performed, especially in the case of cystic fibrosis [73–75]. Triple organ transplantation with liver, lung, and heart is reported to results in 1-year survival of 50% and 5-year survival of 37.5% [74].

Retransplantation

When a primary graft fails, the only rescue therapy available is retransplantation. There has been a decline in the percentage of donor livers used for retransplantation and post retransplant survival has been improving over the past 20 years, but over 15% of liver transplants are currently performed to replace a failed previous graft, and survival rates after retransplantation remain inferior to those after primary transplantation. The most recent SRTR analyses put 1-year patient survival after retransplantation between 71–77% [76–79], significantly lower than the 90% 1-year survival after primary transplantation [3]. Single institution studies with longer follow-up estimate their five year patient survival to be 48–62% [80–82]. The best retransplant outcomes in the literature are from a single institution series in Germany, reporting 70%

patients alive 1-year after liver retransplantation and 67% at 5-year [83]. However, other European studies find their 1-year survival to be in the low- to mid-60% range [81,84]. Results of small series of 3rd, 4th, or 5th liver transplant patients demonstrate even higher mortality than after 2nd transplant [78]. One year graft survival after retransplantation is only 66% [76,79].

Not surprisingly, high MELD, ventilator dependence, renal insufficiency, and ICU status are all poor prognostic factors after retransplantation [80,83–86]. Most large studies suggest that HCV seropositivity is associated with increased risk of graft failure and patient death [79,85,87,88], and this effect is magnified as the MELD at time of retransplant increases. In one SRTR analysis of patients MELD>30, HCV-positive patients had only 42% 1-year survival (as compared to 55% in HCV-negative patients) and 21% 5-year survival (47% in HCV-negative) [85]. PNF as a reason for retransplantation has been variously reported to adversely affect survival [88], have no effect [81], or improve survival [88]. Patients undergoing retransplantation 7–30 days after their primary transplant do worse than those who receive their retransplant within seven days or after months/years for chronic graft failure [80,84]. Advanced donor age [44–54] and cardiac death donors negatively influence patient survival [80,83,89]. Of interest, the presence of preformed antidonor class I HLA antibodies is associated with approximately 20% poorer survival, but only in adult recipients and not pediatric recipients [90]. This study did not document that graft failure (and patient death) in antibody positive recipients was due to rejection.

ABO and HLA matching

Initially, ABO incompatible liver transplantation was associated with rates of graft loss and either death or need for retransplantation as a high as 50% in the first 30 days [91]. Graft failure resulted from antibody induced disseminated intravascular coagulation in the liver [91], arterial thrombosis, cholangiopathy, and rejection [92,93]. Outcomes were especially poor for retransplant and O blood group recipients, whose risk of death was 2.46 and 3.43 times higher than primary transplant and non-O blood group recipients of ABO incompatible organs, respectively [92,94].

As experience grew with modulation of antibody production, varying combinations of plasma exchange, IVIg, plasmapheresis, Rituximab, splenectomy, Cytoxan, and T-cell depleting induction therapy were used in ABO-incompatible liver transplantation, primarily in infants, who tend to have lower anti-A and anti-B titers [95]. However, older children and adults were included, and graft and patient survival in small series (6–14 patients) were reported to approach that for ABO-compatible transplants [96–99]. Although rates of rejection and cholangiopathy varied from study to study, overall, rejection episodes tended to be steroid responsive, and the incidence of biliary lesions was much decreased in the setting of intense immunosuppression and strategies for antibody depletion [96–99]. Interestingly, antibody titers after the immediate post-transplant period (two weeks) were not associated with rejection, either cellular or antibody mediated, and some patients continued to have high titers in spite of antibody depleting treatment while others had low to undetectable titers for many months after stopping treatment [96].

Small series (6–10 patients each) of A2 organs transplanted into O recipients without antibody depleting therapy have been reported with equally good outcomes [100,101]. This has been explained by the fact that organs from A2 donors have lower cell surface expression of A antigens because A2 subtype transferase is less efficient than the A1 transferase at converting the precursor antigen (H) into the A antigen [102]. From an allocation perspective, this is justified by the median wait time for blood group O candidates being twice that for blood group A and AB candidates and nearly five times longer than for blood group AB candidates [103].

Overall, ABO incompatible transplantation accounts for 2–4% of pediatric transplants and <1% of adult transplants in the last decade [104]. Graft survival in infants and children after ABO incompatible transplantation appears to be equivalent to ABO compatible transplantation [104,105], but in adults, graft survival is approximately 10% lower at 1-, 3-, and 5-years, evening out at 10-years [104]. In fact, for grafts surviving beyond three months, long-term survival was equivalent for ABO compatible and ABO incompatible transplants [104].

HLA matching does not appear to have any effect on graft or patient survival after liver transplantation [106,107]. HLA matching in pediatric living related transplantation is associated with a lower rate of rejection during the first 6 weeks post-transplant [108], and anti-HLA antibodies and C4d deposition can be found during episodes of rejection [109,110], this does not appear to have any long-term consequences. However, there are reports that a positive T-cell cross match is associated with a higher risk of acute rejection [111], and 10% lower graft survival at 1-, 3-, and 5-years [112]. Pretransplant cross-matching is not routinely performed in the US, but retrospective cross matches could be used to guide immunosuppression management in patients who may be at higher risk of rejection and graft loss.

Donor factors that affect patient and graft survival

Short-term donor risk factors

The majority of donor factors affect graft and patient survival in the first 90 days post-transplant, manifesting as prolonged graft dysfunction or primary non-function. Donor age is one of the most important, each decade adding a 15–20% increased chance of graft failure until livers from donors >70 are 1.65 times as likely to fail as livers from donors <40 years of age [113]. Each hour of cold ischemia time (CIT) adds only a 1% increase in risk of graft failure [113], but CIT >12 hours interacts with donor age >45 years to increase liver failure [114] and older grafts do particularly poorly in HCV+ recipients. Interestingly, regional sharing increases risk of failure by 11% and national sharing by 28%, independent of CIT [113]. Stroke as a cause of death carries a 16% greater risk of graft failure over death from anoxia or trauma [113]. Livers from African American donors are approximately 1.2 times more likely to fail than livers from white donors [113]. Split livers, or partial grafts, are 50% more likely to fail [113].

It is not clear whether steatosis adversely affects liver allograft function because it is a marker of recent or ongoing hepatocyte injury, or whether the fatty infiltration is directly toxic and contributes to ischemia-reperfusion injury. Microvascular steatosis of any degree is not associated with poor function and outcomes [114], but macrovascular steatosis of >25% incurs a 62% rate of delayed function, 12% rate of primary non-function, and shorter patient survival [114]. In other studies, grafts with ≥30% steatosis experience delayed function with elevated AST/ALT and INR, but 5-year graft survival is not statistically significant [115,116]. Another series showed 1-year graft survival to be 82% with no steatosis, 73% with 0–10% steatosis, 74% with 11–30% steatosis, and 62% with

31–60% steatosis [117]. Very few centers transplant grafts with steatosis >60%. Of note, HCV recurrence is earlier and more frequent in HCV+ recipients who received grafts with >30% steatosis [117]. Steatosis can reverse after transplantation [118] and a number of investigators are studying approaches to "de-fat" steatotic livers pretransplant [119].

Living donor liver transplantation

Unlike in kidney transplantation, where living transplantation confers better recipient and graft survival than deceased donor transplantation (DDLT) [120], living donor liver transplantation (LDLT) does not carry this clear advantage, while subjecting the donor to much higher risk of morbidity and mortality. Post-transplant patient survival in the US is no better following LDLT than DDLT, even though LDLT recipients tend to be younger and have lower MELD at time of transplant [121,122]. At 10 years, there is a slight trend towards better survival, but this has not yet been statistically significant [122], and in fact, HCV+ recipients may have a 12–15% lower survival following LDLT by 1–3 years post-transplant [122]. Acute rejection episodes are more common in DDLT [122], and allograft failure rates following LDLT are higher than for DDLT [123].

Technical complications are more likely to occur after LDLT than DDLT. During the first 90 days, these are predominated by biliary leaks, occurring almost three times more often in LDLT recipients that DDLT (10–32% vs. 8–12%) [124,125]. Later, biliary strictures develop, occurring 2–3 times more frequently in LDLT (28–32% vs. 5–15%) [125–127]. Hepatic artery thrombosis occurs approximately three times as often (6.5% vs. 2.3%) and portal vein thrombosis in 3% of LDLT, being very uncommon in DDLT [126]. Center experience is important in decreasing technical complications post LDLT [124].

However, studies comparing patient survival on an intent-to-treat basis find that LDLT recipients have approximately half the mortality rate of similar transplant candidates who remain on the wait list for a DDLT [128–130]. The LDLT advantage is even greater in wait list candidates with MELD < 15 who have a high risk of mortality that is not represented by their MELD score [130]. This effect is due almost entirely to death on the wait list of candidates without a living liver donor [128–130]. In short, LDLT does offer significant survival benefit to patients who would otherwise die on the wait list without a DDLT, in spite of the risk of developing complications or the need for retransplant. Not unexpectedly, LDLT is utilized more commonly in areas of the country where wait times are longer and the risk of dying on the wait list is higher [131].

Donation after cardiac death

The number of donors after cardiac death (DCD) has increased by over 10-fold in the last 15 years [132,133]. Although the use of DCD livers expands the donor pool, their use is not without risk. Graft failure following transplant with DCD grafts occurs anywhere from 50–85% more often than with donors after brain death (DBD) grafts [132,134], corresponding to 3-year graft survivals of 10–15 percentage points lower [132,133,135,136], even though DCD livers tended to be from younger donors with shorter cold ischemia times [135]. The gap in graft survival was less significant in "low risk" recipients, as determined by young age, primary transplant, normal kidney function, and good medical condition [133,136], suggesting that recipient selection plays an important role in DCD outcomes. DCD livers with less than 30 minutes of warm ischemia time and less than 10 hours of CIT tend to have better outcomes [136]. Patient survival is lower following DCD liver transplantation, as well [133,137].

Ischemic-type cholangiopathic lesions occur more frequently in DCD grafts (20–40%) than DBD grafts (5%) [138–140], although in DBD grafts their incidence correlates with CIT [141]. These biliary strictures, unlike anastomotic strictures, often cannot be managed endoscopically or with surgical revision, and up to 50% require retransplantation [142]; only 1–2% of anastomotic strictures require retransplantation [143].

Hepatitis B and Hepatitis C positive donors

In the US 15% of donors are HBV core antibody positive (HBVcAb+) [144] but surface antigen negative, indicating an exposure to HBV, with ambiguous viral load. The risk of viral transmission from HBVcAb+ donors to recipients is 25–95% without viral prophylaxis, and can be associated with severe hepatitis and graft loss [145]. However, with various combinations of HBIg, lamivudine, adefovir, and/or entecavir, HBVcAb+ livers can be transplanted into even surface antibody negative recipients with a risk of transmission of less than 5% [145–147] and similar graft and patient survival at 30 days, 1-year, and 5-years [144,145].

Similarly, multiple studies have shown no difference in patient or graft survival among HCV+ recipients, whether they receive grafts from HCV+ or HCV− donors [148–152], if the grafts are otherwise normal. However, HCV+ grafts from older donors (age ≥50 years) are nearly six times more likely to fail and result in recipient death than HCV+ grafts from younger donors (age <50 years), an age effect which is much larger than in HCV− grafts, and largely due to HepC related fibrosis [152], Among grafts from donors age ≥50 years, HCV+ grafts are almost three times as likely to fail as HCV− grafts, an effect that is not seen in younger grafts. Even with occasional retransplantation, patient survival followed similar trends [152].

Late complications of liver transplantation

Renal failure

The incidence of Stage IV and V (estimated GFR <29 L/min) chronic kidney disease (CKD) at 1-, 3-, 5-, and 10-years following liver transplantation has been estimated to be 8%, 14%, 18%, and 25%, respectively [153]. The most common cause of end-stage renal disease (ESRD) post liver transplant is calcineurin inhibitor (CI) toxicity. Other pathologic findings include diabetic nephropathy, thrombotic microangiopathy, acute tubular necrosis, focal segmental glomerulosclerosis, and presumed unrecovered hepatorenal syndrome [154,155].

As expected, advanced age, diabetes, hypertension, acute kidney injury, and calcineurin-inhibitor use increase the likelihood of developing chronic kidney disease, with pre-existing kidney disease as the major predictor of post-transplant CKD [153,155]. HCV infection is also a risk factor for developing CKD, probably because of HCV's association with immune complex glomerulonephritis [156] and diabetes [157,158]. Conversion to sirolimus, in order to minimize CI exposure, can sometimes result in improvement in GFR [159–162].

In all non-renal transplant patients, ESRD is associated with nearly five times the risk of death [153], and in one series of liver transplant patients in particular, the 13-year survival in patients with ESRD was only 28%, while in those without kidney disease, it was 55% [154]. As in other non-renal transplant patients [155], kidney transplantation was associated with a 71% 6-year survival

after developing ESRD, compared to only 27% in those who remained on renal replacement therapy [154].

Post-transplant diabetes mellitus

The reported incidence of new-onset diabetes after liver transplantation, both Type 1 and 2, ranges from 5–27% [163–166]. Many more patients require insulin transiently, while on high-dose steroids. Age >45 is thought to double the risk developing diabetes [163], while HCV positivity increases the risk 2–6 times, depending on the series [163,164,166,167]. Even in non-transplanted patients, HCV infection is associated with a higher risk of diabetes than HBV infection [164], and this is thought to be due to changes in insulin sensitivity resulting from cytokines produced in response to infection as well as the virus itself [168]. Insulin resistance increases with the level of viremia [168,169], partially through HCV-core protein induced degradation of insulin signaling proteins (insulin receptor substrate-1) [170,171], and decreased expression of insulin growth factor binding protein-1 [170]. Maintenance immunosuppression with tacrolimus, which decreases insulin secretion by β-cells and is directly β-cell toxic [172], is associated with up to three times the risk of diabetes when compared to cyclosporine [163,164]. Interestingly, receiving a graft with >10% steatosis on biopsy has also been associated with over three times the likelihood of developing diabetes [163].

Infections, renal failure, neurologic, and cardiovascular complications occur more frequently in those with de novo diabetes than in non-diabetics [173,174]. Some authors find similar patient and graft survivals among patients with new-onset diabetes and patients without diabetes [163,165], while others find the risk of death to be over three times higher in diabetics [167]. Some of this disparity may be due to the mix of type 1 and type 2 diabetes in the study populations, as studies distinguishing type 1 from 2 find that patients who develop type 1 diabetes suffer from approximately 40% lower patient and graft survivals, while patients who develop type 2 diabetes have equivalent survival rates as non-diabetics [175].

De novo malignancy

Depending on the series, de novo malignancy is estimated to occur in 3–55% of post liver transplant patients [173,174]. Varying by the type of cancer, this corresponds to relative risk of up to 70 times higher (non-melanoma skin cancer) than in the general population [173], while breast and urogenital cancers appear to occur at similar or lower rates as in the general population [176]. Compared to immunocompetent individuals, the chances of developing malignancy is higher in patients who are in an immunosuppressed state for any reason, whether it be genetic, pharmacologic, or infectious. This is thought to result from failure of T cells, macrophages, and natural killer cells to clear oncogenic viruses and/or malignant cells with aberrant protein expression. Many immunosuppressive medications, including calcineurin inhibitors and anti-metabolites, are also thought to have direct oncogenic activity [174].

As in non-transplant patients, smoking and a history of alcohol are associated with greater likelihood of developing cancer, especially oropharyngeal tumors [176,177], which occur as much as seven times more frequently after liver transplantation as in the general population [173]. Among primary diagnoses, primary sclerosing cholangitis was associated with the highest risk of non-skin malignancies, most often colorectal carcinomas [174,176], although the prevalence of ulcerative colitis (UC) in the PSC patients of those studies is not known. It is noteworthy that in non-transplant patients, the presence of PSC with UC further increases the risk of colorectal carcinoma beyond that associated with UC alone [178], but little is known about the risk of colorectal carcinoma in non-transplants patients with only PSC. Overall, colorectal carcinoma occurs as much as 12 times more frequently post liver transplant as in matched non-transplant patients.

Not only is the risk of developing cancer higher, the diagnosis is likely to carry a worse prognosis after liver transplantation than in the general population. Studies in solid organ transplant patients demonstrate that 5-year survival after diagnosis of colorectal cancer is less than half in transplant patients than in stage matched population controls [179,180] of outcomes following colorectal cancer solid organ. The probability of death in liver transplant patients five years after being diagnosed with any non-skin malignancy is less than 50% [176]. It is not clear whether the observed poor prognosis is the result of transplanted patients having more aggressive disease with different tumor biology, or simply the immunosuppressed state again providing poor defense against a tumor that is otherwise comparable to that in a non-transplant patient. In either case, liver transplant patients are counseled to undergo rigorous skin surveillance for new lesions and some authors speculate that colorectal screening should be performed as often as every three years even in patients under 50 [180], while annual colonoscopy is recommended for all PSC patients [181].

Operational tolerance

Operational tolerance in liver transplant recipients, loosely defined as normal graft function in the absence of exogenous immunosuppression, was first reported among five non-compliant patients who had stopped taking their immunosuppression one year or later after transplantation, yet continued to have normal graft function by clinical parameters and laboratory testing for up to 13 years after cessation of immunosuppression [182]. Subsequent studies of deliberate immunosuppression withdrawal, starting years after transplantation, for side effects such as infection, malignancy, or less commonly, renal dysfunction, report success rates as high as 23% for follow-up periods of as long as 10 years [183–185]. By and large, those that developed abnormal liver function tests and/or biopsy confirmed rejection, were easily treated with re-institution of calcineurin inhibitor (CI)therapy, or the addition of low-dose steroids, with return to baseline liver function and histology. Patients with recurrent HCV disease had stabilization or even improvement of histologic disease after stopping immunosuppression [186]. Immunosuppression withdrawal is not recommended for patients who have an underlying autoimmune etiology for their primary liver disease.

However, there have been reports of chronic rejection developing several years out from cessation of immunosuppression [183,187], although when caught early by protocol biopsy (in the setting of normal liver function tests), those changes, too, reversed with re-institution of CI therapy [187]. This suggests that patients with normal liver function tests after immunosuppression withdrawal may benefit from surveillance biopsies every several years, which some authors have even suggested for recipients who remain on stable immunosuppression [188]. It is not clear, though, whether increasing immunosuppression levels would have any effect on the progression of chronic rejection in the latter population.

One series in which immunosuppression withdrawal was instituted early (six months after transplantation) had a much lower rate of success and more severe cases of rejection in those that failed,

requiring high-dose steroids and even T cell depleting therapy for rescue [189]. Similarly, a clinical trial of immunosuppression withdrawal in pediatric recipients of parents living donor liver transplants has also found that the 60% of patients who have successfully been weaned off suppression had a longer time period between transplant and weaning than those who failed (100 months vs. 73 months) [190].

The search for additional predictors of operational tolerance has included a number of retrospective studies reporting that successfully weaned patients have lower levels of Th1 cytokines [191] and higher frequencies of CD4+CD25+ (presumably regulatory) T cells and gamma-delta T cells [192,193], and B cells [192]. Gene expression analysis reveals that operationally tolerant recipients down-regulate stress and inflammatory response genes and up-regulate DNA repair and cell cycle control genes, when compared to normal controls and patients who failed immunosuppression withdrawal [193,194]. One recent prospective study, profiling graft tissue prior to immunosuppression withdrawal, found that subsequent tolerance was associated with a higher average level of hepcidin antimicrobial protein (HAMP) mRNA [195], which is up-regulated in hepatocytes in response to iron deposition, but is also expressed in neutrophils and macrophages and appears to play a role in innate immunity. Likewise, transferrin receptor (TFRC) mRNA, which is expressed at lower levels in recipients who will experience successful immunosuppression withdrawal [195], is responsible for hepatocyte uptake of transferrin bound iron, but is also up-regulated on T and B cells in response to antigen stimulation. As exciting and provocative as these findings are, the wide, overlapping range of expression levels in patients who do and do not require immunosuppression [195] means that measuring mRNA levels is not yet clinically useful.

Summary

Liver transplantation is now unarguably the best long-term option for patients with ESLD. However, numerous conditions conspire to limit long-term survival. These include issues related to the primary indication and complications associated with the requirements for immune suppression. The future for recipients of a liver transplant remains favorable relative to recipients of other organs, but imperfect when compared to the general public. As such, refinements in the procedure, methods for maintenance immunosuppressive therapy, and improved anti-viral and anti-neoplastic therapies remain paramount in improving long-term outcomes.

CHAPTER 105

Long-term Outcomes after Heart Transplantation

Michelle M. Kittleson and Jon A. Kobashigawa
Cedars-Sinai Heart Institute, Los Angeles, CA, USA

Introduction

Despite advances in pharmacologic and device treatment of chronic heart failure, long-term morbidity and mortality remain unacceptably high with many patients progressing to end-stage heart failure. The 5-year mortality for patients with symptomatic heart failure approaches 50%, and may be as high as 80% at 1-year for end-stage patients [1]. Over the last four decades, cardiac transplantation has become the preferred therapy for select patients with end-stage heart disease. Approximately 2400 heart transplants are performed annually in the US. According to the registry of the International Society of Heart and Lung Transplantation (ISHLT), the median survival of patients post-transplantation is currently 10 years, up to13 years for those surviving the first year post-transplant [2] (Figure 105.1), a significant improvement over that of medical therapy for heart failure.

Critical to the success of heart transplantation are the continual investigational efforts to optimize immunosuppressive regimens. Improvements in immunosuppression, donor procurement, surgical techniques, and post-transplant care have resulted in a substantial improvement in the survival of transplant recipients. Nonetheless, problems still exist and the purpose of this chapter is to provide an overview of long-term complications of heart transplantation in the current era.

This chapter will review the major causes of mortality and morbidity after transplantation. The major causes of mortality include rejection, infection, malignancy, and transplant coronary artery disease. Due to the importance and complexity of transplant coronary artery disease, this topic is discussed in another chapter (Chapter 79). The major causes of morbidity include renal dysfunction, hypertension, diabetes, dyslipidemia, gout, and osteoporosis.

Long-term outcomes after heart transplantation

Survival

Survival after heart transplantation has steadily improved in the past three decades. In the 1980s, 1-year survival was 70% and the conditional half-life, the time at which 50% of patients who survived the first year are still alive, was 9.4 years. In the most recent report from the ISHLT registry [2], 1-year survival is almost 90% with a conditional half-life of 14 years. Notably, the mortality rate beyond the first year after transplant has improved only marginally for patients who received allografts after 1992, and there has been no statistically significant improvement in the past two decades. This fairly constant annual mortality rate of approximately 3–4% is higher than that of the general population, and likely exists because the processes responsible for long-term mortality, including cardiac allograft vasculopathy and malignancy, remain a challenge of detection and treatment. Thus, future improvements in post-transplant survival may result from interventions aimed at the detection and treatment of cardiac allograft vasculopathy and malignancy.

An in-depth analysis of risk factors for survival at 1-, 5-, 10-, 15-, and 20-years post-transplant is provided in the ISHLT registry report [2]. The strongest risk factors for one-year mortality, associated with a 50% or more increase in the risk of 1-year mortality, are mainly related to technical issues and the underlying disease responsible for transplantation, including the use of temporary circulatory support, congenital cardiomyopathy versus non-ischemic cardiomyopathy, prior transplant, pretransplant ventilatory support or dialysis. Risk factors for 5- and 10-year mortality, on the other hand, are most referable to immunological issues and toxicity related to immunosuppression, including dialysis or infection after transplant, rejection during the first post-transplant year, and lack of immunosuppression therapy with a combination of at least two of the following classes: cell cycle inhibitors, calcineurin inhibitors (CIs), and proliferation signal inhibitors.

Transplant era influences 20-year survival; those patients transplanted in 1990 have better 20-year survival than those transplanted in 1985. Other factors affecting 20-year survival include etiology for transplantation, sex, age, ischemic time, and center volume. Patients receiving retransplant and those receiving transplant for ischemic heart disease or valvular heart disease have a lower likelihood of survival past 20 years after transplant compared with patients who receive an allograft for non-ischemic cardiomyopathy. The reasons for this are unclear, and may be related to progression of the underlying disease or older age of recipients with ischemic or valvular disease versus non-ischemic cardiomyopathy. Women also have a somewhat higher risk of death compared with their male counterparts. Younger donor age, younger recipient age, lower allograft ischemic time, and higher center volume are additional factors associated with long-term survival, and these risk factors appear consistent across countries.

Quality of life

Patients not only gain increased quantity of life after transplantation, but quality of life is improved as well. Data from the ISHLT registry indicates that in the first years after heart transplant, approximately 75% of recipients report having a normal healthy

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

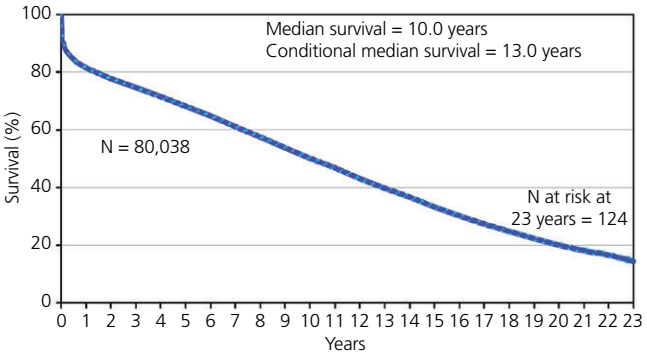

Figure 105.1. Survival for adult heart transplants performed between January 1982 and June 2009. In an analysis of over 80 000 reported heart transplants internationally, the median survival of patients post-transplantation is currently 10 years, up to13 years for those surviving the first year post-transplant. Reproduced from [2] Stehlik et al., J Heart Lung Transplant 2010;29:1089–1103. Copyright © 2010, with permission from Elsevier.

lifestyle or only few disease symptoms, an additional 15% participate in normal activities with some difficulty, and less than 10% report a higher degree of limitations [2].

In-depth analysis of a smaller cohort of transplant patients indicates that the most frequently reported symptoms long-term after heart transplantation, at moderate rates of 50–65%, were fatigue, sexual dysfunction, memory problems, bruising, and cramps [3]. These symptoms are less common in recipients who are married and those with a higher educational level.

Based on information from the international registry, many patients return to work after transplant. Among recipients aged 25–55 years old, approximately 50% were employed five years after transplantation [2]. On the basis of the functional data reviewed above, it is apparent that additional recipients could return to the workplace; however, in the US the structure of disability benefits and health insurance considerations may represent a barrier to this process.

Rejection

Diagnosis

Transplant rejection remains one of the major causes of death after heart transplantation [2]. Rejection is most frequent during the first month after heart transplantation and declines thereafter. Acute rejection may cause significant morbidity and mortality in heart transplant recipients, requiring judicious monitoring and prompt clinical intervention. Because clinical symptoms of rejection are often vague, routine testing for rejection in the absence of symptoms is standard practice. Unlike renal or liver transplantation, there are no laboratory markers for rejection in heart transplantation. The endomyocardial biopsy is the standard approach for the routine surveillance of rejection. The endomyocardial biopsy is most commonly performed via a right internal jugular venous approach under fluoroscopic guidance. This is an outpatient procedure with a low risk of complications. The most serious complications (which occur in 0.5% of cases) include tricuspid valve injury and cardiac perforation which could result in tamponade [4,5]. While the timing of biopsies will vary from center to center, in general biopsies are performed frequently early after transplantation and less frequently as time goes on. At our center, we see patients in clinic twice weekly for the first month and perform biopsies weekly for the first month. Then, the visits are spaced out with biopsies every other week in month 2, monthly biopsies in months 3 through 6, and biopsies every other month in months 8 through 12 (Table 105.1). Thus, patients will undergo approximately 13 biopsies in the first year. At our center, we do not perform routinely scheduled biopsies after the first year, as the risk of rejection is much lower. After year 1, biopsies are performed only if the heart transplant recipient develops symptoms or signs of rejection. However, we monitor such patients in clinic every six months with echocardiograms and every year with annual angiograms to assess for cardiac allograft vasculopathy (as discussed in more detail in Chapter 79).

The purpose of the endomyocardial biopsy is to assess for myocardial damage in the form of cellular or antibody-mediated rejection. The diagnosis of cellular rejection is made in accordance with the revised ISHLT grading scale, published in 2005, which simplifies the prior 1990 classification [6,7]. Biopsies are classified as:

- Grade 0 R — no rejection (no change from 1990);
- Grade 1 R — mild rejection (1990 Grades 1A, 1B and 2);
- Grade 2 R — moderate rejection (1990 Grade 3A); and
- Grade 3 R — severe rejection (1990 Grades 3B and 4).

Grade 2R or higher rejection on biopsy is considered significant and meriting treatment, as discussed in further detail below (see also Chapter 83).

The diagnosis of antibody-mediated rejection is less straightforward, but has achieved greater standardization after a consensus conference in 2010 [8]. By the proposed classification, endomyocardial biopsies are graded based on the presence of histologic and immunologic findings consistent with antibody-mediated rejection. Histologic findings include endothelial activation with intravascular macrophages and capillary destruction. Immunologic findings encompass complement and HLA deposition. The grading scheme stratifies biopsies based on:

- no histologic or immunologic evidence of antibody-mediated rejection (negative, AMR0);
- either histologic or immunologic evidence of antibody-mediated rejection (suspicious, AMR1);
- both histologic and immunologic evidence of antibody-mediated rejection (positive, AMR2); and
- a final category for severe findings of myocardial destruction, AMR3.

Moving forward with a standardized classification scheme for the diagnosis of antibody-mediated rejection will allow further study into the natural history and treatment of this less well-understood condition.

While not required for the diagnosis of antibody-mediated rejection, we also perform screening for anti-HLA antibodies post-transplantation. Antibodies are checked at months 1, 3, 6, and 12 post-transplantation and then annually (Table 105.1). The presence of donor-specific anti-HLA antibodies in high levels (usually median fluorescent intensity above 10 000 or standard fluorescent intensity above 200 000) are considered potentially cytotoxic and may merit a change in treatment, depending on the clinical situation, as discussed further on.

Although performing an endomyocardial biopsy is straightforward, the morbidity associated with this invasive procedure has led to attempts to identify other means of diagnosing rejection. Many non-invasive parameters have been assessed, including changes in the electrocardiogram, echocardiogram, or magnetic

Table 105.1. Post-transplant monitoring

resonance imaging, as well as abnormalities in laboratory findings including B-type natriuretic peptide. However, none have offered adequate accuracy or reliability for inclusion into clinical practice until the Allomap, an 11-gene expression signature derived from peripheral blood mononuclear cells that may predict cellular rejection [9]. In a clinical trial setting, the Allomap gene expression profile has been shown to be non-inferior to the biopsy in the diagnosis of cellular rejection [10]. However, the Allomap has not yet widely been incorporated into clinical practice, mainly because of critical problems with the randomized trial and limitations of its generalized use [11,12].

The landmark randomized controlled trial — the IMAGE study — compared the Allomap gene expression profile to endomyocardial biopsies in patients 6 months to 5 years post-transplant, with 85% of patients beyond one year after transplantation. The utility of the Allomap in this population is unclear, since many centers do not perform routine biopsies after 1-year post-transplantation when the risk of rejection is low [12,13]. Furthermore, the Allomap will not detect antibody-mediated rejection, and cannot be used in patients who have received blood transfusions or hematopoietic growth factors affecting leukocytes (such as granulocyte-colony stimulating factor) within the past 30 days [9]. Thus, the widespread use of Allomap instead of endomyocardial biopsy will likely take time and require further randomized trials or, at the very least, clinical registry experience, prior to adoption by most transplant centers.

Risk factors

The risk factors for rejection vary with the time post-transplant. Risk factors associated with early rejection, within 1-year after transplant, include younger age, female donor, female recipient, positive cytomegalovirus (CMV) serology, prior infections, and OKT3 induction therapy [2]. In contrast, risk factors for later rejection include a greater number of rejection episodes in the first year after transplantation and the presence of prior CMV infections [2].

While rejection is rarer later after transplantation, prompting some centers to eliminate scheduled biopsies in such patients, it still may occur. Late rejection is often prompted by non-compliance with immunosuppressive medications, addition of medications that inadvertently lower immunosuppressive levels (such as rifampin), or discontinuation of medications that have been maintaining levels (such as diltiazem, azole antifungals, or macrolide antibiotics), or infection episodes [14]. Antibody-mediated rejection is more common later after transplantation [15] and may be associated with an increased risk of transplant coronary artery disease [16] and death [17,18].

Table 105.2. The treatment of rejection depends upon the results of the biopsy and the clinical status of the patient, with more aggressive treatments reserved for patients with more unstable clinical presentations

	Asymptomatic	Reduced EF	Heart failure/shock
Cellular rejection	• Target higher CNI levels • Oral steroid bolus + taper • Rapamune • No treatment *Or* • Oral steroid bolus/taper	• Oral steroid bolus/taper *or* • IV pulse steroids	• IV pulse steroids • Cytolytic therapy (ATG) • Plasmapheresis • IV immune globulin • Inotropic therapy • IABP or ECMO support
Antibody-mediated rejection		• Oral steroid bolus/taper *or* • IV pulse steroids +/− • IV immune globulin	

EF, ejection fraction; CNI, calcineurin inhibitor; ATG, anti-thymocyte globulin; IABP, intra-aortic balloon pump; ECMO, extracorporeal membrane oxygenation.

Treatment

The management of rejection proceeds in a step-wise fashion based on the severity of rejection detected on biopsy and the patient's presentation (Table 105.2). Rejection most often occurs early after transplantation, and treatment is similar regardless of the timing of presentation. Grade 1R cellular rejection or findings suspicious for antibody-mediated rejection, AMR1, in the absence of clinical or hemodynamic compromise generally merits no intervention. The management of AMR1 is controversial at this time, and at some centers treatment may proceed as for higher levels of rejection, as described below.

More serious findings on the biopsy, including Grade 2R or higher cellular rejection or AMR2 or higher antibody-mediated rejection, require treatment. The intensity of treatment depends on the patient's presentation. If the patient has no heart failure symptoms and normal left ventricular ejection fraction, treatment options include oral or intravenous pulse steroids, targeting higher

levels of immunosuppressive medications, switching from cyclosporine to tacrolimus [19,20], or switching from mycophenolate mofetil to a proliferation signal inhibitor [21–23]. Given the equivalent success of intravenous and oral corticosteroid therapy for the treatment of asymptomatic cellular rejection [24], an outpatient course of oral corticosteroids is often the first-line treatment for asymptomatic cellular rejection. Asymptomatic antibody-mediated rejection is more challenging. Recent studies indicate that it may be associated with poor outcomes [16–18], but it is unclear whether treatment affects outcomes. At the Cedars-Sinai Heart Institute, such patients will receive an oral corticosteroid bolus, consideration of intravenous immune globulin, and close monitoring of donor-specific HLA antibodies.

For patients with a reduced ejection fraction on echocardiogram, treatment is more aggressive. A reduction in ejection fraction in the absence of biopsy evidence for rejection may be treated with intravenous corticosteroids and cytolytic therapy with antithymocyte globulin in addition to the adjustments in immunosuppressive medications outlined above. If there is evidence of AMR2 or higher, such patients will also receive intravenous immune globulin. If donor-specific anti-HLA antibodies are present in the setting of AMR or a fall in ejection fraction, patients may receive a steroid bolus and taper or more intensive therapy with intravenous immune globulin, rituximab, or bortezomib.

Finally, in patients presenting with cardiogenic shock the results of the biopsy are less important, and aggressive treatment includes intravenous corticosteroids, cytolytic therapy, plasmapheresis, intravenous immune globulin, intravenous heparin (as patients often have thrombotic occlusion of the cardiac microvasculature on postmortem examination [25,26]), and hemodynamic support with intra-aortic balloon counterpulsation or even extracorporeal membrane oxygenation (ECMO). Such aggressive treatment with ECMO support can lead to acceptable outcomes if used in a timely fashion prior to cardiac arrest and accompanied by aggressive treatment for rejection [27].

The protocols for treatment for rejection will vary between transplant centers, as there are no randomized trials comparing strategies. However, given the relatively small number of heart transplants performed internationally and the relative rarity of rejection, such trials would be difficult to conduct or power to assess differences between treatment strategies. Thus, as clinicians, one must rely on experience and judgment to formulate the treatment plan that maximizes benefit and minimizes toxicity of these therapies.

Long-term management

While cellular rejection is often successfully treated with corticosteroids and cytolytic therapy, resulting in a resolution of heart failure and normalization of the ejection fraction [28], management of antibody-mediated rejection is often more complicated. Patients often have a persistent reduction in ejection fraction, restrictive physiology leading to recurrent heart failure symptoms, and accelerated progression of transplant coronary artery disease [28].

The management of such patients with a persistent drop in ejection fraction after treatment of symptomatic rejection is not well established. At the Cedars-Sinai Heart Institute, we often rely on therapies to reduce the levels of donor-specific anti-HLA antibodies, including rituximab and bortezomib, as well as long-term photopheresis to alter the function of T cells. In small case series, such therapies have shown benefit [29,30], although often such patients go on to require redo transplantation.

Infection

Overview

Due to immunosuppressive therapy, cardiac transplant recipients are at risk for infection in a generally predictable pattern based on time after transplantation [31] (see Chapter 94, Figure 94.1). Bacterial infections such as staphylococcus and streptococcus occur in the early postoperative period and usually involve wound infections. Opportunistic infections usually do not occur until at least several weeks following cardiac transplantation. Opportunistic infections may be caused by fungi (candida, aspergillus), parasites (pneumocystis, toxoplasmosis), and viruses (CMV).

While prophylaxis against common opportunistic infections is key in the decreased incidence of certain infections in transplant recipients, such as oral candidiasis, pneumocystis pneumonia, toxoplasmosis, and cytomegaloviruses, such infections can and do occur. Furthermore, detection of active infection in a transplant recipient is challenging as the classic signs and symptoms of infection may be blunted by the suppressed immune response. The diagnosis of infection in solid organ recipients must proceed aggressively, as infections can progress rapidly in immunosuppressed individuals. Furthermore, the treatment of infection in solid organ recipients will often start broadly, and the guidance of an infectious disease specialist well versed in transplant infectious disease is essential in guiding diagnosis and treatment.

Infection risk

As with acute rejection, monitoring for immune status and infection risk remains problematic. This has led to several investigational attempts for monitoring assays, none of which are well validated at present, and there is currently no standard approach to accurately assess a transplant recipient's risk for infection. However, an immune- monitoring assay (ImmuKnow; Cylex, Columbia, MD) performed on peripheral blood, which measures adenosine triphosphatase (ATP) release from activated lymphocytes, may offer some guidance in profoundly immunosuppressed patients [32,33]. In the largest study to date in heart transplant recipients, the average immune monitoring score was significantly lower in patients who developed an episode of infection within one month after the measurement compared with steady-state patients [34]. An immune monitoring score of less than 200 ng ATP/ml was associated with future infection.

At our center, we may target lower CI trough levels or reduce mycophenolate mofetil doses in patients with scores less than 200 ng ATG/ml, especially those with recurrent infections. However, the assay has limitations. It does little to provide guidance for finer adjustments in immune management outside of profoundly immunosuppressed patients, and over-infection itself is one of the most valid indicators of over-immunosuppression. Furthermore, whether dynamic changes in the immune monitoring score in response to adjustments in immunosuppression alters patient outcomes has not yet been determined.

Donor transmission or recipient reactivation

While rare, donor transmission or recipient reactivation of infection can be a catastrophic complication of organ transplantation. While every effort is made to screen potential donors for transmissible diseases and recipients for re-activating disease, such infections can still occur, primarily early after transplantation during the period of most intense immunosuppression.

Donor transmission can occur through infection that is latent in transplanted tissue or active bacteremia. Latent infections include

cytomegalovirus (which is why the donor exposure status is key in determining the length of recipient prophylaxis as outlined below), tuberculosis, and *Trypanosoma cruzi* (Chagas disease). Viremia or bacteremia may also be undetected at the time of organ procurement. Rarer causes of donor-transmitted infections include West Nile virus, rabies, human immunodeficiency virus (HIV), and lymphocytic choriomeningitis infection. Missed infections occur because serologic testing is not 100% since seroconversion may not occur during acute infection and not all infections are tested for. Molecular diagnostics may improve the accuracy of donor screening in the future, and augmented screening on a regional basis (with, for example, screening for Chagas disease in Texas and the southwestern US) may improve detection of potential transmissible infections. Once such an infection is detected, aggressive prophylaxis and treatment may stem the progression of disease in the recipient.

Recipient reactivation of infection is also a concern and potential solid organ transplant candidates with active infection are excluded from transplantation. However, temporally distant infection may occur post-transplantation with parasites such as Strongyloides or Chagas disease. At Cedars-Sinai Heart Institute in southern California, patients from Chagas-endemic areas are screened for exposure pretransplantation and followed closely for reactivation post-transplantation with a polymerase chain reaction (PCR) assay. Patients with a positive PCR for the *T cruzi* organism receive prophylaxis with benznidazole under the guidance of the transplant infectious disease specialist.

Fungal infections

All transplant recipients receive antimicrobial prophylaxis for oral candidiasis. At Cedars-Sinai Heart Institute, such prophylaxis is given for three months, coinciding with a drop in corticosteroid dosing to below prednisone 10 mg daily. Options for prophylaxis include clotrimoxazole troches (lozenges) or nystatin oral preparations. In patients who present a higher risk for systemic fungal infections, such as those from an area endemic for coccidioidomycosis, fluconazole or itraconazole may be prescribed prophylactically. The –azoles increase the concentration of CIs and proliferation signal inhibitors, and thus the dosage of cyclosporine, tacrolimus, sirolimus, and everolimus must be reduced up to 50% when initiating –azole therapy, with close follow-up of trough levels.

Parasites

It is standard for transplant recipients to receive trimethoprim-sulfamethoxazole (TMP-SMX) for pneumocystis for one year. TMP-SMX has virtually eliminated pneumocystis pneumonia in heart transplant recipients, and also prevents Nocardia infection and toxoplasmosis. For patients with sulfa allergies, dapsone may be used as long as the patient has no evidence of G6PD deficiency. In such patients, atovaquone is a reasonable alternative.

Viral infections

Prophylaxis against CMV depends on the patient's risk group, defined by the CMV IgG titer. The risk of CMV infection is highest in transplant recipients who have a negative CMV IgG titer (indicating no prior exposure to CMV) and are given a heart from a donor who is CMV IgG positive. At the Cedars-Sinai Heart Institute, these patients receive one year of valganciclovir therapy. The lowest risk of CMV infection occurs in cases where both the donor and the recipient are CMV IgG negative, and these patients receive valganciclovir or acyclovir (which provides inferior CMV protection but is less expensive) for three months. Other patients will receive valganciclovir for six months. Of course, after any treatment for acute rejection with high-dose steroids or cytolytic therapy, patients will receive three months of valganciclovir and TMP-SMX prophylaxis.

Vaccines

The use of vaccines in heart transplant recipients remains controversial. Live vaccines are definitely contraindicated because of the patients' immunosuppressed states. Even dead vaccines may pose a risk because they can promote activation of the immune system and cause rejection. In the Cedars-Sinai Heart Institute, we recommend dead vaccines such as the influenza or pneumococcal vaccines only to patients more than six months after transplant and with no history of rejection within the previous six months.

Malignancy

Incidence

After cardiac allograft vasculopathy (CAV), malignancy is the second most common cause of mortality in heart transplant recipients [2]. Malignancies are approximately two- to fourfold more common in heart compared with renal transplant recipients [35–38]. The ISHLT registry demonstrates that cumulative risk of malignancy is 26% by eight years, most (18%) due to skin cancer [2]. The enhanced risk of cancer among cardiac transplant recipients is thought to reflect the greater degree of immunosuppression that heart transplant recipients receive, either due to inherent immunologic requirements or the lack of a non-invasive monitoring test for rejection such as transaminases or serum creatinine in liver and kidney transplant recipients, respectively [39].

The risk of malignancy from immunosuppressive agents is due to reduced immune surveillance for neoplasia. All immunosuppressive agents are believed to contribute to the cumulative risk of malignancy, with the possible exception of corticosteroids. In Kaposi sarcoma, sirolimus has resulted in complete regression in renal transplant recipients [40] and other studies in solid organ transplant recipients indicate a decrease in the incidence and progression of malignancy with use of a proliferation signal inhibitor, sirolimus or everolimus [41–43].

Clinical presentation

Cancer in solid organ transplant recipients usually presents three to five years post- transplantation. Cutaneous malignancies are the most common type after heart transplantation, mainly squamous cell and basal cell carcinomas [44]. Compared with the general population, organ transplant recipients are approximately 65–250 times more likely to develop squamous cell carcinoma, and 10–16 times more likely to develop basal cell carcinoma [45,46]. Risk factors for the development of skin cancers include fair skin, previous history of skin cancer, geographic location (in areas of high sun exposure), and intensity of immunosuppression [47,48].

Post-transplant lymphoproliferative disorder (PTLD), most commonly a B cell lymphoma related to Epstein-Barr virus (EBV) infection, may occur after transplantation. An increase in the total burden of immunosuppression increases the risk of developing lymphoma, so that PTLD may sometimes occur within the first year after transplantation, when the level of immunosuppression is the highest [49,50]. More than 50% of patients with PTLD present with extranodal masses involving the gastrointestinal tract, lungs, skin, liver, central nervous system, and the allograft itself. Risk factors

for the development of PTLD include a higher level of immunosuppression, including the use of cytolytic therapy for induction [50] and EBV serostatus (with EBV-seronegative recipients of EBV-seropositive donors being at the highest risk) [51].

Finally, neoplasms common in the general population also occur in heart transplant recipients, including breast, lung, and prostate. Lung cancer is more common in heart and lung transplant recipients than in recipients of other solid organs, likely because smoking, a strong risk factor for lung cancer, may also contribute to end-stage heart and lung disease requiring transplantation [52].

Treatment

The most critical point of treatment of malignancies is prevention. We encourage all heart transplant recipients at our institution to undergo routine health maintenance screenings with their primary care physicians, including mammograms, pap smears, prostate exams, and colonoscopies as indicated for non-transplant patients. In addition, patients are instructed to utilize sun protection and to establish care with a dermatologist for routine skin exams. While the utility of annual chest radiograph screening has not been established in the early detection of lung cancer, we have anecdotally detected many early lung cancers in this manner, and thus perform annual chest radiograph screening at our center.

The initial approach to malignancy is reduction of immunosuppression, and this may be the only treatment required for some forms of PTLD. In our institution, we will consider switching patients with newly diagnosed malignancy to a proliferation signal inhibitor such as sirolimus or everolimus, due to its possible protective effect in malignancies, in place of a CI or mycophenolate mofetil (MMF). Compared with CI-based regimens, immunosuppression with the mammalian target of rapamycin (mTOR) inhibitors sirolimus or everolimus may reduce the risk for malignancies, including non-melanoma skin cancer, in organ transplant recipients [41–43]. An immune monitoring assay, such as the Cylex blood test described above, may offer insight into the patient's global state of immune suppression [32–34] and thus provide a target for lowering immunosuppressive agents in patients with malignancy.

Beyond reduction in immunosuppression and switching the CI or MMF to a proliferation signal inhibitor, further treatments are at the discretion of the consulting specialist. Dermatologists will often perform extensive and frequent excisions for the treatment of squamous and basal cell carcinomas. PTLD may require treatment with chemotherapeutic agents, most commonly rituximab combined with cyclophosphamide, doxorubicin, vincristine, and corticosteroids (commonly referred to as R-CHOP).

General medical management

It is essential that all heart transplant recipients receive regular care from an internist for routine health maintenance. Such patients require the same general medical surveillance as non-transplant patients, including age-appropriate cancer screening for malignancies of the cervix, breast, colon, and prostate. Since cutaneous malignancies are so common in heart transplant recipients, annual screening by an internist or dermatologist is essential, especially in fair-skinned individuals or those with a history of skin cancer. Internists may also manage the long-term complications of heart transplant recipients, including renal dysfunction, hypertension, dyslipidemia, diabetes, osteoporosis, and gout. However, it is essential to instruct transplant recipients to inform the transplant center of any new medication recommended by the internist, and there may be unforeseen interactions that should be monitored, as described below.

Renal dysfunction

Renal insufficiency is a common adverse effect of the CIs, and often worsens over time, such that up to 8% of transplant recipients will develop end-stage renal disease at five or more years post-transplant [2,53,54]. "Renal-sparing" immunosuppressive regimens are often utilized in such patients, including a reduction in CI dose or substitution of the CI with sirolimus [55]. To be successful, the timing is important; if the creatinine is too high, often above 2.5 mg/dL, the renal damage may be irreversible. When replacing CIs with sirolimus, the key to preventing rejection is to withdraw CIs gradually over a period of 2–4 weeks while awaiting therapeutic sirolimus levels, and monitoring patients with a follow-up echocardiogram and biopsy at one month after complete withdrawal of the CI [56]. While randomized trial data of renal sparing regimens are not yet available, we have found that, with these caveats, renal-sparing protocols appear efficacious, safe, and beneficial for select patients.

Hypertension

Hypertension after cardiac transplantation is primarily a result of CI use and occurs in up to 80% of patients [2]. Post-transplant hypertension is often difficult to control and often requires a combination of several antihypertensive agents [57,58]. No agent has been shown to be superior in clinical trials of renal [59–61] or heart transplant recipients [62]. However, beta blockers are often avoided in heart transplant recipients because the denervated heart relies on circulating catecholamines to maintain cardiac function during exercise, and thus heart transplant recipients often experience significant fatigue with beta blocker administration. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers may not be tolerated due to renal dysfunction or hyperkalemia. Dihydropyridine calcium channel blockers such as amlodipine and nifedipine are often effective, but may result in troublesome dependent edema and will increase levels of CIs, which should be monitored after initiation.

Dyslipidemia

Lipid abnormalities are common after heart transplantation, due to the use of steroids, calcineurin inhibitors, and proliferation signal inhibitors [63]. The 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins) are effective in reducing total and LDL cholesterol in heart transplant recipients. Notably, treatment initiated within two weeks of transplantation with statins is associated with a lower frequency of hemodynamically compromising rejection episodes and improved survival over the first transplant year [64]. These agents likely have an immunosuppressive effect in addition to their lipid-lowering activity. As hyperlipidemia is so common following transplantation, all cardiac transplant recipients should receive statin therapy. Pravastatin is the statin of choice, since it is not metabolized by the cytochrome 3A4 system, reducing the possible interactions with CIs [14].

Diabetes

Given that diabetes mellitus is a major cardiovascular risk factor leading to the development of end-stage heart disease, diabetes is common in patients pretransplant. Furthermore, the use of steroids and tacrolimus post-transplant may cause or worsen diabetes; up to 32% of heart transplant recipients are diabetic by 5-years

post-transplant [2]. While diabetes is associated with poorer long-term survival [64], there are few data regarding the treatment of these patients. In general, since renal insufficiency in so common in these patients, metformin is often avoided. Furthermore, thiazolidinediones are not preferred due to the risk of fluid retention. Shorter-acting sulfonylureas may be the agents of choice for many heart transplant recipients [14].

Osteoporosis

Osteoporosis resulting in vertebral compression fractures is a common and debilitating problem after heart transplantation, exacerbated by steroid use. At our institution, we recommend screening bone-density examinations by internists on an annual basis. To prevent osteoporosis, patients should receive supplemental calcium and vitamin D, engage in weight-bearing exercises, and receive bisphosphonates as recommended by the primary care physician.

Gout

Causes of gout after heart transplantation include CI use, diuretic use, and renal insufficiency. Non-steroidal anti-inflammatory agents are often avoided in heart transplant recipients due to the potential exacerbation of renal insufficiency. Colchicine may be used to treat acute attacks, although there is a risk of myoneuropathy when colchicine is given in conjunction with CIs. Thus, for acute flares, systemic or intra-articular steroids are often the treatment of choice. Allopurinol is useful as suppressive therapy, as long as the patient is not receiving azathioprine, since the combination may result in severe myelosuppression. Given the potential for adverse effects and drug interactions, consultation with a rheumatologist is often helpful in management of gout in heart transplant recipients.

Summary

Improvements in immunosuppression, donor procurement, surgical techniques, and post-transplant care have resulted in a substantial improvement in the survival of heart transplant recipients. Nonetheless, problems still exist and include rejection, infection, malignancy, transplant coronary artery disease, renal dysfunction, hypertension, diabetes, dyslipidemia, osteoporosis and gout. Newer strategies in prevention and management of these complications are ongoing, and future advances in non-invasive monitoring assays will allow better assessment of rejection and the level of immune response. This will allow clinicians to tailor current therapies to the needs of individual heart transplant recipients to maximize benefit and minimize toxicity.

CHAPTER 106

Long-term Outcomes after Lung and Heart-Lung Transplantation

Toshihiro Okamoto, David Wheeler, and Kenneth R. McCurry
Heart and Vascular Institute, Cleveland Clinic, Cleveland, OH, USA

Introduction

End-stage lung failure remains a common cause of morbidity and mortality in the United States and worldwide. For many of these patients, lung transplantation offers the only hope for a longer life. Since the first successful lung transplant in 1983, the number of programs offering lung transplantation and the volume of transplants performed has steadily increased. In particular, over the last decade, the volume of lung transplants performed annually in the US and worldwide has grown significantly. In the US alone, approximately 1700–1800 lung transplants are performed yearly with over 3500 performed annually worldwide [1,2] (Figure 106.1).

Commensurate with the increase in volume, we have seen a steady improvement in patient outcomes over time particularly when follow-up care is delivered at an established large volume transplant center [1–3]. Critical to the incremental success of lung transplantation over the years has been continual efforts to modify immunosuppressive therapy to diminish the effects of steroids on bronchial healing and other complications, improved assessment and preservation of lung grafts and improved surgical and post-transplant management. These are specifically detailed in chapters 26, 59, and 72 covering organ resuscitation and preservation, the surgical technique and perioperative immune management, respectively. While these efforts have led to improved survival, particularly short-term survival, the median survival following lung transplantation remains a disappointing five years [1]. Late (i.e. more than 1-year from transplant) graft failure and death most commonly occurs as a result of bronchiolitis obliterans syndrome (BOS) and infection, a consistent finding for the last two decades. In addition to these often fatal complications, morbidity related to renal dysfunction, hypertension, diabetes or osteoporosis remains common.

The short-term outcomes following lung transplantation are discussed in chapters 72 and 80. This chapter will review the long-term outcomes following adult lung transplantation including the major causes of mortality and morbidity. While heart-lung transplantation is performed less frequently than isolated lung transplantation, the long-term outcomes more closely resemble those of lung transplant recipients than of heart transplant recipients. For that reason, long-term outcomes following heart-lung transplantation will also be discussed. Specific consideration and coverage of pediatric lung transplantation can be found in Chapter 116.

Long-term outcomes

Survival

Survival following lung transplantation has steadily improved over the last two decades. In the 1980s and early 1990s, 1-year survival approximated 70% with a half-life of 3.9 years and a conditional half-life, the time at which 50% of patients who survived the first year are still alive, of 7.0 years [2] (Figure 106.2). In a report from the International Society for Heart and Lung Transplant (ISHLT) Registry, 1-year survival has improved to 81% for recipients of lung transplants between 2004 and June, 2010 while the half-life has increased to 5.9 years [2] (Figure 106.2). This temporal improvement in survival is demonstrated in the US data, as well [1]. The improvement in long-term survival is largely driven by the increase in early survival, as the rate of attrition following the first year from transplant has been relatively constant (Figure 106.2). Despite these improvements, survival statistics for lung transplant recipients remain comparatively lower than other solid organ transplants with heart, kidney and liver transplant recipients enjoying a half-life of greater than 10 years following transplantation.

Factors affecting survival

As in prior reports, the most recent report from the ISHLT Registry demonstrates a greater survival for recipients of a double lung transplant (DLT) compared to recipients of a single lung transplant (SLT) [2]. These data should be interpreted with caution, however, as differences in survival according to procedure type may be due to clinical factors that influenced the decision regarding procedure type (such as recipient age, comorbidities and diagnosis as well as donor issues). Many investigators have examined survival by procedure type in conjunction with recipient diagnosis [4–9]. Meyer et al. found that recipients of a bilateral lung transplant for chronic obstructive pulmonary disease (COPD) had a higher median survival than single lung COPD recipients (6.7 vs. 4.6 years, respectively); although there was no statistically significant survival benefit in recipients older than 60 years [10]. Additionally, others have suggested that procedure type may impact risk of BOS. Hadjiliadis et al. reported that COPD recipients of a DLT were more commonly free from BOS than SLT recipients at both 3 years (57.4% vs. 50.7%) and 5 years (44.5% vs. 17.9%) after transplant [5]. While conjecture, this may be partially explained by additional lung reserve in DLT recipients.

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

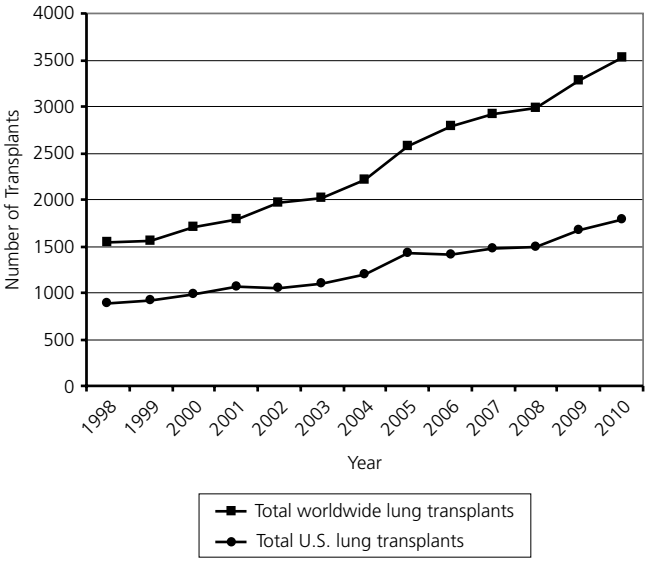

Figure 106.1. Number of yearly lung transplants performed worldwide and in the US between 1998 and 2010. The International Society for Heart and Lung Transplantation (ISHLT) registry reports that 3519 lung transplants (2599 double and 920 single) were performed worldwide in 2010 (the highest yearly total to date). In the US, the Annual Report of Organ Procurement and Transplantation network (OPTN) reported that 1785 lung transplants (1246 double and 539 single) were performed in 2010 in the US. Figure generated from data from the ISHLT registry and the 2011 Annual Report of OPTN.

Among recipients with a diagnosis of interstitial pulmonary fibrosis (IPF), it was reported in the 2011 ISHLT Registry Report that unadjusted survival with a DLT is better than that of SLT three years or more after lung transplantation [6]. However, in an analysis of the UNOS registry that included 3327 patients with IPF, survival was not significantly different between DLT and SLT following adjustment for recipient and donor baseline characteristics [7]. Weiss et al. analyzed the survival of high-risk IPF patients after the introduction of the Lung Allocation Score (LAS) in the US. DLT was associated with a 14.4% decrease in mortality at 1-year, suggesting that it may be advantageous over SLT [8]. Regarding pulmonary arterial hypertension (PAH), many reports suggest that DLT is favorable in recipients with a diagnosis of PAH [9].

The number of transplants being performed in patients 65 years or older has increased dramatically over the last decade. In 2001 in the US, 3.4% of lung transplants were performed in recipients 65 years or older while in 2011 this had increased to 26.6% [1]. This trend is also seen in the ISHLT Registry [2]. With this demographic shift in mind, it is also clear that survival rates after lung transplantation differ by recipient age. In particular, in recipients 65 years and older survival half-life is 3.6 years while that in recipients 35–49 years old is 6.5 years [2]. The main reason for the difference in outcome appears to be late events leading to worse long-term survival as 1-year survival appears comparable between selected recipients older than 65 and younger recipients [2].

Disease-specific differences in survival are apparent but may be confounded by differences in severity of illness, co-morbidities,

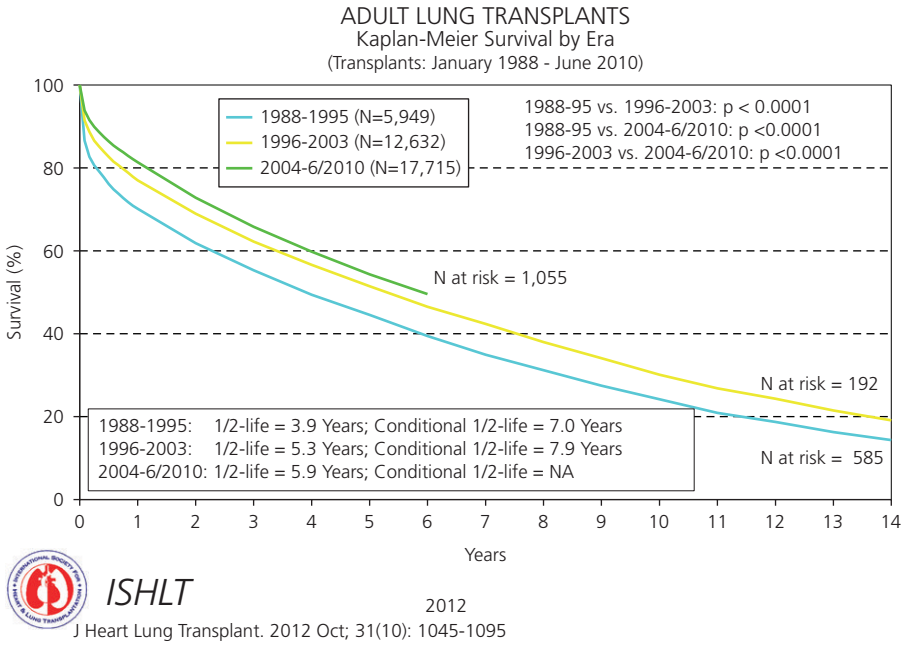

Figure 106.2. Adult lung transplant survival by era calculated using the Kaplan-Meier method. This incorporates information from all transplants for whom any follow-up has been provided. Since many patients are still alive and some patients have been lost to follow-up, the survival rates are estimates rather than exact rates because the time of death is not known for all patients. Survival rates were compared using the log-rank test statistic. No adjustments were made for multiple comparisons. (Source: International Society for Heart and Lung Transplantation, accessible from http://www.ishlt.org/registries/slides.asp?slides=heartLungRegistry)

and average age among disease populations. In addition, certain diagnoses carry higher risks of operative complications and primary graft dysfunction. Among recipients surviving at least 1-year, there were better conditional half-lives after transplant for the primary diagnoses of cystic fibrosis (CF) with an average half-life of 10.4 years, PAH with an average half-life of 10.0 years, sarcoidosis with an average half-life of 8.4 years, and α_1-antitrypsin deficiency with 8.6 years, compared with both COPD and IPF at 6.8 years [2]. Recipients with a primary diagnosis of COPD have the highest 1-year survival and recipients with PAH have the lowest 1-year survival. Lung transplant recipients with IPF have lower 1-year and 10-years survival than others.

It is important to note that most of the published survival data on US outcomes are for recipients who were transplanted under the umbrella of the previous organ allocation system, in which priority was given to recipients with protracted wait-list times. In May of 2005, the new lung allocation score (LAS) System was initiated, prioritizing patients on the basis of the risk of death, *(urgency)*, and the likelihood of 1-year survival post-transplant, (*utility*) [11]. The LAS system is, in part, a scoring system based on the severity of illness, which may have a significant impact on the characteristics of patient selection as well as survival outcomes [12]. Immediately after initiation and implementation of the LAS System, wait-list times and wait-list deaths showed a modest but significant decrease. Over time, the mean LAS score for transplant recipients has increased [13] and, while controversial, some data suggest that a high LAS score may be associated with increased morbidity and mortality after lung transplantation [14,15]. How this will impact outcomes and organ allocation in the US is unclear at this point. As part of the LAS system, wait-list deaths and post-transplant survival will be continually monitored and the LAS system modified as needed. The impact of the LAS on waitlist management is covered in Chapter 40.

An in-depth analysis of risk factors (in addition to those discussed previously) for mortality following lung transplantation is included in the most recent ISHLT Registry Report [2]. The strongest categorical risk factors for 5-year mortality include recipient use of intravenous inotropes (relative risk [RR] 2.13) and recipient dialysis (RR 1.79). Continuous risk factors associated with 5-year mortality, conditional on surviving 1-year, include low and higher recipient age and low transplant center volume.

Heart-lung transplantation

The volume of adult heart-lung transplants performed annually is significantly less than that of lung transplants with a worldwide volume of 86–114 yearly since 2003 [2]. The predominant indication for heart-lung transplantation continues to be congenital heart disease and PAH with a diminishing number being performed for CF. Heart-lung transplantation survival rates differ from lung transplantation survival rates with a relatively higher rate of early mortality in heart-lung transplantation recipients. Heart-lung transplantation recipient survival rate is 63% at 1-year; however, the survival rate following the first year is relatively good with a conditional half-life of post 1-year survival of 10.0 years. As with lung transplantation, survival following heart-lung transplantation has improved significantly in every decade between 1982 and 2010. In heart-lung transplantation recipients, pretransplantation diagnosis is also associated with survival outcomes. Eisenmenger syndrome is associated with the best overall survival when compared to recipients with a primary pretransplant diagnosis of PAH and other congenital heart diseases [2].

Quality of life

The goal of lung transplantation is not only to extend survival of those afflicted with end-stage lung disease but to also improve health-related quality of life (HRQL). While outcomes analyses of survival and lung function following transplantation are common, in depth analyses of HRQL following lung transplantation have been relatively infrequent. The ISHLT Registry does compile functional status post-transplant and, although limited due to incomplete reporting, data suggest that more than 85% of surviving patients at 1-, 3- and 5-years have no activity limitations and that at 5-years post-transplant, 35% of surviving recipients are working either part- or full-time while 46% are not working and 19% are retired [2]. In a recent thematic analysis of published studies of HRQL in lung transplant recipients, Singer et al. found several important insights [16]. First, their analysis found that the literature supports the assertion that lung transplantation results in clinically meaningful and significant improvements in HRQL with greatest improvement in the physical health and functioning domains. Second, they found that lung transplant recipients may derive greater HRQL benefits than other solid organ transplant recipients when comparative data, although limited, is analyzed. Third, lung transplant recipients manifest substantial residual impairments in HRQL compared to population norms suggesting that the significant benefits in HRQL is attributable to the extremely poor HRQL in patients awaiting lung transplantation. Lastly, their data supports that HRQL following lung transplantation remains an understudied field. While they identified 73 studies on HRQL following lung transplantation published between January 1, 1983 and December 31, 2011, a similar search yielded 1131 HRQL articles published in heart transplantation, 1291 in liver and 1689 in kidney. This undoubtedly will be an area of increasing investigation in the future.

Acute rejection

Despite the application of new immunosuppressive medications in lung transplantation, acute and chronic rejection remain common. Indeed, the burden of rejection is perhaps greater in lung transplant recipients that in other solid organ recipients with the possible exception of small bowel recipients. Exposure of the lung to the external environment (including infection) and the rich immune milieu in the lung are felt to be contributing factors (which may also be true for the small bowel). Historically, acute cellular rejection (ACR) was felt to be the predominant form of acute rejection in the lung; however, antibody-mediated rejection (AMR) is now also felt to play a role, as it does in other solid organ transplants. The leading cause of mortality after the first post-transplant year is BOS and remains the main barrier to long-term survival. These issues are discussed in the following sections. Where pertinent differences exist between lung transplant recipients and heart-lung transplant recipients, they are discussed.

Acute cellular rejection

The clinical and histopathological features of ACR are presented in their entirety in Chapters 72 and 84. However, ACR remains an important factor in subsequent outcome and is thus presented here in that context. Lung transplant patients with ACR can be asymptomatic or present with a wide range of symptoms and findings. Non-specific symptoms can include cough, dyspnea and sputum production while non-specific physical exam findings can include hypoxemia, fever and abnormal breath sounds that can be difficult

Table 106.1. Revised classification and grading of pulmonary allograft rejection

Category of rejection	Grade	Severity	Histological finding
Grade A:	0	None	Normal lung
Acute cellular vascular rejection	1	Minimal	Scattered, infrequent mononuclear perivascular infiltrates
	2	Mild	More frequent perivascular infiltrates identifiable at lower scanning magnification, eosinophils may be present
	3	Moderate	Easily recognizable, dense perivascular infiltrates with extension into peribronchial septa and airspaces commonly associated with endothelialitis, eosinophils, and neutrophils may be present.
	4	Severe	Diffuse perivascular, interstitial, and air space infiltrates with prominent pneumocyte damage and endothelialitis.
Grade B:	0	None	No evidence of bronchiolar inflammation
Acute cellular airway rejection	1R	Low grade	Infrequent and scattered lymphocytes (or forming a circumferential band); no epithelial damage or intra-epithelial infiltration
	2R	High grade	Larger and activated lymphocytes in bronchiolar submucosa with more frequent eosinophils and plasmacytoid cells; intra-epithelial lymphocyte infiltration associated with epithelial damage
	X	Ungradeable	Tissue ungradeable
Grade C:	0	None	Obilterative Bronchiolitis absent
Chronic airway rejection	1	Present	Obilterative Bronchiolitis present
Grade D:			Accelerated graft vascular sclerosis
Chronic vascular rejection			

R, denotes revised grade to avoid confusion with the 1996 scheme.
Based on the 2007 revision of the working formulation for the standardization of nomenclature (21).

to differentiate from symptoms and signs of infection [17]. Similarly, findings on imaging studies and pulmonary function studies (PFTs) are not sensitive or specific and typically cannot be reliably differentiated from infection [18,19]. As a result, bronchoscopic transbronchial biopsy (TBBx) has been and remains the gold standard for the diagnosis of ACR. The risks of TBBx including bleeding and pneumothorax have prompted many investigators to attempt to correlate protein or cellular markers in bronchoscopic-guided bronchoalveolar lavage (BAL) fluid with ACR. To date, however, no single BAL marker has proven to have sufficient sensitivity or specificity to supplant TBBx in the diagnosis of ACR [20]. Similarly, although there is some promise, surrogate cellular and molecular markers in peripheral blood have, thus far, proven insufficiently strong to diagnose ACR reliably.

ACR is graded pathologically and is subdivided into acute cellular vascular rejection (Grade A ACR) and acute cellular airway rejection (Grade B ACR) with various grades of severity within each category [21] (Table 106.1). ACR is common following lung transplantation with at least one-third of lung transplant recipients experiencing ACR within the first year post-transplant. After the first year post-transplant, the frequency of ACR declines significantly. The management of lung transplant recipients, while controversial, includes the routine use of surveillance bronchoscopy with TBBxs at many lung transplant centers [22]. While some lung transplant programs perform TBBxs only when dictated by clinical circumstances [23], many believe that surveillance TBBxs (at least for the first 18–24 months post-transplant) provide valuable information that allows appropriate treatment of asymptomatic rejection and fine tuning of immune suppression [24]. There are no data, however, to demonstrate that a protocol including surveillance TBBxs impacts BOS or survival.

While in its severe form ACR can be fatal, ACR is usually treatable and is responsible for less than 2% of deaths following lung transplantation [2]. ACR remains a major focus of post-lung transplant care, however, and is the most significant risk factor for development of BOS. Studies suggest that higher grade ACR, increased frequency of ACR , recurrent high grade ACR and Grade B ACR (lymphocytic bronchiolitis) independent of Grade A rejection are risk factors for BOS [25–27]. In addition, minimal Grade A1 ACR has been identified in some studies as a risk factor for BOS [28] as has large airway inflammation [29].

Although the risk factors for ACR are presented in detail in Chapter 72, a brief recounting here is necessary given the link between ACR, BOS and long-term outcomes. Reported categorical risk factors for ACR include donor : recipient HLA disparity, type of immune suppression, recipient factors and infection. Several large studies have examined the association between HLA disparity and ACR risk and, while the exact relationship requires further study to define, it appears clear that increasing HLA disparity worsens lung transplant outcomes and appears associated with risk of ACR [30,31]. With regards to immunosuppression, unadjusted data from the ISHLT Registry suggests that induction with an IL-2R antagonist is associated with significantly lower ACR rates in the first year post-transplant as is use of a tacrolimus-based maintenance regimen [2]. While results have varied in several randomized comparative trials of cyclosporine versus tacrolimus-based maintenance immunosuppression, the most recent and largest randomized trial found that tacrolimus was associated with a lower cumulative incidence of BOS despite no difference in the rates of ACR [32]. Recipient factors that appear to be related to ACR risk include genotypes that have been associated with either a reduced or heightened ability to mount an immune response [20] as well as gastroesophageal reflux disease that could enhance alloimmune responses against the graft leading to greater ACR [33,34]. Finally, various viral and bacterial infections have been associated with enhanced risk of ACR and/or BOS and worse long-term outcomes [35].

While most lung transplant recipients are treated lifelong with a maintenance triple drug immunosuppression regimen consisting of a calcineurin inhibitor (CI), an antimetabolite and steroids, there is a lack of consensus regarding the optimal regimen and considerable variability in the use of induction agents [2,36]. Similarly, there is no standardized approach between centers to the treatment of ACR and a paucity of randomized trial data to support an evidence-based approach to selection of agents. There is, however, general consensus that rejection episodes of ACR Grade 2 or higher require treatment. Initial therapy is commonly with pulse dose steroids (500 mg to 1000 mg/day) for 3–5 days followed by an oral steroid

taper and/or increase in other maintenance immunosuppressive agents [36]. With higher grades of acute rejection associated with graft dysfunction, some centers choose to utilize polyclonal or monoclonal anti-lymphocyte preparations. Persistent or recurrent ACR is generally treated with a repeat course of steroids, a change in maintenance immunosuppressive agents (e.g. change in CI or addition of a mTOR-inhibitor) and/or polyclonal or monoclonal anti-lymphocyte preparations [36]. Other approaches reported in small series have included the use of alemtuzumab [37], inhaled cyclosporine [38], total lymphoid irradiation [39] and extracorporeal photophoresis [40]. Although, as discussed above, Grade A1 and Grade B (lymphocytic bronchiolitis) acute rejection have been associated with the development of BOS, there is inconsistency between programs as to whether to treat and whether treatment alters the risk of later BOS. In a recent US survey, 80% of respondents would treat symptomatic Grade A1 rejection while only 35% would treat asymptomatic Grade A1 rejection. Furthermore, 12% of respondents stated that they would not treat lymphocytic bronchiolitis [22]. To complicate matters further, there was significant variability in the grading of lymphocyte bronchiolitis.

Antibody-mediated rejection (AMR)

The contribution of anti-HLA alloantibody to rejection in renal and cardiac transplantation has been recognized for some time, and is discussed in depth mechanistically and clinically in Chapters 6 and 89, respectively. Its importance in lung transplantation, outside of hyperacute rejection, has become increasingly evident over only the last 10–15 years but it now seems well established that pulmonary AMR exists and that the consequences of pulmonary AMR can include persistent and refractory ACR and BOS [41]. Based on the recent ISHLT Pathology Council consensus publication [41], the classic diagnostic components that comprise lung AMR include:

1 the presence of clinical allograft dysfunction,
2 circulating donor-specific antibodies (DSA), and
3 pathologic findings [41].

The authors emphasized that the histopathologic findings, covered in Chapter 84, in AMR are non-specific patterns of injury that are seen in a variety of disorders and also noted that capillary C4d immunoreactivity while commonly seen in AMR with circulating DSA can also be seen in the absence of such antibodies. They also emphasized that, based on current definitions and the experience of most transplant pathologists, AMR is a relatively infrequent finding and that diagnosis of AMR should rely on the interaction of pathologist, immunologist and clinician. They also encouraged centers to that develop protocols to routinely assess for DSA in conjunction with clinical visits or at the time of surveillance bronchoscopy.

There are no randomized controlled trials evaluating treatment of established AMR in lung transplantation — or kidney transplantation, for that matter. Existing data regarding therapeutic approaches comes mostly from single center reports. Plasmapharesis (to remove circulating antibodies), immunoglobulin (IVIG — which causes B cell apoptosis, blocks binding of donor reactive antibodies and inhibits complement activation) and rituximab (an anti-CD20 antibody) are the common agents utilized alone or in combination [20]. Two new agents that are now being used by some programs include bortezomib (an inhibitor of the 26s proteasome that causes plasma cell apoptosis) and eculizumab (an antibody against complement component C5 that results in blockade of terminal complement activation) [20]. Adjunct therapies have typically included polyclonal anti-lymphocyte preparations and mycophenolate mofetil for its anti-B cell proliferative effects. Many unanswered questions remain regarding components of therapy, length of therapy and effects on clinical outcome (including risk of BOS).

Questions also remain regarding patients who have discordance in the classic diagnostic components of AMR and how to manage those patients. For example, many patients have been found to have circulating DSA in the absence of demonstrable histologic findings or C4d staining and with or without allograft dysfunction. Whether this is a marker of inadequate immunosuppression resulting in T cell activation and early alloantibody production or something else is unclear at this point. Additionally, humoral autoimmunity to the self-epithelial antigen K alpha-1 tubulin has been associated with development of BOS and, in at least one study, the development of DSA preceded the development of anti-K alpha-1 tubulin antibodies suggesting that DSA mediated injury may have augmented development of autoimmunity [42,43]. Much work remains to elucidate these complex interactions, the clinical consequences and the efficacy of potential therapies.

Chronic lung allograft dysfunction

Historically, chronic rejection of the lung was felt to result from cellular alloimmunity resulting in fibroproliferative narrowing and occlusion of small airways and culminating in allograft dysfunction. Because the diagnostic yield of transbronchial biopsies identifying lesions characteristic of chronic rejection was felt to be low [44], a clinical grading scale of obstructive decline in forced expiratory volume in 1-second (FEV1) of at least 20% compared with the best postoperative values in the absence of other identifiable factors was developed and termed BOS. BOS was felt to be an obstructive, irreversible decline in pulmonary function resulting from fibrotic occlusion of bronchioles. Recently, investigations have suggested that not every decline in FEV1 meet the criteria for BOS and the term chronic lung allograft dysfunction (CLAD) has been proposed as an overarching name with BOS encompassing one phenotype. Two other emerging phenotypes of CLAD, neutrophilic reversible allograft dysfunction (NRAD) and restrictive allograft syndrome (RAS), have subsequently been proposed with what appear to be distinct clinical patterns and therapeutic response rates. This section provides an overview of these entities.

BOS

The most common form of CLAD is BOS and is the leading cause of death after one year from transplant. In the 1–3 and 3–5 year intervals following lung transplantation, BOS is the leading cause of death at 26% and 29.2%, respectively [2]. BOS also causes significant morbidity, reduction in HRQOL and escalates cost in lung transplantation. The incidence of BOS, as reported from the ISHLT Registry, is 48% by 5 years and 76% by 10 years after transplantation, while that of BOS during first year post-transplant is 9.6% [2].

BOS is defined as a sustained (>3 weeks) decline from the best baseline FEV1 in the absence of alternative causes of graft dysfunction (e.g. infection, acute rejection, and airway stenosis, anastomotic stricture) [45]. The best baseline is defined as the average of the two best FEV1 values measured post-transplant at least 3 weeks apart. A decline from baseline of at least 20% is defined as BOS with progressive loss of function defined in progressive stages of BOS (Table 106.2). The typical pathological findings of BOS, when available, include:

Table 106.2. Bronchiolitis obliterans syndrome classification

	Original classification 1993		Current classification 2001
BOS 0	$FEV_1 > 80\%$ of baseline	BOS 0	$FEV_1 > 90\%$ of baseline and $FEF_{25-75} > 75\%$ of baseline
		BOS 0-p	$FEV_1 > 81–90\%$ of baseline and/or $FEF_{25-75} \leq 75\%$ of baseline
BOS 1	$FEV_1 > 66–80\%$ of baseline	BOS 1	$FEV_1 > 66–80\%$ of baseline
BOS 2	$FEV_1 > 51–65\%$ of baseline	BOS 2	$FEV_1 > 51–65\%$ of baseline
BOS 3	$FEV_1 < 50\%$ of baseline	BOS 3	$FEV_1 < 50\%$ of baseline

BOS, bronchiolitis obliterans syndrome; FEF_{25-75}, mid-expiratory flow rate; FEV_1, forced expiratory volume in one second.
Modified from Estenne M, Maurer JR, Boehler A, et al. Bronchiolitis obliterans syndrome 2001: an update of the diagnostic criteria. J Heart Lung Transplant 2002; 21:297.

- submucosal lymphocytic inflammation and disruption of the epithelium of small airways in early phase,
- ingrowth of fibromyxoid granulation tissue into the airway lumen, resulting in partial or complete obstruction, and
- granulation tissue in a cicatricial pattern and resultant fibrosis, which finally obliterates the airway lumen.

Typical symptoms are non-specific and include; dyspnea, cough, sputum production, and limitation of exercise capacity. Chest computed tomography (CT) might show bronchiectasis with peribronchial thickening and air trapping. In patients with RAS (see further on), chest CT typically demonstrates interstitial opacities, upper lobe fibrosis, ground glass opacities and honeycombing. BOS is most commonly diagnosed between 1.5 and 4 years post-transplant [46]. The course is highly variable and may be insidious in onset and progression or result in a gradual decline in function over months to years or may result in an abrupt, severe decline in function over weeks [47]. Initial deterioration with subsequent stabilization at a lower level has also been described [47]. Early onset BOS and high-grade onset BOS [2,3] predict worse survival [46].

The pathogenesis of BOS is complex and can involve alloimmune and non-alloimmune mechanisms acting independently or in concert. Classically, BOS is felt to be the result of alloimmune-mediated injury to the graft. Supporting this thesis, as discussed previously, is the relationship of ACR to BOS with both Grade A ACR (persistent/refractory, high grade and late onset) and Grade B ACR (lymphocytic bronchiolitis) being strong risk factors for BOS. Similarly, and as discussed previously, humoral alloimmunity to HLA is associated with development of BOS, as well. Much work over the last decade has also focused on the role of autoimmunity rather than alloimmunity as a cause of BOS [42,48]. Data suggest that epitopes of collagen type V exposed during lung injury (such as during ischemia reperfusion injury around the time of transplantation) and K-alpha1 tubulin can lead to autoimmunity resulting in graft injury and BOS. Much ongoing work is focused in this area and potential therapeutic interventions.

Abundant evidence has demonstrated other risk factors for BOS that are seemingly not alloimmune related. These include primary graft dysfunction, gastroesophageal reflux and various infections including cytomegalovirus (CMV) infection and community-acquired viral infection (CARV) as well as others. While the mechanism inciting development of BOS is not clear, some have suggested that graft injury from these events results in a heightened inflammatory state in the lung leading to enhanced alloreactivity while others have suggested other pathways including aberrant healing following injury [49,50].

Primary graft dysfunction, (PGD) is a risk factor of BOS that is independent of acute rejection, lymphocytic bronchitis, and community-acquired respiratory viral infections, and this risk is directly related to the severity of primary graft dysfunction [51]. A retrospective series by Whitson et al. reported that bilateral lung recipients with Grade 3 PGD had worse long-term survival, higher incidence of BOS, and compromised pulmonary function [52]. The mechanisms of this co-relation between PGD and BOS are thought to be oxidative stress, reduced nitric oxide production, and up-regulation of HLA class II antigens in ischemia reperfusion injury.

Gastroesophageal reflux (GERD) has been suggested to occur with a frequency in lung transplant recipients as high as 73% in one single center study [53]. Much evidence suggests that GERD is associated with the development of BOS and data suggest that early surgical intervention (gastric fundoplication) for lung recipients with GERD can result in greater freedom from BOS compared to patients treated medically [53,54]. Much work continues in this area with many investigators hoping to conduct a randomized clinical trial.

CMV infection has long been considered a risk factor of the development of BOS [55]. While this result was not confirmed in a single-center study [56], a second single-center cohort study demonstrated that treated CMV pneumonitis within the first 6 months after transplantation significantly increased the risk for BOS [57]. Similarly, in single center reports, CARV [58], human herpesvirus-6 [59] and *Chlamydophila pneumonia* [60] infection were associated with development of BOS. In a single-center analysis of 161 cases, Valentine et al. found that pneumonia and airway colonization with gram positive bacteria, gram negative bacteria, and fungal pathogens were independent determinants of chronic allograft dysfunction [61]. Additionally, Weigt et al. reported that *Aspergillus* colonization was strongly associated with BOS and BOS related mortality [62].

To date, there is no proven treatment for BOS. Historically, many agents and therapeutics have been evaluated in single center studies but the results of many of these studies are viewed with skepticism due to small sample sizes, lack of suitable controls and endpoints such as stabilization of FEV1 or reduction in rate of FEV1 decline (as opposed to improvement) that can occur during the natural history of BOS. Approaches have included alteration of maintenance immunosuppression converting from cyclosporine to tacrolimus as well as converting from azathioprine to mycophenolate mofetil [63,64]. Cytolytic therapy with an antilymphocyte or antithymocyte preparation or with alemtuzumab (a humanized CD52-specific antibody) also has been reported to have an effect in some patients [65,66].

Perhaps the approaches with the greatest evidence are azithromycin, extracorporeal photopheresis (ECP) and surgical fundoplication (discussed previously) in those patients with GERD. Gerhardt et al. first reported the use of azithromycin (250 mg three times per week) in BOS patients in a small pilot study in 2003 [67]. In the study, 5 of 6 patients demonstrated a significant improvement in FEV1 resulting in much interest in azithromycin as a therapy for BOS. Most subsequent studies have also suggested that a subset of patients with BOS respond to azithromycin with improved FEV1 and many studies have also suggested that those likely to respond have BAL fluid (BALF) neutrophilia [68].

This has led many investigators to suggest that the group of patients with BALF neutrophilia represents a distinct phenotype of CLAD; accordingly they have termed this neutrophilic reversible allograft dysfunction (NRAD).

ECP is performed via a closed loop intravenous system and involves removal of approximately 700 ml of the patient's blood and isolation of leukocytes with subsequent exposure to ultraviolet light in the presence of 8-methoxypsoralen (8-MOP) [69]. The induced bonding between 8-MOP and DNA pyrimidine bases results in lymphocyte apoptosis. ECP is safe and, since US Food and Drug Approval in 1998, has been used to successfully treat cutaneous T cell lymphoma as well as acute and chronic graft versus host disease and a variety of other diseases including acute cellular rejection in heart transplant recipients [70,71]. Although the exact mechanism of action is not clear, it has been suggested that ECP causes immunomodulation, possibly via the induction of Tregs [72]. The first successful use of ECP in lung transplant recipients was reported in 1995 where it was used to treat acute rejection [73]. Since then, several studies have suggested efficacy in lung transplant recipients with refractory acute rejection or BOS. Interpretations of results and enthusiasm have been limited, however, due to small sample size, non-comparable adjuvant immunosuppression and short-term follow-up, as well as expense and need for intravenous access. Recently, however, Greer et al. published a retrospective series of 65 well-characterized patients with BOS, 64 of whom had deteriorated despite azithromycin therapy. With a median follow-up of 503 days, this study demonstrated efficacy of ECP in 54% of treated patients and identified three subgroups of CLAD (restrictive allograft syndrome, rapidly progressive and non-neutrophilic) that were significantly less likely to respond to ECP [69]. This study is likely to generate renewed enthusiasm for studying ECP as a treatment for CLAD.

Lastly, retransplantation can be life saving for patients with BOS; however, retransplantation remains controversial due to limited number of donor lungs as well as the generally lower survival rates and higher rate of BOS that that following primary transplants [74].

Strategies to prevent BOS (and other forms of CLAD) have been partially discussed previously. Given the strong link between acute rejection and BOS, monitoring strategies including use of surveillance bronchoscopy and TBBx are used by many centers with the hope of preventing and aggressively treating acute rejection. There is no clear evidence, however, that surveillance biopsies and TBBxs have any impact on BOS or survival. Clouding this issue, however, is the potential for TBBx sampling error [75] and interobserver agreement between pathologists on ACR grading [76] to result in under diagnosis of acute rejection. In the ISHLT Registry, the use of induction therapy is associated, in unadjusted analysis, with longer survival [2]. The limited clinical trial data, however, is indeterminate and further multicenter studies are needed. The use of tacrolimus as compared to cyclosporine is also associated with improved survival in ISHLT Registry data [2] and, as discussed previously, randomized trial data supports a lower incidence of BOS and perhaps ACR [32]. In 2011, Vos et al. published a randomized trial of azithromycin prophylaxis started at discharge from the hospital after lung transplantation [77]. At 2 years following transplantation, BOS occurred significantly less frequently in the azithromycin group compared to the placebo group (12.5% vs. 44.2%, $P = 0.0017$). The azithromycin group also demonstrated a better FEV1 and lower BALF neutrophilia.

Neutrophilic reversible allograft dysfunction and restrictive allograft syndrome

Following the initial publication of azithromycin treatment of BOS by Gerhardt et al. [67], numerous studies corroborated the finding while some did not. The reason why some patients did not respond was not initially clear but later studies correlated BALF neutrophilia and high BAL IL-8 levels with response to azithromycin [69,78]. Investigators characterized the phenotype of responders as having a high percentage of neutrophils in BALF (>15%), CLAD (obstructive physiology) developing early after transplant and they had an improvement in FEV1 of at least 10% after 3–6 months of azithromycin. This group appears to have a good prognosis with azithromycin treatment.

Restrictive allograft syndrome is a term that was coined by the Toronto Lung Transplant Program and describes lung transplant recipients that suffer from a persistent decline in FEV1 (>20% compared with the best postoperative baseline) and a restrictive pattern of pulmonary mechanics (defined as a decline in total lung capacity [TLC] of >10% compared with baseline) [79]. This pattern is observed in about 25–30% of lung transplant patient suffering from CLAD. Diagnosis is made with PFTs and high-resolution chest CT which demonstrates interstitial opacities, upper lobe fibrosis, ground glass opacities and honeycombing compared to patients with BOS or NRAD [79]. Patients with RAS have a lower survival rate after diagnosis with a median survival of 8 months in a series from Belgium and a median survival of 16 months in the Toronto series (compared with 35 months and 46 months for patients with obstructive BOS, respectively) [79,80]. No beneficial therapy has been identified to date and the general impression is that RAS patients do not respond to azithromycin. The landscape is made a bit more complex in that some investigators have noted that some patients first develop a classical obstructive BOS pattern (no change in TLC) and then later develop findings of RAS (decline of >10% in TLC). Further studies are needed to delineate these patterns and to better understand the pathophysiology.

Infection

As with all solid organ transplant recipients, and as covered generally in Chapters 92–94, recipients of lung transplants are at increased risk of infection due to the requisite immunosuppressive therapy. However, lung transplant recipients are generally thought to be more susceptible to infection than most other solid organ recipients, and thus, infection is presented with specific reference to lung transplantation here. The factors exacerbating the risk of infection in lung transplant recipients include the generally higher level of immunosuppression required as well as impaired local defense mechanisms (loss of lymphatic drainage, diminished mucociliary function, and reduced cough) and a constant environmental exposure to organisms inhaled through the tracheobronchial tree. As a result, infection remains a common cause of morbidity and mortality following lung transplantation. Indeed, non-CMV infection is second only to graft failure as the most common cause of reported death in the first year following transplantation (20% of deaths) and secondary only to BOS as the most common of cause of reported death after the first year [2]. Bacterial and viral infections predominate following lung transplantation, however, fungal and mycobacterial infections also occur at an increased frequency. Prophylaxis against opportunistic organisms such as CMV, fungi and *Pneumocystis jirovecii* is common in

clinical practice and reduces infection risk for these organisms but infections with these organisms still occur.

The diagnosis of pulmonary infection in the lung transplant recipient can be quite vexing. Symptoms and signs include fever, shortness of breath, sputum production and hypoxemia and can be difficult to distinguish from acute rejection. While a positive sputum culture and/or a positive BAL culture with a negative biopsy for ACR can be highly suggestive or definitive, there are few other definitive tests and an amalgam of findings and diagnostic studies is frequently necessary to guide therapy. The Cylex Immune Cell Function Assay (ImmunoKnow; Cylex, Inc., Columbia, MD) was developed to assess global immune function in solid organ transplant recipients and to aid in the diagnosis of infection or rejection. The assay measures ATP production in stimulated peripheral blood T cells and correlates with both infection and rejection in kidney, liver, heart and small bowel transplant recipients [81]. Although there appears to be some correlation between very low ATP levels and infection and very high ATP levels and ACR, the test remains inadequate to diagnosis infection or ACR and guide therapy [82,83].

Bacterial infection

Bacterial infection, especially gram-negative bacteria, is the most common cause of pneumonia after lung transplantation [84]. The majority of gram-negative bacteria as a cause of pneumonia are: *Pseudomonas aeruginosa*, *Acinotobacter* species, *Enterobacteriaceae*, *Stenotrophomonas* species, and *Burkholderia* species. Colonization of the airway before transplantation must be considered, especially in patients with cystic fibrosis, because it may result in postoperative complications, such as pneumonia. Regarding the multi-drug resistance of colonized bacteria, *Burkholderia cepacia* may merit heightened watchfulness and investigation. *Burkholderia cepacia* was previously known as Pseudomonas cepacia and consists of nine distinct species. Recent studies suggested that a specific species of *Burkholderia cepacia*, *B. cenocepacia* (genomovar III), is associated with increased post-transplant mortality [85]. As a result, many lung transplant programs will not offer transplantation to patients (most commonly with cystic fibrosis) with *Burkholderia cepacia* colonization. The multi-drug resistance of *Pseudomonas aeruginosa* in the pretransplant period is not considered a risk factor of mortality [86]. Conversely, the post-transplant colonization of *Pseudomonas aeruginosa* is associated with the high incidence of BOS and a shorter period of BOS-free survival [87].

Viral infection

CMV infection is the most significant viral infection and the second most common infection overall, after bacterial infection [88], in lung transplant recipients. As a result, lung transplant programs focus attention on the prevention of CMV as a routine regimen. The lung transplant recipient is at increased risk of significant CMV viral load when compared to other sold organ transplants. Without aggressive prevention, it is estimated that CMV disease occurs in 38–75% of lung transplant recipients [89].

Risk factors for CMV infection include the serostatus of the donor and recipient; the combination of seropositive donor and seronegative recipient is at the highest risk. According to Zuk et al. 94.9% of centers use prophylaxis against CMV for donor positive, recipient negative patients [90]. Regarding the duration of the prophylaxis, the 2010 Transplantation Society International CMV Consensus Group guidelines recommended at least 6 months of prophylaxis for CMV D+/R− recipients, and three to six months in CMV D+/R+ and D−/R+ individuals [91]. In a recent multicenter randomized trial, extended CMV prophylaxis (12 months) in lung transplant patients at high risk for CMV infection resulted in a significant decrease in the incidence of CMV disease compared to recipients who received prophylaxis for 3 months [92]. CMV infection accounts for less than 1% of deaths more than 1 year after transplantation, however, as previously discussed, CMV infection appears to be a risk factor for development of BOS [57] and, thus, may contribute to the mortality of recipients with the development of BOS.

In addition to CMV, numerous other viruses are increasingly being recognized as having a potentially important impact on short- and long-term outcomes in lung transplant recipients. As discussed previously, community-acquired respiratory viral infections are common in lung transplant recipients and have been demonstrated to be a common trigger for acute rejection and/or BOS [93]. Previous exposure to varicella-zoster virus is common and reactivation of latent virus can cause painful shingles and rarely wide spread cutaneous or visceral involvement. The seroprevalance of human herpes virus 6 (HHV-6) and human herpes virus-7 (HHV-7) are high in adults and reactivation following solid organ transplantation common [94]. Reports have linked HHV-6 to acute and chronic rejection in liver transplant recipients [95]. Studies thus far in lung transplant recipients have revealed an association between HHV-6 and interstitial pneumonia but have not demonstrated an association with acute rejection or BOS [96,97].

Fungal infection

While bacterial and viral infections are more common, fungal infections occur in 15–35% of lung transplant recipients and are associated with a higher mortality [98]. *Aspergillus* and *Candida* species are the major causes of fungal infection in lung transplant recipients with the prevalence of *Candida* infections declining. Other less common fungal pathogens that cause infection in lung transplant recipients are *Fusarium*, *Scedosporium* and *Zygomycetes*. Invasive infection with these organisms is associated with 34–78% mortality despite antifungal therapy [99].

Forty-four percent of all invasive fungal infections in lung transplant recipients are due to *Aspergillus* and lung transplant recipients have the highest incidence of invasive aspergillosis (IA) among all solid organ transplant recipients [100], perhaps because *Aspergillus* is pervasive in the environment and is acquired via inhalation. As a result, much attention is focused on *Aspergillus* in lung transplant recipients. Isolation of *Aspergillus* from the tracheobronchial tree may be an indication of colonization (absence of disease), tracheobronchitis with airway anastomotic infection or invasive pulmonary or disseminated disease (i.e. IA). *Aspergillus* tracheobronchitis has become less common than in previous eras and typically develops around a mean of 50 days following transplantation [99,101]. Complications include airway anastomotic dehiscence, stenosis and bleeding. *Aspergillus* tracheobronchitis is associated with a mortality of 20% and without antifungal therapy may progress to IA with a greater risk of death.

The mean time to development of IA is currently longer than in previous eras, occurring around 500 days post-transplant [102]. This temporal shift may be due to the frequent use of fungal prophylaxis post-transplant (see further on). Risk factors for invasive aspergillosis include colonization before or after transplant, single-lung transplantation, CMV infection, hypogammaglobulinemia, environmental exposure, chronic rejection and the net state of immunosuppression [99]. The treatment of IA is reduction of

immune suppression followed by an anti-fungal agent (voriconazole is first-line therapy) according to the 2008 Infectious Diseases Society of America guidelines on the treatment of aspergillosis [102]. Due to advances in management, mortality from IA has declined from 81% in previous eras to 38% [98]. Despite a lack of evidence demonstrating efficacy, prophylaxis against fungal infection is commonly practiced. In a recent worldwide survey, 59% of lung transplant programs stated that they use universal antifungal prophylaxis in the first 6 months post-transplant with 97% targeting *Aspergillus*. The agents used were variable with most programs employing voraconazole alone or in combination with inhaled amphotericin. Most agreed that antifungal prophylaxis guidelines are needed [103].

Malignancy

Solid organ transplantation is a significant risk factor for malignancy and is discussed generally in Chapter 95. The mechanism of developing malignancy is thought to be decreased immunologic surveillance due to chronic immunosuppression in the postoperative period. Malignancies account for a small percentage of mortality in the first year after transplantation and beyond the first year, 9.1–15.9% of all deaths are due to cancer [2]. Non-melanoma skin cancer is the most prevalent malignancy overall but post-transplant lymphoproliferative disease (PTLD) is the m*ost common malignancy among 1-year survivors of lung and heart-lung transplantation* and is second most common overall.

Post-transplant lymphoproliferative disorders

Post-transplant lymphoproliferative disorders (PTLD) are defined as lymphoid and/or plasmacytic proliferations, which occur in both of solid organ transplant and allogeneic hematopoietic cell transplantation. The development of PTLD is mediated by the activation of Epstein-Barr virus (EBV). As a result of reduced suppression of T-cell response, EBV induces B cell proliferation, which leads to simple lymphoid hyperplasia or non-Hodgkin's lymphoma-like aggressive lesion. General features of PTLD are presented in Chapter 96.

Risk factors for development of PTLD include; amplified T cell immunosuppression and recipient EBV seronegative status, primary CMV infection, male-gender, and older recipient age [104]. According to a single center study by Kremer et al. the incidence of PTLD is 4.8% and has decreased recently [105]. The authors suggested that the earlier usage of anti-thymocyte globulin (ATG) as an induction therapy before 2000 might be correlated to the incidence of PTLD.

PTLD within the first year after surgery tends to present in the thorax including allograft or mediastinal lymph nodes. Late PTLD has an extrathoracic presentation with the gastrointestinal tract a common site of the disease. The time to diagnosis of PTLD after lung transplant is 22.5–40 months [105–107].

Important factors in preventing PTLD are identification of high-risk EBV-naïve patients, routine surveillance of EBV viral load, antiviral prophylaxis, and a reduction of immunosuppression in patients with seroconversion of EBV status and rising EBV viral load. The treatment of PLTD includes reduction of immunosuppression, antiviral therapy, anti-CD20 (Rituximab, monoclonal B cell inhibitor), and sometimes chemotherapy with CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisolone). In cases presenting with large masses or abdominal obstruction, surgical intervention can be one option of treatment. Anti-CD20 is reported to have a 66% response rate in PTLD lung transplant recipients [108]. Similar results of anti-CD20 treatment have been reported [109]. Chemotherapy with CHOP is selected for patients presenting with disseminated disease, clinical progression on rituximab, or non B cell PTLD. One clinical trial of rituximab followed by chemotherapy of CHOP for PTLD demonstrated a 60% clinical remission in solid organ patients and extended survival on average of 6.6 years [110].

Skin cancers

Skin cancers represent approximately 40% of all malignancies in organ transplant recipients [111,112]. The most common skin cancers in recipients are squamous cell carcinoma, basal cell carcinoma, melanoma and Kaposi's sarcoma. Risk factors for squamous cell carcinoma and basal cell carcinoma include intensity and duration of immunosuppressive treatment, older age at transplantation, as well as ultraviolet exposure and geographic location. Although it remains unclear if a specific type of immunosuppressive agent contributes to malignancies in recipients, recent evidence indicates that mycophenolate mofetil may be linked to a lower risk for skin cancer than azathioprine-based immunosuppression [113]. Sirolimus was reported to reduce the risk of malignancy and non-melanoma skin cancer in renal transplant recipients in a prospective, randomized controlled trial [114] while cyclosporine and azathioprine use has been correlated with development of skin cancers in solid organ transplant recipients in several studies [115,116]. These agents are suggested to have carcinogenic effects [117,118]. Regarding other medications commonly used in lung transplant recipients, prolonged usage of voriconazole has been reported to be associated with non-melanoma skin cancer in renal transplant recipients and in lung transplant recipients [119,120]. The prevention of skin cancers in recipients requires patient education and counsel on the hazards of sun exposure. The effect of retinoid as a prophylaxis has been not conclusive.

Other medical morbidities

Morbidity related to immunosuppressive drug toxicity on other organ systems are common following lung transplantation as they are following other solid organ transplants. Common morbidities include hypertension, renal insufficiency, hyperlipidemia, diabetes mellitus and osteoporosis. Many of these complications have onset in the first year following transplantation but, despite the gradual tapering of immunosuppressive medications over time after that, the cumulative prevalence continues to rise. The most recent ISHLT data suggests that the incidence of hypertension in the first year post-transplant is 52% and rises to 83% of surviving recipients at 5-years post-transplant [2]. Similarly, the incidence of diabetes at 1-year post-transplant is 26% and increases to 41% at 5-years while that of hyperlipidemia is 25% at 1-year and rises to 58% at 5-years. It is important to manage these medical issues well as all three are major risk factors for cardiovascular disease.

Renal insufficiency can be quite troubling following lung transplantation as chronic kidney disease can severely negatively impact HRQOL and dramatically escalates mortality risk [121]. According to ISHLT data, the incidence of severe renal dysfunction among survivors at 5-years post-transplant is substantial with 4% of recipients requiring dialysis or having undergone renal transplantation while 15.5% have an abnormal creatinine above 2.5 mg/dL [2]. At 10-years post-transplant, the percentage of survivors requiring dialysis or having received a renal transplant rises to 14.4% [2]. In

general, lung transplant programs have tried to utilize nephron-protective strategies such as aggressive weaning of calcineurin agents and/or conversion to a sirolimus based immunosuppressive regimen. Similarly, post-transplant osteoporosis related, at least in part, to immunosuppressive medications is common and can lead to fractures that negatively impact HRQOL [122].

Summary

Significant improvements in recipient and donor selection, surgical technique, immunosuppression and post-transplant care have facilitated the growth and application of lung transplantation resulting in improved HRQOL and survival for many patients. Despite these advances, significant difficulties and challenges remain. Survival has improved largely due to enhanced 1-year survival with persistent and constant late attrition largely due to chronic rejection and infection resulting in disappointing long-term survival. In addition, the ravages of immunosuppression including infection, malignancy, hypertension, hyperlipidemia, renal insufficiency, diabetes and osteoporosis are common. With a better understanding of the mechanisms that lead to chronic lung graft injury and, hopefully, better and more non-invasive methods to tailor immunosuppressive therapy, results will improve.

CHAPTER 107

Long-term Outcomes after Pancreas Transplantation

Philip Y. Wai[1] and Hans W. Sollinger[2]

Introduction

Pancreas transplantation offers select patients with type 1 diabetes (T1D) the potential for normal glycemic control without the need for exogenous insulin. In patients with concomitant end-stage nephropathy, simultaneous pancreas-kidney transplantation (SPK) represents the optimal long-term therapeutic approach. Successful SPK transplantation liberates patients from dialysis and re-establishes normoglycemic regulation. This therapeutic benefit is balanced against the morbidity related to the operation and the adverse effects of life-long immunosuppression; two significant barriers that often limit the number of potential surgical candidates. Over the last four decades, there has been a significant improvement in both the early and long-term outcomes after pancreas transplantation [1–4]. Advancements in surgical technique, progress in immunosuppression, and refinements in post-transplant clinical care have all contributed to enhanced graft and patient survival.

Appropriate allocation remains a challenge as recipient risk must be individualized to regional waiting times and balanced against the relative benefits of reversing uremia versus reversing diabetes in patients requiring both kidney and pancreas transplantation. The availability of living kidney donors raises the real issue of whether some patients are better served with living donor kidney transplantation (LDK) first, followed by pancreas transplantation (PAK). Recent updated data on the natural history of patients receiving SPK has been analyzed and these long-term outcomes should inform the decision-making process for diabetic, uremic patients selecting optimal therapy.

In the following chapter we describe the evolution of the surgical technique involved in pancreas transplantation, discuss the data on the long-term outcomes of this procedure, the associated complications, the effects of pancreas transplantation on secondary diabetic complications, and novel ways to expand the donor pool. The surgical technique itself is covered in depth in Chapter 60. Finally, this chapter will summarize the current recommendations for optimizing pancreas allograft and patient survival. Additional information on the recognition and treatment of pancreas rejection is covered in Chapter 73, and consideration of the criteria for candidacy for pancreas transplantation, and its investigational alternative, islet transplantation, is considered in Chapter 32.

Evolution of surgical technique in pancreas transplantation

A complete discussion of long-term outcomes after pancreas transplantation requires acknowledgement of the evolution in surgical technique. Pancreas transplantation with long-term allograft and patient survival was dependent on the development of improved immunosuppression, but also on pioneers who modified the operation. Kelly et al. performed the first pancreas transplant on December 17, 1966 using a duct-ligated segmental graft implanted simultaneously with a kidney from a deceased donor in a 28 year old recipient [5]. This milestone was followed by a series of pancreas transplants using whole pancreatic duodenal allografts with and without the spleen attached, duct-injection strategies, and segmental grafts with the main pancreatic anastomosed to the ureter. These efforts uniformly failed to provide long-term function or acceptable patient survival as a result of technical complications and immunologic rejection. One-year graft survival was reported at 21% and 1-year patient mortality was 39% (International Pancreas Transplant Registry; 1980).

The method of preparing the pancreaticoduodenal allograft and the technique for surgical implantation has been previously described [6–9]. At the University of Wisconsin, the pancreas and liver are removed en bloc in donor recoveries performed by the transplant team (see Chapters 21 and 22 for detailed descriptions of the abdominal organ recovery procedures). Using this technique, the pancreas is separated from the liver and the allograft is subsequently prepared on the back-table in ice-cold UW solution (ViaSpan, Bristol Myers Squibb, Garden City, NY). When several different recovery teams are present for multi-organ recoveries, en-bloc removal is often not performed and the organs are separated in situ. Care must be taken to preserve the pancreatic vasculature and parenchyma, both of which can be easily damaged. The back table preparation of the allograft continues to be the most critical step with respect to the technique of pancreas transplantation. Careful inspection of the pancreas includes examination for fat content, fibrosis, the texture of the pancreatic parenchyma, size and quality of the pancreatic vasculature as well as the donor vessels retrieved for transplant, and the presence of anomalous anatomy [6,9]. Splenectomy is performed by dissecting the pancreatic tail away from the spleen and selectively ligating the distal splenic arteries and proximal splenic veins. The duodenal segment is shortened

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

with oversewing of the proximal and distal staple lines. Neurolymphatic tissue in the area of the superior mesenteric artery (SMA) and splenic artery is carefully removed. Ligation of small venous branches allows lengthening of the portal vein, and arterial reconstruction is routinely performed with an iliac Y-graft [6]. In situations where the procurement will yield a pancreas and a separate intestinal allograft, the mesentery of the small bowel must be divided while maintaining the proximal SMA and superior mesenteric vein (SMV) and their tributary arcades that supply the pancreatic head and duodenum with the pancreatic allograft [9].

The pancreas is often transplanted on the right side with the venous anastomosis performed to the distal inferior cava or common iliac vein (Figure 107.1). Recent reports continue to confirm that no survival advantage is conferred by either portal venous or systemic venous drainage techniques [2,10]. Venous extension grafts are not routinely used and the duodenal portion of the allograft is usually directed cephalad. The arterial anastomosis is performed to the proximal right common iliac artery. Although the bladder-drainage technique was developed at the University of Wisconsin and is still performed in certain centers, enteric drainage of the pancreas is preferentially performed by sewing the donor duodenal segment to the recipient jejunum, ~20–60 cm distal to the ligament of Treitz, using a two-layer hand sewn anastomosis technique. The kidney is implanted into the left iliac fossa, with vascular anastomoses performed to the left iliac vein and iliac artery. Although the pancreas is often transplanted first at the authors center with no observed increase in the frequency of thrombosis, other centers have reported some advantage to reducing the risk of pancreatic thrombosis with placing the kidney first when more than one operative team is involved and more than one operative exposure is required [11]. Current analysis of the largest repository of pancreas transplant recipients demonstrated that the majority of current pancreas transplants performed in the US have changed from bladder drainage to primary enteric drainage and that the donor portal vein is more commonly anastomosed to the systemic venous drainage in the recipient [2]. Approaches that have reinvigorated the use of certain historical techniques such as the use of segmental donor allografts in living donor pancreas transplant [12] and portal-gastric (donor jejunum-recipient gastric) anastomosis [13] have continued to advance the field but are not routinely performed across US centers.

Long-term outcomes after pancreas transplantation

More than a decade ago, Ojo et al. demonstrated that pancreas transplantation in patients with T1D and resultant diabetic neuropathy increased patient survival in comparison to deceased donor kidney transplantation alone or dialysis [14]. Recent data from several comprehensive reports have described the most current long-term outcomes after pancreas transplantation (Table 107.1).

Registry data and large multicenter data

The International Pancreas and Islet Transplantation Registry (IPITR) founded in 1980 and housed at the University of Minnesota under the direction of Professor David E.R. Sutherland, maintains the most comprehensive database for all reported

pancreas transplants worldwide (www.iptr.umn.edu). Their recent analysis of 18 159 pancreas transplants performed across eras from July 25, 1978 to December 31, 2005 demonstrated improved short-term and long-term graft survival over the last three decades. In the US, the number of pancreas transplants being performed demonstrated a constant increase from 1966 to 2005, and a decrease in the overall number of cases since then, with the most significant reduction seen in the SPK cohort [1–3] (Figure 107.2 and Figure 107.3). Recent 5-, 10-, and 20-year graft function rates were 80%, 68% and 45%, respectively, for SPK; 62%, 46% and 16%, respectively, for pancreas after kidney (PAK); and 59%, 39%, and 12% , respectively, for pancreas transplants alone (PTA) [1–3] (Figure 107.4 and Figure 107.5). Five-year patient survivals after transplantation were 87%, 83% and 89% in SPK, PAK, and PAT patients, respectively [2]. As of December 2010, more than 37 000 pancreas transplantations have been reported to the IPTR (25 000 in the US; 12 000 outside the US) [2]. Analysis of trends over the last three decades demonstrated a change from bladder to enteric drainage, evolution of immunosuppression protocols from predominantly cyclosporine/azathioprine to tacrolimus/mycophenolate mofetil based with patients currently receiving primarily anti-T cell induction, a significant increase in the age of pancreas transplant recipients across all three pancreas categories, an increased focus on utilizing younger donors with shorter ischemic preservation times, and a significant decrease in rates of early technical and immunological graft loss [2].

Reporting of outcomes outside of the US to the IPTR is not mandatory and the IPTR registry data regarding the non-US experience is often incomplete. The non-US experience has been described largely in multi-institutional series and registries [2,15–18]. Perosa and colleagues published the most comprehensive report of non-US pancreas transplants. In this analysis of 10 108 reported transplants, the majority were performed in Europe (n = 6766), followed by Latin America (n = 1945), Canada (n = 671), Oceania (n = 499), Asia (n = 222), and Africa (n = 5) [15] (Figure107.6). This study also demonstrated that previous IPTR analyses have under-reported the number of non-US transplants performed [3] and that the number of non-US transplants performed reaches approximately 1100 annually, with over 10 000 pancreas transplants performed in total outside of the US [15]. Interestingly, in Perosa's study period a higher proportion of SPK transplants were performed in non-US countries (85% compared to 67%) [15,19]. In a comparative analysis of 13 selected European countries versus the US, differences in pancreas transplant rates were shown to be independent of deceased donor activity rates [19]. Some of these data described by Perosa et al. were derived from collaborative databases. These registries often do not have detailed information on allograft survival and patient outcomes. For example, Eurotransplant® is responsible for the allocation of donor organs in Austria, Belgium, Croatia, Germany, Luxembourg, the Netherlands, and Slovenia [20]. This international collaborative includes all transplant hospitals, tissue-typing laboratories and hospitals where organ donations take place. Available data from the Eurotransplant agency includes number of donors used for pancreas transplantation, type of pancreas transplant performed, and wait-list information, but long-term outcomes and the fate of the transplanted organs are not reported. Similarly, the Council of Europe which is based in Strasbourg, France, has diverse interests including maintaining human rights, social justice, cultural identity

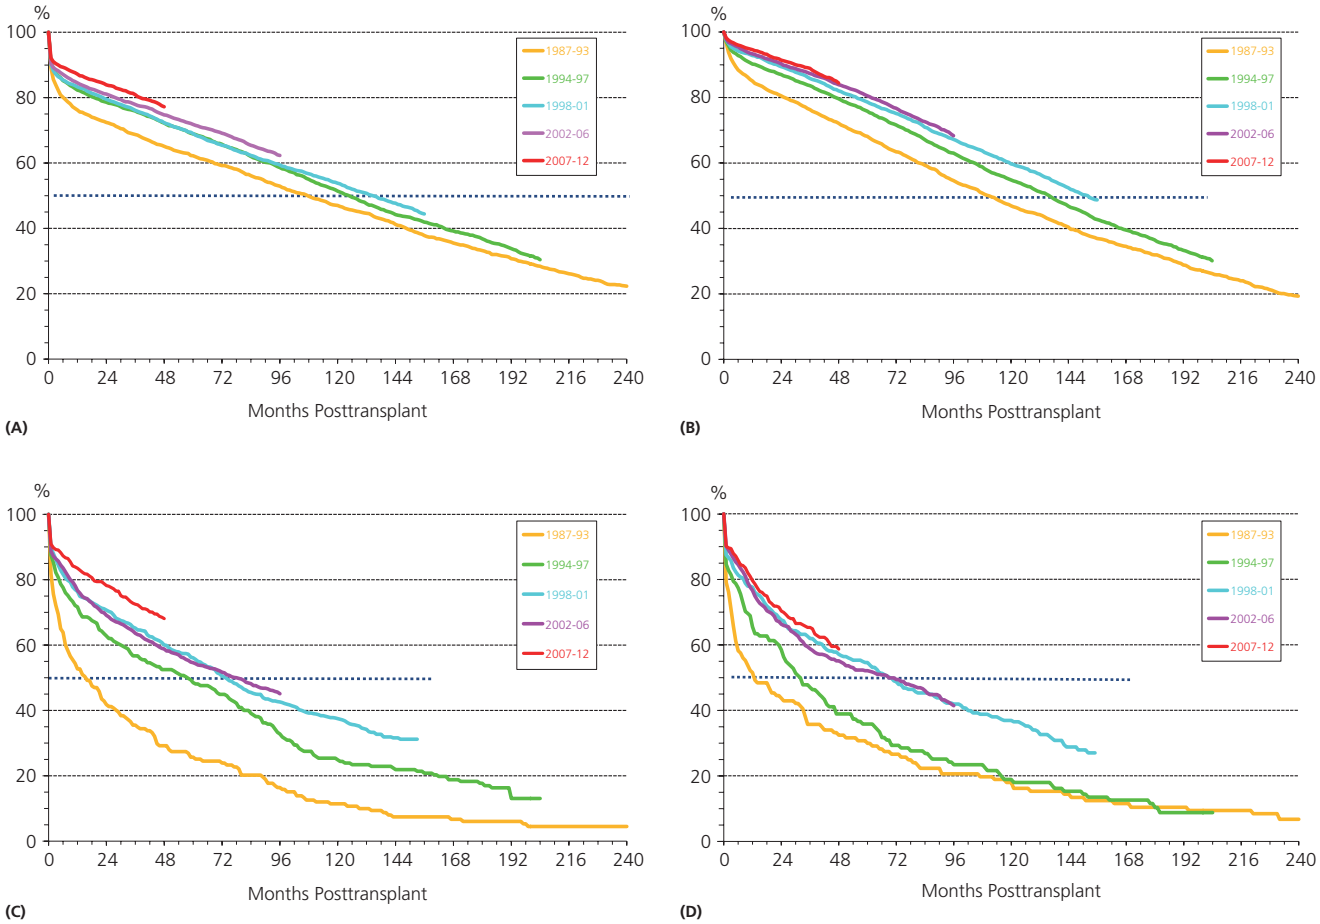

Figure 107.5. Primary deceased donor graft function over five eras for simultaneous pancreas kidney (SPK): pancreas graft (A); SPK kidney graft (B); pancreas after kidney (PAK) pancreas graft (C); and pancreas transplant alone (PTA) pancreas graft (D). and also gathers and publishes an annual newsletter that contains data on the number of transplants performed in the European Union (EU). In 2010, 769 pancreas transplants were reported to be performed from 9206 deceased donors in the EU (n = 27 countries) [21]. In contrast, European single-center studies often analyze their own long term outcomes and have published 10-year survival results after SPK of 94%, 62%, and 69% for patient, kidney and pancreas allograft survival, respectively, that are not dissimilar from those noted by the IPTR in the US [17,18].

In Latin America, a recent study of 500 pancreas transplants represents the largest reported series from this continent. One-year patient survivals were 82%, 93%, and 95% for SPK, PAK, and PTA, respectively, while 1-year pancreas graft survivals were 70%, 86%, and 77% for SPK, PAK and PTA, respectively [16]. Interestingly, these data indicated a lower survival for SPK patients. As discussed by the authors, this trend reflected the survival of recipients in an impoverished socioeconomic region where the leadership and centers decided to expand the donor and recipient selection criteria in order to enable transplantation [16].

Simultaneous pancreas kidney (SPK) transplantation

In patients with T1D and resultant end-stage nephropathy, therapeutic options include dialysis, deceased donor kidney transplant (DDK), living donor kidney transplant (LDK), simultaneous pancreas-kidney transplant (SPK) or pancreas after living or deceased donor kidney transplant (PAK). Mortality is high for patients maintained on hemodialysis alone without kidney transplantation with a patient survival of 9.6–11.2% at 10 years (USRDS Data; Ten Year Survival Probabilities: Incident hemodialysis patients).

Cumulative studies with long-term follow-up have demonstrated that simultaneous pancreas-kidney transplantation in T1D patients with diabetic nephropathy increases patient survival compared with live-donor kidney or deceased donor kidney transplantation and remains the optimal therapeutic approach in these patients [2–4]. Based on IPTR data for 2010, SPK transplants accounted for 72% of pancreas transplants performed in the US [2]. Wait-time analysis performed for patients who actually received a transplant demonstrated that median time until a PTA patient received a pancreas transplant was 110 days, and 243 days for a SPK patient [2]. Enteric drainage was utilized in 91% of SPK patients. Era analysis showed that one year primary SPK pancreas graft function increased from 77.2% in 1987–1993, to 85.5% in 2006–2010. SPK transplants have been noted to have a 72% and 80% 5-year function rate for the pancreas and kidney, respectively and these rates of survival have not seen a significant improvement since 1996 [1]. Five-year patient survival after SPK has been noted to be ~87% [2,4].

At the University of Wisconsin, we have focused on transplantation with SPK since 1985 and we have recently reported our outcomes from 1000 SPK transplants with a 22-year follow-up [4]. In this series which represents the largest published SPK experience in the world, we demonstrated that the 5-, 10-, and 20-year patient survival for SPK recipients was 89%, 80%, and 58%, respectively [4], and these rates are similar to registry data at the 5- and 10-year mark [2]. A significant observation derived from our study is that patient survival after SPK was shown to exceed even that of diabetic uremic patients receiving LDK (Figure 107.7), an observation that contradicts some of the data in previous reports. In a study by Young et al. [22], 1-year patient survival was higher in the living kidney alone cohort compared to SPK (97% vs. 95%), however, at 6 years, patient survival was noted to be higher in the SPK cohort (85% vs. 80%). Other studies have also noted a survival advantage with SPK and this modality continues to be the most durable and efficient therapy for achieving normoglycemia [23–25]. The notion that the pancreas allograft can exert a protective effect on either the kidney allograft or the patient is not new and Kleinclaus et al. have previously shown that kidney function in PAK patients is superior to that seen in patients who have received LDK transplant alone [26]. Together, these data suggest that improved metabolic control potentially confers a survival advantage over correction of uremia alone. However, cumulative evidence from studies that describe a significant change in the progression of secondary complications such as diabetic retinopathy, cardiac deterioration, and vascular disease after SPK, are limited and insufficiently controlled [27–29]. As such, the causative factors underlying these significant observations remain undetermined.

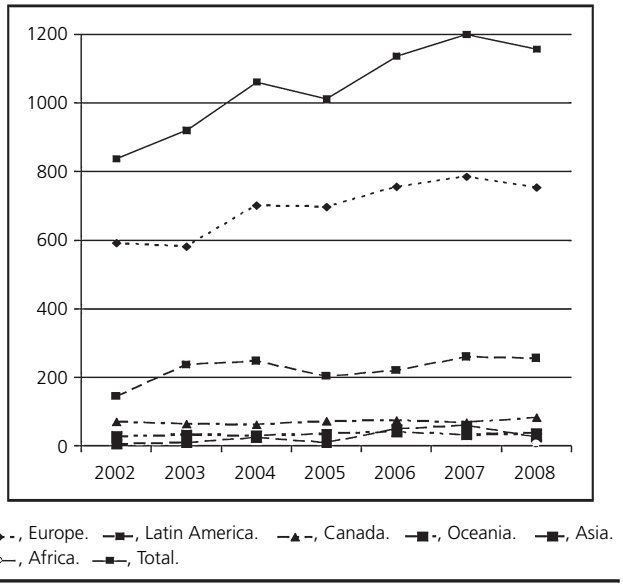

Figure 107.6. Patient survival in type 1 diabetic patients. Reprinted from [4] Sollinger HW, Odorico JS, Becker YT, D'Alessandro AM, Pirsch JD. One thousand simultaneous pancreas-kidney transplants at a single center with 22-year follow-up. Ann Surg 2009, 250(4):618–630, with permission from Wolters Kluwer Health.

The survival advantage conferred by SPK transplant is dependent on a technically successful pancreas transplant. Preserved function at 1-year has been shown to be an important factor as early graft loss was associated with decreased patient and kidney graft survival [24,30]. Careful selection of recipients and matching with appropriate donor organs continues to be of paramount importance in SPK transplantation. Historical factors that have contributed to reduced patient and pancreas survival include donor obesity [31], recipient obesity (BMI $> 30\,kg/m^2$) [32], older donor age (>45 years) [33] and older recipient age (>50 years [34,35]. However, recent studies have suggested that acceptable outcomes are achieved if selected older recipients, obese donors, or obese recipients are judiciously considered [36–39].

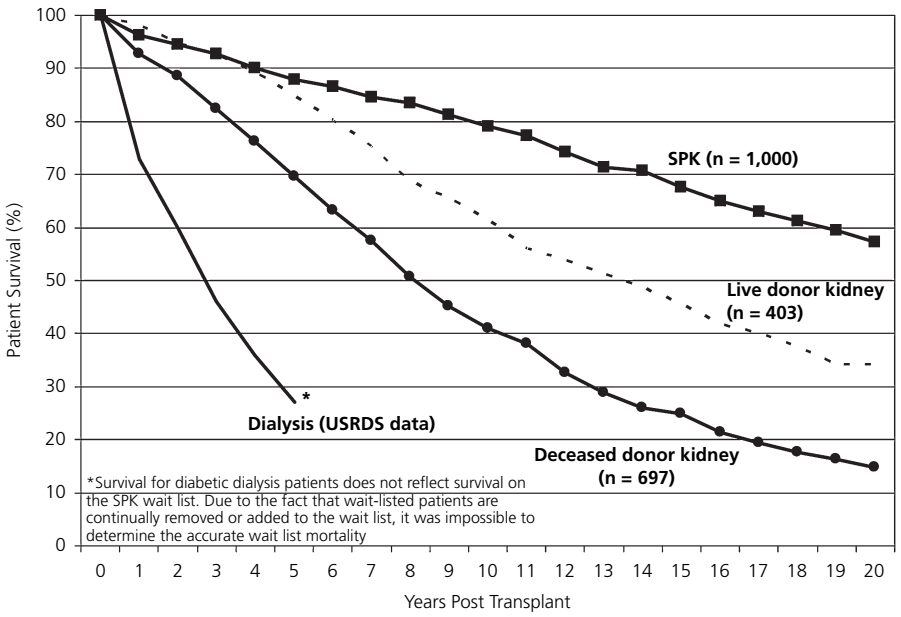

Figure 107.7. Number of pancreas transplants performed per year in non-US areas. Reprinted from [15] Perosa M, Boggi U, Cantarovich D, Robertson P: Pancreas transplantation outside the USA: an update. Curr Opin Organ Transplant 2011, with permission from Wolters Kluwer Health.

Improvements in graft and patient survival have led to increased numbers of patients presenting with failure of either the kidney or the pancreas allograft after SPK. In a recent analysis, pancreatic allograft survival was examined after subsequent kidney retransplantation in primary SPK patients [40]. Pancreas survival rates were 78%, 49%, and 40%, respectively at 1-, 5-, and 10-years. Although this represents a reasonable risk to the pancreas allograft (20–25% patients may experience pancreas allograft loss), the risks of reinitiating dialysis and the relative success of renal retransplantation, should allow medically appropriate patients to pursue retransplantation [40]. Repeat SPK after primary SPK has also been described [41]. The majority of patients underwent transplant nephrectomy (89%) or transplant pancreatectomy (78%) either prior to or at the time of re-transplant [41].

Pancreas after kidney transplantation

Diabetic end-stage renal disease (ESRD) patients that receive a kidney from a living donor have a unique opportunity to minimize or avoid exposure to dialysis. From a pragmatic perspective, these live donor transplants also decrease demand of organs from the deceased donor kidney pool [42]. Allocation rules and different geographical waiting times may limit SPK transplantation such that pancreas after living donor kidney transplantation becomes the primary approach for certain patients. These differences in pancreas and kidney allograft availability are important considerations for patients deciding between waiting for SPK versus proceeding with living donor kidney transplantation and subsequent pancreas transplant. Specific discussion on organ allocation policy can be found in Chapter 137. In addition, differences in long-term pancreas allograft survival between PAK and SPK recipients represent another significant consideration. While the gap is closing, pancreatic allograft survival in PAK recipients is still inferior to graft survival in SPK (80% vs. 86%) [2,25,34,43]. The differences in outcome could be partially attributable to a higher rate of rejection and increased rates of 3-year graft loss due to immunological causes in PAK (14%) compared to SPK (5%) [34].

The fate of the kidney allograft after subsequent pancreas transplantation continues to be a concern in the published literature and represents a challenging decision for kidney transplant recipients considering a subsequent pancreas transplant. Cumulative evidence suggests that cardiovascular risk stratification and careful assessment of kidney allograft function at the time of PAK are two important considerations in the appropriate selection of candidates for successful PAK transplant. Poor outcomes for the kidney allograft after PAK may be related to surgical risk of the operation, recipient co-morbidities, immunological events, and/or medication induced nephrotoxicity [44]. Rigorous analyses performed in a prospective, randomized and controlled manner comparing kidney allograft outcomes for patients undergoing PAK to kidney allograft outcomes in diabetic patients who have only undergone kidney transplant are unlikely, given the inherent selection bias; not all patients after kidney transplantation are eligible to undergo PAK. As a result, many existing studies do not provide a "fair" assessment of outcomes. However, Browne et al. recently approached this analytical dilemma by adjusting their analysis accordingly using a PAK propensity score and utilizing time-dependent and time-varying variables in multivariate models [42] rather than restricting the analysis to only those patients wait-listed for PAK as in prior studies [43,45,46]. Their results demonstrated a higher risk of kidney allograft failure in PAK recipients compared to kidney only transplant recipients during the first two weeks after PT, with the risk equalizing at 143 days, and after 366 days the risk reversed with PAK recipients demonstrating a significant improvement in long-term kidney survival [42]. These findings corroborate the increased risk of perioperative death after pancreas transplantation that has been previously reported [47] and emphasize the importance of appropriate patient selection for PAK. More importantly, Browne et al. demonstrated a 69% 10-year kidney graft survival and that long-term renal function could be preserved. They determined that PAK represents a safe and viable approach. The conclusions drawn from this report contrasted with a prior study of 126 PAK recipients that cautioned against subsequent pancreas transplantation in kidney transplant recipients with a pre PAK-glomerular filtration rate (GFR) <45 mL/min, an interval >1-year between kidney to pancreas transplant, kidney rejection episodes prior to PAK, and proteinuria [44]. In both studies, decreased pre PAK-GFR (<40 mL/min/1.73 m^2 or <45 mL/min/1.73 m^2) is associated with subsequent kidney allograft failure. Although in Browne's study this effect was not apparent until three years after PT. Adequate long-term follow-up is required for accurate analyses transplant outcomes and although the nature of the study was retrospective, our recent 20-year follow-up analysis is unique in the reported literature. Recent findings reported by Poommipanit et al. suggest that pancreas after living kidney transplantation (PALK) is associated with improved patient survival compared with SPK [43]. In these data, survival analysis was performed for up to five years post-transplant. The authors acknowledge that the major difference in survival was seen in the early post-transplant period with a 2.3% and 3.7% survival difference seen at 3 months and 12 months, respectively. Among their patients who had a functioning kidney graft at 12 months, they found no difference in survival between PALK and SPK in the subsequent four years. Patient survival was also similar in PALK and SPK when the pancreas transplant was considered the index date [43]. The differences in reported survival at 1-year were small (99.24% vs. 95.55%; PALK vs. SPK) and largely reflect the early advantage conferred by LDK. In our series, small variations were also noted when SPK was compared to LDK survival in T1D patients in the early post-transplant period [4]. However, the major differences in survival in our series were detected at 5-years and thereafter with >20% survival difference noted more than 10-years after transplant (Figure 107.7). The 20-year longitudinal follow-up in our series provides significant long-term analysis that is absent from studies with shorter follow-up. Post PAK rejection of the kidney or pancreas was associated with increased kidney and pancreas allograft loss and patient death [44]. Interestingly, the association between the interval of kidney and pancreas transplant and subsequent kidney allograft failure [44] was not observed in other studies [42,48]. Together, these data suggest that the mortality risk of PAK transplant and the risk for subsequent kidney allograft failure may be minimized in this most current era and support pancreas after living kidney transplantation as a safe alternate strategy in regions where SPK transplantation is infrequent or if the patient is already on dialysis (Table 107.2) [49]. If SPK is available as a primary mode of therapy and the patient is not yet on dialysis, the treatment of choice for an appropriate T1D diabetic recipient with nephropathy is SPK transplant.

PTA

The evidence that PTA provides a benefit to long-term patient survival and ameliorates secondary complications associated with diabetes in patients with T1D without pre-existing diabetic nephropathy remains debatable. Successful PTA in this patient

Table 107.2. Summary of advantages and disadvantages of transplant options for diabetic kidney disease

	Advantages	Disadvantages
Living donor kidney transplant alone (LDKA)	**1** Minimizes waiting time/time spent on dialysis **2** Low early morbidity and mortality	**1** No normalization of blood glucose **2** Inferior patient survival over time when compared with SPK recipients with functioning grafts
Simultaneous pancreas-kidney transplantation transplant (SPK)	**1** Normoglycemic regulation **2** High quality deceased donor kidney transplant	**1** Higher earlier morbidity and mortality compared to kidney transplant **2** Early failure of pancreas (<1 year), outcomes worse versus LDKA
Pancreas transplantation after living donor kidney transplant	**1** Normoglycemic regulation	**1** Two separate surgical procedures, increased mortality postoperatively following pancreas transplant **2** Potential risk to kidney transplant

(Adapted from [49] Wiseman AC: Pancreas transplant options for patients with type 1 diabetes mellitus and chronic kidney disease: simultaneous pancreas kidney or pancreas after kidney? Curr Opin Organ Transplant 2012, 17(1):80–86 with permission from Wolters Kluwer Health)

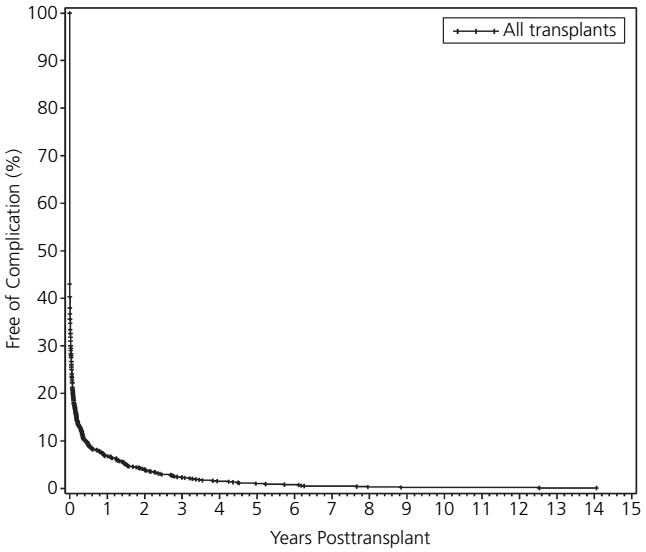

Figure 107.8. Overall complications following SPK transplantation from 1985–2007. Reprinted from [4] Sollinger HW, Odorico JS, Becker YT, D'Alessandro AM, Pirsch JD. population largely represents an improvement in quality of life and has not been demonstrated to offer a survival advantage in large, controlled studies. Selection of PTA recipients is usually limited to patients with:

1 A history of severe metabolic complications (hypoglycemic unawareness, hyperglycemia, ketoacidosis) requiring medical attention.
2 Failure of insulin-based management [50].

From an immunological standpoint, PTA still represents the highest risk across the three pancreas categories with 1-year graft loss rates noted to be 6.0% in PTA compared to 3.7% in PAK, and 1.8% in SPK [2]. Recent studies report a 5-year patient survival of 90–98% after PTA [51], a 5-year graft survival of 73–89% [1,52], with a pancreas graft half-life of ~9 years [53]. There does not appear to be a clear survival advantage for PTA in comparison with patients on the waiting list [46,47,54], and the improvements in outcome for microvascular diabetic complications are not based on prospective, randomized studies [55]. Interestingly, Boggi and colleagues recently reported a significant decrease in hemoglobin A1C and lipid profiles in pre versus post-transplant PTA recipients [52]. However, adequate controls were missing with no comparisons made to untransplanted patients controlled with insulin therapy, nor with patients who were non-candidates for PTA. More importantly, the potential deleterious effects of calcineurin inhibitors (CIs) and other nephrotoxic drugs may offset the beneficial effects of glycemic control conferred by PTA. Various authors have demonstrated nephrotoxicity from long-term immunosuppression with 32% of patients undergoing PTA experiencing a ≥40 mL/min/1.73 m^2 decrease in estimated GFR and up to 9.9% patients required subsequent renal transplantation [56]. In a cohort of patients undergoing solitary pancreas transplant (both PTA and PAK), the rate of renal failure after transplantation requiring dialysis or kidney transplantation was 8% [45]. Data from protocol biopsies corroborated these adverse effects on the kidney allograft from cyclosporine and tacrolimus [57,58].

Complications after pancreas transplantation

Early technical failure after pancreas transplantation

The IPTR definition of technical failure includes graft thrombosis, pancreatitis, anastomotic leak, infection, and bleeding [3]. Technical failure accounts for approximately 50% of the causes of graft loss in the first six months after pancreas transplantation [59]. In a recent analysis of 6282 SPK recipients, early pancreas graft failure was associated with subsequent reduction in kidney allograft and patient survival [60]. Prevention of early graft failure involves utilization of standardized selection criteria and protocolized post-transplant chemoprophylaxis regimens [61]. Overall complications after SPKT are high (Figure 107.8) [4], but have been greatly reduced over the years at our center and others due to improvement in immunosuppression and refinements in our post-transplant management. Meticulous care to avoid early complications is critical to long-term success and avoidance of early reoperative surgery is directly associated with improved outcomes [62]. Patients with early technical failure are still candidates for pancreas retransplantation and the long-term outcomes for pancreas allograft survival, patient survival, and rate of acute rejection are not dissimilar to primary SPK [63].

Bleeding

The most common cause of post-transplant relaparotomy continues to be postoperative bleeding. In contrast to graft thrombosis, postoperative bleeding does not typically result in graft loss (<0.3% of pancreas grafts) [3]. After pancreas transplantation, bleeding can develop in the intra-abdominal compartment, in the gastrointestinal tract, or within the bladder in bladder-drained patients. Perioperative anticoagulation is associated with a significant proportion of cases of intra-abdominal bleeding [64]. The clinical management of a significant intra-abdominal hematoma involves cessation of anticoagulation, correction of any underlying or ongoing coagulopathy, and prompt re-exploration if hemodynamic instability is

encountered or if a washout is indicated to evacuate a potential source of secondary infection within the hematoma. Early gastrointestinal bleeding after pancreas transplantation often originates from the duodeno-jejunal anastomosis [64,65]. Late bleeding is often caused by gastritis, gastric or duodenal ulcers, colitis, or Dieulfoy's lesion, aorto-enteric fistula and mycotic aneurysms [64,66]. Late bleeding often requires intervention and represents a significant and morbid event. The development of an aorto-enteric fistula or a pseduoaneurysm can be a threat to graft viability and potentially patient survival. A high index of suspicion is required for prompt endovascular or operative management [66].

Thrombosis

Arterial and venous thrombosis can develop after pancreas transplantation but venous thrombosis is more common by 2-fold [67]. Thrombotic events can be classified as early or late, and partial versus complete. Total venous or arterial occlusion often results in allograft loss requiring pancreatectomy, although graft salvage has been reported with early thrombectomy [66]. Many centers utilize some form of anticoagulation following transplantation including aspirin, unfractionated or low-molecular weight heparin, with warfarin less frequently employed [66,67]. In our experience, the rate of bleeding requiring re-exploration has been minimized by avoiding systemic anticoagulation with heparin or dextran while also maintaining a very low rate (<1%) of pancreatic graft thrombosis [68]. This rate of thrombosis is lower than the rate reported by others (10–20%) [69–71]. The incidence of pancreas graft thrombosis based on data from the IPTR seems to be fairly consistent (4–8%) over the last several decades [1]. These registry data also indicate that SPK recipients have less pancreas graft thrombosis compared to PAK or PTA recipients [3]. This observation may partially be explained by the anticoagulant effects of uremia and the lower incidence of rejection seen in SPK recipients [67]. Other groups, including Troppmann et al. have previously identified risk factors for thrombosis and these include donor age, cardiocerebrovascular causes of donor death, the use of an aortic Carrel patch, arterial pancreatic graft reconstruction using a splenic artery to superior mesenteric artery anastomosis, interposition graft between the splenic artery and the superior mesenteric artery, portal vein extension graft, left-sided implantation into the recipient, and graft pancreatitis [69]. More recent data have also demonstrated that use of histidine-tryptophan-ketoglutarate (HTK) is associated with increased thrombosis rates, particularly when the cold time exceeded 12 hours [72]. Early after transplantation, the causes of vascular thrombosis are multifactorial, but beyond the two week time frame, thrombotic events are predominantly caused by inflammation and acute rejection [67]. An important caveat is whether portal venous thromboses were symptomatic or asymptomatic. Incidentally identified partial thromboses may be amenable to system anticoagulation [73]. Common factors associated with successful non-operative management included the absence of symptoms and the presence of collateral venous drainage [74]. In our experience, we also believe that not using a venous interposition graft to extend the portal vein is critical in reducing the risk of pancreas graft thrombosis and this practice is supported by others [69]. Graft thrombosis was a very infrequent cause of graft loss in our long-term experience. Less than 3.6% of recipients with pancreatic allograft loss were caused by thrombosis in our series [75]. This rate is low in comparison with other published reports (3–17%) [3,71,76]. Certainly, once thrombosis is identified, there is a high risk of graft loss. Although early exploration is associated with a higher negative laparotomy rate (43%), timely re-exploration may permit salvage thrombectomy in 45% of grafts [77].

Anastomotic leak

Anastomotic leaks represent less than 0.5% of all causes of graft loss [1,3]. The rate of anastomotic leak was higher in BD SPK (pancreaticocystotomy, 22.8%) compared to ED-SPK patients (pancreaticojejunostomy, 5.7%) [4]. Recipients with leaks from ED pancreas transplants present with drainage of enteric contents and potentially peritonitis while leaks from BD pancreas transplants often follow a more benign clinical course. Increase systemic amylase and lipase, reflecting peritoneal uptake of enteric drainage can be an early sign and should prompt suspicion. Given the effects of immunosuppressive medications, peritoneal signs can be remarkably unimpressive despite frank intraperitoneal soilage. Surgical repair was more favorable and more likely to succeed in ED SPK where the use of Roux-en-Y diversion was frequently employed. In BD SPK, repair was less successful and management with Foley drainage sometimes resulted in closure of leaks. Ongoing sepsis should prompt graft pancreatetomy.

Cardiovascular complications

Cardiovascular events represent the major cause of death in SPK patients (7.2%) [4]. These events, usually myocardial infarction, were documented either by autopsy, clinical presentation or laboratory diagnosis. As a result, stricter preoperative screening criteria were utilized in the recent era of our program at the University of Wisconsin. Stringent SPK patient selection criteria (see Chapter 32) may have contributed to the differences observed at our center compared to others. Cardiovascular mortality represents an important contributor to overall patient outcome. The frequency of pretransplant cardiac interventions in this series was low and possibly reflects a low overall cardiac risk profile of these patients. This in turn may contribute to the higher perceived survival in this group. Other causes of death in our series include infection (3.4%), stroke (1.8%), renal failure (1.5%), malignancy (1.3%), and bleeding (0.8%) [4]. A large number of deaths (n = 57) occurred where accurate diagnosis was not possible and/or autopsy was declined or inconclusive.

Enteric drainage, bladder drainage and enteric conversion

After 390 bladder-drained SPKs, our center (University of Wisconsin) began performing pancreas transplants using enteric drainage [6]. We analyzed kidney graft survival and pancreas graft survival between enteric-drained (ED) and bladder-drained (BD) SPKs. Interestingly, we found no statistical difference in survival for either the kidney or pancreas allograft between the two groups (Figure 107.9 and 107.10). This represented an unexpected result given the high frequency of rejection and infectious complications that occurred in BD patients and the subsequently improved immunosuppression with mycophenolate and tacrolimus in the ED patients.

Although there was no difference in allograft survival between ED SPK versus BD SPK, our experience shows that ED pancreas transplantation improves quality of life compared to BD. Complications related to BD include metabolic acidosis, high incidence of urinary-tract infections, hematuria, urethritis, urethral disruption and dysuria. In more than half of our surviving BD patients, enteric conversion was performed to correct serious urinary tract infections and intractable metabolic acidosis. Within 15 years after

transplantation approximately 50% had undergone enteric-conversion [4]. Our experience revealed a higher complication rate from anastomotic leak when conversion was performed late after transplantation due to the increased friability of the duodenal segment. Although comparable pancreatic graft and patient survival rates at 1-, 5-, and 10-years were reported in a recent study between EC and primary ED SPK patients [78], it should also be noted that the authors observed a significant early complication rate after EC (surgical complications — 31.3; re-operation — 25%; and early graft loss — 6.3%). Enteric conversion should be offered judiciously in these patients and when performed, the use of Roux-en-Y loop is indicated in these late conversions. It is now our current practice to always perform ED at the time of primary transplant.

Proponents of BD argue that the ability to measure urine amylase levels as a method of detecting early rejection offers an advantage to ED. Results from our own center (University of Wisconsin) with the use of ED in solitary pancreas transplants (SP-ED) do not support this notion. In this study, acute rejection was confirmed by pancreas biopsy and the rates of rejection and allograft survival were compared between SP-ED recipients versus SPK recipients [79]. We hypothesized that if BD is critically important in the pancreas transplant setting then one would expect a lower graft salvage rate following acute rejection in SP-ED patients where monitoring of urinary amylase is not possible. In comparison with SPK, where kidney allograft function would enhance the detection of rejection, we demonstrated that the graft salvage rate following acute rejection was not different between solitary and combined pancreas transplants [79]. These data confirm that diagnosis and treatment of graft rejection based on allograft biopsies can be preserved in SPK without the need for BD. More complications requiring relaparotomy are seen in the early postoperative period in ED recipients compared to BD recipients. Complications in 24% of ED SPK transplants occur in the first 30 days after transplant compared to 15% in BD SPK. However, the majority of complications (76%) requiring reoperation in BD SPK occurs late (>1 year) with many related to the need for enteric conversion [4].

Recurrent T1D after transplant

Dr. Sutherland first described recurrence of T1D after pancreas transplantation with his series of HLA-identical siblings receiving pancreas allografts at the University of Minnesota [80–83]. Recurrent T1D was observed 4–8 weeks after transplantation in the absence of immunosuppression and was characterized by insulitis with mononuclear cell infiltration and selective β-cell destruction in the absence of pancreas rejection [83]. Based on these initial studies and other observations, the utility of immunosuppression was proposed to be 2-fold; suppression of rejection in non-HLA identical transplants and inhibition of autoimmunity in the pathophysiology of recurrent insulitis. However, as the field advanced, recurrent T1D was identified as a clinical entity even in patients with adequate immunosuppression to prevent rejection [84,85]. Cardinal features of recurrent disease include clinical symptoms of hyperglycemia without rejection, biopsy-proven insulitis with selective β-cell loss, persistence or reappearance of auto-antibodies (GAD, IA2), preserved exocrine function, and the presence of circulating autoreactive T cells [83]. These features are important to document, as post-transplant hyperglycemia can develop [86] and may or may not represent autoimmune T1D recurrence. A key finding is that autoantibody conversion, as opposed to persistence or negativity, is associated with a high risk of developing recurrent diabetes. The rate of recurrent disease was noted to equal

the incidence of chronic rejection in a series from the University of Miami, and accounted for up to 5% of patients. Post-transplant hyperglycemia from chronic allograft rejection may be challenging to differentiate from recurrent T1D. In these studies by Pugilese et al. their pancreas recipients were transplanted with the technique of bladder drainage and this was instrumental in their ability to document preserved exocrine function. Enteric drainage has become the predominant approach in the US [2], and measurement of urinary amylase is not possible in these patients. Improvements in diagnosis, prevention, and therapy are required to appropriately manage this clinical entity. An additional discussion of recurrent disease in pancreas transplantation can be found in Chapter 77.

Effect of pancreas transplantation on secondary complications of diabetes

Restoration of both endogenous insulin secretion and renal function has been demonstrated to have beneficial effects on the secondary complications associated with diabetes and evidence has shown that transplantation prolongs life expectancy in T1D. However, many studies addressing this topic are not prospective, adequately powered or controlled with regard to relative medical co-morbidities, stage of diabetic disease, and variability in controls where comparative groups are often derived from non-transplanted patients or patients with failed transplants. Additionally, measured parameters are often utilized as surrogate markers for the complex secondary complications of diabetes and in certain cases it remains debatable if these measures are correlative or clinically relevant.

Nephropathy

The pathophysiological lesions of diabetic nephropathy are characterized by thickening of the basement membrane, mesangial matrix accumulation, hyalinosis of glomerular arteries, and glomerular sclerosis [55,87]. Studies performed by Bohman et al. demonstrated that the development of diabetic glomerulonephropathy was prevented in patients undergoing successful pancreas transplantation [88,89]. Markers of diabetic glomerulopathy including glomerular basement membrane width, total mesangial and total mesangial matrix volumes were unchanged at 5-years but became markedly decreased at 10-years suggesting that diabetic glomerular and tubular lesions in humans are reversible. More recent studies have shown that these lesions of diabetic nephropathy could be reversed in the native kidneys of non-uremic recipients of pancreas transplants alone [58,90,91]. However, the lessons learned in the PAK patient population remain relevant as nephrotoxicity from long-term immunosuppression complicates the balance. Additionally, although long-term morphological changes related to diabeteic nephropathy have been shown to improve or stabilize, it remains debatable as to whether a clinically significant difference in renal function as measured by GFR reduction has been shown in a carefully designed, controlled analysis. An additional discussion of recurrent diabetic nephropathy can be found in Chapter 77.

Retinopathy

Most of the studies showed little impact on progression of retinopathy. Ramsay et al. demonstrated that retinal events occurred in up to 30% of patients during the first three years following successful pancreas transplant and remained stable thereafter [92]. However patients with failed grafts continued to have retinal events. These data have been substantiated in recent studies [27,93]. Giannarelli et al. analyzed 33 patients that underwent pancreas transplant and compared them to 36 T1D patients who were not transplanted and at 30-months follow-up, amelioration or stabilization of retinopathy occurred in 91% of transplanted patients but only in 43% of non-transplanted patients [93]. These results need to be considered with the parallel observations that retinopathy can deteriorate immediately post- transplant in 10–35% of patients with unstable eye disease [55] and that steroid and calcineurin use may exacerbation cataracts and glaucoma [94].

Neuropathy

Several studies have demonstrated an improvement in peripheral nephropathy in pancreas transplant recipients. Solders et al. showed that neuropathy improved in patients receiving a pancreas transplant whereas progression occurred in those with no transplant or with a failed graft. Kennedy et al. evaluated diabetic autonomic and sensory motor neuropathy progression in pancreas-transplanted patients by comparing them with the patients undergoing intensive insulin treatment [95]. The two groups were compared at 12-, 24- and 42-months after transplantation and progression was noted in both sensory motor and autonomic neuropathy in insulin-treated patients, whereas an improvement was demonstrated in transplanted recipients. Recent studies by Martinenghi et al. confirmed these findings by showing that increases in nerve conduction velocity occurred in combined pancreas-kidney transplanted patients with a functioning graft compared with those with failed pancreas transplant [96]. The drawback to these studies involves the difficulty with measuring neuropathic progression. Symptoms are often subjective and may be challenging to quantify while improvement in conduction velocity may or may not be clinically relevant.

Peripheral vascular disease

Overall, diabetics have a 15 times higher risk of lower extremity amputation than non-diabetic individuals [97]. Returning patients to normoglycemia would in theory reduce the risk of peripheral vascular disease. However, there continues to be a limited number of well-designed, sufficiently powered and adequately controlled analyses on the outcomes of peripheral vascular disease after pancreas transplantation [98–100]. Morrissey et al. demonstrated that peripheral vascular complication rate (defined as amputation, ischemic ulcer requiring treatment, and lower extremity bypass surgery or angioplasty) appeared to be accelerated early after transplant in SPK recipients compared to diabetic patients that underwent kidney transplantation alone (KTA) [101]. Although, peripheral vascular complications before transplantation were comparable between groups ($P = .94$), after transplantation, there were 35 new vascular complications in 18/39 SPK recipients versus 32 events in 20/65 KTA recipients ($P = .005$). These data were limited by patient numbers and also by the controls as patients who underwent KTA were not adequately controlled for their candidacy for pancreas transplant, relative medical co-morbidities, renal function, and degree of hyperglycemic regulation. The more recent study by Biesenbach et al. noted a reduction in peripheral vascular complication rate in SPK compared with KTA patients [99]. However, only 12 SPK patients and 10 diabetic subjects with KTA were included in the study and the difference in outcomes observed for myocardial infarction (16% vs. 50%), stroke (16% vs. 40%) and amputations (16% vs. 30%) must be considered with caution.

In the analysis released by the Centers of Disease Control, the age-adjusted rate of leg and foot amputations fell from 11.2 per 1000 individuals with diabetes in 1996 to to 3.9 per 1000 in 2008 [102]. The incidence of T1D patients requiring amputation after

pancreas transplantation have been reported to be ~8–9.5% [100,103,104]. In comparison, amputation rates for type II DM patients have been reported to be 6.1–19% [105–107]. In patients with T1D, the cumulative probability of having a non-traumatic lower extremity amputation was 11.0% for women and 20.7% for men [108]. Many studies have utilized amputation rates as a surrogate for peripheral vascular disease or as a primary measure of outcome. However amputations are the net result of multiple factors including neuropathy and repetitive injury to the foot, followed by impaired wound healing, impaired immune response to bacterial infection, and progressive intimal vasculopathy. Amputation rate alone cannot be an adequate measure of peripheral vascular disease in this population. In patients with T1D receiving pancreas transplants, the protective effects associated with improvement in metabolic regulation and correction to normoglycemia should be weighed against the physiological progression of age-related vasculopathy, pre-existing disease and the adverse effects of immunosuppressive medications on worsening arteriopathy and further studies are required to assess the net effect on peripheral vascular disease.

Expanding the donor pool

Donation after cardiac death and pancreas transplantation

At the University of Wisconsin, we have routinely accepted select donor after cardiac death (DCD) donors for SPK and solitary pancreas transplantation [109]. We apply our customary criteria for assessing the appropriateness of donation for pancreas transplantation and use an index warm ischemia time of 30–45 minutes. In our series, 8.6% of SPKs were recovered from DCD donors [4].

Patient survival rates at 10-years for SPKT from DBD and DCD donors are similar (80% vs. 84%, respectively; $P = 0.97$) [4]. Pancreas allograft survival at 5- and 10-years is also similar between DBD versus DCD donors (5-yrs: 76% vs. 75%; 10-yrs 64% vs. 60%; $P = 0.57$). Kidney allograft function using GFR and creatinine as markers were similar in DBD versusDCD SPK recipients ($P = 0.89$ and $P = 0.78$, respectively) even though DCD kidneys exhibited a higher rate of delayed graft function. These data are consistent with other reports in the literature that have compared extended donors versus conventional donors in pancreas transplantation [110].

Living donor pancreas transplantation

Living donor pancreas transplantation is offered in very few centers. The incentive for using segmental transplantation of the pancreas allograft from suitable living donors derives from the advantage in shortening the time to transplant for recipients waiting for deceased donor transplantation and for allowing patients who are allosensitized to HLA antigens access to transplant. In a recent report, the University of Minnesota published their cumulative experience in which Sutherland et al. describe a significant decline in their technical failure rate as the learning curve was negotiated over the last few decades, with equivalent graft survival rates between living and deceased donor pancreas recipients, and the prediction that this technique will expand as more pancreas transplant recipients are added to the waiting list [12]. Currently, the technical expertise required restricts candidates to a few, select centers and the attendant risks related to surgical complications and postdonation diabetes limits the pool of potential surgical candidates.

Influence of donor- and recipient-specific factors on outcomes

Much of the challenge in modern transplantation lies in matching the donor with the appropriate recipient. The idea of a donor-risk index has been established in the liver transplantation literature by Feng et al. In the arena of pancreas transplantation, emerging reports have sought to characterize donor-specific and recipient-specific factors that may guide allocation and influence outcome [111]. Axelrod et al. have recently published a pancreas donor risk index (PDRI) that predicts pancreas transplant graft outcome at the time of organ offer [112]. Increased PDRI was associated with a significant reduction in 1-year pancreas graft survival. The appropriate application of such a risk index would vary by region and center and the authors themselves conclude that this continues to be a work in progress. While most pancreas transplant centers prefer to procure their own donor allografts, the use of imported pancreatic allografts from beyond the region should be considered a safe and viable way to enable transplantation [113]. Increased utility of these organs will require close monitoring of cold-ischemic times and attention to the appropriate donor-recipient risk factors. In separate studies, other risk factors identified by Luan et al. include recipient race as they recently demonstrated that African American SPK recipients had 38% and 47% higher risk for late death-censored kidney and pancreas graft failure, respectively, and African Americans were twice as likely to lose their allografts from rejection [114].

Role of immunosuppressive medications

Initially, routine maintenance immunosuppression for pancreas transplantation at our center consisted of cyclosporine A in combination with azathioprine, and prednisone. In 1995, azathioprine was replaced by mycophenolate mofetil and tacrolimus was introduced. Our current maintenance regimen includes tacrolimus, myfortic, and low-dose prednisone. Induction therapy evolved from antithymocyte globulin, muromonab, daclizumab, Campath-1H, to basiliximab. General discussions on induction and maintenance immunosuppressive therapy can be found in Chapters 65 and 66, respectively.

The introduction of MMF represented a paradigm shift for us (University of Wisconsin) as our incidence of acute rejection reduced dramatically for both the kidney (34% vs. 75%, $P = 0.001$) and the pancreas (7% vs. 24%, $P = 0.003$) allograft, and also decreased the incidence of steroid-refractory rejection episodes requiring antilymphocyte rescue therapy (15% vs. 52%, $P = 0.01$) [6]. Others have published a similar experience with antithymocyte globulin induction even conferring a negative effect (vs. daclizumab), while fewer complications were observed with tacrolimus combined with MMF in direct comparison with tacrolimus combined with rapamycin or cyclosporine compared combined with MMF [111].

Our recent experience using Campath-1H (alemtuzumab) demonstrated that there was no survival advantage in comparison to induction with IL-2 receptor antibodies [115]. Moreover, there was a statistically higher incidence of cytomegalovirus infection and viremia in the alemtuzumab treated group. The consensus within our group is that Campath-1H does not offer a substantial benefit and we currently use basiliximab induction for patients receiving their primary transplant.

Summary

Selecting the appropriate therapy for a recipient with T1D with renal failure continues to be a critical decision for programs offering pancreas transplantation. A variety of therapeutic options including dialysis, DDK, LDK, SPK, or PAK exist. The principles and guidelines at our center (University of Wisconsin) are driven by the benefit of the SPK transplant needing to outweigh the increased morbidity of the surgical procedure and the use of lifelong-immunosuppression. Cumulative evidence from the literature suggests that correction of the metabolic derangements associated with hyperglycemia through combined pancreas-kidney transplantation may provide a survival advantage over kidney transplantation alone. Appropriate selection should be based on the morbidity inherent in each individual organ recipient and the variable waiting times particular to each region. A summary of the findings and our recommendations for clinical practice are as follows:

- Current 5-year pancreas graft function rates are 80%, 62%, and 59% in SPK, PAK, and PTA, respectively. Five-year patient survivals after transplantation are 87%, 83% and 89% in SPK, PAK, and PAT patients, respectively. SPK should be offered as the primary option in T1D patients with diabetic nephropathy who are not yet on dialysis as it represents the treatment option that provides a survival advantage to the allograft and patient. Living donor kidney transplant may be an option for T1D patients that have already initiated dialysis and if their region has long wait times for SPK. Meticulous surgical technique, especially with regard to back-table preparation of the allograft, is linked to long-term success and graft survival. Appropriate selection of patients prior to pancreas transplantation is required to avoid interruption of renal allograft function in PAK candidates, with careful consideration of two important pre-operative parameters: cardiovascular status and renal allograft function.
- Early technical failure after pancreas transplant results in decreased renal allograft and patient survival.
- Graft thrombosis and cardiovascular events represent the most morbid complications after pancreas transplant. While routine use of systemic anticoagulants varies amongst centers and no regimen has been demonstrated to be superior, attention to surgical technique and donor graft quality continue to be important factors in the development of graft thrombosis.
- Enteric drainage is the recommended approach for managing exocrine secretions in pancreas transplantation and is currently the most widely practiced option. Enteric conversion from bladder drainage should be considered in patients with overt symptoms, metabolic derangements, and alterations in quality of life. Careful selection and decision-making is required in patients who present distant to their primary operation.
- Some improvement in secondary complications of diabetes is seen with pancreas transplantation but the data for these studies are often lacking in prospective design, power, and adequate controls.
- Use of donor after cardiac death organs or imported allografts should not deter transplantation if careful and judicious selection of donor-recipient matches are made

Acknowledgments

The authors thank the staff and team at the University of Wisconsin Pancreas Transplant Division who have played a pivotal role in the history of this program. Marilyn Groshek, Elaine Snyder, Michael Armbrust, Munci Kalayoglu, Stuart Knectle, L. Thomas Chin, our transplant fellows, Barbara Voss, Glen Leverson, Judy Kozminski, and Janet Fox. This manuscript was prepared without conflict of interest and we have no financial relationships to disclose.

CHAPTER 108

Long-term Outcomes after Islet Transplantation

A.M. James Shapiro[1] and Camillo Ricordi[2]

[1] Clinical Islet Transplant Program, University of Alberta, Edmonton, AB, Canada
[2] Diabetes Research Institute, University of Miami, Miami, FL, USA

Introduction

Remarkable progress has occurred in the past 12 years in outcomes and activity of clinical islet transplantation [1–6]. Once just a curiosity, this established, minimally invasive treatment provides reliable, robust glycemic control for selected patients with unstable type 1 diabetes mellitus (T1DM) that cannot otherwise be stabilized by alternative means. Currently over 1000 patients have undergone islet transplantation in approximately 40 international sites (752 islet allografts and 333 autografts were registered with the Collaborative Islet Transplant Registry (CITR) at the time of this writing) [5,7]. Interestingly, in contrast to solid organ transplantation, access to deceased donor pancreas organs has not been the only impediment limiting further expansion of activity. Restricted availability of clinical islet isolation facilities with the required clinical good manufacturing practice (cGMP) ultra-clean room environment, skills and expertise involved in islet manufacture, general inefficiencies in procuring islets from available organs, combined with marked restrictions in clinical research funding also are rate limiting factors. In the US, plans are underway to secure a Biological Licensure Application (BLA) with the Food and Drug Administration (FDA), and when this occurs, Medicaid, Medicare and other third party reimbursement will likely have major impact on further expansion.

In the longer term, a limited islet supply and need for intensive immunosuppression are perceived as the two drawbacks that restrict broader application in T1DM [3,7]. The risks of poorly controlled diabetes and immunosuppression are well defined. Many in the diabetes community have a hyperinflated perception of the transplant and immunosuppressive risks, while those caring for islet transplant patients on a daily basis may conversely perceive heightened risks from ongoing complications of diabetes. As islet transplantation becomes more routine, and immunosuppressive management more streamlined, it is likely that the risks of transplantation and life-long immunosuppression will balance favorably with those of even the most stable insulin-controlled diabetes. This would broaden the procedural indications and would open up the therapy to include application in the pediatric population [8]; the earlier successful islet transplantation is applied in the course of diabetes, the greater the potential protective impact in preventing secondary complications. Conversely, the longer the lifetime duration of immunosuppression, the greater will be the accrued risks of malignancy, infection and renal injury [9–12]. Only carefully controlled trials that randomize patients with T1DM to insulin or transplantation and provide lifelong follow-up on an intent-to-treat basis in both arms will define when such a balance has been met.

In the meantime, acknowledgement of a lack of immediate proximity of transplantation tolerance, stem cell-derived and xenogeneic islets for routine clinical delivery has led several funding organizations to explore alternative ways of stabilizing glycemic control, including high technology insulin pumps with closed-loop sensors to serve as bridge or destination therapies, perhaps with avoidance of transplantation altogether [13]. It is our premise and bias that sustained normoglycemia cannot be achieved by exogenous subcutaneous insulin depot delivery, and that even the best pumps and sensor approaches will fall short of the precise moment-to-moment control provided by islets within the native pancreas, or within an adequate mass of transplanted islets. This chapter discusses clinical outcomes currently achieved in clinical islet transplantation, and takes on the challenges of the next steps required to further transition this therapy in preparation for matched randomized controlled trials.

Risks of diabetes and alternative intervention strategies

T1DM is an emotive and pervasive disease that affects both children and adults, cannot be prevented presently, and is increasing in incidence; furthermore, insulin therapy, while life-saving, is not curative. The incidence varies from 17–40 per 100 000 population, with the highest incidence observed in Finland and Sardinia, and this risk is accelerating rapidly [14]. There are an estimated 490 100 children under the age of 15 with T1DM [15]. While mortality rates vary considerably between first and third world countries, even in wealthy countries the mortality rates for both children and adults with T1DM are at least twice that of people of similar age without the disease [16,17]. In the US, diabetes is the seventh leading cause of death, is the leading cause of renal failure, non-traumatic limb amputations, and new cases of blindness amongst adults, and consumes more than $174 billion in estimated healthcare costs [17,18]. While the Diabetes Control and Complications Trial (DCCT) clearly demonstrated that improved glycemic control from intensive insulin substantially lowered risk of secondary complications with lower glycosylated hemoglobin (HbA1C), the risks of hypoglycemia increased markedly [19–21].

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Hypoglycemia has been long-recognized as a complication of excess insulin therapy, and indeed the early definition of one "Unit" of insulin was that amount required to induce fatal hypoglycemia in a rabbit [22]. The subcutaneous site for glycemic monitoring and depot delivery of insulin represents an imperfect approach, with response lag inevitably failing to provide complete physiologic glycemic control. Efforts to correct HbA1C and further reduce risk of secondary complications can exacerbate risk of troublesome hypoglycemia, especially in a subset of more susceptible individuals [21,23,24]. Car drivers both in the US and in Europe with T1DM experienced twice as many collisions as their non-diabetic spouses, in part related to neuroglycopenia, retinopathy and peripheral neuropathy [25–27].

The "dead in bed" syndrome remains one of the most feared complications of unrecognized hypoglycemia from insulin therapy in T1DM, where patients are typically found dead in the early morning, and accounts for 4.7– 7.3% of unexplained deaths overall, and for 6% of deaths overall in T1DM patients younger than 40 [27–30]. Figure 108.1 demonstrates the glucose parameters of two patients wearing continuous subcutaneous glucose monitoring

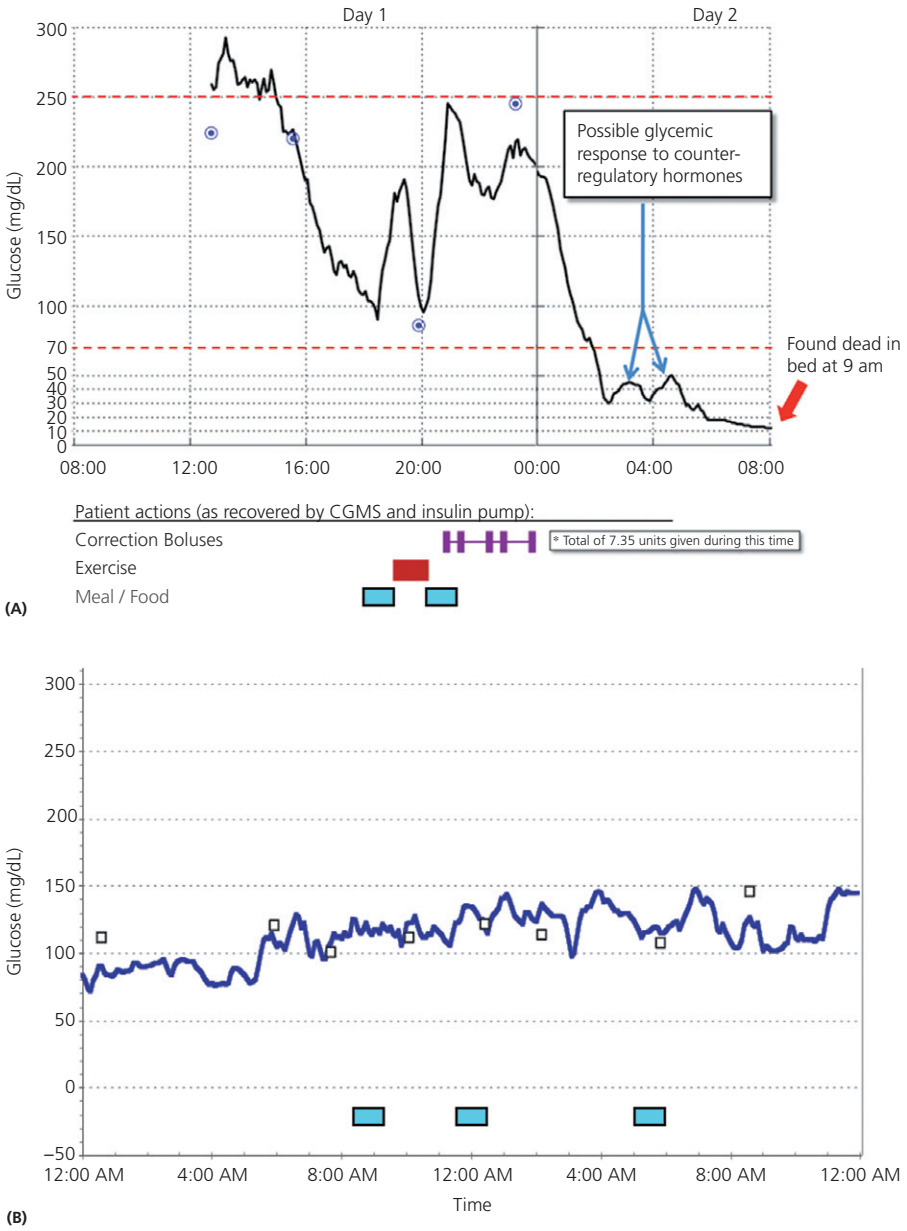

Figure 108.1. Continuous subcutaneous glucose monitoring systems (CGMS) records from: (A) A 23-year old man with T1DM using an insulin pump, complicated by severe hypoglycemia, was found convulsing by his mother, taken to the Emergency department, and treated with orange juice. The following morning he was discovered by his family at 9am unresponsive and pulseless. CGMS records and autopsy confirmed death by hypoglycemia (dead in bed syndrome). (B) A 44-year old woman with previous T1DM treated with two islet transplants at the University of Alberta, with sustained normoglycemia as demonstrated by CGMS, and with HbA1C of 5.5%, and not requiring insulin for 3 years.
Figure 1A modified from the original published in reference [31], and generously provided by Professor R.J. Tanenberg with kind permission. Reprinted from Endocrine Practice, Vol 16, Confirmation of hypoglycemia in the "dead-in-bed" syndrome, as captured by a retrospective continuous glucose monitoring system, p.246, Copyright (2010), with permission from the American Association of Clinical Endocrinologists.

systems (CGMS), where in (A), a 23 year old male died from fatal hypoglycaemia, dead in bed syndrome despite use of an insulin pump (HbA1c 6.4%), as recorded by CGMS [31], and (B), a 44 year old female with previous severe hypoglycemia and lability achieved sustained normoglycemia without exogenous insulin with HbA1C of 5.5% after islet transplantation.

Refined technological advancements in improved insulin delivery algorithms and glucose-sensing technologies offer potential to prevent hypoglycemia while correcting HbA1C, thus broadening the therapeutic window of tolerability for insulin [32,33]. However, the hysteresis lag in current sensor monitoring, delivery and absorption of infused insulin in the subcutaneous site will remain persistent limitations of this technology. The low glucose suspend (LGS) automated insulin shut-off on insulin pumps linked to closed loop sensors are one key advance that may mitigate risk of severe hypoglycemia [34–37]. Ongoing limitations of this technology include suboptimal accuracy, reliability and sustainability beyond a few days with continuous glucose monitors and time-lag delays associated with subcutaneous insulin delivery. The use of insulin alone, without additional counter-regulatory glucagon, is also seen as an additional shortfall in this approach.

Advances in both short and long-acting insulin formulations have led to improvements in glycemic control. The initial switch from beef and porcine to recombinant synthetic human insulin led to a concerning increase in hypoglycemia and unawareness, with reduced counter-regulatory responses [38–40]. The more recent introduction of a long-acting basal micro-crystalline insulin analogue, glargine (Lantus, Sanofi-Aventis Inc., Paris France) with a more prolonged 18–26 hour duration profile, has generally been associated with lower risk of severe hypoglycemia when compared with neutral protamine Hagedorn (NPH) insulin, but still may not resolve severe recurrent hypoglycemia in susceptible patients [41–44]. Development of inhaled insulin was initially promoted as a promising and innovative approach for more rapid vascular absorption, and seemed attractive as it avoids a need for repeated injection. In practice, controlled trials failed to demonstrate superiority of the approach, and Pfizer withdrew manufacture of Exuberta in 2007, and other companies followed suit, with the exception of MannKind Inc., which is still undergoing FDA review. Concerns relating to a slightly increased risk of lung cancer, lack of superiority, and considerable and unjustified increased expense, will certainly hamper ongoing developments with this approach [45,46].

Efforts aimed at prevention and early intervention in T1DM have met with disappointment, despite enormous promise generated by data generated in mouse models of autoimmune diabetes. Over 463 interventional treatments have been shown to prevent or reverse autoimmune diabetes to varying degrees in non-obese diabetic (NOD) mouse models [47]. Efforts focused on translation of several of the most promising approaches from mice to T1DM have met with frustration, despite enormous investment and a series of large-scale recent clinical trials [48]. This has brought in to question the utility of this mouse model as a surrogate of the human disease [49]. Encouraging preliminary clinical pilot data suggested that a non-Fc binding CD3 antibody [50–53], mycophenolate mofetil (MMF) + daclizumab [54], rituximab B-lymphocyte depletion [55,56], a soluble NBI-6024 altered insulin peptide ligand [57], vitamin D3 [58], nicotinamide [59], parenteral insulin, oral insulin, nasal insulin, and the elimination of cow's milk from infant feeding could potentially mitigate diabetes onset, or at the very least prolong endogenous C-peptide and sustain the honeymoon period [48,59–61]. To date, none of these approaches have proven robust benefit when subjected to adequately powered randomized clinical trials [61]. Perhaps the most promising approach to date has been the use of intravenous non-myeloablative autologous hematopoietic stem cell transplantation after mobilization with granulocyte colony-stimulating factor, and conditioning with thymoglobulin and cyclophosphamide, as first described by Voltarelli et al. in Brazil [62–67]. This approach of "immunological reset" was designed to eliminate both autoreactive and non-autoreactive lymphocyte clones, with subsequent immune reconstitution. Updated reports indicated that 20 new onset T1DM patients achieved insulin independence, and 12 maintained this state for a mean of 31 months, a remarkable achievement without mortality, but with nosocomial pneumonia in two cases, and oligospermia in nine cases [63,68,69]. The mechanism underpinning this approach appears to be restoration of apoptosis-related gene deregulation that may have contributed to breakdown of immune tolerance and T1DM [70]. Ongoing trials are much needed to further define the risk-benefit and sustainability of this interesting approach.

Thus, standard or intensive insulin therapy currently remains the gold standard therapy for the majority of patients with T1DM, with a clear understanding that tighter glycemic control lessens the risk of secondary diabetic complications, but substantially increases the risk of troublesome and occasionally life-threatening hypoglycemia. Insulin pumps, CGMS and improvements in insulin crystalline structural design represent considerable improvements for many T1DM patients. For a substantial minority however, a life with frequent hypoglycemia or inexorable threat of progressive secondary complications represents an intolerable burden. For these individuals, islet transplantation represents an increasingly attractive option. Whole pancreas transplantation offers the potential to restore euglycemia, and can generally resist the metabolic strain with far greater reserve than an islet transplant. Both require similar levels of immunosuppression, but islet transplantation represents a more elegant solution (Figure 108.2). Replacement of the endocrine without the exocrine component in islet transplantation is readily accomplished through a non-surgical and exceedingly low risk approach. In contrast, the risks and outcomes of whole pancreas

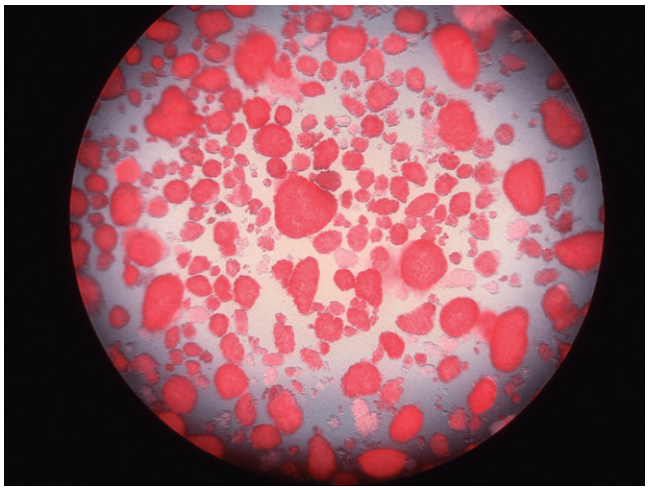

Figure 108.2. Purified human islets in the final preparation, stained with dithizone for quantification. Islets vary in size between 50–500 μm, and the final islet mass is estimated as Islet Equivalents (IEQ), with a preparation of >5000 IEQ/kg recipient weight generally being sufficient for transplantation.

Table 108.1. Indications for islet transplantation

A. Islet transplant alone (ITA)
Type 1 diabetes, duration >5 years
Age >18 years, weight <90 kg, insulin requirement <1.0 U/kg/day
Absence of malignancy or untreated infection
Ability to comply with immunosuppression and close follow-up
Refractory hypoglycemia or lability despite:
1 Optimal intensive insulin or insulin pump with appropriate monitoring
2 Supervision of a diabetologists of endocrinologist
3 Evidence of increased hypo risk:
I. Clark Score ≥4
II. HYPO Score ≥1000
III. Lability Index (LI) ≥400
IV. Combined HYPO ≥400 and LI ≥300
B. Islet after kidney (IAK)
Type 1 diabetes, successful prior renal allograft
Tolerating maintenance immunosuppression
Prednisone ≤5 mg/day
Absence of BK virus, or other active opportunistic infection
Non-sensitized (PRA < 20%)

For Clarke Score, see ref [80].
For HYPO Score and Lability Index, see ref [81].

transplantation have improved substantially over the past quarter century, and more than 30 000 have been performed internationally [71–74]. From a patient's perspective, avoiding potential risks of laparotomy, pancreatitis, graft thrombosis, surgical site infection and occasional mortality in pancreas transplantation make islet transplantation the more attractive option, provided that similar metabolic reserve is sustained over time [75–78].

Patient selection and procedural indications for islet transplantation

Patients are selected for clinical islet transplantation based on indications summarized in Table 108.1. Additional discussion of patient selection for and management of patients awaiting islet or pancreas transplantation can be found in Chapters 33 and 41.

Islet transplant alone

The indications for islet transplant alone (ITA) require evidence of T1DM (C-peptide negative), with sufficient duration (>5 years) to justify that all reasonable alternative attempts have been made by an independent diabetologist or endocrinologist to correct and stabilize refractory glycemic control, including optimized intensive insulin or insulin pump therapy combined with frequent glycemic monitoring [79]. A series of objective scores are applied that involve a detailed patient questionnaire (the Clark Score) [80], and stringent review of detailed glycemic records allows for calculation of the hypoglycemia score (HYPO) and lability index (LI), as originally developed by Ryan et al. [81]. The threshold values summarized in Table 108.1 represent currently accepted indications for islet transplantation used in the major centers or in the CIT Consortium trial centers [79]. Selection of patients with a duration of T1DM >5 years provides assurance that adequate opportunity for optimized medical management has been provided. The restriction of age >18 years reflects general consensus that a lifetime commitment to immunosuppression should be avoided in the pediatric population, except in exceedingly rare instances where the risk of death or irreversible brain injury from hypoglycemia cannot be avoided by alternate means [8]. Avoidance of subjects of weight >90 kg or with daily insulin requirement >1.0 U/kg avoids futility of transplantation where there is marked insulin resistance (Table 108.1A).

Islet after kidney

The indications for islet transplantation in the setting of islet after kidney (IAK) transplantation are much more straightforward, as patients are already subjected to the chronic risks of immunosuppression (Table 108.1B). In IAK transplantation, patients must have a well-functioning prior kidney transplant and be able to tolerate standard maintenance immunosuppression. Corticosteroids are used by some centers for maintenance therapy in kidney transplantation, and although there are concerns regarding both insulin resistance and islet toxicity from prednisone, any negative impact is perceived to be negligible if the dose is ≤5 mg per day, and indeed islet transplant rejection has been reversed successfully by pulsed steroid therapy [82–85]. Kidney transplants are more susceptible than other organs to infection with BK virus, so-named after the initials of the first renal transplant patient to have this polyoma virus isolated from urine in 1971 [86]. Exacerbation of BK nephropathy can be especially problematic, and can be potentiated by depletional therapies, and therefore avoidance of additional risk by screening for BK virus in potential IAK subjects is appropriate [87]. Finally, avoiding subjects with broad HLA sensitization and high panel reactive antibody (PRA) from previous kidney transplant rejection, blood transfusion or pregnancy may have important bearing on the success of an upcoming islet transplant [88,89]. Furthermore, recognizing that kidney transplants have a limited half-life of 8–15 years [90,91], and that kidney retransplantation may soon be the commonest indication for kidney transplantation (up to 20% of patients on kidney transplant lists are due to failed previous transplants), further increased PRA from additional islet sensitization could be especially problematic in this population [92–94]. Therefore an initial PRA <20% is felt to be a reasonable cut-off for IAK transplantation.

Risks of islet transplantation

Procedural risks

Islet transplantation is especially attractive as this cellular therapy can be delivered safely into the intrahepatic portal venous system by a simple percutaneous transhepatic approach that avoids need for surgery. In fact, in experienced high volume islet transplant centers, this procedure is currently far safer than for any other solid organ transplantation. Nonetheless, there are potential risks of the intraportal approach including intraperitoneal bleeding and portal venous thrombosis, both of which are avoidable if the procedural details of catheter tract ablation and intraportal and therapeutic heparinization are adhered to closely [95]. The technical details of islet transplantation are discussed in depth in Chapter 61.

The commonest complication is of mild pain or discomfort either at the catheter insertion site, or as referred pain to the right shoulder tip, is transient, occurs in up to 50% of patients, is easily controlled by standard analgesic medications, and generally resolves fully in 24–48 hours.

Bleeding

Despite the use of therapeutic anticoagulation with heparin (70 units per kg recipient weight intraportally followed by intravenous infusion at 3 units per kg per hour adjusted to PTT of 60–80 seconds), significant bleeding requiring surgical intervention is

now an extremely rare occurrence in our hands, with a current frequency of <1% (3 of 342 cases at the University of Alberta) [95,96]. Use of a 4 or 5 French catheter leaves a narrower tract in the hepatic parenchyma, and ablation of this tract with Avitene paste or D-STAT for a track length of at least 4 cm effectively prevents intraperitoneal bleeding [97–99]. Using this approach, we have not needed to give either a blood transfusion, laparoscopic or surgical intervention for intraperitoneal bleeding in the most recent 150 procedures in Edmonton [95,96]. In one unusual case we encountered bleeding within the right chest cavity, which was recognized early and readily controlled by angiographic coil ablation of an intercostal artery followed by chest tube insertion. Such an injury would not be controlled by track ablative techniques. The use of ultrasound guidance to facilitate portal access, and avoiding the inferior rib or costal border with the initial puncture, may help to avoid such an injury [100–102].

Portal venous thrombosis

Complete thrombosis of the entire portal venous system is one the most feared complication of intraportal islet transplantation [103–105]. However, complete thrombosis with sequelae of chronic portal hypertension has now proven to be an exceedingly rare complication in the current era of low-endotoxin collagenase, continuous gradient purification, routine islet culture, close portal pressure monitoring, therapeutic heparinization and limiting the infused islet tissue mass to ≤5 cc packed cell volume [106–115]. At the University of Alberta, we have yet to encounter complete thrombosis of the main portal vein following islet transplantation now in 342 separate percutaneous intraportal infusions in 164 patients (0% incidence). Furthermore, none of our patients have ever manifested signs of portal hypertension with up to 13 years of follow-up [95,96].

Branch occlusion of segments of the portal tree on the other hand is a rare but entirely benign finding occasionally observed in our hands, has not been associated with propagation into the main tree, and is not associated with portal hypertension. Branch portal occlusion has been documented in 3.7% of cases previously, but the frequency has decreased markedly in the past five years since the introduction of therapeutic heparinization [95,116]. Treatment with heparin followed by a vitamin K antagonist (warfarin) for three months has been often used, but this is probably not necessary as the inciting factor (islet deposition) is a finite event. Patients with an underlying thrombophilia including protein C, S, antithrombin 3 deficiency, Factor V Leiden mutation may be at increased risk of this complication, and screening of patients with a prior thrombotic history may lower this risk [117].

Gallbladder puncture and inadvertent biliary cannulation

The percutaneous transhepatic approach can potentially lead to inadvertent puncture of the gallbladder, but this is an entirely avoidable complication if ultrasonic guidance is applied routinely [97,99,100]. Intraparenchymal cholangiography is anticipated with the 22 gauge seeker Chiba needle, and generally does not lead to bile leak [118].

Transient elevation in liver function, and hepatic steatosis

Transient mild elevation in liver transaminase has been described previously after intraportal islet transplantation, occurred in up to half of the cases, may be up to fivefold increased in 27%, and normalize completely by one month without intervention [119]. Interestingly, with routine adoption of islet culture protocols, improved collagenase enzymes, therapeutic heparinization and the use of anti-inflammatory agents (infliximab, etanercept, Anakinra, aspirin) both the incidence and severity of transaminitis has decreased markedly in our more recent experience.

Hepatic steatosis has also been observed on ultrasound, magnetic resonance imaging (MRI) and in liver biopsies of islet allograft and autograft recipients in up to 20% of cases [120–124]. The fat deposits are usually macrovesicular, focal, and likely reflect local high insulin release from functioning islets. These changes are reversible when islets are rejected [120,122]. These changes have not been associated with non-alcoholic steatohepatitis (NASH) in islet recipients, but their long-term consequence will be defined by additional follow-up.

Risk of liver cancer

Concern has been expressed previously regarding potential transformation of hepatocytes to hepatocellular carcinoma (HCC) in the longer term when islets are embolized to the liver. Dombrowski et al. initially described high rates of hepatic adenomas and HCC in streptozotocin-induced diabetic rats receiving low islet engraftment mass, and subsequently observed similar changes in spontaneously diabetic BB/Pfd rats, attributing this increased risk to a series of trophic factors released locally by intrahepatic islet transplants [125,126]. This is an observation that appears to be unique to the rat. Clinical islet auto- and allo-transplants have been carried out in over 1500 humans since 1977, and there has yet to be a single case report of this complication, thus presumably the risk of malignant transformation after clinical islet transplantation is negligible [7,127–129].

Transmissible infection, and contaminated islet preps

The risk of donor-derived serious infection (bacterial, fungal, viral or prion-related) is well described in solid organ transplantation. Notable examples include transmission of hepatitis C, human immunodeficiency virus (HIV), lymphocytic choriomeningitis from a donor's pet hamster fatal in three organ recipients, rabies virus in a donor bitten by a bat with fatal outcome in four recipients of kidneys, liver and an arterial segmental graft [130–133]. Fortunately donor-derived transmissible infection has been rare in islet transplant recipients. A fatal case of untreated West Nile viral encephalitis was described in a 45 year old woman who received two remote islet transplants three years earlier [134]. In this case, there was a history of a recent mosquito bite at a horse stable, and the infection was clearly not of donor origin [134]. Careful screening of donors, avoidance of high-risk donors for non-lifesaving transplants, and protracted additional testing of donor tissue during islet culture can further lessen the risk of donor-derived infection. Nucleic acid testing (NAT) for HIV, hepatitis B and C has been advocated in selected, high-risk cases to shorten the detection window in donor infection, and we delayed several islet transplants from high-risk donors from proceeding until NAT testing has been released and found to be negative [135]. More thorough consideration of donor derived infectious risks can be found in Chapter 92.

When islets are isolated and stored in culture, there is a potential for bacterial contamination of the preparation. Addition of antibiotics to the culture media may reduce this risk. A Gram stain of the final islet product must be negative, the endotoxin content must be low (<5 EU/kg recipient weight), and a sample of the islet product that has not been exposed to antibiotics must be set aside for post hoc bacterial and fungal culture. High endotoxin content from

impure collagenase enzymes used prior to 1998 may have contributed to poor islet function in the recipient [136,137]. Current collagenase blends have low entotoxin content.

Prophylactic broad-spectrum antibiotic treatment of the recipient at the time of islet transplantation is advised in all cases. Nonetheless, despite inadvertent infusion of contaminated islet products in rare cases, there have been no sequelae of intrahepatic abscess or systemic infection observed; this is clearly reassuring [138]. This risk is probably low because the hepatic blood-flow is high, and the liver contains active phagocytic Kupffer cells in the sinusoidal linings.

Challenges of immunosuppression

Control of autoimmunity and rejection without islet toxicity

Generalized immunosuppression required to suppress the allograft response is associated with a host of well-characterized risks and side effects, most notably an increased risk of opportunistic infection and malignancy. These risks occur with increasing frequency depending on the type, dose and combination of agents used. In clinical islet transplantation, the combination therapy must be sufficient to suppress both potent autoreactivity from recurrent T1DM as well as alloreactivity. Furthermore, islet rejection with progressive hyperglycemia tends to be a late and usually irreversible hallmark of endocrine failure, in contrast to solid organ liver or kidney transplantation where graft dysfunction is detectable at an earlier stage [3,83,139]. Islet rejection has only rarely been reversed in the clinic with corticosteroid therapy [84], and therefore adequate and sustained prophylaxis from the outset is seen to be a critical component of success [1]. Recurrence of autoimmune T1DM clearly occurs after whole pancreas transplantation, despite the use of potent immunosuppressive combination therapies, and may be the underlying explanation for the 50% insulin independence rate persisting by five years after pancreas-alone transplantation [140–143]. Recurrent autoimmunity has also been clearly established in liver biopsy specimens after clinical islet transplantation with selective beta cell destruction [144], and is the most likely explanation for the inexorable loss of insulin independence observed after five years in the original Edmonton Protocol series [145–147]. Roep and colleagues have developed an elegant series of in vitro assays for detection of autoreactivity following islet transplantation, and have recently applied HLA Qdot nanotechnologies to more precisely define islet epitope responses to preproinsulin, islet antigen 2, glutamic acid decarboxylase 65, islet amyloid polypeptide and other targets [148–152]. It is clear from these and other studies that effective control of both autoreactivity and alloreactivity is essential for the long-term functional survival of islet allografts in T1DM [153–155].

While potent immunosuppression is therefore required, it is also increasingly apparent that many of the key agents used are also specifically toxic to beta cells [156]. This adds a unique challenge for islet transplantation, as it cannot be assumed that immunosuppressive strategies tuned for optimal solid organ transplantation success will also be appropriate in islet transplantation [82]. Using lineage tracing techniques, Nir et al. demonstrated that both tacrolimus and sirolimus, drugs used in the Edmonton Protocol, are potent inhibitors of beta cell regeneration in mice [157]. Ricordi et al. highlighted early direct toxicity of tacrolimus on human islet function in immunodeficient mice, and more recent studies by Rostambeigi et al. suggest that both insulin secretion mitochondrial density are decreased [158,159]. It is known that portal levels of immunosuppressive agents expose islets to particularly high local drug levels, especially in the early post-transplant period [160,161]. Interestingly, sirolimus was shown to improve insulin secretion in culture and in vivo, and the anti-inflammatory effects of this agent could potentially improve islet survival in culture [162,163]. Conversely, Zhang et al. observed reduced islet engraftment and impaired beta cell function in a marginal mass mouse islet transplant model [164]. Merani et al. observed that the long-acting glucagon-like peptide 1 (GLP-1) analogue was protective against immunosuppressive toxicities from both tacrolimus and sirolimus in a human islet mouse model [165]. Newer agents such as the sphingosine-1-phosphase receptor modulator FTY720 lack beta cell toxicity, and looked promising in marginal mass islet transplant models both in mice and primates, but the Achilles' heel proved to be accelerated rates of macular degeneration in early clinical trials, an unfortunate side effect for patients with T1DM and pre-existing retinopathy [166–171]. Taken together, there is no ideal immunosuppressive drug for use in islet transplantation, and a compromise that provides reliable protection from both auto and alloreactivity, while at the same time does not excessively impair islet function, is the current pragmatic approach.

A practical approach to immunosuppression in islet transplantation

Chapters 65, 66, and 67 provide a general review of induction, maintenance and rescue immunosuppressive management strategies. We herein focus on current practical approaches to immunosuppression as they relate to clinical islet transplantation.

Induction therapies — daclizumab, basiliximab, thymoglobulin and alemtuzumab, and risk of CMV, EBV and PTLD

The anti-IL2R monoclonal antibodies (mAb) daclizumab and basiliximab have been used widely in islet transplantation since 2000 [1,2]. Daclizumab is no longer being made available for commercial sale, a fiscal rather than biological decision by its licensing company. Although well tolerated without side effects, these agents add only marginal potency to immunosuppressive regimens, and have minimal impact on T1DM autoimmunity. Indeed, large-scale clinical interventional trials using daclizumab and mycophenolate mofetil failed to preserve beta cell function or extend the honeymoon period in new-onset T1DM [54]. We therefore advocate use of lymphocyte depletional approaches in clinical islet transplantation, as first introduced by Hering et al., especially for initial islet transplants [4,172–174]. A wealth of preclinical studies suggests that lymphocyte depletion is a strong adjunctive strategy in autoimmune regulation and tolerance [151,152,175–177]. Bellin et al. have recently analysed data from both Minnesota and from the CITR CITR, demonstrating a profound impact of initial depletional therapy on 5-year insulin independence outcomes, regardless of the maintenance immunosuppressive regimen, and especially in combination with tumor necrosis factor-alpha (TNF-alpha) blockade (vide infra, Figure 108.3) [172]. Thymoglobulin (rabbit ATG, Genzyme in the US or Fresenius outside of the US) is given as a cumulative dose of 6 mg/kg by peripheral intravenous infusion over 2–3 days, with the goal being to infuse at least 2 mg/kg prior to islet infusion while islets are maintained in culture, to avoid transplantation during the depletional cytokine storm [178]. In Edmonton, we have favored depletion with alemtuzumab 30 mg by peripheral

intravenous infused over 3 hours, based on potency, tolerability, sustained effect and cost. Predosing for alemtuzumab includes acetaminophen 650 mg oral, together with intravenous diphenhydramine 50 mg and solumedrol 250 mg. Calne et al. were the first to develop alemtuzumab induction for clinical organ transplantation with their *prope* tolerance approach in combination with low dose cyclosporine [179–181]. We began using alemtuzumab for islet transplantation in 2002, initially in combination with sirolimus monotherapy, but observed high rejection rates, similar to the early experience seen in kidney transplantation [182–185]. After switching to tacrolimus (target trough $\geq$10 ng/mL for 3 months, followed by 8–10 ng/mL thereafter and mycophenolate mofetil up to 2 g daily as tolerated in divided dose, we have found that this approach is best tolerated by patients and provides superior insulin independence at 5 years (Shapiro 2012, personal observation). Tan et al. used alemtuzumab induction with sirolimus and tacrolimus maintenance in seven IAK recipients in Fuzhou, China, with 4/7 patients independent of insulin at one year [186]. Froud et al. from Miami used alemtuzumab induction with short-term calcineurin inhibition, using tacrolimus and sirolimus for 3 months followed by sirolimus and mycophenolate mofetil thereafter, with insulin independence observed in 2 of 3 subjects treated [187]. Over two thousand patients have received alemtuzumab induction in solid organ transplantation, suggesting the apparent safety of this approach despite profound and sustained lymphocyte depletion [74,188–204]. Ongoing trials at the University of Alberta and elsewhere are currently exploring the role of alemtuzumab in control of autoimmunity in islet transplant recipients. We have reported increased rates of CMV transmission and reactivation in islet recipients receiving depletional therapies with either thymoglobulin or alemtuzumab, especially at later time points beyond the period of initial CMV prophylaxis [205–207]. Fortunately these episodes have been largely sub-clinical, and detectable only by serial PCR monitoring, and have not led to specific organ related disease, and have been readily treatable with intravenous ganciclovir or oral valganciclovir (Roche Canada) [205].

While OKT3 and ATGAM have been previously linked to increased rates of EBV-related post-transplant lymphoproliferative disorder (PTLD), the risk appears to be lower with thymoglobulin and alemtuzumab [208,209]. The incidence of PTLD in a meta-analysis of 2246 kidney and heart transplant recipients receiving thymoglobulin was 0.98% at 5 years, and was significantly lower (0.63%) where antiviral prophylaxis with valganciclovir was given [210,211]. Kirk et al. reviewed the incidence of PTLD in 59 560 kidney transplant recipients in a large US database, and found a significantly lower risk of PTLD with alemtuzumab (0.37%) than with thymoglobulin (0.67%) [212]. The use of mTOR inhibitors overall was strongly associated with PTLD in this analysis, leading the authors to conclude that lymphocyte depletion per se is not an independent risk factor for PTLD, rather the overall intensity of immunosuppression is the more correlative metric [212]. Interestingly, alemtuzumab has been used effectively to treat PTLD in the setting of bone marrow transplantation and hematological malignancy [213,214]. In the setting of bone marrow and stem cell transplantation after lymphoablation, the use of alemtuzumab has been associated with very low rates (<1%) of PTLD despite EBV reactivation in this high-risk group [215]. In solid organ transplantation there have been very few anecdotal reports of PTLD after alemtuzumab induction. Currently, there have been no reports of PTLD following islet transplantation in any of the major trials, irrespective of the induction and maintenance regimen, and although a report from Cure et al. found late EBV reactivation in three IAK recipients treated with tacrolimus and sirolimus, none transformed to PTLD [1,2,101,118,146,216,217].

Maintenance immunosuppression

Selection of synergistic maintenance immunosuppression that is universally tolerated has been especially challenging in islet transplantation. A desire to use "islet-friendly" medications that lack beta-cell toxicity does not necessarily mesh well with a need to provide potent and sustained protection from both auto- and alloimmunity [7,156]. High-dose sirolimus (levels 12–15μg/L for the initial three months, then reduced to 10-12μg/L thereafter) combined with low-dose tacrolimus (4-6μg/L) was advocated in the Edmonton Protocol as a means to reduce calcineurin-inhibitor exposure in patients with underlying overt or covert T1DM nephropathy [1,218]. While this approach led to unprecedented high rates of one-year insulin independence in the three leading islet transplant centers [219], it became apparent that such a combination was difficult to titrate when extended to the setting of an international multicenter trial [2,220]. High dose sirolimus was perceived as the major culprit in this regimen [221], with intolerable rates of mouth ulceration [105,118], ovarian cysts and amenorrhea in female patients [222–224], fatigue, diarrhea, occasional severe small bowel ulceration [225], pneumonitis [226], peripheral and retroperitoneal edema [123,227] and accelerated proteinuria due to sirolimus, that was reversible after drug withdrawal [228,229]. Although sirolimus remains an integral component of the CIT registration trials in the US, the University of Alberta has abandoned the routine use of this agent in islet transplantation, based on the above experience of side effects. The more standard transplant combination of tacrolimus and mycophenolate mofetil has been tolerated with a far superior side effect profile and compliance in our hands. The substantial increase in 5-year insulin independence rates observed with depletional induction and high-dose tacrolimus and mycophenolate mofetil maintenance suggests that despite theoretical concerns regarding islet toxicity, in practice this combination can provide effective prophylaxis from rejection and recurrent autoimmunity. The downside of this approach is a need to exclude patients with underlying diabetic renal impairment at baseline, with current recommendations requiring evidence of adequate renal reserve, with a baseline estimated glomerular filtration rate $>$60 mL/min/1.73 m^2 and albumin excretion rate $<$300 mg/g creatinine.

Calcineurin-inhibitor avoidance in islet transplant

Since diabetes is the commonest indication for renal transplantation, approaches that provide equivalent immunoprophylaxis without side effects, but avoid calcineurin inhibitors (CNI), are seen as a major priority for the field. While the combination of sirolimus and mycophenolate mofetil can provide effective short-term prophylaxis, it is only generally effective when used in combination with depletional induction therapies in islet transplantation, and it remains unclear whether complete elimination of CNI will impact the 5-year insulin independence rates [172,187]. Posselt et al. have explored two different induction strategies that may accomplish these goals [230]. They found that depletion induction with thymoglobulin and induction and monthly maintenance costimulation blockade infusions of belatacept facilitated a CNI-free regimen requiring only sirolimus or mycophenolate mofetil

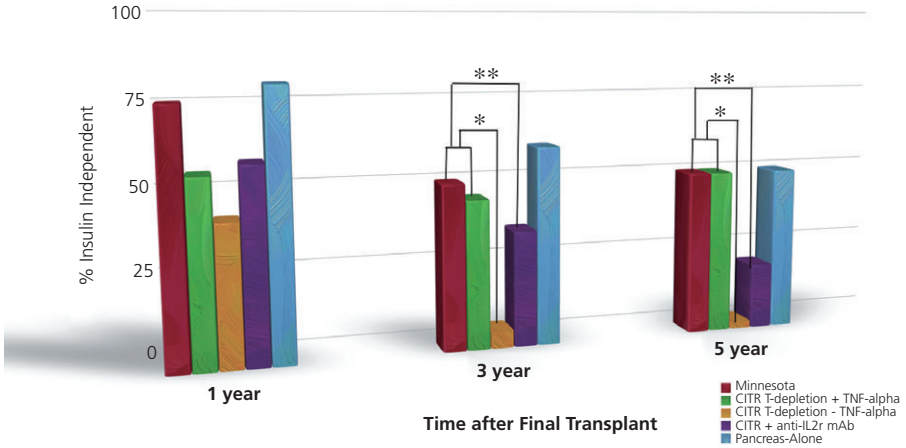

Figure 108.3. Five-year insulin independence rates comparing pancreas alone transplantation (PTA) with different induction and anti-inflammatory strategies in clinical islet transplantation. This data from the American Journal of Transplantation (reproduced from [172] Bellin et al. 2012, with kind permission from Wiley) demonstrates outstanding 5-year insulin independence rates of 50% when T-depletional therapies + TNF-alpha blockade (etanercept) are given in combination. These results equate to the 50% insulin independence rates of PTA observed at five years from the International Pancreas Transplant Registry Data.
* $p < 0.01$; ** $p \leq 0.05$.

[230]. Alternatively, they tested an anti-leukocyte functional antigen-1 antibody (anti-LFA1 mAb, efalizumab) in place of costimulation blockade [230]. While most encouraging, these early observations are currently limited to five subjects per group, and the anti-LFA1 antibody has unfortunately been withdrawn from the market because of exceedingly low rates of progressive multifocal leukoencephalopathy (PML) seen in psoriasis-treated patients (three confirmed cases and an additional case suspected in >46 000 treated) [231–233]. The ability to combine belatacept with depletional therapies in ongoing trials may be further restricted by the licensure trials and post-market surveillance of belatacept therapies in transplantation, which may necessitate a low-risk tolerance approach by Bristol Myers Squibb. Therefore an ideal CNI-free approach in clinical islet transplantation is not readily available for more widespread and long-term testing at present.

Adjunctive peritransplant prophylactic management

Antibacterial, antifungal, and antiviral prophylaxis generally follows local practice guidelines, in concert with a transplant infectious diseases specialist. Generally we recommend that broad-spectrum antimicrobial prophylaxis be administered before intraportal islet transplantation.

Anticoagulation

The anticoagulation regimens are outlined in detail in the techniques chapter 61. In brief, heparin (70 units per kg recipient weight) is delivered intraportally with the islets, and a heparin infusion is initiated in the radiology department at 3 units per kg per hour, then titrated to maintain a PTT of 60–80 seconds, and continued for 48 hours post-transplant. This approach, combined with intensive insulin therapy, has improved our single donor islet engraftment success [116]. We then continue low-molecular weight heparin (enoxaparin 30 mg twice daily s.c.) for 7 days, and aspirin 81 mg enteric coated for 14 days post-transplant, provided there are no concerns regarding bleeding or thrombosis on the doppler ultrasound examinations.

Anti-inflammatory medications

Concomitant medications may include vitamin E (800 iU oral pre-transplant then for 7 days post), anti-TNF-alpha blockade with etanercept (50 mg intravenous pre-transplant, then 25 mg s.c. on days 3, 7 and 10 post, as described by Hering et al.) [4,174]. Farney et al. initially described this approach in mice [234]. McCall et al. from our group recently found remarkable potentiation of marginal mass human islet engraftment in immunodeficient mice when the combination of etanercept and an anti-IL1 beta receptor antibody, anakinra was used [235]. Preliminary clinical data from Matsumoto et al. suggested that this combination might be beneficial in a small series of islet recipients [236]. Encouraging data from Bellin et al. suggests that potent anti-inflammatory, anti-TNF alpha strategies given at the time of islet transplantation with etanercept or infliximab may have lasting positive impact on 5-year insulin independence rates, and especially when combined with depletional induction therapies (Figure 108.3) [172]. We generally give pentoxifylline 400 mg orally tid for 7 days post-transplant, following the original Giessen protocol [237].

CMV prophylaxis

CMV and EBV prophylaxis using valganciclovir is recommended for all subjects receiving depletional therapies, irrespective of donor and recipient CMV status, starting at 450 mg once daily for 14 days, then increased to 900 mg once daily for 12 weeks post-transplant [205]. We further recommend sulphamethoxazole 400 mg — trimethoprim 80 mg once daily for 6 months for *Pneumocystis jiroveci* prophylaxis post-transplant. If allergic to sulphonamide, then pentamidine 300 mg by inhalation may be substituted, but dapsone should be avoided as it interferes with HbA1C determination [238].

Other long-term risks in islet transplanted patients

Death

The risk of death following islet transplantation has fortunately been exceedingly rare. Currently at the University of Alberta, our

actuarial survival rate is 96% with 13 years of follow-up (6/164 subjects). We have encountered no deaths as a direct or indirect result of immunosuppression, to the best of our knowledge. Of six deaths, four were cardiovascular from underlying cardiac microangiopathy, coronary occlusion or arrhythmia, one was from fatal hypoglycemia in a patient with a failed islet transplant and off immunosuppression for a protracted period, and one resulted from an inadvertent methadone overdose in a patient that had severe ocular pain, had been taking escalating doses of methadone previously, stopped taking the drug for two years, then resumed at his former dose by self-administration.

Data from the most recent CIT International Registry (including the six deaths in Edmonton above) currently documents a total of 18 deaths, or 1.3% overall, with 15 of the 18 deaths occurring in patients transplanted between 1999–2003 [239]. Of these cases, three were possibly related, and one definitely related to islet transplantation or immunosuppression. While robust comparative data has not been collected in an appropriate non-islet transplant control group in formal analysis, we have encountered a similar number of deaths from severe hypoglycemia in patients on waiting lists for islet transplantation, providing accumulating evidence of equipoise for islet transplantation versus optimal medical insulin therapy for a head-to-head trial.

Malignancy

In terms of malignancy, in the CITR there have been 16 cases of basal or squamous cell carcinoma of the skin arising in 13 patients, with an overall rate of 2.3% [239]. Most of these are presumably related to chronic immunosuppression, and were fully treated by excision. Additionally in the CITR there were two patients with breast cancer, two lung cancers and two thyroid cancers (0.35% incidence respectively) [239]. Sirolimus may have a beneficial protective role in reducing the incidence and severity of several malignancies in transplant populations, with a growing body of evidence [240–249].

HLA sensitization

The risk of HLA sensitization has been highlighted as a concern, as patients receiving islet transplants from more than one donor with inadequate immunosuppression may become highly sensitized from rejection, and this may preclude them from future successful islet, pancreas or renal transplantation. Campbell et al. from Edmonton demonstrated that the presence of preformed HLA antibodies are linked to worse islet transplant survival, emphasizing the need for detailed high-resolution, standardized HLA antibody screening and prospective cross-matching where indicated, before proceeding with transplantation [88]. We have previously reported high rates of broad HLA sensitization with high panel reactive antibody (PRA) in subjects that became C-peptide negative with failed islet transplants, but this sub-group represents only a small fraction of the total numbers of subjects treated, with an overall risk of 16% [89]. Complete withdrawal from immunosuppression may have been the inciting factor, and the possibility that sensitization could be prevented by continuation of low-dose maintenance monotherapy remains in question. Interestingly, the more potent alemtuzumab tacrolimus and mycophenolate mofetil protocol has been associated with exceedingly low rates of PRA sensitization (unpublished data, Shapiro Edmonton). The Geneva-GRAGIL network have reported low rates of HLA sensitization (10.8% risk) in IAK recipients, despite the use of multiple donors, in rates equivalent to kidney transplantation alone [250]. Review of the CITR database for risk of HLA Class I sensitization suggests that a post-transplant rise in PRA by $\geq$20% is associated with a 3.6-fold risk of graft failure [251]. Rickels et al. have made clear recommendations to minimize risk of sensitization, including avoidance of multiple islet transplants, waiting for negative cytotoxic cross-match by high resolution techniques before proceeding, and avoiding donor-recipient antigen mismatches where there is an identifiable alloantibody present prior to transplant [252].

Long-term outcomes

Current detailed data accrued in 570 patients in the most recent CIT registry, and from a series of recent presentations from the leading islet transplant centers indicate substantial improvement in 5-year insulin independence rates [172,239]. The original Edmonton Protocol series reported on inexorable loss of insulin independence by five years post-transplant, with only 15% of patients remaining completely free of insulin (Figure 108.4A) [2,7,145,146]. Although the Edmonton longer-term results fell short of their target, profound stabilization in glycemic control was sustained in 73% of subject followed beyond ten years with correction of HbA1C to less than 6.5% with complete protection from recurrent hypoglycemia. Similar results have been reflected in the CITR database [253]. This remarkable stabilization in glycemic control is rarely if ever achieved by insulin pumps and CGMS monitoring, but requires life-long immunosuppression to sustain, and have met with mixed opinions [254–259]. Explanations for deteriorating insulin reserve have been varied, but are clearly multifactorial. Recurrent autoimmunity, rejection, and inhibition of beta cell proliferative capacity are likely the dominant culprits, adding additional stress to an injured, inflamed and under-dosed initial islet engraftment mass (Figure 108.4B) [124,260–264]. Metabolic overstimulation of a marginal islet transplant mass can trigger endoplasmic reticulum linked islet cell apoptosis and with amyloid protein deposition likely deleterious to islet functional survival [265–268]. Over 80 clinical trials are currently registered with ClinicalTrials.gov that will address many of these opportunities, with the goal being to restore a full, physiological initial islet engraftment mass in a non-injured and non-inflamed state as an essential starting point for future tolerance trials that will obviate a need for a lifetime of immunosuppression.

Currently, at least five independent islet transplant centers are reporting 50–70% insulin independence at five years post-transplant (Edmonton, Minnesota, Geneva-GRAGIL and Lille) using different induction and maintenance strategies (International Islet and Pancreas Transplant Association meeting, Prague, 2011) [4,172–174,269,270]. The results for islet-alone transplantation represent a substantial advance, and outcomes now approximate results of whole pancreas transplant alone (PTA) at five years, according to the International Pancreas Transplant Registry [71,172]. The implications of this equivalency in outcome will take time to resound amongst both patients and transplant communities. The attraction of a simple, percutaneous cellular implant for islet transplantation with avoidance of major surgery and life-threatening complications must to be offset by a current need for more than one islet donor, an 50% failure rate during islet processing, and the fact that islet transplantation, although desirable, is restricted to limited centers with cGMP islet manufacturing skills, and probably more importantly is not universally reimbursable at present. Recent impressive data from the San Francisco group indicate an 82% processing success rate in 45 pancreas organs from donors under age 50 and

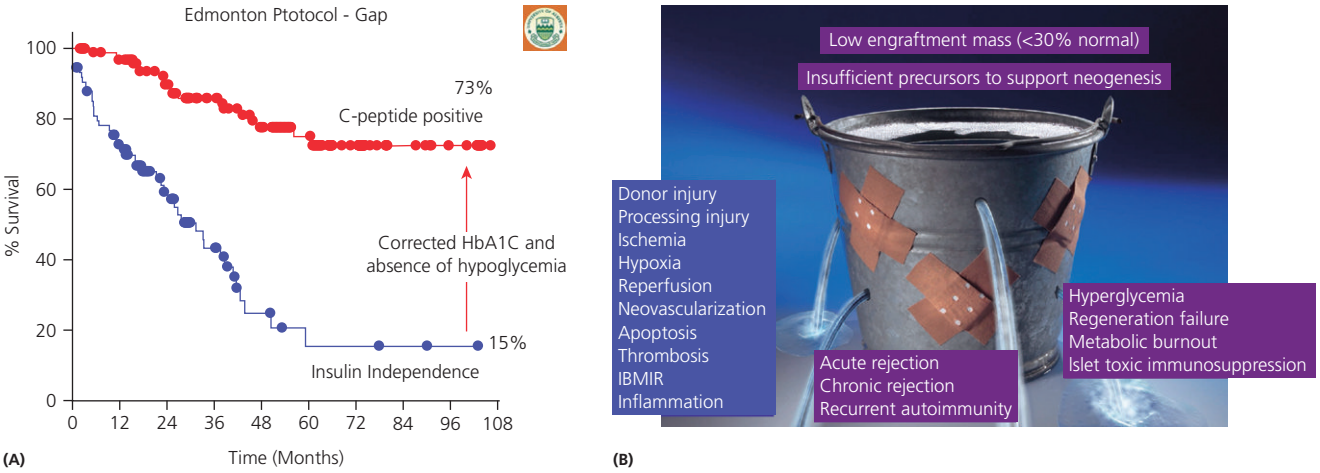

Figure 108.4. (A) Inexorable loss of insulin independence at 5 years in the original Edmonton Protocol, but with maintenance of regulated C-peptide secretion, correction of HbA1C and prevention of hypoglycemic episodes in 73% of cases. Data from [2,7,145,146].
(B) Possible multifactorial explanations for the gradual loss of insulin independence in these patients. A limited initial islet engraftment mass, failure of regeneration, and especially recurrent autoimmunity represent the dominant challenges that must be overcome in future islet transplant trials. Background image; www.tsamedien.de.

mean BMI of 34, with a mean islet isolation mass of 630 000 IEQ (Gregory Szot, personal communication). If this level of islet isolation success can be transferred to other centers, this will have major bearing on pancreas allocation paradigms with younger, more optimal donors.

CIT consortium trials, and other government funding

The CIT consortium is a $75 million initiative begun in 2004, funded jointly by the National Institute of Allergy and Infectious Diseases (NIAID) and the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) from the National Institutes of Health (NIH) designed to advance clinical islet transplantation [5,271]. A total of ten islet manufacturing sites and 12 clinical centers are active participants, including centers in the US, Canada and Sweden. The major goals of the consortium have been to develop two Phase III registration trials (CIT-07, islet alone IAT, and CIT-06, IAK) that will be used by the FDA to justify a Biologic License Application (BLA) and subsequent third-part, Medicaid and Medicare reimbursement for islet transplantation in the US [5]. This will be a critical step, as it will free up limited research funding to focus on the detailed refinements needed to take islet transplantation to the next stage, without having to fund the routine, clinical and manufacturing components of the treatment. A BLA requires submission to the FDA of complete, standardized details of the islet manufacture process, together with a comprehensive account of the medical effects of the biologic product. To this end, the CIT consortium group has developed standardized procedures for islet manufacture, clinical patient care, and rigorous end-point definitions for impact and risk in the two different ITA and IAK populations [5]. It is anticipated that the CIT-07 subjects reach their primary one-year end-point of correction of HbA1C and protection from hypoglycemia by late 2012, with follow-up completed in 2013, with submission of a final study report in 2014–2015. This final study report will form the basis for the BLAs.

Other CIT center Phase I/II trials are currently investigating approaches to improve islet engraftment by inhibition of the instant blood mediated inflammatory reaction (IBMIR), safer, CNI-free immunosuppression using costimulation blockade with belatacept, deoxyspergualin, or with combined B cell and T depletional therapy, or exenatide (GLP-1) therapy [5].

Table 108.2. National reimbursement for islet transplant

Country	Agency	Year
Canada	Provincial Reimbursement Government of Alberta	2001
UK	National Institute of Clinical Excellence (NICE)	2008
Australia	Government of Australia Juvenile Diabetes Research Foundation (joint funding)	2011
Switzerland	Swiss Government GRAGIL Consortium	2000
Nordic Network	Government of Sweden	2008
USA	FDA Biological License Application (BLA)	pending 2014–2015

Several other countries have successfully engaged government support, most notably in Canada (Provincial funding through the Government of Alberta), the UK (through the National Institute for Health and Clinical Excellence — NICE), Switzerland, and in Australia, with joint partnership between the Government of Australia and the Juvenile Diabetes Research Foundation (JDRF) (Table 108.2).

Islet-alone versus islet-after-kidney transplantation — similar outcomes

In contrast to whole pancreas transplantation where only 18% of transplants are carried out as PTA, 84% of islet transplants have been ITA in the past decade, with only 16% carried out as IAK [71,73,239]. This reflects a general perception that T1DM with end-stage renal failure is best managed surgically with a combined or sequential solid organ transplant, whereas T1DM patients with brittle control and good renal function are better served with an islet approach, as outcomes have been less stellar, and risk higher with PTA than with SPK transplantation [71,77,272]. Simultaneous islet-kidney (SIK) transplantation has been carried out successfully

in a limited number of cases, but requires considerable logistics to achieve this with the same cadaveric donor, and with a potential 50% islet isolation failure has not been popular [186,273,274].

Further consideration of IAK transplantation seems appropriate, as the prior kidney transplant takes the risk-benefit balance of immunosuppression out of the equation. IAK transplantation is a major parallel current focus of the CIT consortium BLA trials in CIT-06 [5]. In the early days, there was concern that an islet transplant would increase the immunological risk to the transplanted kidney through donor sensitization, but this has not been the case in the current era, and indeed the presence of functioning islets has been protective to the kidney [250,273,275–278].

Islet transplantation and impact on secondary diabetic complications

Compelling data has been accrued in whole pancreas transplantation clearly demonstrating that near-perfect glycemic control has major protective benefit in stabilizing and reversing coronary artery disease, intimal carotid thickness, diabetic glomerulopathy, neuropathy, retinopathy and other secondary complications of T1DM, and can decrease cardiovascular mortality [279–291]. Equally compelling data is beginning to emerge in clinical islet transplantation to suggest a similar protective impact of sustained euglycemia in stabilization and reversal of secondary diabetic complications. The Milan group has demonstrated consistently that clinical islet transplantation with positive c-peptide can stabilize both macro and microangiopathic changes in T1DM, irrespective of insulin independence status [263,277,292–296]. Thompson et al. from the Vancouver group conducted a prospective, cohort crossover study comparing the intervention of islet transplantation against optimal medical therapy [297]. There was a reduced progression of retinopathy in the islet transplant group, and a trend towards improvement in nerve conduction velocity [298]. Furthermore, despite the addition of CNI immunosuppression, there was a reduced decline in glomerular filtration rate in the islet transplant group compared to medical therapy [297]. Further large-scale randomized control trial data without cross-over will be needed to further corroborate these important positive findings, but may be difficult to fund and implement.

Single-donor islet transplantation

The use of multiple donor islet preparations in the 2000 Edmonton Protocol series (median 2, range 2–4) provided an adequate engraftment mass to sustain short-term (1–3 year) insulin independence, but raised concerns about the practicality of this approach as well as potential risk for HLA sensitization [1,88,89]. The concept that a single pancreas could provide sufficient islets to treat multiple recipients was first demonstrated in rats by Payne et al., and subsequently in large animal canine islet autografts by Griffin et al. [299,300]. While such an approach would have major bearing on islet supply and impact in the broader treatment of T1DM, it has yet to be demonstrated clinically. Perhaps the closest demonstration has been a successful living donor islet allotransplant in a mother to daughter transplant in Japan, where the T1DM recipient was rendered insulin independent using only a distal 50% pancreatectomy [301].

The Minnesota series therefore represented a substantial advance, as high rates of single-donor engraftment were consistently achieved when a non-Fc-binding anti-CD3 antibody was used for induction, together with optimized gradients for islet purification using Opti-prep, islet culture in the presence of insulin-like growth factor I, transplantation under the cover of etanercept anti-TNF alpha blockade, and peritransplant insulin and heparin [4]. Unraveling the secrets of consistent single donor success has been complicated by potential bias in donor and recipient selection for factors possibly favoring high islet potency, yield, insulin requirement and resistance in recipients, but clearly this is a highly desirable outcome [302]. Several other centers and approaches have reported variable rates of single donor engraftment success (Table 108.3). Markmann et al. similarly achieved single donor islet engraftment success in 5 of 7 cases with an Edmonton-like approach using higher BMI donors [303]. We confirmed the utility of Hering's approach with intensive peritransplant insulin and heparin as an adjunctive engraftment-promoting strategy, and found that our single donor insulin independence rate rose from 10% to 40% with this approach, as an encouraging clinical demonstration of the IBMIR effect [116,304,305]. The Emory and San Francisco groups both described high rates of single donor islet engraftment in the presence of efalizumab (anti-LFA1) in a CNI-free strategy, but no longer clinically available (discussed earlier) [230,306,307]. Until we have precision islet potency assay that is universally applied across trial sites, it will be difficult to define which specific components of which protocols contribute most to single donor engraftment success. Efforts by the CIT consortium to incorporate islet oxygen consumption rates, glucose-dependent oxygen consumption rates and laser-scanning cytometry for mitochondrial and beta cell viability, will help to provide comparative data, as well as predictive potency assays that the FDA requires for quality control testing of the manufactured islet product [308–310].

Table 108.3. Single donor islet protocols

Author	Center	Approach	Year [Reference]

GLP-1 analogues in clinical trial

The use of a short-acting GLP-1 analogue exenatide has been evaluated extensively by the Miami, Vancouver and University of Illinois groups as a means to facilitate both single donor and supplemental islet engraftment [311–317]. While exenatide clearly has both positive direct and indirect effects on islet function, therapy is needed continually to sustain marginal mass graft function. Up to 30% of patients cannot tolerate exenatide because of severe nausea. An alternate, long-acting GLP-1 analogue, liraglutide, has been associated with much lower rates of nausea and clinical intolerance. Merani et al. found that liraglutide improves marginal mass human islet engraftment in mice, and protects against immunosuppressant

beta cell toxicity in vitro and in vivo [165]. When tested in a rapidly growing large animal pig islet autotransplant model, the presence of liraglutide helped to resist metabolic graft failure over time [318]. When added to the islet culture media, liraglutide significantly improved human islet survival, reduced apoptosis, and facilitated marginal mass engraftment in mice [319]. Based on this data, Novo Nordisk is currently conducting a major international trial at 16 sites (Shapiro, principal investigator), for a randomized placebo-controlled comparison of outcome of liraglutide in clinical islet transplantation [320].

Alternative strategies in current clinical trials

Control of IBMIR

The Swedish group has had a longstanding interest in innate IBMIR-islet injury triggered in minutes following intraportal islet transplantation through the increased expression of tissue factor, platelet aggregation and inflammation [304,321]. High circulating levels of thrombin-anti-thrombin complex and C-peptide released from dying islets confirm that this is a clear clinical entity, and the detectable loss of labeled human islets by positron emission tomography imaging in patients undergoing intraportal islet transplantation confirm that this is a major for islet protection in the peritransplant period [322,323]. Peritransplant insulin and heparin can partially modify this response and increase single donor engraftment rates [116]. The surface binding of heparin to islets is one effective approach tested in pig islet transplant models, and awaits further evaluation in the clinic [305]. Furthermore, anchoring of surface-immobilized vascular endothelial growth factor on the islet surface similar to heparin can potentially stimulate islet angiogenesis [324]. Several strategies will likely be further tested clinically, including low molecular weight dextran, direct thrombin inhibitors (e.g. hirudin, desirudin, melagatran, dabigatran) and other high-specificity inhibitors of the extrinsic coagulation pathway. Balancing a positive impact on islet survival while avoiding excessive risk of bleeding with these approaches will be critical.

Control of apoptosis

Our basic laboratory has focused on temporary inhibition of islet apoptosis since our initial studies demonstrated the damaging effect of this pathway in human islets. Emamaullee et al. demonstrated that ex vivo viral transduction of islets with x-linked inhibitors of apoptosis proteins (XIAP) led to substantial improvement in marginal mass islet graft survival [325–327]. A fluoromethylketone (FMK) agent called ZVAD-FMK was also highly effective, but too toxic for potential clinical application [328]. Nakano et al. demonstrated that a FMK-derivative caspase-3 inhibitor was protective of human islets in culture, but the lack of pan-caspase inhibition may have lowered the potency of this approach [329]. We further explored a potent pan-caspase inhibitor called EP1013, and found that just 10–30% of the usual marginal islet mass was required to reverse diabetes in mice with mouse or human islets, and furthermore this strategy was highly effective as a facilitator in costimulation-blockade induced tolerance induction in mice [330,331]. EP1013 lost patent and status, and is no longer available for trials. We therefore tested a similar pan-caspase (IDN-6556, Conatus Pharmaceuticals Inc., San Diego) inhibitor in mice, with human islets and subsequently in a large animal marginal mass pig autograft model, all with similar compelling data [332]. This agent is now undergoing preliminary Phase I/II safety and efficacy studies in clinical islet transplant patients in Edmonton. While there are potential theoretical concerns relating to malignant transformation when apoptosis is inhibited especially in combination with potent immunosuppression, short-term (two-week) temporary therapy should hopefully offset this risk.

Immunological tolerance

Complete restoration of self-tolerance with elimination of autoreactive T cell clones active in T1DM, together with means to permanently eliminate alloreactivity, would be the key transformative step that could move islet transplantation from the status of treatment to cure. Achieving dual tolerance to these separate but interlinked pathways of attack has been phenomenally difficult to translate to the clinic, although such tolerance can be attained routinely in mice, and occasionally in large animal non-autoimmune primate transplant models [3]. Chapters 11 and 76 address the mecanisms of tolerance and specifics related to its clinical translation respectively and in detail, and will not be reiterated here. Costimulation blockade was a promising approach to induce peripheral tolerance induction in mice, but due to different maturity, exposure, avidity binding, receptor expression and the confounding effects of heterologous immunity, costimulation (using either CTLA4-Ig or belatacept) has failed to induce clinical tolerance when used as a sole strategy [333–340]. The more potent strategy of anti-CD40L (Hu5c8) met with considerable excitement in primate renal transplantation, failed to yield similar result in the clinic, but furthermore led to fatal thromboembolic events in patients [341]. An alternative chimeric anti-human CD40 antibody lacks thromboembolic risk, and also has potent immunosuppressive properties [342]. Adams *et al* demonstrated marked synergy of anti-CD40 with belatacept in a cynomolgus monkey islet allograft model, an approach that could potentially be translated to the clinic [343].

While costimulation blockade has not at this point shown clinical tolerogenic effects, myeloablative and non-myeloablative conditioning approaches with HLA-matched allogeneic bone marrow infusion have certain shown tolerance and promise in combined kidney and bone marrow transplantation in patients with hematological malignancies, provided potent conditioning strategies (usually involving total lymphoid irradiation) are given [344–350]. Translation of similar strategies to islet transplantation will likely occur over time, as further knowledge on bone marrow enrichment, dosing and conditioning are more fully developed. A recent collaborative study of the Fuzhou and Miami groups from The Cure Alliance (www.thecurealliance.org) and the Diabetes Research Institute (DRI) Federation have evaluated the potential of autologous mesenchymal stem cells (MSC) as an inductive strategy in clinical living-related renal transplantation [351]. A total of 159 patients were randomized to receive autologous MSC's dosed at 1–2 $\times$ 10^6/kg, with standard or low dose CNI maintenance, and were compared with control subjects receiving standard anti-IL2R plus CNI. The salient findings were a lowered the risk of rejection, decreased risk of opportunistic infection and improved renal transplant survival [351]. Similar approaches combined with T depletion have demonstrated remarkable regenerative potential in new onset T1DM with insulin independence (vide supra) and if combined with this approach could provide the missing link for both elimination of autoreactivity and control of alloimmunity. Peripheral infusion of regulatory T cells, alone or in combination with MSC's could further facilitate such an approach.

In addition, a recent collaborative study between Ildstad group in Louisville and the Leventhal group in Chicago reported successful establishment of durable chimerism and donor-specific tolerance in renal transplant recipients, using a non-myeloablative conditioning of the recipients [352]. Should this approach be confirmed also in autoimmune conditions it could become transformational not only for solid organ and islet cell transplantation, but also for restoration of self-tolerance in intervention trials for patients with T1D.

Summary

This chapter has thoroughly reviewed the current risks and status of T1DM, and the alternative strategies currently being developed to further improve glycemic control. Islet transplantation offers the potential to restore euglycemia, completely protect against hypoglycemia and lability in a way that exogenous insulin is unable to do, and with far less risk than whole pancreas transplantation. Remarkable strides have occurred since the Edmonton Protocol was introduced in 2000, and currently over 1000 patients have undergoing islet auto or allotransplantation in up to 40 international sites. While the initial five year results showed a sharp loss of insulin independence but continued protective reserve, recent reports from five independent clinical islet centers, the CITR registry and most notably the Minnesota center, are reporting insulin independence rates exceeding 50%, which now match the registry results for whole pancreas transplantation. Steady progress has occurred in single donor islet transplantation, and will likely accelerate with a series of current exciting clinical trials. A BLA for islet manufacture in 2014–2015 will have major impact on reimbursement and activity for centers in the US, as trials currently move forward within the CIT consortium. Parallel clinical trials aimed at restoration of self-tolerance and regulatory T cell or MSC infusion trials will take us several steps closer from refined treatment to robust cure for T1DM.

CHAPTER 109

Long-term Outcomes after Intestinal and Multi-visceral Transplantation

Introduction

Intestinal transplantation is a life-saving procedure for patients with complicated intestinal failure. Although its results lag behind those of most other solid organs, its potential for sustained success is manifest by the existence of several patients alive more than 20 years after transplantation who are nutritionally independent, with restored health and social life. The primary problems impeding ideal outcome after intestinal transplantation are related to a comparatively unrelenting risk of graft loss or mortality due to rejection, disease recurrence or infection. These likely relate to the complex interplay between the gut barrier and immune function of the donor organ with the alloimmune response of the recipient. Inclusion of the liver and other components of a multivisceral graft appear to mitigate this somewhat, but the inclusion of an intestinal allograft continues to place an additional immune burden in play for the patient and physician. This chapter will review the long-term outcomes of intestinal transplantation, highlighting the known factors of influence.

Long-term graft and patient survival

Although progress in intestinal transplantation is continuously being made and outcomes have improved, long-term results still lag behind the results that have been achieved in kidney, liver and heart transplantation; they resemble the results of lung transplantation. According to the Intestinal Transplant Registry, as of the 12th International Small Bowel Transplantation Symposium (2011), 2611 intestinal transplants had been performed worldwide, more than half (55%) in children (covered explicitly in Chapter 117). Five-year patient survival is only about 50%, with some improvement for patients who received a transplant after the year 2000. With time, the survival rate shows continuous decline: 35% of the patients are alive at ten years, with no difference between children and adults. Composite grafts (multivisceral and composite liver-intestinal grafts) have better long-term outcomes than isolated intestinal grafts (55% and 65% versus 45% at 5-years post-transplant, respectively). Risk factors included age <1 year of age at the time of transplantation, lack of induction immunosuppression and the patient's condition at the time of transplant, with location of the patient in the hospital — particularly ICU — being a foreboding indicator. Improved outcomes are noted for patients who are at home at the time of transplant and being transplanted in a center with high volumes. Receiving a liver as part of a composite graft is associated with improved survival in all eras with a hazard ratio of 0.68 ($P = 0$) [1,2].

Similar results were found when analyzing the outcomes of adult recipients who survived >5 years after intestinal transplantation at our center [3]. From 1994–2010, 115 adult patients received 126 transplants, with 79 patients transplanted during 1994–2005. Thirty-six patients (42%) survived longer than 5 years. Median follow-up period was 9.2 ± 3.2 years. All survivors were off parenteral nutrition (PN). There was no difference between long-term survivors and non-survivors in regards to induction immunosuppression, donor age, donor/recipient HLA matching (number of loci) or cross matching (negative/positive). However, patients receiving a liver-containing graft (liver-intestine or multivisceral) had significantly improved survival rates 5 years post-transplant versus patients who received non-liver containing grafts (modified multivisceral and isolated intestine) (Figure 109.1). Additionally, there was a significant difference in pretransplant condition: 52% of long-term survivors were at home at the time of transplant versus 78% of non-survivors ($P = 0.015$) [3] (Figure 109.2). It appears that pretransplant condition not only affects short-term outcomes but is a contributing factor in long-term outcomes as well.

In a recent presentation before the American Surgical Association, investigators from the University of Pittsburgh, site of the oldest and largest single-center series worldwide, reported 5-year patient and graft survival of 60% and 50% respectively. Conditional patient survival beyond 5 years was 75% and 61% at 10 and 15 years respectively. Corresponding graft survival was 59% and 50% [4]. Leading causes of death were rejection, infection and renal failure. The latter was more common among adults than children. Leading cause of graft loss was rejection.

The study firmly corroborated previous standing observations:

- The vast majority of the long-term survivors (92%) achieved nutritional independence with regular diet.
- The vast majority of the long-term survivors (92%) had intact graft function quantified with physiologic and anthropometric measures.
- Quality of life is significantly better in patients who had transplants versus patients on parenteral nutrition.

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

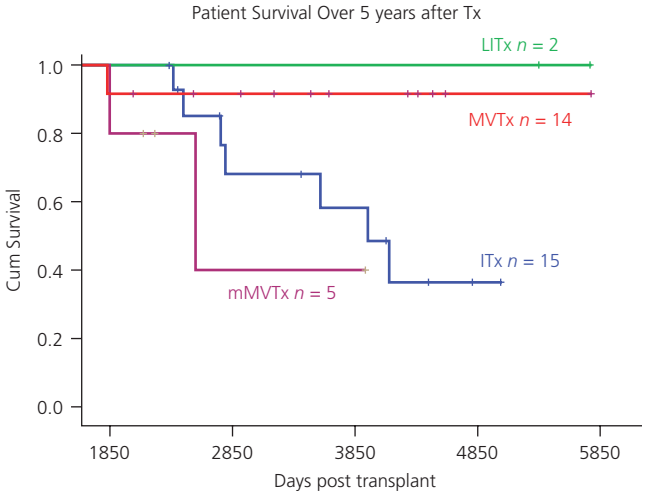

Figure 109.1. Long term survival for patients who served at least 5 years from the University of Miami Miller School of Medicine showing the attrition of survival by organ type. Shown are progressively worsening results for patients who received a liver/intestine transplant (LITX), multivisceral transplant (MVTX), intestinal transplant alone (ITX), and modified multivisceral transplant (mMVTX).

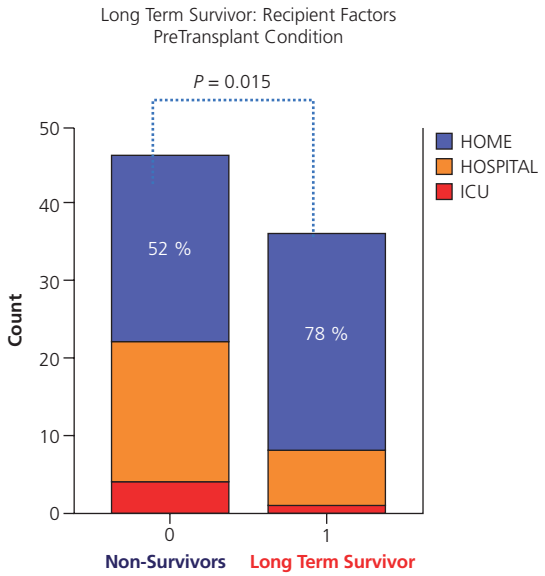

Figure 109.2. Characteristics of patients who are long-term survivors following intestinal transplantation stratified by pretransplant location. Long-term survival is associated with patients who were healthy enough to be at home when called in for transplantation.

- There was a high incidence (greater in children) of long-term neuropsychiatric and behavioral disorders such as depression, anxiety and impaired cognitive functions.
- Paradoxically, in spite of the high incidence of these disorders, these patients have an extraordinary ability for social adjustment. The majority of the children attend school and the majority of the adults maintain their families and have a productive occupation.

The study showed for the first time that the most important risk factor for long-term survival is the lack of social support, testament to the rigors of coping with the myriad complications of this procedure and its associated therapies. The non-inclusion of the liver in the graft emerged as a second-most significant risk factor for long-term survival. Other predictors included early rejection, recipient age and sex, type of immunosuppression, splenectomy and HLA mismatch.

Chronic renal failure is a common complication after intestinal transplantation with an overall reported incidence of 21.3% at 5 years. The requirement for renal replacement treatment in long-term survivors is also significant and reported to range from 5–9%. Renal failure may be a fatal complication after intestinal transplantation because lack of venous access can be prohibitive for dialysis or even kidney transplantation. Similarly, there is an increased incidence of malignancies, mainly of lymphoid origin post-transplant lymphoproliferative disorder (PTLD). Other, common malignancies (skin, colon, etc.) seem to be more frequent in other solid organ transplantation.

Clearly the leading cause of death for long-term survivors, rejection, should be preventable or treatable. The diagnosis is usually based on biopsies (see Chapter 86) following clinical signs of rejection (abdominal distention, diarrhea or ileus, bloody enteric output). Specific details of the clinical presentation and management of intestinal rejection can be found in Chapter 74. Most of these patients live far from the transplant centers. With the stoma closed, there is no easy access for endoscopy.

We have shown that decreasing serum citrulline levels may be useful for diagnosis. They stabilize at 3 months post-transplant. A decrease from baseline of more than 25% or an absolute value of less than 13–15 m/L in the absence of concurring serious infections are both strong indicators of rejection [5]. Additional research is being carried out at our center and others to create a panel of non-invasive markers of rejection.

There is also increasing evidence suggesting that panel reactive antibody and disease- susceptible antigen levels correlate with the development, severity and response to treatment of acute rejection [6]. Their role in the long-term prognosis is uncertain and currently also the target of scrutiny.

Pediatric growth and development

Children receiving an intestinal transplant despite being weaned off parenteral nutrition, often require prolonged enteral nutrition for catch-up growth beyond the first 2–5 years post-transplant [7–10]. This is likely due to long-standing food aversion and anorexia in some cases.

In a report by investigators from Paris, data on 31 pediatric patients free from PN showed that 84% of children remained PN free, while 45% continued to require enteral nutrition [10]; persistent fat malabsorption made higher energy intake by means of enteral supplementation necessary in order to attain normal growth [10].

Intensive nutritional support that provides 20–30% more calories than the recommendation (by age) will be the key for suitable growth [11].

Patient function, quality of life and graft failure

Rejection is the most common cause of graft loss in intestinal transplantation. Early detection of rejection requires judicious implementation of screening protocols including endoscopy and a few available, yet non-specific, biomarkers (citrulline, calprotectin).

Acute rejection

After intestinal transplant, late-onset acute rejection continues to be an issue in late survivors. One large single-center review, including 36 adult survivors >5 years after intestinal transplant, reported incidence of late acute rejection at 14%. All of these patients had received an isolated intestinal graft and were treated with thymoglobulin [3].

Late acute rejection is commonly associated with non-compliance or follows an episode of gastroenteritis [12,13]. Although late acute rejection is rare, it is often severe, leading to graft loss.

Chronic rejection

Early, recurrent and/or severe episodes of acute rejection predispose a patient to chronic rejection. In addition, recipients of isolated intestinal transplants are at an increased risk for chronic rejection as compared to recipients of liver-containing grafts. A full-thickness biopsy is required for accurate diagnosis of chronic rejection and as such, its clinical diagnosis is often made based only on clinical signs, with the diagnosis confirmed at time of retransplant enterectomy, or sadly, at autopsy. The reported incidence of chronic rejection by many centers is around 15% [12–14]. There is currently no treatment for chronic rejection other than retransplantation.

Retransplantation

Graft failure, defined as a necessity for graft removal, often leads to retransplantation. Reports in the Intestinal Transplant Registry [1,2] showed very poor results for early recipients of intestinal retransplantation. More recently, better outcomes have been reported, with a patient survival of 71% [15]. Similar results were reported in 500 adult and pediatric recipients [16].

Infection

Infection is the most common complication in intestinal transplant recipients and the leading cause of death [1]. Infections are more common early after transplant with 50% occurring within the first 3 months, 25% during months 3–12, and only 25% after 12 months post-transplant [17]. However, even after the early post-transplant period infections account for 60% overall mortality [1]. Late-onset infectious enteritis poses a difficult challenge because presentation resembles acute rejection at a time when stomas are usually closed and immediate access to endoscopy is not available. This becomes even more critical since infectious enteritis can trigger development of rejection [18–20].

Neoplastic disorders

De novo malignancies occur in a significant number of intestinal transplant patients, with a reported incidence of 15% [21]. Of these, 13% were PTLD, and only 3.2% non-lymphoid cancers. PTLD is covered in depth in Chapter 96. Given the higher level of immunosuppression needed to maintain an intestinal transplant free of rejection, and given the large amount of lymphoid tissue present in an intestinal graft, the risk of PTLD is highest in intestinal transplant recipients when compared to other solid organ transplants (SOT). The majority of cases of PTLD are Epstein-Barr virus (EBV) driven with abnormal B cell lymphoproliferation but T cell, Burkitt's lymphoma and EBV negative subtypes have also been described [22]. The most common site of PTLD involvement is the intestinal graft. Overall cumulative risk was 8% at 6 months, 11% at 1 year, 16% at 5 years and 27% at 10 years post-transplant [21]. Primary immunosuppression, recipient age, splenectomy and treatment of rejection were identified as significant risk factors for the development of PTLD. Pediatric recipients are at a higher risk for developing PTLD since the majority of children are EBV-naïve at time of transplant, though the incidence of PTLD has decreased to 7% in most recent cohorts [21]. Management of PTLD has also improved due to early detection by means of blood EBV quantitative polymerase-chain-reaction assay and the use of rituximab [23].

The cumulative risk of non-lymphoid cancer is 4% at 5 years and 10% at 10 years with adults being more commonly affected [21]. Non-lymphoid cancers most commonly included non-melanotic skin cancer. Other malignancies have been described including lung, testicular, breast, uterine, colorectal, vulvar and prostate. Lastly, after intestinal transplant for Gardner's syndrome, desmoid tumors can recur, likely related to immunosuppression.

Graft-versus-host disease

The abundance of donor-derived lymphoid tissue in intestinal grafts accounts for a higher incidence of graft-versus-host disease (GVHD) in intestinal transplant recipients compared to other SOT. Incidence of 5–10% has been reported in intestinal transplant patients as compared to 1–2% of other SOT recipients [24,25]. Mortality is quite high after development of GVHD, especially if the patient fails initial steroid therapy [26]. Most of the deaths are due to ensuing infection and multi-organ failure. Aggressive, proactive monitoring of donor chimerism levels in the peripheral blood of intestinal recipients may allow for an earlier diagnosis just as symptoms arise and prove to be an important longitudinal tool in determining treatment success.

Renal dysfunction

Several studies have shown that intestinal transplant patients appear to have the highest risk of chronic renal failure compared to all other SOT recipients. Ojo et al. [27] were the first to demonstrate this, reporting a 21.3% risk at 5 years post-transplant. These patients tend to have multiple episodes of dehydration before transplant as well as after transplant, and calcineurin inhibitors and episodes of dehydration contribute heavily to the development or worsening of nephrotoxicity.Predictors of eventual renal dysfunction include preoperative eGFR <75%, preoperative ICU location and high-dose FK- immunotherapy. GFR <75% post-transplant was a predictor of poor patient survival [28]. Researchers from the Thomas E. Starzl Institute in Pittsburgh reported that 9% of long-term survivors >5 years post-transplant required renal transplant [4].

Summary

Intestinal transplantation remains a challenging procedure the results of which lag behind most other transplanted organs. While the types of allospecific and protective immune complications are similar in type as those seen across the spectrum of SOT, their magnitude and frequency remains high, and their occurrence persistent. Appropriate patient selection, with particular attention toward family social support and patient cognizance of the risks, is critical for optimal outcomes. Regardless of the challenges, intestinal transplantation remains the best available option for patients in selected circumstances.

CHAPTER 110

Long-term Outcomes after Vascularized Composite Allograft Transplantation

Alessandrina M. Freitas[1] and Linda C. Cendales[2]

[1] Department of Surgery, Emory University School of Medicine and Vascularized Composite Allotransplantation; Emory Transplant Center, Atlanta, GA, USA
[2] Division of Plastic and Reconstructive Surgery and Division of Transplantation; Vascularized Composite Transplantation, Duke University, Durham, NC, USA

Introduction

Vascularized composite allotransplantation (VCA) is a developing field for the reconstruction of multi-tissue defects unable to be ameliorated with autologous tissue. Thus far, these transplants have been used to provide form and function to over 90 patients worldwide. The most common VCAs reported to the international registry include transplantation of the hand(s) and/or digit(s) (54 patients), larynx (16 patients), abdominal wall (9 patients), and face (7 patientss). Other transplants, including knee, uterus, femoral diaphysis, and lower limb have also been reported [1].

VCA is possible today due to advancements in microsurgery and transplantation. The technical aspects of VCA are essentially those of free tissue transfers, techniques that have been extensively used in reconstructive surgery for several decades. Advancements in immunosuppression, after the introduction of cyclosporine, are now being applied to VCA. Similar to other organ transplants, today, the individual immunosuppressive regimens vary amongst the centers performing VCA. However, most patients are currently maintained on multi-drug regimens typically inclusive of tacrolimus, mycophenolate mofetil, and steroids. Considering that VCA is a quality of life (QoL) transplant, a barrier for its more widespread application is the side effects and toxicities related to these conventional immunosuppressive agents.

Acute and chronic rejection in VCA

At the time this chapter is written, acute rejection episodes have been observed in up to 85% of VCA recipients within the first year [2]. There are several theories as to why the incidence of rejection episodes is higher than in solid organ transplantation. First, the dermis and epidermis are rich in dendritic cells, imparting a high degree of immunogenicity to the skin. Secondly, the number of acute rejection episodes diagnosed may partially reflect the fact that we are constantly able to observe the transplanted skin and this may result in detection of rejection episodes that in a solid organ transplant might go unnoticed. Third, the number of tolerance trials in VCA may condition for sub-therapeutic levels of immunosuppression. Finally, VCAs are in constant contact with the environment and the skin can show changes due to environment exposure (temperature, sun exposure, allergens) that may grossly be mistaken for rejection.

In 2005, in an effort to standardize reporting, facilitate prospective data collection and collaboration amongst the various centers performing VCAs, and advance the understanding of VCA pathology, an international consensus group developed the Banff working group. This was published the 2007 working classification of skin-containing composite allograft pathology [3], and now serves as the basis for ongoing reporting of rejection-related histology in VCA.

Chronic rejection and antibody-mediated rejection (AMR) has been reported in VCA and the numbers will likely increase as the case volume and graft survival times accumulate. Possible features of chronic injury in VCA proposed by the Banff 2007 consensus include vascular narrowing, adnexal loss, atrophic changes to skin and muscle, deep tissue fibrosis, nail changes, and myointimal proliferation [3]. To date, there is one report of suspected chronic rejection in VCA in the western countries. This patient, who underwent transplantation in Louisville under the immunosuppression regimen of alemtuzumab induction and mycophenolate mofetil/tacrolimus maintenance therapy, experienced severe graft ischemia necessitating amputation of his transplanted hand at nine months. Examination revealed severe intimal hyperplasia confined to the arteries of donor origin as the cause of graft ischemia. At the time of graft loss, superficial punch biopsies did not show histologic rejection, although deeper tissues contained cellular infiltrates. Class I and II donor-specific antibodies, not detected previously, became positive following immunosuppression cessation and graft excision [4]. Additional information on the clinical features of VCA rejection can be found in Chapter 75, and a more comprehensive treatment of the histopathological presentation of rejection can be found in Chapter 85.

Complications in VCA

Immunosuppression complications

Complications related to immunosuppression include metabolic disturbances, malignancy, and opportunistic infections [5]. Other chapters in this text review the incidence of immunosuppression complications in various solid organ transplants. Reports specific to immunosuppression-related and psychosocial complications in VCA recipients are common and are reviewed in this chapter. VCAs are considered QoL transplants and as such, the risk benefit ratio

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

(potential risks: improvement of life) necessitates close examination of additional factors compared to a life-saving transplant.

This chapter will aim to focus on the long-term outcomes of VCA, which to date have been largely undefined. We will define long-term as the period beyond one year post-transplant. As with most emerging fields, quantifying the outcomes of VCA is challenged by the relatively small number of transplants performed to date and, consequently, the very small number of patients available for long-term follow-up. Additionally, the follow-up methods differ greatly amongst the centers performing these transplants, which further hinder the ability to collect unifying data. We must look to the experience of solid organ transplantation for guidance in monitoring long-term outcomes and gathering objective data that can be compared across multiple centers. Renal transplants are commonly monitored by serial serum creatinine, graft failure signified by the need for return to dialysis, and death with and without functioning allografts. Similarly, cardiac and pulmonary transplants are followed functionally by ejection fraction and pulmonary function testing, respectively. As the field moves forward, it will be necessary to standardize objective, functionally significant outcome measures to report. Because the specific risks and methods of follow-up vary greatly among the tissue(s) transplanted, we will now focus on some specific types of VCAs to allow more specific discussion of what are, at least functionally, widely variable transplants.

Hand transplantation

Background

Hand transplantation is technically feasible, with the surgical technique and technical complications (e.g. arterial thrombosis, venous congestion, etc.) similar to those associated with microsurgical replantation of an autologous limb, and covered in detail in Chapter 64. To our knowledge, at the time this chapter is written, 45 patients have received hand transplantation(s) in the western world (23 unilateral and 22 bilateral). However, only 21 unilateral and 18 bilateral patients in western countries have been reported to the International Registry [1]. Furthermore, details have been published in the scientific literature of only 13 unilateral and 14 bilateral patients.

Patient selection

Appropriate patient selection, screening, and a multidisciplinary evaluation are critical; their importance cannot be overemphasized. Due to the novelty of this therapy, candidates may display eagerness to take the risk, but they might not be suitable for the procedure. Candidates may be medically appropriate, but short of proof of compliance, social support, or a methodical follow-up commitment. Patient recruitment should include education, information about international outcomes, standard-of-care options including prosthesis and surgical reconstruction with autologous tissue, immunosuppression, rehabilitation, complications, and the overall transplant process [6].

Debate continues as to whether unilateral amputees should be offered hand transplantation. Rationale for limiting potential candidates to bilateral amputees includes the reality that the QoL after bilateral hand loss is poor even with use of prosthesis, and that bilateral amputees may be more apt to follow rehabilitation programs [7]. It has been suggested that there is a higher propensity for patient dissatisfaction in unilateral transplants because the patient may compare the function of the transplanted hand to that of their native hand [5]. However, based on the reports of patient satisfaction documented in the literature, this hypothesis has not been supported. Furthermore, the replantation literature generally supports efforts at unilateral upper extremity replantation, demonstrating that patients who have unilateral replantations are more likely to have "excellent" or "good" long-term outcomes (by Carroll score) than those patients who undergo revision amputation and use prosthetic devices [8].

The Louisville Instrument for Transplantation (LIFT) analyzes the amount of risk an individual deems acceptable for various VCAs. LIFT utilizes both time trade-off and standard gamble techniques to assess health risks [9,10]. It has shown, in both healthy controls and kidney transplant recipients, that the level of acceptable risk is equivalent for bilateral hand and kidney transplantation. In addition, the risk acceptance for transplantation of a unilateral hand is significantly higher than that for a foot [9].

Outcomes of hand transplantation

Patient mortality

A patient death has been reported two months following combined bilateral hand and face transplant. Contributing to this patient's death was pseudomonas infections of both his hand and face allografts, leading to eventual cardiac arrest and anoxic injury due to airway occlusion [11]. A second death took place within the first week after a bilateral transplantation (personal communication between Martin Iglesias and Linda Cendales, September 2010). No further data has been made available at this time. This translates to a mortality rate of 4.5% among hand transplant recipients.

Allograft survival

Thus far, four patients have experienced allograft loss requiring amputation within one year of transplant. The first was a perioperative loss of a unilateral transplant due to arterial thrombosis [12]. The second patient experienced graft ischemia due to severe intimal hyperplasia at nine months [4]. The third and fourth patients, though not yet reported in the academic literature, have been confirmed by the surgical teams and via media press releases to have lost their hand allografts (one of these performed in conjunction with a facial allograft) within the first week after transplant [13]. Therefore, the rate of hand transplant recipients experiencing graft loss within one year is estimated as 8.9%.

Of the 41 patients in the western world whose hand allografts survived beyond a year, one patient who underwent transplantation in 1998 is reported to have experienced subsequent graft loss. The graft loss was the result of patient non-compliance with his prescribed immunosuppression regimen, leading to graft rejection and the patient's eventual request to have the transplanted hand amputated after 29 months [14]. Therefore, the rate of hand transplant recipients experiencing hand allograft loss after one year is currently 2.4%.

Functional outcomes of hand transplantation

Sensorimotor function

Sensorimotor recovery following hand transplantation is multifactorial. Neural regeneration is critically important and it appears that this regeneration is accelerated in allotransplantation when compared to replantation due to the use of the calcineurin inhibitor tacrolimus, which has been shown to promote axonal regeneration [7]. The time required for muscular reinnervation is one of the reasons that the expected functional outcomes may be correlated to the level of transplantation, with some cases evidencing a faster and more complete return of function with more distal transplants

[15]. This may be, in part, due to the length of time the intrinsic hand muscles remain denervated, resulting in some degree of muscle atrophy following transplantation. After replantation of amputated limbs, functional outcomes vary with the level of injury; the likeliness of regaining useful control increases with more distal amputations [8,16,17]. However, less functional recovery is expected for replantations at certain levels of injury within the hand (Zone II of the fingers) [18].

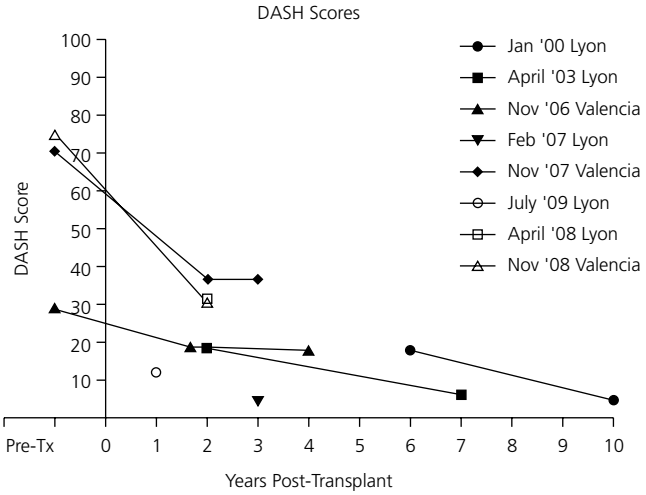
In addition, functional recovery is undoubtedly related to the mechanism of injury, surgical reconstruction, and therapy programs required of all hand transplant recipients, with some authors citing intense rehabilitation and patient compliance as the two most important determinants of success in limb transplantation [19]. Likewise, the upper extremity replantation literature supports compliance with rehabilitation and the psychosocial disposition of the patient as important prognostic indicators for functional outcomes [17]. The time to commence, intensiveness, splinting, modalities (e.g. electro-stimulation, ultrasound), and length of rehabilitation specific for limb transplantation have not yet been established. Currently, every center has adopted a rehabilitation plan following its own experience with reconstructive procedures.

The long-term functional assessment of hand transplant patients is a challenging process, currently being approached in various ways by the teams performing these complex procedures. The majority of measures of limb/hand function were designed to quantify upper extremity disability or for evaluation after replantation. Some of these measurement tools are now being applied to the evaluation of hand transplant patients.

The Carroll test is one of the objective upper extremity scoring devices now being applied to follow functional recovery in hand transplantation. Only three unilateral and one bilateral hand transplant patients (all from the same transplanting center) have had their Carroll scores formally reported in the literature. Besides purely functional measurements such as the Carroll test, several tools attempt to include the impact of hand function on a patient's life. For example, some hand transplant centers are using the Chen score, a measure commonly used to assess hand function after replantation. To stratify function into four grades, the Chen score takes into account range of motion, muscular power, sensibility recovery, and ability to achieve independence and/or return to work. A change in Chen score can be used to compare pre and post-transplant functional status. However, the Chen score has not been tested for validity, responsiveness, or reliability; and at any given time, a patient may not neatly fall into a single category [20]. Tamai's and Ipsen's scores are similar scoring systems to Chen's, with modifications primarily related to the level of detailed evaluation and the number of digits examined [21]. Among the five hand transplant patients who have had their Chen scores reported in the literature, all patients have achieved Chen Grade II status post-transplant [15,20,22].

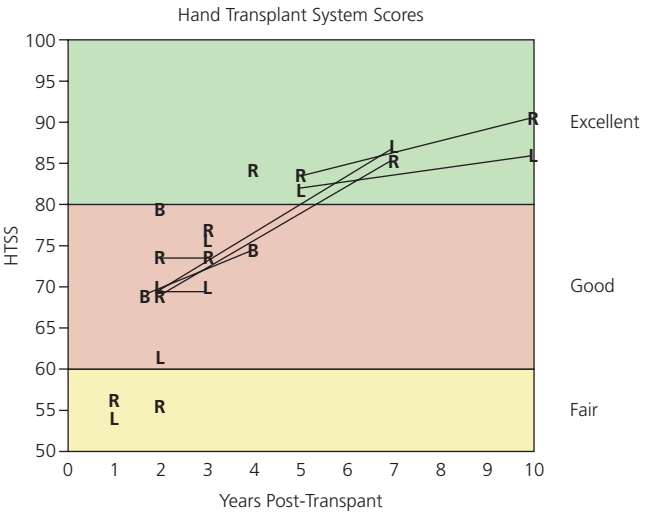
The DASH (Disability of the Arm, Shoulder, and Hand) Score is a validated 30-item patient-reported disability measure of the upper limb in which a higher score reflects a greater level of disability (Figure 110.1). It asks patients to score on a five point scale their ability to perform various tasks, limitations posed by their upper extremity deficit, pain level, and interference with self-image and social activities [23]. One benefit of the DASH score is that it can be used to comprehensively compare the amount of disability before and after transplantation.

The International Registry of Hand and Composite Tissue Transplantation put together a Hand Transplant Score System (HTSS) in 2007 (Figure 110.2). This score system proposes a tool for reporting of functional results amongst the various centers but has not yet been validated. The HTSS provides a weighted score (maximum 100 points) evaluating six aspects of hand function: movement; sensibility; appearance; psychological and social acceptance; daily activities and work status; and patient satisfaction and general well-being [2]. One limitation of the HTSS is that it is solely a measure of post-transplant function and therefore, the clinician is unable to directly compare a patient's outcome to their pretransplant baseline. Of the nine patients whose teams have reported their HTSS scores, the longest available follow-ups have most patients falling within the "good" range [14,20,22] (Table 110.1).



[13, 19]

Figure 110.1. DASH scores reported in hand transplantation.



[13, 14, 19, 21, 29]

Psychosocial outcomes

Given that the primary goal of hand transplantation is to improve the QoL of the recipients, patient satisfaction with their transplanted limb is perhaps one the most important outcomes

Table 110.1. Hand transplantation score system

Appearance (maximum 15 points)		
Skin color and vascularization	Normal	3 points
	Abnormal	0 points
Skin texture	Normal	3 points
	Abnormal	0 points
Hair growth	Normal	3 points
	Abnormal	0 points
Nail growth	Normal	3 points
	Abnormal	0 points
Matching with contralateral hand (monolateral tx: size, color, texture)	Excellent	3 points
	Good	2 points
	Fair	0.5 points
	Poor	0 points
Matching with upper limb/body (bilateral tx)	Excellent	3 points
	Good	2 points
	Fair	0.5 points
	Poor	0 points
Movement (maximum 20 points)		
Active ROM		
Forearm (combined pronation-supination)		
	>150	2 points
	>120	1 point
	>90	0.5 points
Wrist (combined flexion-extension)		
	>90	2 points
	>45	1 point
	> 25	0.5 points
Thumb & long fingers (total digital ROM of contralateral or normal hand – %)		
	>50	2 points
	>25	1 point
	>10	0.5 points
Strength (Jamar dynometer)		
Grip	>10kg	2 points
	>5kg	1 point
	>2.5kg	0.5 points
Pinch	>2kg	2 points
	>1kg	1 point
	>0.5kg	0.5 points
Intrinsic muscle activity		
	Clinically useful	6 points
	EMG detectable	3 points
	None	0 points
Cortical reintegration of the hand		
	Yes	4 points
	No	0 points
Psychological and Social Acceptance (maximum 15 points)		
Social behavior (1 point each behavior)		
Holding/shaking hands		
Feeling well in a group		
Overcoming sense of embarrassment		
Sense of being accepted		
Ability to create new relationships		
Being able to overcome handicap		
Satisfactory global social acceptance		
Affectiveness (1 point each aspect)		
Caressing		
Hugging		
Touching		
Sense of intimacy with partner		
Satisfactory global affectiveness		
Body Image (1 point each aspect)		
Sensation of having a complete body		
Self-confidence in personal appearance		
Use of jewelry (watch, etc) on hand(s)		
Sensibility (maximum 20 points)		
Tactile sensation (Semmes-Weinstein Monofilament testing)		
Median nerve	Green (1.65–2.83)	3 points
	Blue (3.22–3.61)	3 points
	Purple (3.84–4.31) 2 points	
	Red (4.56)	1 point
	Red (6.65)	0 points
Ulnar nerve	Green (1.65–2.83)	3 points
	Blue (3.22–3.61)	3 points
	Purple (3.84–4.31) 2 points	
	Red (4.56)	1 point
	Red (6.65)	0 points

Radial nerve		1 point
Discriminative sensation		
Median nerve	S2PD-grade S4	3 points
	S2PD-grade S3+(7–12 mm)	2.5 points
	S2PD-grade S3 (>15 mm)	1.5 points
	S2PD-grade S2 (none)	0 points
Ulnar nerve	S2PD-grade S4 (2–6 mm)	3 points
	S2PD-grade S3+(7–12 mm)	2.5 points
	S2PD-grade S3 (>15 mm)	1.5 points
	S2PD-grade S2 (none)	0 points
Sweating	Normal	2 points
	Abnormal	0 points
Daily activities and work status (maximum 15 points)		
Activities of daily life (1 point for each activity)		
Driving/riding a bicycle		
Combing hair/personal hygiene/shaving		
Grasping glass		
Pouring water from bottle		
Using cutlery/chopsticks		
Brush teeth		
Holding hands		
Writing		
Symmetrical use of hands		
Work Status		
	Employed	6 points
	Unemployed	0 points
Patient satisfaction and general well being (maximum 15 points)		
Patient satisfaction		
	Very satisfied	5 points
	Satisfied	3 points
	Unsatisfied	0 points
Well-being	Physically and mentally healthy	5 points
	On pharmacological treatment for side effects	0 points
	Permanent side effects/pathologies from drugs	−5 points
Quality of life	Improved a lot	5 points
	Improved	3 points
	Same	0 points
	Worsened	−3 points
	Worsened a lot	−5 points

Reproduced from [2] Lanzetta M, Petruzzo P, Dubernard JM et al. Second report (1998–2006) of the international registry of hand and composite tissue transplantation. Transplant Immunologyl 2007;18:1–6, Copyright 2007, with permission from Elsevier.

measured. Nonetheless, few transplant centers have reported formal QoL measures [12]. However, of the hand transplant patients reported in the scientific literature (13 unilateral and 14 bilateral), over 51% are independent in daily activities and/or have returned to employment after transplantation.

In addition to the patient who requested amputation after medication non-compliance, thus far there is only one report in the literature of a patient being unsatisfied with the achieved functional result. This patient experienced a burn to his transplanted limb, which resulted in ankylosis of the right elbow [14].

Cortical reorganization after hand transplant

Cortical plasticity in VCA, particularly hand transplantation, is an area of interest being studied by several groups. The primary motor cortex (M1) contains the motor homunculus, a somatosensory "map" of individual body segments oriented along the central sulcus [24]. Non-invasive modalities to investigate cortical changes include functional MRI (fMRI) and transcranial magnetic stimulation (TMS). It is known that the brain is an ever-evolving structure and cortical changes begin to occur in as little as 24 hours following amputation of an upper extremity [25]. Hand transplantation offers the opportunity to study the reversibility of these cortical changes (sometimes years after amputation), the extent to which allografted limbs can integrate into a recipient's M1, and the potential prognostic, rehabilitative, or functional implications derived from such information. It has been demonstrated in a limited number of patients that the cortical reorganization that occurs in amputation can be reversed following hand transplantation and that newly transplanted intrinsic muscles are capable of acquiring representation within the recipient motor cortex [26,27].

Complications reported in hand transplantation

Immunosuppression complications

The most common metabolic complications reported in hand transplantation are renal dysfunction, hyperglycemia, and dyslipidemia (Table 110.2). Viral infections have included at least five patients with cytomegalovirus and one patient each with herpes simplex virus I, Ebstein-Barr virus, and varicella zoster virus

Table 110.2. Complications reported in hand transplant recipients

June 2010 Wroclaw, Poland	polyuria with normal renal function	none reported	perioperative arterial thrombosis, epidermolysis and necrosis of distal left phalanges requiring amputation	[12]
May 2011 Boston, USA*	none reported	pneumonia	perioperative bilateral hand allograft loss	[13]

CMV, cytomegalovirus; VZV, Varicella zoster virus; EBV, Ebstein-Barr Virus; POD, postoperative day; * simultaneous facial allograft

[4,5,12,14,20,28]. Bacterial infections of the allografts have been reported [11,13,14]. There is one report of cutaneous fungal infection [20]. There are two reports of oncologic complications in the form of basal cell carcinoma of the nose and a marginal zone lymphoma [4,20].

Psychosocial complications

At the time this chapter is written, non-compliance with immunosuppression has been reported as the causative factor in the loss of one unilateral hand allograft [14]. Factitious disorder, manifested as acute vision loss, has also complicated the care of one patient [29].

Face transplantation

Background

The first face transplant was performed in 2005 and to date, 18 facial allografts have been performed worldwide [1,30,31]. However, only seven of these transplants have been reported to the International Registry [1] and only eleven transplants (representing eight transplant teams) have published their outcomes in the scientific literature. The limited number of facial allografts reported shows that the procedure is technically feasible and has the potential to restore functional and aesthetic properties that may not be attainable through traditional reconstruction. However, this potential comes at a significant risk including death.

Several studies have been conducted to determine the relative risk that people would accept in order to receive a face transplant. It has been demonstrated that both healthy subjects and patients who have already received a kidney transplant (thereby already susceptible to immunosuppression risks) would accept a higher level of risk to receive a face transplant than a kidney transplant [9]. The highest level of risk was accepted for a full-face transplant as compared to five other proposed vascularized composite allografts and kidney transplantation [9]. In a population of people with facial disfigurements, 77% would undergo face transplantation after being presented with 20 potential immunosuppression side effects and 71% would undergo a face transplant if the chance of rejection was 50% in the first year [10].

Outcomes of face transplantation

Patient mortality

There have been two deaths in recipients of face transplants, bringing the percentage of fatal outcomes to greater than 11%. The first

Table 110.3. Sensorimotor outcomes of face transplantation

Transplant date, location	Motor outcome	Sensory outcome	Citations
November 2005 Amiens, France	1 week – able to eat/drink 6 months –complete labial contact 18 months – symmetric smile	6 months – normal temperature and light touch	[34]
2006 Xi'an, China	2 years- able to eat, drink, and talk but facial nerve not fully functional. No symmetric smile. Patient death at 27 months.	3 months –discriminatory sensation restored 8 months – temperature sensation restored	[32,38]
January 2007 Paris, France	POD 10 – Able to speak/eat EMG: 3 months-minor motor response to facial nerve stimulation (left orbicularis oculi) 6 months: activity during voluntary contraction of left orbicularis oculi and bilateral orbicularis oris 9 months: spontaneous mimicry 12 months: motor reinnervation of facial and trigeminal territories (motor responses to nerve stimulation and involuntary blink reflex)	3 months – mechanical and temperature sensation present	[11,39]
December 2008 Cleveland, USA	Can eat/drink, smell, purse lips.	Not reported	[32]
March 2009 Paris, France	POD 24 – intelligible speech 8 months: complete mouth closure	Deep pressure sensitivity regained	[11]
April 2009 Paris, France	N/A – patient death at 2 months	N/A – patient death at 2 months	[11]
April 2009 Boston, USA	Immediate speech improvement. POD 3 – oral intake 1 year: nasal breathing, able to smell, symmetric smile	By 6 months – sensation to light touch, pinprick, cold; 2PD = 15 mm	[41]
August 2009 Valencia, Spain	16 months – able to swallow (transplant included tongue)	Not reported	[75]
August 2009 Paris, France	POD 20 – intelligible speech 8–12 months: complete mouth closure	Not reported	[11]
January 2010 Seville, Spain	Improved speech, able to eat By 6 months: Motor recovery of levator labi and buccinator muscles.	3 months – sensory recovery began 6 months – near complete sensation to pain and temperature	[35]
March 2010 Barcelona, Spain	10 weeks – soft diet 120 days – EMG showed initial signs of muscle activity.	4 months – sensation recovery in forehead, eyelids, cheeks, and intraoral mucosa. No sensation to lips.	[40]

of these deaths is presumed due to immunosuppression non-compliance and multi-organ failure 27 months post-transplant [32]. The second death occurred two months following combined facial and bilateral upper extremity transplantation. This death resulted from anoxic cardiac arrest following tracheostomy occlusion, resulting in an irreversible brain injury [11,31]. However, the pathology leading to this series of fatal complications was an overwhelming pseudomonas infection of the allografts.

Allograft survival

At the time this chapter is written, no cases of facial graft loss have been reported. The consequences of a facial allograft loss are potentially profound when considering the limited options for reconstruction. As graft loss is to be anticipated in at least some sub-set of recipients at some point post-transplant, the management of facial allograft loss is certain to be a critical topic in determining the risk-benefit ratio of this procedure.

Functional outcomes of face transplantation

Sensorimotor function

The goal of face transplantation is both functional and cosmetic. From a functional standpoint, the ideal outcome would allow for emotional expression through animated facial expression, effective mastication allowing for normal eating, improved speech, ability to control oral secretions and breathe nasally, and allow for protection of the eyes. All of these functions are dependent on the regeneration of peripheral nerve function within the allograft. Several invasive and non-invasive modalities have been used to evaluate motor and sensory recovery after face transplantation. However, at this time there is no standard battery of tests to evaluate function following face transplantation and this makes the objective comparison of outcomes across centers extremely difficult (Table 110.3).

Psychosocial outcomes

The social importance of an aesthetically acceptable face should not be underestimated. The goal is an outcome superior to what could be obtained through conventional reconstructive techniques. A severely disfigured face is detrimental to a person's ability to interact normally with society and negatively impacts self-esteem and QoL [30]. The impact of severe facial disfigurement on QoL has been shown to be comparable to serious medical conditions such as HIV, diabetes mellitus type I, and end stage renal disease (ESRD) requiring hemodialysis [33]. It has been shown in a sample of the general population that if afflicted with a severe facial deformity, they would be willing to accept a 34% risk of death and would trade 12 years of their life to undergo face transplantation [33]. Most of the reported outcomes regarding QoL following face transplant are qualitative, with teams reporting patients returning to work and reintegrating into their premorbid social lives [11,34,35]. At this point, few quantitative measures of QoL following face transplant are reported in the literature.

Aesthetic outcomes

One of the ethical concerns raised in face transplantation is the potential transference of donor appearance to the recipient. Anatomic studies have been conducted in cadaveric models of subsuperficial musculoaponeurotic system face transplantation and demonstrate that the transplanted faces more closely resemble the recipient than the donor for some anthropometric measurements (skull base width, craniofacial height); while other aspects

(intercanthal width, middle third depth) are approximately equally similar to donor and recipient appearance [36]. Cadaveric study of osteocutaneous face transplantation has demonstrated grossly visible similarity to the donor face [37]. The presence or degree of appearance transfer in facial transplants containing both bone and soft tissue is an ongoing area of inquiry [30].

No formal instrument is in place to measure aesthetic improvement after face transplantation, but the subjective improvement is in the published reports. At the time this chapter is written, there are no reports of patient dissatisfaction with their esthetic result and there are numerous reports of patients being satisfied with their appearance, resuming normal social lives, and returning to work (Figure 110.3) [11,34,35,38–41].

Complications reported in face transplantation

Immunosuppression complications

Of the 11 patients with reported outcomes, two have experienced renal dysfunction and two have developed new-onset diabetes after transplantation [34,35,38,41]. Six of the 11 patients have had infectious complications [11,34,38,42]. Viral infections have included two patients with cytomegalovirus, two patients with herpes simplex virus I, and one patient with a poxvirus [11,34,42,43]. Bacterial infections of the allografts, lungs, and gastrointestinal tract have been reported [11,41,43]. Oral candidiasis has also been reported in one patient [44]. There is one report of oncologic complication in the form of carcinoma in situ of the cervix detected 50 months after transplant [43].

Psychosocial complications

Non-compliance with immunosuppression has contributed to the death of one face transplant recipient (Table 110.4) [32].

Abdominal wall transplantation

Background

Abdominal wall transplantation is carried out in conjunction with small bowel or multivisceral organ transplantation in patients with either loss of abdominal domain or severely damaged abdominal walls due to multiple surgeries, enterocutaneous fistulae, or tumors. The functional goal of the transplanted abdominal wall is to allow closure of the abdomen after multivisceral transplant and to provide ongoing coverage and support for underlying organs. Therefore, the immunologic considerations and follow-up of abdominal wall transplants is unique because so far, the recipients have required lifelong immunosuppression for their primary transplants and the role of the VCA is supporting.

Outcomes of abdominal wall allografts

At the time this chapter is written, there are 15 abdominal wall transplants in a total of 14 patients reported in the literature, with only nine of these cases having been formally reported to the international registry [1,45]. Of these 14 patients, four have been pediatric recipients. All patients underwent another transplant in conjunction with the abdominal wall (nine intestine, four multivisceral, two multivisceral without liver). Two patients received their abdominal wall allografts in a second surgery days after their visceral transplant. All patients received induction immunosuppression with alemtuzumab (anti-CD52) and maintenance with tacrolimus monotherapy, except one child who received daclizumab induction and tacrolimus and methylprednisolone for maintenance [45].

Two of the 15 reported abdominal wall transplants have been lost to vascular thrombosis within one week of transplant (one patient underwent subsequent retransplantation with a second abdominal wall), bringing the rate of perioperative graft loss to 13%. One patient was subsequently retransplanted with a second abdominal wall [45].

Of the 14 patients whose allografts survived the immediate postoperative period, nine patients have died due to sepsis, multi-organ failure or, in one case, lymphoproliferative disease. No deaths have been attributable to the abdominal wall allograft. Of the five surviving patients, one abdominal wall allograft failed. As of the most recently published reports, the longest follow-up of an abdominal wall allograft is 7.1 years (Figure 110.4) [45].

There is also one reported case of a vascularized posterior rectus sheath fascia transplanted to allow abdominal wall closure in a pediatric liver and double kidney recipient. In this case, a 10×20 cm segment of posterior rectus fascia was procured in continuity with the falciform ligament and received blood supply via the single hepatic artery anastomosed as part of the orthotopic liver transplant. Immunosuppression consisted of steroid induction and maintenance with steroids, tacrolimus, and daclizumab. No signs of rejection were noted on tissue biopsies. However, the patient died due to fungal septicemia of a presumed respiratory source 51 days following transplant [76].

Laryngeal transplantation

Background

Conventional methods to restore laryngeal function after traumatic or oncologic loss are not ideal and patients without a functioning larynx experience impairment of their QoL [47]. Ability to speak is lost, inability to protect the upper airway results in tracheobronchial infections, and taste and smell may be diminished. Similar to issues raised with other QoL transplants, debate exists whether these functions justify surgical and immunosuppression risks of transplant.

Several studies have examined QoL with regard to laryngeal transplant [48–50]. Twenty percent of healthy volunteers, if faced with laryngeal cancer, would choose radiation therapy over surgery in order to retain natural speech, even though this choice imparts a 20–30% lower survival rate at three years [50]. In one study of laryngectomees, 75% would undergo laryngeal transplantation under ideal conditions and this number was not significantly lower in situations where a stoma had to be maintained or a prolonged hospital stay was necessary. Furthermore, one-half of laryngectomees would accept transplantation even if it did not result in a normal voice but less than 20% were willing to risk their lives for this procedure [48]. Laryngectomees as a group are much less risk-accepting than kidney transplant recipients and healthy controls [49]. Despite this risk aversion, over one-half were still interested in laryngeal transplant after being presented with the side effects of immunosuppression and over one-third would pursue a transplant with a 50% chance of rejection [49]. The vast majority of patients who undergo laryngectomy have cancer. The appropriateness of transplant immunosuppression in oncology patients is controversial, especially in QoL transplants.

Sixteen laryngeal transplants have been reported to the International Registry, the first performed in Cleveland, Ohio, in 1998 and the remainder from a team in Colombia [1].

However, of these16 known laryngeal transplants, only one patient's outcomes have been formally reported in the literature

[51,52]. The recipient of this transplant was a 40-year-old man who had been aphonic for 20 years due to crush injury sustained in a motorcycle accident. The transplant included larynx, trachea, pharynx, and thyroid and parathyroid glands. Immunosuppression included cyclosporine, mycophenolate mofetil, methylprednisolone, and steroids. Tacrolimus replaced cyclosporine after 15 months. Additionally, he received muromonab-CD3 for the first week after transplant [51]. No further follow-up has been reported.

Outcomes of laryngeal transplantation

In the first case, first speech occurred on postoperative day 3. By 4 months, the right vocal cord assumed midline position and by 6 months the left vocal cord was para-midline. Reinnervation of bilateral vocal cords and cricopharyngeus muscles was confirmed by EMG. By 36 months, all speech characteristics fell within normal range. No thyroid abnormalities were encountered. After 14 weeks, return of an adequate swallow allowed for oral feeding without aspiration. Olfactory and taste senses have returned. The patient reported QoL improvement and is employed as a motivational speaker [51].

Complications reported in laryngeal transplantation

Immunosuppression complications

Hypertension and increased creatinine responded to oral antihypertensive agents and cyclosporine dose reduction. Infectious complications included oropharyngeal thrush, tracheobronchitis, and Pneumocystis carinii pneumonia [51].

Table 110.5. Outcomes of knee joint transplantation

Transplant date	Function achieved	Complications	Allograft/limb outcome	Citations
April 1996	6 months – complete osseous integration 12 months – full ROM	Vascular pedicle occlusion, implant infection after TKA	Rejection at 15 months. TKA. AKA.	[53]
November 1996	12 months – stable joint, able to walk and participate in sports, returned to work	Non-compliance with immunosuppression leading to graft loss, implant infection after TKA	Rejection at 36 months. TKA. AKA.	[53]
December 1996	N/A	Surgical site infection	Allograft removal at 5 weeks. Arthrodesis.	[53]
July 1997	Stable joint, able to walk, returned to work (after TKA)	Fatigue fracture at 2 years, implant infection after TKA	Rejection at 24 months. TKA. AKA.	[53]
February 1998	Full ROM after TKA	Fatigue fracture at 14 months, infection after re-injury following TKA.	Rejection at 14 months. TKA. Arthrodesis	[53]
April 2002	8 weeks – partial weight bearing 6 months – returned to work 1.5 years – good ROM, full weight bearing 4 years – full weight bearing, satisfactory ROM	Infection resulting from necrosis/ischemia from vessel changes attributed to rejection	Rejection at 56 months. AKA.	[53,54]

TKA, total knee arthroplasty; AKA, above knee amputation; ROM, range of motion.

Psychosocial complications

An episode of patient non-compliance with the prophylaxis regimen resulted in the aforementioned pneumonia [51].

Knee joint transplantation

Background

Knee joint allotransplantation attempts to reconstruct a functional joint damaged by extensive trauma or infection. The International Registry records six knee transplants performed at a single center in Murnau, Germany [1]. All of the recipients had suffered loss of bone, cartilage, and experienced deficient extensor mechanisms of the knee joint due to trauma or infection [53]. No operative complications were reported and cold ischemia times ranged between 18 and 25 hours [53]. Five of the knee transplant patients received induction therapy with thymoglobulin, cyclosporine, azathioprine and steroids and two-drug maintenance immunosuppression with cyclosporine and azathioprine. The sixth knee transplant patient received induction therapy with thymoglobulin, mycophenolate mofetil, tacrolimus, and steroids and maintenance immunosuppression with mycophenolate mofetil, tacrolimus, and steroids [53,54].

Outcomes of knee joint transplants

No patient deaths subsequent to vascularized knee joint transplantation have been reported. One knee allograft was lost due to surgical site infection at 5 weeks. The remaining five allografts were lost to complications related to rejection at 14, 15, 24, 36, and 56 months [53,54]. Of note, the graft loss at 36 months was subsequent to patient non-compliance with immunosuppression [54]. Clinical signs of rejection included joint instability, decreased range of motion, and swelling [54]. Four patients have eventually required above knee amputation and the remaining two underwent arthrodesis [53,54].

A significant problem encountered in the first five knee transplants was an inability to immunologically monitor the allograft since there was no visible portion and no defined biomarker has been identified. The transplant team used local signs of inflammation to herald rejection, but this likely resulted in undiagnosed episodes of rejection throughout the clinical course [55]. To better monitor the transplant with a visible transplanted tissue, the sixth patient received a vascularized skin segment in conjunction with the knee, which was used for immunologic monitoring. Important contributions to VCA made by the group's experience are the blood vessel changes observed in some of the patients. The first patient in this series experienced vascular pedicle occlusion at 15 months, which when considered in conjunction with perivascular lymphocytic infiltration, has retrospectively been deemed rejection-related [56]. The final patient in this series also experienced graft loss due to vessel occlusion. Predicated by superficial skin necrosis of the sentinel skin graft, biopsies from the synovial and soft tissues of the allograft revealed perivascular infiltrates, intimal proliferation, and concentric obliteration or occlusion of arteries. These vessel changes led to graft necrosis, deep infection, and eventual graft loss. The transplant team suggest this myointimal proliferation as a sequelae of ongoing rejection [54].

No metabolic or oncologic side effects of immunosuppression were reported. However, 100% of the knee allograft recipients had their clinical courses complicated by infections [53–55]. Given that all patients eventually experienced allograft failure requiring amputation, more investigation is taking place relative to the acute, antibody-mediated, and chronic alloimmune injury (Table 110.5 and Figure 110.5) .

Femoral diaphysis transplantation

Background

The International Registry records three femoral diaphysis transplants performed at a single center in Murnau, Germany [1]. The bone defects ranged from 12–33 cm and were due to osteomyelitis in two cases and chondrosarcoma with a 5-year period of disease-free survival in one case. No operative complications were reported and cold ischemia times ranged between 16 and 25 hours. Immunosuppression was initiated with four-drug therapy of cyclosporine, azathioprine, anti-T lymphocyte globulin, and methylprednisolone. Patients were converted to two-drug maintenance therapy with cyclosporine and azathioprine after one week [57].

Outcomes of femoral diaphysis transplants

No patient deaths have been reported subsequent to vascularized knee joint transplantation. Two patients achieved bone healing [56]. The third patient necessitated allograft removal due to

Figure 110.5. Range of motion 1.5 years after vascularized knee joint allotransplantation. Reproduced from [53] with permission from John Wiley and Sons.

recurrent deep infection at 18 months and underwent autologous bone graft reconstruction [55]. All three patients are reported to be fully-weight bearing with unencumbered flexion of knee and hip joints [57].

Other VCAs

Lower extremity transplantation

There is one report of a unilateral lower limb transplantation from one ischiopagus twin, afflicted with an unsurvivable cardiac anomaly, to her twin. This transplant was performed in 2003 on a three-month-old patient, who has now been followed for over 6 years. By 30 months after transplant, voluntary leg movement and gross sensation was observed. Improvement continued and has resulted in a normal tone limb with good strength in all movements other than reduced dorsi- and plantar flexion of the foot. Patellar and plantar reflexes are absent. The transplanted limb is shorter than the native leg and this results in a pelvic tilt and Trendelenberg gait. However, the child is able to run short distances, participate in sports, attend school, and has experienced no significant psychological issues (Figure 110.6) [58].

Although not yet reported in the academic literature, a surgical team in Valencia, Spain confirmed by press conference that they performed bilateral above-knee leg transplants in July 2011 [59]. It is too early in this patient's course to comment on functional recovery.

Vascularized fibula transplantation

In 1988, a Japanese group transplanted a vascularized fibula from a living mother to her 2-year-old son in order to reconstruct a large

Figure 110.6. Lower extremity transplant. (A) Preoperative appearance of ischiopagus twins. Twin A is the donor with a lethal cardiac anomaly; Twin B is the recipient. tibial defect due to congenital pseudoarthosis and neurofibromatosis after failed surgical procedures. The vascular pedicle included donor peroneal artery and veins; these were anastomosed to the recipient anterior tibial artery and veins. Immunosuppression included cyclosporine and a 2-week course of steroids. One day following transplant, technicium bone scan demonstrated moderate tracer uptake. However, 2 weeks following transplant, unintentional drop of cyclosporine levels below target range resulted in rejection. Repeated bone scan 3 weeks after transplant showed decreased tracer uptake, and arteriography at 3 months demonstrated vessel obstruction. Bony union was achieved only at the distal end. In order to achieve proximal union, a short vascularized fibula autograft was performed 1 year after transplant [60].

Uterus transplantation

Uterus transplantation has been suggested as possible treatment for women with either a congenital absence or following surgical removal of the uterus. There is one reported case of human uterus allotransplantation, performed in Saudi Arabia in 2000. The 26-year-old female, 6 years following hysterectomy for postpartum hemorrhage, received an orthotopically transplanted uterus from a 46-year-old unrelated living donor. Immunosuppression regimen included cyclosporine, azathioprine, and steroids. One episode of acute rejection at 9 days was reported and treated with antithymocyte globulin. The suspicion of rejection was initiated by systemic symptoms such as vaginal discharge, abdominal pain, fever, and malaise. Doppler ultrasound revealed myometrial edema. Flow cytometric analysis of peripheral blood also revealed a reversed CD4/CD8 ratio. No biopsies were taken to confirm histologic rejection or its resolution. Initial functional success was evidenced by endometrial proliferation in response to hormonal therapy and two episodes of withdrawal bleeding. However, hysterectomy of the transplanted uterus was necessary after 99 days due to acute vascular thrombosis resulting in uterine infarct. The vascular thrombosis was attributed to lack of uterine support resulting in kinking of the vascular grafts [61]. However, an antibody-mediated response cannot be excluded as a cause of graft loss. At the time this chapter is written, there are no other reports of human uterine transplantation.

Tongue transplantation

A tongue transplant was performed in 2003 in Vienna, Austria, to a 42-year-old recipient who had lost the ability to speak, eat, or swallow due to squamous cell carcinoma of the tongue. Radical en bloc resection of the tumor immediately preceded transplantation. Induction immunosuppression with antithymocyte globulin and steroids, followed by maintenance with tacrolimus mycophenolate mofetil, and steroids was administered. No perioperative complications or rejection episodes were reported. At 10 months, the patient was able to speak, swallow saliva and small amounts of pulp-consistency foods, and the tongue was partially sensate. Tongue motility was never achieved. One year after transplant, tumor recurrence was identified in the patient's neck and the patient died at 13 months post-transplant from a presumed pulmonary embolism (Figure 110.7) [46,62].

Fasciocutaneous radial forearm transplantation for hemi-face reconstruction

In 2008 an Egyptian team transplanted a vascularized fasciocutaneous radial forearm allograft from a living mother to her child, who was afflicted by xeroderma pigmentosa (XP). XP is a disease characterized by defects in DNA repair and results in numerous skin cancers upon exposure to ultraviolet light. Patients typically die before 20 years of age. In this unique case, surgeons performed this VCA as a prophylactic measure to replace the patient's own skin with donor skin that does not carry the XP defect. Full thickness excision of the recipient's hemi-face native skin was performed and replaced by an allografted fasciocutaneous radial forearm allograft. Immunosuppression included steroids, mycophenolate mofetil, and cyclosporine. Initial healing was uneventful. An isolated area of skin discoloration was noted on the allografted skin 6 weeks after transplant, but this resolved without intervention. However, after missing three consecutive follow-up appointments and presenting with below-target immunosuppression levels 5 months after transplantation, the allograft experienced irreversible rejection and required complete removal. The wound was then left to heal by secondary intention. Of note, no cancers developed on the transplanted skin, although new cancers continued to develop on the contralateral side that was not transplanted [63].

Summary

Throughout history, clinical transplantation has developed in close relation with research. VCA has made significant progress in the last decade; however, similar to other transplants, VCA has its challenges and considerations, some of which are common across allograft types, and others that are unique to VCA. Although these transplants are technically feasible, many challenges remain: defining the best candidates; balancing the burden of immunosuppression with a QoL transplant; defining the appropriate timing of the transplant; achieving the timely reporting of outcomes to the scientific community; and defining the immunological specificities that, although beyond the scope of this chapter, must be recognized and kept in the forefront of this investigational field.

From their inception, VCA programs should target an interdisciplinary approach. Currently, groups from at least 17 countries have performed these complex transplants. At this time, there are fewer than ten patients alive with VCAs longer than 10 years since transplant. Patient non-compliance with immunosuppression or prophylaxis regimens has been reported in hand, face, larynx, and knee transplant recipients and has been implicated in one hand allograft loss and the death of one face transplant recipient [14,32]. The natural history of these transplants, even in conditions of optimal immunosuppression and rehabilitation, is unknown. The profile of chronic rejection and antibody-mediated processes in VCA is undefined. Critical areas of investigation as the field develops include: cortical plasticity, the impact of ischemia-reperfusion injury on function, potential VCA applications for congenital and pediatric defects, tissue donor acceptance and public education, and regulatory issues. Today, transplantation continues to be a unique setting for the study of immunology and transplant-related applications to improve patient care. As a partner in transplantation, VCA should advance with a focus on ensuring the best outcomes for VCA recipients, both present and future.

SECTION 8

Pediatric Transplant

CHAPTER 111

An Introduction to Pediatric Organ Transplantation

Steven A. Webber[1] and Allan D. Kirk[2]

[1] Vanderbilt University School of Medicine, Nashville, TN, USA

[2] Duke University Medical Center, Durham, NC, USA

The chapters in this section focus exclusively on pediatric transplantation. Although many aspects of transplantation of children bear close parallels to transplantation in adults, there are many ways in which pediatric transplantation is unique. The current section is designed to focus on these differences and to complement and not replace earlier chapters in this text.

The assembly of a section specifically dedicated to pediatric practice has its rationale in recognizing that the care of children typically involves a distinct set of practitioners, and similarly, that pediatric transplantation must be clearly distinguished from adult transplantation not only on technical grounds, but also with regards to specific differences in immunobiology, pathology, pharmacology, psychology and protective immunity that manifest in unique clinical challenges. Investigators and practitioners need to recognize these issues as a primary condition of caring for pediatric recipients of transplanted organs.

In the first section, Urschel and West provide a detailed description of the maturation of the immune system and its relevance to organ transplantation across the age groups. Although it is often stated that the immune system is quite mature in humans at birth, any neonatologist or pediatrician caring for young infants knows this is not entirely correct. While its antigen receptor repertoire is certainly established at birth, it is now clear that immune function develops with increasing immune experience. A clear account is provided of the protean ways in which all aspects of the immune system differ between birth and adult life, with differences in both quantity and quality of all components of the immune system. These findings help explain age-related differences in alloimmune responses, with clear patterns of lower rates of acute rejection and chronic graft dysfunction in patients transplanted in the earliest stages of life. These findings are perhaps most noticeable in neonatal and early infant heart recipients, since transplantation of other organs is rare in this very young age group. This can be considered a period of relative "immunologic privilege", although the precise window for this immunologic advantage is not entirely clear. By contrast, these young transplant recipients have high rates of infection, and children have the highest rates of lymphoproliferative disorders.

There follows organ-specific chapters focusing on kidney, liver, heart, lung and intestinal transplantation. These chapters remind us of the prominent role that pediatric transplantation has played in the history of organ transplantation. Pediatric transplantation evolved in parallel with adult transplantation, not as a result of the success of the latter. Few are aware that the first pediatric kidney transplant was performed in Paris on Christmas Eve, 1952 [1]. The graft worked immediately, but was lost, presumably due to rejection, on the twenty-first day leading to the death of the teenage patient. None-the-less, feasibility of the procedure was demonstrated. The first pediatric heart transplant was planned (1966) prior to the pioneering first human heart transplant by Christian Barnard in December 1967. The donor deteriorated and the transplant was abandoned. A new recipient was identified late in 1967 and the transplant was performed only three days after Barnard's first procedure. This second ever orthotopic heart transplant in a human occurred in a three-week old infant with lethal congenital heart disease. The donor was an anencephalic newborn who had been transported to the recipient center [2]. The organ beat for approximately six hours. Infants and young children also feature prominently in the history of liver transplantation, including the first recipient operated upon by Starzl in March 1963. Unfortunately, the recipient procedure could not be completed and the "three year old bled to death as we worked desperately to stop the hemorrhage" [3]. Although most of the earliest transplants were not successful, these observations affirm the place of children and their families as pioneers in the field of solid organ transplantation and much was learned from these earliest experiences.

The organ specific chapters on pediatric transplantation draw attention to the manner in which pediatric transplantation differs from transplantation of adults. The most notable difference perhaps relates to the markedly different spectrum of causes of end-stage organ failure in children. This requires specialized pretransplant evaluation with teams who are focused on the care of the child with end-stage organ failure. Some of these differences mandate specialized surgical techniques, for example for children with congenital urinary tract anomalies, or congenital heart disease. These differences can make the transplant procedures technically very challenging, requiring a surgical team with extensive experience in reconstruction of these congenital anomalies. Failure of adequate reconstruction of congenital anomalies frequently leads to early graft loss.

Post-transplant management strategies are also influenced by age and pretransplant diagnosis. Immune maturity may influence immunosuppressive strategies, and patient size and anatomic variations may impact ability to perform post-transplant biopsies of the allograft. Corticosteroid avoidance has been pioneered in pediatric populations, a strategy now being studied in many adult transplant

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

programs. Prior infectious agent exposure (notably human herpes viruses) informs us of infection risk, and risk of lymphoproliferative disorders, and influences strategies for post-transplant viral prophylaxis and detection.

Following the organ-specific chapters, we focus on several issues of critical importance to the pediatric transplant recipient and their families. The goal of organ transplantation is to prolong recipient survival as long as possible, return the recipient to optimal state of health, to enhance quality of life, and to return the child to normal, age appropriate, activities. Many barriers exist to achieving these goals. Medications have many side effects, and growth and puberty may be delayed for many recipients. The impact of corticosteroids, and the use of therapeutic growth hormone, on somatic growth have now been extensively studied in pediatric organ recipients. Cognitive development may also be impaired and psychiatric disorders are common. Non-adherence to immunosuppressive medications may be the most challenging problem facing the pediatric transplant team members and barriers to achieving adherence are now the focus of a number of studies. Studies of novel interventions to enhance adherence are also described. This section concludes with discussion of a topic of great importance to both pediatric and adult transplant team members, that is "transition of care". This is a vulnerable period for all recipients associated with increased risk of graft rejection and loss. Specific recommendations for creation of an effective transition program are made.

In summary, this section focuses on pediatric aspects of organ transplantation. The chapters can be considered in isolation as a monograph on the unique aspects of pediatric transplantation, but are best read in concert with other sections of the book, which are all relevant to the field of transplantation in children. References to chapters in the more general sections of the text are made to highlight where common practice exists between adult and pediatric transplantation.

CHAPTER 112

Developmental Immunity: From Birth to Adult

Simon Urschel and Lori J. West
Alberta Transplant Institute, University of Alberta, Edmonton, AB, Canada

Introduction

Ontogeny of the immune system occurs in distinct stages in exquisitely integrated interplay, giving rise to 'critical windows' in the continuum of immune development [1,2]. Antigen exposures or therapeutic interventions during these windows may have long-term or even permanent consequences both unfavourable and favourable (Table 112.1). In contrast to other organ systems that are closer to being fully developed in their anatomy and functionality by the end of gestation, the immune system is incompletely formed and is subject to major developmental changes throughout childhood and youth. Immunologic immaturity at the time of birth is related both to general lack of antigen contact and to inherent processes that undergo continued maturation long after birth. Understanding the various aspects of immune development and their influence on optimal decision-making in pediatric transplant medicine requires integration of knowledge gathered from various fields of medical research and clinical practice including infectious diseases, autoimmunity, immunodeficiencies and endocrinology. Not the least, information from animal models and other experimental work over more than half a century contributes to the understanding of the complex changes that occur during immune maturation. In this chapter we will compile current concepts of developmental immunology in the context of their relevance to transplant medicine. It will complement the more general discussion on physiological immune function found in Chapter 2.

Natural development of the immune system with childhood maturation

When considering neonatal immune responses it is important to acknowledge that despite abundant information on development derived from elegant experimental systems, particularly murine models, the complex in vivo interplay in the intact human neonate is clearly less amenable to precise analysis. Nonetheless, since experiments carried out by Peter Medawar and colleagues in the 1950s [3,4], the neonatal mouse has served as an ideal model for the investigation of immunologic development as a species that is both readily available for laboratory investigation and easy to manipulate, as well as very immature at the time of birth. The event of birth, of course, does not imply any particular degree of immunologic maturation but rather marks the moment of departure of the individual from the intrauterine environment. The degree of immunologic development reached at birth, as well as the rate of post-natal maturation, varies with the species; the maturity of the neonatal mouse is far less advanced than that reached by the human at the time of birth (developmental stages between mice and humans are roughly approximated in Table 112.2) [5].

Innocent and naïve: The immune system of the neonate and infant

While the strict definition of a neonate includes children aged from 1 to 28 days after birth, changes of the immune system are obviously fluid and proceed with wide individual variability. This is particularly relevant given that birth and survival of a newborn currently may occur as early as 23 weeks gestational age, thus 17 weeks before the new human being would be expected to be prepared for life outside the protective maternal environment. Together with deficits in the developmental stage of other organs, the child born prematurely faces additional challenges associated with immune immaturity, thereby increasing the risk of infection. However, all newborns are vulnerable to severe systemic infections caused by agents that are not particularly harmful later in life. Elements that have been reported to contribute to less than fully effective immunity in neonates include quantitative and qualitative factors in both the adaptive and innate compartments that have been described in murine models as well as in humans. These are summarized in Table 112.3 and discussed in detail in the following sections.

Innate immune responses of the newborn and infant

As described in Chapter 7, the innate immune system includes a variety of cells and enzymes that respond to structures indicating the presence of pathogenic or non-human organisms, or altered human cells, and can be summarized as a non-specific first-line defense. As the name suggests, innate immune responses are operative at birth, likely beginning early in gestation, and are not dependent on exposure to specific antigens or to the development of immune memory. However the term 'innate' also implies a misconception that no maturation occurs or is required; in truth, immaturity in innate immunity is illustrated in various clinical and experimental observations. As one example, about 2 in 1000 mature newborns experience early onset sepsis; in ~41% the causative agent is Group B *Streptococcus*, a bacterium to which the neonate has limited resistance, acquired from otherwise harmless colonization of the maternal birth channel [6]. Neonatal phagocytic cells show a reduced response compared to cells from adults when stimulated with various pathogen-associated and damage-associated

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Table 112.1. Major stages of human development

1 Preconceptual: that is, oocyte and spermatozoa development, particularly important for oocyte development as susceptibility may be prolonged for many years before fertilization
2 Gestational: embroynic to mid-gestation, late fetal (organogenesis, cell migration, growth education)
3 Perinatal: early postnatal (lactation)
4 Infancy: early childhood — infectious exposures
5 Middle childhood — thymic involution
6 Adolescence — hormonal influences
7 "Maturity"
8 Senescence

Table 112.2. Comparison of T cell development stages between mouse and human

Function	Mouse	Human
Length of gestation	21 days	40 weeks
Lymphohematopoietic cells colonize primordial thymus	11–12 days	week 9
Morphologic division of thymus into cortex and medulla	13–14 days	weeks 11–14
Expression of γδTCR then αβTCR	14–16 days	weeks 11–13
Proliferative response demonstrable in MLR	16–18 days	week 12 (thymus) week 19 (spleen) (weak until week 23)
Mitogen responsiveness	day 18 (thymus) (to some mitogens only after birth)	weeks 13–14 (thymus) weeks 16–18 (spleen, peripheral blood)
Cytotoxic response demonstrable (CML)	Weak until postnatal day 7	Beginning from about weeks 20–23 (thymus)

molecular patterns (PAMPs and DAMPs) through pattern recognition receptors (PRRs) including toll-like receptors (TLRs) [7,8]. Dendritic and monocytic antigen-presenting cells of neonates have been found to have reduced expression of a number of cell surface structures important to effective responses, including class II major histocompatibility complex (MHC) [9,10] as well as costimulatory molecules such as CD40, CD80 and CD86 [11]. During bacterial infection and sepsis, proliferation and release of polymorphonuclear neutrophils from the bone marrow of neonates exhaust faster than later in life [12] leading to neutropenia during sepsis with associated higher mortality [13,14]. The capability of neutrophils of newborns to migrate spontaneously and to follow chemotaxis factors is also reduced [15], particularly in the context of sepsis [16]. The complement factor C9, a crucial component of the membrane attack complex in the response to bacterial infections, has been reported to be reduced in quantity in neonates [17]. Possibly associated with the lack of well-developed adaptive immunity and consequently specific antibodies, neonates show no detectable activation of complement through the classic pathway during bacterial infections, but an overwhelming response through the alternative pathway, identified through increased plasma levels of C3a and C5a [18].

This summarizes only some of the most relevant amongst currently recognized and studied elements that limit innate immune responses of the newborn and infant. The impact on allo-immune responses in transplantation remains mostly unknown although it is increasingly evident that the interplay between innate and adaptive immunity has been vastly underestimated. Recognition of the augmentation of antigen-specific adaptive immunity through innate immune responses, and thus the potential for increased long-term graft damage, is essential. This will not only provide better understanding of inter-individual differences in early and long-term graft acceptance but may also reveal possible therapeutic targets for intervention at the time of organ implantation that will ultimately improve graft survival.

Table 112.3. Immature components of the immune system of newborns and infants compared to older individuals

Innate immune system
- **Phagocytic cells**: low responsiveness of pattern recognition receptors
- **Dendritic cells and monocytes**: low expression of MHC II and costimulatory molecules
- **Polymorphonuclear neutrophil leukocytes**: small reservoir and impaired chemotaxis
- **Complement system**: low quantities of C9, predominance of alternative activation pathway
- **Natural killer cells**: numbers generally low at birth and functionally ineffective

Adaptive immune system
- Lymphopenia at birth, lymphocytosis in the first year
- **T cells**: phenotypical and functional naïveté; lack of memory; broad spectrum of newly generated non-replicated T cells; Th2 bias in specific immune response
- **Regulatory T cells**: high presence of naïve T regs, few activated T regs
- **B lymphocytes**: low numbers at birth, predominant lymphocyte in first year; lack of memory phenotypes and marginal zone B cells; predominance of naïve cells; increased proportion of transitional B cells
- **Antibodies**: maternal IgG at birth with nadir around six months; endogenous production of IgG, IgA, IgM starting at birth and reaching adult concentrations around ten years of age; impaired IgG2 production
- **Spleen and lymph nodes**: architecture (e.g. germinal centers) under development; absence of splenic marginal zone in the first 3–6 months

Developing T and B cell responses from the prenatal period to early childhood in animals and humans

The susceptibility of infants to various infectious agents is related not only to incompletely developed innate responses as described above, but also to lack of preexisting immune memory and to a paucity of lymphocytes and other adaptive immune components in peripheral lymphoid organs (Table 112.3). Deficiencies in lymphocytes (both T cells and B cells) have been described. Subsets of immune cells are differentially represented in quantity over the course of development, and may also have both phenotypic and functional differences compared to adult-derived cells (reviewed in [19,20]). T and B cells are both phenotypically and functionally naïve, typically lacking cells with memory phenotype and function. Natural killer (NK) cells are infrequent at birth and functionally ineffective. A relative lymphopenia has been reported, with peripheral T cell numbers lowest at birth and increasing thereafter [21,22], together with under-developed peripheral lymphoid organs containing few cells.

For decades, neonatal mice were reported to have T cells that are not only few in number but with defective function. However, more recent studies have reported the capability of neonatal T cells to mount effective responses in a variety of in vitro and carefully manipulated in vivo models [23–25]. Furthermore, murine neonatal helper T cell responses have been found to be not so much 'deficient' as skewed toward the Th2 lineage [26,27], thought to be caused, at least in part, by delayed maturation of an IL-12-producing dendritic cell subset [28]. It is not entirely clear that this is true in humans, as T helper responses in terms of both Th1 and Th2

function have been reported to be diminished in some cases but equally effective in others [29–31]. $CD4^+$ T cells of fetal origin are likely to persist in neonates, influencing early responses towards the Th2 bias that predominates in utero [32,33]. Furthermore, there are contradictory reports in the literature as to the effectiveness of neonatal $CD4^+$ T cell function and, as noted, wide diversity in T helper responses. Although $CD8^+$ T cells in neonates have been reported to develop mature cytolytic function in certain circumstances including congenitally acquired infections [34–36], their function in normal healthy neonates is nonetheless generally diminished compared to adults [37]. Additionally, the relative lymphopenia of neonatal life may give rise to homeostatic proliferation, well-studied in mice but not in humans, which may influence the emerging T cell repertoire. During early life, peripheral cell numbers increase as T cells continuously leave the thymus, resulting in higher proportions of recent thymic emigrants in neonatal spleen and lymph nodes compared to adults [38,39]. These cells are phenotypically and functionally distinct in neonates, with quantitative and qualitative differences compared to adults in terms of cytokine production and proliferative responses. This likely contributes to the diverse T helper responses observed in neonates. Recent studies of human cord blood-derived T cells using analysis of T-cell receptor (TCR) excision circles (TREC) as a marker of recent thymic emigrants have demonstrated higher numbers that proliferate in response to IL-7 than naïve $CD4^+$ cells in adults, suggesting that a functional distinction may also be present in humans [39,40].

The circulating B cell proportion is higher in newborns than later in childhood; however, neonatal B cells have an immature phenotype [41] and different isotype switching patterns compared to adult cells. These factors together with inadequate provision of 'help' from neonatal $CD4^+$ T cells for effective B cell function contribute to commonly noted deficiencies in neonatal antibody responses: later onset and shorter duration, low antibody levels and decreased antibody affinity and avidity. Marginal zone B cells are largely absent during the first months of life [42]; circulating plasma cells are rare. Lymphoid organogenesis is ongoing during early newborn life, with lymph node and splenic architecture still under development (germinal centres, marginal zone). Thus both 'T-dependent' and 'T-independent' antibody responses are less effective than later in life [43]. T-independent responses in particular are noted to be markedly impaired [44]; a number of factors have been reported to contribute to this as described below.

Inadequate capacity for antigen presentation further contributes to limited immune responsiveness during the neonatal period. Dendritic cells are few in number, with some reports describing poor function and low expression of costimulatory molecules. In clinical organ transplantation, recapitulation of this 'immature' phenotype in older individuals is sought through immunosuppressive strategies using pharmacologic or biologic blockade of costimulation pathways.

Regulatory cell populations are increasingly recognized as central participants in many aspects of immunity, and may also contribute to an enhanced state of 'suppression' during infancy that plays a role in prevention of the emergence of autoimmunity. $CD4^+$ regulatory T cells have been reported to be present in higher quantities in young children than in older individuals, however their functional abilities remain incompletely explored. Neonates mainly have regulatory T cells with a naïve phenotype, which is considered to be beneficial for tolerance to both self and, in experimental models, non-self antigens [45,46]. With regard to recently described regulatory B cells [47], evidence is emerging suggesting also a higher prevalence in infants [48] than in [49] older individuals, but the impact remains to be clarified. Additionally, the role of inhibitory pathways such as PD-1 [50] in transplant immunity in children remains to be explored.

Interaction between innate and adaptive immune system in early childhood

Elements of innate and adaptive immunity interact co-activate and modulate each other on many levels. In the context of transplantation the 'T-independent' response to polysaccharide structures is of major importance in regards to the immune response to non-self ABO blood group epitopes. Similar to other polysaccharides, ABO antigens have generally been thought not to be presented through the MHCII complex resulting in classic T-mediated B cell activation, but rather activate B cells through interaction with innate immune elements. If an antigen is complexed with complement fragment C3d, activation of its corresponding B cell receptor (BCR) requires a 100–1000 fold lower antigen concentration than without complement. This effect is mediated through binding of C3d to its receptor CD21, part of the B cell co-receptor complex that mediates its effect on the BCR through CD19 [51]. The complement-mediated co-signal plays a crucial role in the development of tolerance to self-antigens [52,53] and possibly to alloantigens. The impaired function of this interaction in infants is reflected clinically in a higher incidence and severity of infections with polysaccharide encapsulated bacteria [44]. Analyses of peripheral blood from children after ABO-incompatible and ABO-compatible heart transplantation (described in detail below) did not show a clear age dependency of C3d levels; however, recipients of ABO-incompatible heart transplants as infants were found to have significantly less C3d in the plasma than ABO-compatible counterparts [54]. While the presence of CD21 on B cells of neonates and infants was not found to differ significantly compared to later in life [54], the effect induced through complement binding appears to be impaired, be it through an altered signalling capacity [55] or due to mechanisms further downstream. A role for complement in the long-term accommodation of ABO-incompatible kidney grafts in adults has also been previously described [56].

Passive immunity through maternal immunoglobulins

Starting as early as 13 weeks gestational age, immunoglobulin G (IgG) starts to transfer through the placenta from the maternal into the fetal bloodstream [57,58]. This process is hugely enhanced after 32 weeks gestation and leads to a nearly complete reflection of the maternal serology in the fetus by about 36 weeks. A full-term newborn actually exceeds the maternal concentration of specific IgG by 20–30% [57]. This transfer occurs in an active manner as high molecular weight structures are prevented from passing the placental barrier by diffusion. Maternal IgG is bound to receptors for the crystallizing moiety of IgG (Fcγ) on the fetal side of the placenta ('neonatal Fcγ Receptor', FcRn) [59]. These MHC class I-like receptors are pH-sensitive, having 100 $\times$ higher affinity for Fcγ at a pH of 6.0 compared to the physiological human pH of 7.4 faced in the maternal blood. The current concept assumes that the maternal IgG is captured by fluid phase endocytosis in endosomes with low pH but protected from degeneration by lysosomal enzymes. The endosomes are actively transcytosed through the cells and fuse with the membrane facing the fetal blood vessels, where the IgG is released from the FcRn now again facing the physiologically higher pH in the fetal blood [60].

Maternal IgG provides the newborn with a certain degree of protection against infectious agents previously encountered by the maternal adaptive immune system or via immunization. The presence of IgG in the mother indicates previous contact with the antigen; strength of maternal antibodies partly reflects the time interval since this encounter. In the setting of infections that can be transmitted through transplacental transfer to the child, positive maternal serology indicates an increased risk of infection in the child compared to seronegative mothers, simply by being a surrogate of previous infection of the mother [61]. However, higher maternal antibody levels against certain pathogens have been found to decrease the risk of infection with these agents, confirming the passive protection provided to the child. For example, the risk of neonatal sepsis with Group B *Streptococcus* was found to be inversely correlated with the antibody titre detected against these bacteria in maternal and cord blood [62]. Nonetheless, passively transfused IgG can only provide partial protection, especially against intracellular pathogens, and the transfer of various IgG subclasses is unequal, with subclass IgG2 having the lowest transfer [63]. Analysis of commonly present antibodies shows that the proportion of placental transfer varies depending on the nature of the antigen. Antibodies against proteins such as tetanus toxoid were represented in higher proportions (median 165%) in the infant compared to maternal plasma, while anti-polysaccharide antibodies (e.g. against *Haemophilus influenzae* and *Escherichia coli* lipopolysaccharides) were slightly lower than in the mother [57]. This observation is of major importance for infant transplantation because the antigens defining the blood groups of the ABO system are surface polysaccharides and IgG2 is the predominant antibody subclass produced in response to polysaccharide antigens [64]. One might speculate that this contributes to protection of the fetus from hemolysis induced by maternal antibodies in constellations of a blood group O mother pregnant with an A or B fetus, or a blood group AB child being carried by a mother of any other blood group. The specific implications of transplacental immunoglobulin transfer are discussed further on.

Breastfeeding

In contrast to various other animals, humans do not express the FcRn in the intestine and hence seem not to have active absorption of undigested immunoglobulins from the gut lumen [65]. Consequently, healthy infant IgG levels undergo a physiological drop, reaching a low at approximately 6 months of age with a subsequent slow but steady increase by early adolescence [66] with median values in the normal adult range by the age of about 9 years. Plasma IgG (and IgM) levels of infants are not different in breastfed versus formula-fed children [67]. IgM and IgA are not transferred through the placenta nor via intestinal absorption but are produced by the child, showing a steady increase from birth until adult values are reached by 17 to 18 years of age [66]. However, based on selective enrichment of IgA-expressing B cells in the mammary acini, human breast milk contains high concentrations of maternal IgA (secretion of up to 5000 mg/day) in the colostrum and moderate concentrations of IgG and IgM (up to 70 mg/day in the first week, decreasing to 10 mg/day from post-partum weeks 3–4) [68,69]. Despite the lack of intestinal absorption, this provides protection to the newborn and infant via intra-luminal binding and neutralization of antigens and toxins [70]. Interestingly plasma IgA levels were found to be higher in breast-fed compared to formula-fed children, possibly due to adaption or conservation of the child's own IgA [67].

Elements of the maternal immune system are also transferred into the child's gastrointestinal tract through leukocytes. While macrophages form the largest proportion of up to 85% of transferred leukocytes [71], with the obvious function of engulfing and inactivating harmful substances [72], the presence of mainly memory phenotype T and B cells indicates that a fully functional adaptive immune response of maternal cells may occur within the child's intestinal tract [68]. Additional immunologically active substrates within breast milk include lactoferrin, reported to impair bacterial adhesion capacity to the mucosal surfaces [73], and lysozyme, which contributes to intraluminal lysis of bacteria [74].

A variety of primary non-immunologic components of breast milk play an immunological role within the developing infant immune system such as non-digestible oligosaccharides that compete with structures of the mucosal surface for bacterial adhesion receptors, reducing the likelihood of the bacteria to bind to and invade the infant circulation [75]. Immunomodulating effects of intra-luminal immune components of maternal origin are assumed given the lower incidence of atopic disorders in breast-fed infants [76] and lower likelihood of necrotizing enterocolitis associated with breastfeeding in premature infants [77]. It has been proposed that this imparts a possible 'priming' effect on the immature immune system, facilitating the discrimination between 'benign' foreign substances tolerated as nutritional or otherwise essential elements of ingestion and potentially harmful substances targeted and destroyed by the immune system. Mechanisms include reduction of physical interactions with pathogenic substances, modification of the immunological milieu by secretion of cytokines and interactive cellular 'cross-talk' of intra-luminal maternal lymphocytes [68].

Despite the vastly uniform opinion amongst experts that various specific and non-specific immune components in breast milk provide the child with some degree of protection towards harmful substances [78], there are very few controlled clinical trials proving this assumption. The published trials were mostly performed in developing countries reflecting different threats to newborns than faced in 'developed' countries by infants awaiting organ transplantation. Several Cochrane reviews have concluded that the summation of available scientific data strongly supports breastfeeding as the best option for newborns, particularly in developing countries, leading to recent WHO guidelines recommending exclusive breastfeeding up to 6 months of age whenever possible [78].

The impact of breastfeeding on transplantation options and diagnostics in the newborn are considered further on.

Toddler and school age: gaining maturity and experience

In contrast to infants and the elderly, in whom susceptibility to infections is noted to be higher and outcomes generally worse due to immunologic naïveté and senescence, respectively, the middle childhood years typically represent a period of vigorous immune responses. A number of infectious diseases are reported to have lower mortality rates and milder disease course during the ages of approximately 4 to 13 years of age when compared even to healthy young adults [79,80]. Notable examples of this robust immunity are observed with regards to decreased susceptibility to influenza and tuberculosis infection in children compared to all other age groups, and decreased severity of disease manifestations when viruses such as varicella, measles, mumps and Epstein-Barr virus (EBV) are first encountered as children. This is partly due to the acquisition of memory B cells that can persist for many years and

can be rapidly activated to produce protective antibodies, and also by antibody levels maintained in serum for long periods of time by terminally differentiated long-lived plasma cells [81–86]. Memory $CD4^+$ and $CD8^+$ T cells also contribute to protective immunity against pathogens due in part to the speed with which their effector functions develop. In addition to immune memory and protective antibodies, it has been suggested that regulation of the balance between protective versus pathogenic aspects of immune responses may be different in children compared to older individuals, ultimately favouring tissue repair and regeneration after pathogen elimination over ongoing or extensive destruction [87].

In the setting of transplantation, the impact of these normal developmental processes on clinical outcomes has not been extensively studied from the perspective of their evolution in children transplanted as infants. However, for children initially undergoing (heart) transplantation during the middle childhood years, it can be noted that long-term outcomes are not as favourable as in those patients undergoing transplantation during the first year of life [105].

Adolescence

As in many other aspects of life adolescence is a critical period of human development. The highest rate of graft losses in organ transplantation, independent of time post-transplant and other risk stratification, is found in the age group between 15 and 25 years, a consistent observation independent of the organ transplanted [88–90]. The inferior outcomes for patients of this age are likely due to the summative impact of various factors. They are reviewed here, and treated in depth in Chapter 120.

Behavioural impact

First and foremost amongst factors contributing to worse transplant outcomes in adolescents are the huge mental and psychosocial changes occurring during this developmental stage. Children become adults and struggle with transition of their roles and responsibilities. This includes an increasing wish to take control over their lives while mostly not yet possessing the tools to perform challenging tasks appropriately and reliably such as the medical regimen associated with post-transplant care. Authority figures are questioned and challenged including parents and medical staff; aggressive, risk-taking and self-destructive tendencies are paired with immature coping mechanisms and increased emotional sensitivity. Obviously adherence to medical treatment and associated restrictions in everyday life are frequently poor in this age group [90,91]. The need for daily immunosuppressive medications and recommended limitations regarding recreational substance use are often in direct opposition to the individual perception and aspiration not to be different from the peer group. Inconsistency in immune suppressive medications can therefore partially explain the higher rate of acute rejection, higher frequency of development of donor-specific human leukocyte antigen (HLA) antibodies and graft failure observed during adolescence [92]. However, limiting consideration solely to these explanations ignores major metabolic and immunologic changes associated with puberty.

Impact of hormonal and metabolic changes on the immune system

Neuroendocrine factors, sex hormones and steroids as well as growth hormones have a major impact on various aspects of the immune system. During adolescence all these hormones undergo massive changes in quantities and patterns of secretion. Differences of the immune system between the sexes have been clinically recognized and scientifically investigated for decades; nonetheless, many aspects have yet to be explained and understood fully. Female humans, similar to many other animals, manifest a higher prevalence of autoimmune disorders than males [93]. Further correlations have been identified of variations in the activity of autoimmune disorders with the quantitative differences in sex hormones during the menstrual cycle and during pregnancy. Similarly, recurrent symptomatic flares of persistent infections such as herpes simplex have been found to be associated with the menstrual cycle and associated alterations of immune components and cytokines/chemokines [94]. Some disorders such as multiple sclerosis [95] and rheumatoid arthritis [96] have been found to exhibit significantly decreased activity during pregnancy. In contrast, for other disorders such as systemic lupus erythematosus, both exacerbation and reduction of inflammatory activity have been observed, and hormonal changes associated with the end of pregnancy have been found to be a trigger for disease flares [97]. This effect is not limited to hormonal influences but also involves exposure to the HLA molecules of the fetus, with the degree of disparity possibly contributing to modulation of immune responses [98]. Corticosteroids, whether generated by the adrenal glands or taken as medication, enormously affect both innate and adaptive immune elements. Steroids are thus used therapeutically to modulate immune responses in a variety of autoimmune and allergic disorders, as well as to reduce the allo-immune response post-transplant. Androgens and estrogens intrinsically have glucocorticoid effects; similar impact on the immune system was shown when high doses of sex hormones were administered [99]. High doses of testosterone were further found to cause release of tumor necrosis factor alpha (TNF-α) and apoptosis of $CD4^+CD8^+$ 'double positive' immature thymocytes [100].

Involution of the thymus was found to correlate strongly with increased secretion of sex steroids and their regulatory hormones [101], and to be reversible by surgical gonadectomy or chemical castration [102]. Additionally, it has been reported that many cells of the innate and adaptive immune system are impacted by growth hormones [103] and sex hormones [104], however the physiological function and clinical relevance remain to be determined. These hormones reach lifetime peaks during adolescence; the effects of this 'chaos' of hormonal interactions may cause changes of the developing human far beyond the isolated effect of each endocrine messenger. This indicates that the impact on immune maturation, immune responsiveness as well as tolerance and other therapeutic consequences is currently underestimated and warrants further investigation.

Implications of immune maturation on transplantation and vice versa

'Permissive' environment of early childhood

When organ transplantation is performed in early life, at a time of dramatic immunologic change, two major factors inherent in the process have an impact that remains poorly understood and incompletely explored: implantation of a large and persistent source of foreign antigens and introduction of chemical immunosuppression neither designed for nor tested in a rapidly changing developmental framework. In the setting of heart (and lung) transplantation, this is further complicated by the potential

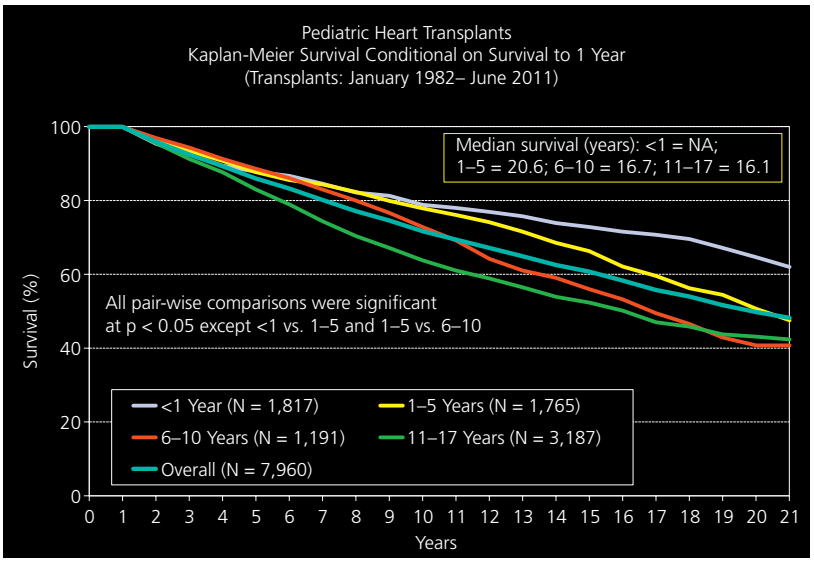

Figure 112.1. Conditional actuarial survival of pediatric heart transplant recipients surviving the first year post-transplant, stratified by age at transplant.
Source: International Society for Heart and Lung Transplantation, accessible from http://www.ishlt.org/downloadables/slides/2013/heart_pediatric.pptx

effects of neonatal thymectomy on immune function. The immunologic consequences of clinical organ transplantation are not limited to increased infectious complications (i.e. a higher susceptibility to infectious pathogens across a wider spectrum compared to later in life and a different course of post-transplant infections with common viruses). In contradistinction may also include provision of an advantageous environment in terms of transplant outcomes. The developing immune system is susceptible to tolerance induction and carries a degree of plasticity, diminishing over time, that renders it somewhat malleable, capable under the influence of chronic immunosuppression of 'adaptation' to the presence of a transplanted organ. Thus, the immature state offers unique opportunities to the very young patient such as safe blood group (ABO)-incompatible organ transplantation (see below), whereas later, the neurohormonal changes of adolescence paired with psychological and behavioural issues give rise to remarkable and complex challenges for the clinical teams taking care of transplanted children.

Superior long-term outcomes

It is well documented in the registry of the International Society for Heart and Lung Transplantation (ISHLT) [105] that children under one year of age at the time of heart transplantation have the best long-term survival compared to every other age group despite the higher early mortality found in multiple collaborative studies [106,107]. Infants undergoing heart transplantation are often in a more critical clinical state than older children before transplantation, including approximately 12% needing mechanical circulatory support in the form of extracorporeal membrane oxygenation (ECMO), and an increasing number being transplanted from ventricular assist devices (VADs). Despite the anticipated higher early post-transplant mortality, the actuarial survival curves for infant transplant recipients cross those of older children and adults, leading to a significantly better graft 'half-life', currently 19.7 years. The superior survival becomes particularly obvious when considering the conditional survival of children who have survived the first year after transplantation (Figure 112.1), which currently has not yet reached the 50% graft survival benchmark over more than 21 years of documentation [105].

After pediatric liver transplantation, nearly 20% of children achieve a state of operational tolerance, defined as normal graft function and absence of clinically relevant rejection without maintenance immunosuppressive drug therapy [108,109], a much higher proportion than reported in adults thus far. The same 'immunologic privilege' may also apply to very young kidney and lung recipients, but the low frequency of these transplants in very young children makes it harder to demonstrate any advantage of immunologic immaturity.

In transplant recipients, the role of regulatory T cells in the control of anti-donor immune responses is unclear. The effects of induction therapy and chronic immunosuppression on development and function of regulatory T cells and, in pediatric thoracic transplantation the additional impact of thymectomy, have yet to be studied in depth. T cell subsets and the T cell repertoire are clearly affected by neonatal thymectomy, which is typically performed with sternotomy procedures [110,111]. Preliminary data suggest that regulatory T cells in peripheral blood are indeed altered in these patients, with their numbers being significantly lower in heart transplant recipients compared both to thymectomized non-transplant patients (who do not receive T cell depletion and maintenance immunosuppression) and to healthy age-matched controls [112,113]. Moreover, the proportion of naïve versus effector regulatory T cells appears to be lower in transplant patients compared to healthy controls [114]. It remains to be elucidated whether this alteration in the diversity of regulatory T cell subsets under the persistent presence of allo-antigens together with immunosuppression promotes the development of stable donor-reactive regulatory T cells and contributes to better graft survival.

In summary, infants manifest particular maturational differences in components of the immune system that increase their susceptibility to various infections compared to older individuals. Development of effective vaccines for infants is aimed at overcoming these

immaturities to increase immune responses at an earlier age. It may be that these same developmental differences contribute to superior outcomes observed in infant transplant recipients and could be exploited still further to overcome remaining obstacles. Although documented only rarely in the literature [115], there is a common perception amongst pediatric transplant physicians that younger children generally require less intensive immune suppression after transplantation than older individuals. Many centers do not use induction therapy in infants, wean steroids earlier in young children (or avoid them altogether), and have lower target levels for calcineurin inhibitors in children transplanted at the younger childhood ages than required for older children. A recent multi-center study led by our group found de novo donor-specific HLA antibodies to occur only in children transplanted at older ages [116]. Moreover, de novo anti-class II HLA antibodies assessed by sensitive flow-based screening did not develop in any patients transplanted under the age of six years. Graft vasculopathy, representing chronic rejection, occurs least frequently in newborn and infant transplant recipients even as they age, while the incidence increases in the group of 1–10 year olds, and in teenage recipients is equal to that observed in adults [105].

Clearly this effect cannot be explained solely by immature immunity and is confounded by the lower frequency of additional risk factors in young children compared to adults including hypertension, non-favourable plasma lipid profiles and absence of associated disorders including extra-cardiac atherosclerosis, diabetes mellitus and chronic kidney failure [117]. Nonetheless there is little doubt that the developing immune system of young transplant patients provides them with a better chance of persistent graft acceptance than patients undergoing transplantation at any time later in life.

Acceptance of ABO-incompatible grafts

Beyond infancy, implantation of an ABO-incompatible graft in an unconditioned recipient carries a high risk of hyperacute antibody-mediated rejection due to high levels of pre-formed isohemagglutinins. In adult kidney transplantation, the barrier of ABO-incompatibility between donor and recipient has been successfully surmounted when preexisting antibodies to the donor blood group can be reduced at the time of transplant by a variety of means [118–123], thereby expanding the potential donor pool. For infants needing heart transplants, ABO-incompatible transplantation was initially contemplated as a reasonably safe option due to their natural lack of the immune mediators of hyperacute rejection, together with their inordinately high risk of death while awaiting an ABO-compatible donor [124]. In the decade since our original report of the first cohort of ten intentional ABO-incompatible heart transplants, it has been demonstrated that ABO-incompatible heart transplantation in young children carries no higher risk of mortality or morbidity than ABO-compatible transplantation and is an effective strategy for expanding the available donor pool for infants [125–127]. Indeed, pediatric cardiac transplant centres in a number of countries now routinely list very young patients for transplant without requiring donor blood group compatibility [128,129], although the limits of safety remain to be determined conclusively [130]. It is notable that in contrast to Canada and the UK, UNOS regulations continue to impair realization of the full benefits of this strategy in the US. [130–132]. Based on organ allocation rules developed decades ago for adult kidney transplantation, donor organs must first be allocated to ABO-identical then ABO-compatible recipients before being considered for ABO-incompatible recipients, despite this policy having no scientific rationale or relevance for infant heart transplantation.

In adult recipients of ABO-incompatible kidney grafts, it was noted decades ago that when antibodies to the donor blood group eventually re-accumulated, the graft was often resistant to antibody-mediated injury. Platt and colleagues described this phenomenon as 'accommodation' [56,133]; mechanisms of graft accommodation in the setting of both HLA and ABO antibodies are still under active investigation and are considered in detail in Chapters 4, 6, and 36. In contrast, young recipients of ABO-incompatible heart grafts, generally lacking abundant isohemagglutinins before transplant, typically remain deficient over time in the development of antibody production to the donor blood group while producing antibodies to other non-self antigens (Figure 112.2), a pattern more consistent with B cell tolerance than graft accommodation [134–138]. Moreover, when challenged with various specific and non-specific stimuli in vitro, cultures of peripheral blood cells from ABO-incompatible transplant recipients did not produce

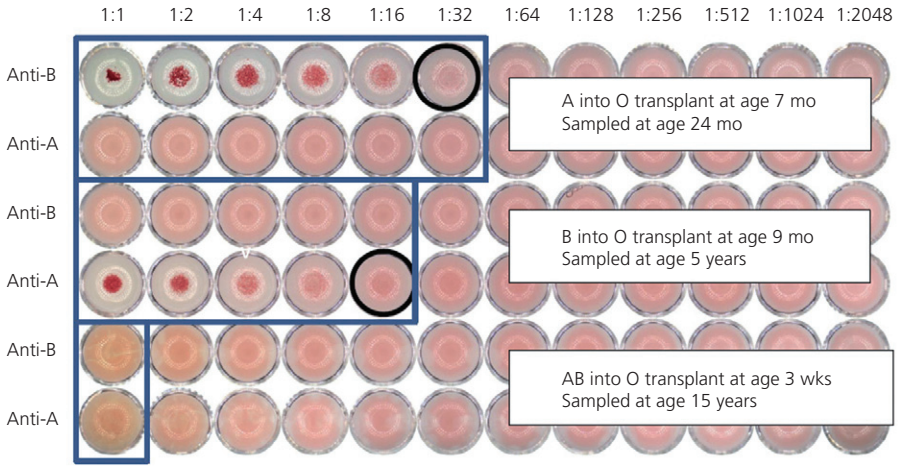

Figure 112.2. Examples of isohemagglutinin titres following ABO-incompatible heart transplantation assessed by microplate agglutination assay. Reproduced from [138] West LJ. (2011). ABO-incompatible hearts for infant transplantation. Curr Opin Organ Transplant 16:548–554 with permission of Wolters Kluwer Health.

antibodies against the donor blood group, suggesting that chronic exposure of maturing B cells to graft A/B antigens in this setting during early life results in their elimination in a process analogous to the development of self-tolerance [139].

When considering ABO antibodies and their potential importance in the setting of ABO-incompatible transplantation, it is crucial to understand the inherent limitations of the methods currently used for clinical measurement of isohemagglutinins [140]. Agglutination of reagent erythrocytes by antibodies present in serially diluted serum samples is read and reported as 'antibody titre'. It is widely known that this method has many limitations, including subjective assessment of degree of agglutination as well as lack of standardized methods from centre to centre [141]. Another potential confounder to interpretation of ABO antibody titres is that expression of ABO carbohydrate structure sub-types varies between reagent erythrocytes used for agglutination testing and tissue expression in organ transplants. Erythrocytes have been reported to bear all six carbohydrate chain sub-types of the A and B antigens while tissues generally do not [142,143]. This gives rise to the obvious conclusion that antibodies detected solely by agglutination of erythrocytes bearing A or B antigens that are not present in tissues may be clinically irrelevant in the setting of ABO-incompatible organ transplantation. Thus information from the ABO agglutination assay must be interpreted cautiously. While lack of agglutination may reliably indicate *absence* of ABO antibodies, agglutination of A or B erythrocytes may indicates presence of antibodies that may not be donor specific in regard to the organ graft.

Impact of transplacental immunity and breastfeeding on transplantation

Infectious disease diagnostics in the newborn and infant

Examination of the serum from newborns reflects the serologic memory of the mother and therefore cannot be used as a reliable diagnostic marker of infant infection. However, for infections that can be transmitted vertically from mother to child such as toxoplasmosis and cytomegalovirus (CMV) this situation leads to a diagnostic challenge [144,145]. One parameter that allows distinction between passively acquired maternal antibodies and infection of the child is the presence of IgM isotype antibodies in the child's serum. IgM pentamers do not undergo transplacental transfer due to their large molecule size and are not subject to FcRn-mediated active transcytosis. Therefore, unless the child received plasma infusion, IgM isotype antibodies in the infant blood will have been produced by the child's immune system and confirm infection of the child. However, IgM antibodies represent the first-line response of the adaptive immune system that subsequently switches to the IgG isotype and are found only for the first few weeks post-infection. Consequently, absence of IgM antibodies in presence of IgG in the infant's serum does not rule out infection earlier during pregnancy with an already faded IgM response. Direct testing for the infection may be helpful but does also not provide 100% sensitivity. In some cases of suspected infection the only reliable procedure is to treat the child as infected until the parallel fading of total and antigen-specific IgG confirms absence of infection [146].

In the context of neonatal and infant transplantation, infections of particular concern include CMV, EBV, toxoplasmosis and Herpes simplex (HSV), with the first two viruses having a major impact on long-term outcomes in pediatric transplantation. In the presence of positive IgG serology for CMV, cultures for virus detection from urine and a throat swab provide a sufficiently high negative predictive value to allow labelling a child as non-infected. For EBV, testing for virus capsid antigen (VCA)-specific antibodies is helpful to indicate recent infection; presence of IgM suggests infection of the infant, while high IgG titers not correlating with the maternal serology will be suggestive [147]. Nucleic acid testing polymerase chain reaction (PCR) has a very high specificity for infection if positive [148].

Since maternal antibodies from breast milk are not absorbed, breastfeeding should generally not alter infectious disease serology testing for infections acquired during the post-partum period. However, the significant presence of maternal leukocytes in the breast milk carries a risk of transmission of maternal infections to the child, especially in the setting of impaired host defence due to post-transplant immunosuppression. Therefore caution with breastfeeding is indicated whenever the mother develops clinical symptoms of an infection. Serious infectious diseases in the mother such as human immunodeficiency virus (HIV) that carry a risk of vertical transmission through breast milk should prohibit breastfeeding, as well as newly acquired or clinically re-activated infections with specific risk for immunosuppressed patients such as CMV or EBV [149]. A unique situation arises if the child of a seropositive CMV mother is deemed CMV-negative based on negative cultures and is transplanted with an organ from a CMV-negative donor. Given the low but existing risk of infection through breast milk in this case, post-transplant breastfeeding would be discouraged.

HLA and ABO diagnostics in the infant and newborn

It has been reported that up to 60% of healthy adults without previous surgeries or blood transfusions may have HLA antibodies when screened with highly sensitive techniques [150]. As with other IgG isotype antibodies, those directed against HLA epitopes are subject to transplacental transfer and can lead to passive presence of HLA antibodies in the newborn [57] that may persist up to 18 months of age with declining intensity [151,152]. Therefore, assessment of neonatal sensitization can be difficult and may only be confirmed by documenting the course and natural decline of the maternal antibodies relative to the infant's own immune response. Even a newborn is capable of generating a specific antibody response towards foreign HLA molecules if, for example, early cardiac surgery is required involving transfusion of thrombocytes and other blood products, cardiopulmonary bypass and especially implantation of human tissue allografts ('homografts') to reconstruct vessels. Indeed, infant recipients of vascular tissue allografts typically mount a robust and broad antibody response due to continuous exposure to the foreign tissue antigens in a setting in which immunosuppression is not used [153–155]. For those subsequently requiring transplantation, this clearly confers a high immununologic risk. Our group previously reported that simple intraoperative immersion of the homograft in glutaraldehye solution effectively prevents sensitization while not impairing homograft integrity [156]. Infant HLA sensitization is now rarely encountered at our centre, an enormous advantage for cardiac surgery patients who later require transplantation.

Differentiation between active HLA sensitization and passive antibody acquisition is crucial for planning peri- and post-operative clinical management. With passive antibody acquisition, antibody removal at the time of transplant should be sufficient to protect the child from antibody-mediated rejection, whereas actual sensitization with presence of immune memory may require aggressive

desensitization before proceeding with transplant, including antibody removal, B cell depleting (rituximab) and plasma cell reducing (bortezomib) treatments and immune modulation with IVIG. These patients may be excluded from transplantation if a suitable donor cannot be identified against whose HLA the patient does not have specific antibodies; if crossing the HLA-incompatibility, they face high risk of aggressive early antibody-mediated injury. The long-term burden of anti-HLA antibodies in a child with genuine sensitization and production of (donor-specific) antibodies and immune memory is much higher than in cases of transient passive antibody acquisition. These transplant recipients are at high risk of later re-activation of their immune response leading to antibody-mediated graft injury. This may not be limited to acute antibody-mediated rejection but may also include accelerated chronic rejection processes such as rapid graft vasculopathy in heart transplantation.

The differences in placental transfer of IgG subclasses and specificities may partly explain our observation that passively acquired anti-A and anti-B antibodies in neonates considered for ABO-incompatible heart transplantation are typically found less frequently and at lower titres than other antibodies, for example antibodies against infectious agents such as CMV or EBV. Also, in our own experience and observations from other groups, maternal blood group-specific antibodies tend to decline rapidly or disappear within a few weeks in infants whereas other maternal serologic markers persist regularly until 9 to 12 months of age and sometimes up to 18 months.

As detailed earlier in this chapter, maternal IgG or IgM antibodies are not absorbed through the intact intestinal barrier, hence the presence of maternal HLA or ABO antibodies should not preclude breastfeeding for infants awaiting transplant or post-transplant.

Transfer into adulthood: the recovering immune system

Children represent only a small proportion of organ transplant recipients; nonetheless, knowledge of mechanisms and elements of immaturity that contribute to superior graft acceptance in young children compared to adults has a major impact on transplant medicine for all ages. In preparation for hematopoietic cell transplantation, the recipient's own lymphoid system is depleted through irradiation and leukocyte-depleting agents. One could postulate that this represents a virtual 'reset' of the immune system leading to a relatively more forgiving immunologic environment of the graft toward host allo-antigens. Analysis of the recovering immune system in this setting shows that regeneration of the various components follows similar stages as observed in the developing immune system of the newborn [157–159]. However, overall reconstitution depends on multiple additional factors that are different in the adult compared to the infant or young child [160]. This includes some aspects discussed above such as absence of the thymus, differential representation of sexual hormones and growth hormones, and possibly differences in the grafted tissue itself after completion of growth and development and structural changes associated with multiple cell cycle replications. Even current multipronged approaches to eradicate the immune system in preparation for hematopoietic cell transplantation with a combination of 'lethal' irradiation and additional therapies do not deplete every immune cell [161]. In particular, cells that are in a resting or hibernating stage may persist and be reactivated during recovery. Thus the recovering adult immune system is not likely to achieve the same level of naïveté, or the potential to adapt to non-self antigens, as the evolving immune system of the very young. Indeed, attempts to induce immune tolerance in adults to transplanted organs using lymphocyte depletion strategies, or with partial bone marrow depletion and reduced dose irradiation, have met with limited though improving success, as described in Chapter 76. Therefore, for development of targeted therapeutic approaches in adults and older children, precise identification and characterization of immature pathways and interactions become even more important. In this regard, a possible key role for B cells is emerging. Following bone marrow depletion, newly produced B cells undergo similar developmental stages as during prenatal life and early infancy. In particular there is a high occurrence of the different stages of transitional B cells. These are characterized by surface expression of CD5 and CD10 and, in the first stage, low density CD21 [162]. During maturation, associated with 'Bruton tyrosine kinase'-dependent genetic rearrangement, transitional B cells increasingly express CD21 as well as CD23, CD44, Bcl-2, BAFF-R and IgD [162]. In a murine islet transplant model, this immature cell type was successfully induced by blocking B cell maturation signals or their receptors [163,164] and led to humoral allograft tolerance [165]. Similar findings were observed in humans when analyzing reconstitution of the B cell compartment in the first successful clinical trial of operational tolerance in kidney transplant recipients, in which long-term survival and function of HLA-mismatched grafts was achieved by partial bone marrow depletion followed by transfer of stem cells from the kidney donor, described in Chapter 76 [166]. It was noted that transitional B cells and plasma levels of the B cell activating factor (BAFF) were higher in patients in whom tolerance induction was successful [167].

Whether the state of donor-specific tolerance observed in infants receiving ABO-incompatible heart transplants (described earlier in this section) will develop in adults through depletion of B cells with monoclonal antibodies such as rituximab remains subject to speculation. In larger cohorts of adult recipients of ABO-incompatible kidney grafts, the majority showed eventual re-accumulation to some degree of antibodies to the donor blood group post-transplant, albeit at lower titres than pre-transplant and typically without clinical rejection. However, a group was observed with persistent absence of antibodies to the donor blood group, while a different minority was found to develop unmanageably high titres and graft loss [120,122]. Thus, only a minority of adults showed reconstitution after B cell depletion mimicking the primary immaturity of infants, while the majority followed a different pattern.

Summary

In conclusion, understanding the immature and developing immune system will not only help personalize and adapt clinical transplantation to the specific needs of the individual along the continuum of human development, but will also continue to open windows into the delineation of mechanisms of self-tolerance and allo-tolerance. Exploiting naturally occurring aspects of immaturity to the benefit of graft and recipient survival must be a major part of transplantation research.

CHAPTER 113

Pediatric Kidney Transplantation

William Harmon
Boston Children's Hospital, Boston, MA, USA

Introduction

Kidney transplantation is in children, as in adults, the preferred treatment for most causes of end stage renal disease, particularly in children over 10 kgs. However, the indications bringing children to require transplantation differ from those of adults, as do the co-morbidities. Additionally, the pediatric population offers unique technical (particularly urological) challenges related to congenital anomalies, social support concerns and issues of non-adherence, and nuances of immune, physical and emotional maturity that clearly distinguishes the practice of pediatric transplantation from adult transplantation. This chapter will provide an overview of pediatric kidney transplantation with particular attention directed toward those aspects of the patient population served that define the field. This chapter complements the information on adult kidney transplant conduct and patient management found in numerous chapters elsewhere in this title.

The role of transplantation in children

Chronic dialysis and renal transplantation are both excellent treatments for end-stage renal disease (ESRD). The majority of adults with ESRD are receiving dialysis rather than undergoing renal transplantation. The number of adults seeking kidney transplantation is rising but the number performed has been limited by the lack of appropriate donors [1]. There is a survival advantage of transplantation for virtually all candidates. Renal transplantation was recognized as the better form of treatment for children with ESRD almost three decades ago [2] and has repeatedly shown to provide a survival benefit for children [3,4].

Both peritoneal dialysis, delivered as continuous ambulatory or cyclic peritoneal dialysis (CAPD or CCPD), and hemodialysis provide a worse quality of life and unsatisfactory growth rate as well as ongoing complications. Data from the dialysis component of the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) registry [5] show that the overall height deficit of −1.8 standard deviation (SD) became more negative reaching a value of −2.16 SD at 24 months after initiation of dialysis. Additionally, children do not tolerate being "dependent" on the modality and maintenance dialysis which induces loss of self-esteem and emotional maladjustment in them [6]. Cognitive achievement testing may diminish with prolonged time on dialysis [7]. In contrast, the mobility and freedom from dietary restrictions afforded by a functioning renal transplant enable children to live nearly normal lives. Although renal transplantation has not lived up to the promise of normal growth for all children, dramatic short-term improvements in height can be seen in many and final adult height is improving after transplantation [8–12]. Importantly, successful transplantation permits the child to attend school and to develop normally, and school function testing improves dramatically following transplantation [13,14]. Young children have the best long-term outcomes of all age groups of transplant recipients, verifying the utility of transplantation in this age group [15,16]. For all of these reasons, successful renal transplantation remains the primary goal of programs that care for children with ESRD [3,17]. Pediatric recipients of kidney transplants have the highest percentages of living donors; and, they receive substantial preference on the deceased donor (DD) transplant waiting list [18], leading to potentially short waiting times. Thus, pediatric patients with ESRD should not have substantial delays in undergoing renal transplantation after they develop ESRD, although the goal of rapid progression to kidney transplantation has not been universally achieved [19].

The incidence and frequency of pediatric renal transplantation

Between 2008–2012, there were about 16 500 kidney transplants performed in the US annually and about 800 of these were in children younger than 18 years [19] (Figure 113.1), suggesting that pediatric patients comprise about 5% of all transplant recipients. Although the number of pediatric transplants performed each year has generally varied by no more then 10%, the donor origin has undergone substantial changes. The Scientific Registry of Transplant Recipients (SRTR) data show that living kidney donation has expanded substantially and the number of living donors (LDs) exceeded the number of DDs for the first time in 2001 [20]. However, the number of LDs rose slightly until 2004 and has fallen since that time; while the number of DDs has remained stable [21]. Living donation now accounts for 36% of all kidney transplants in the US. In 1987, only 40% of all transplants performed in children were from a LD source; by 1991, the figure had risen to 53%, and until 2005 LDs were the predominant source of donors for pediatric kidney transplantation. A change in DD allocation that provided substantial preference to waiting children as soon as they were activated on the DD list led to a surge in DD transplants and a current predominance in DDs for children awaiting kidney transplantation (Figure 113.1). Although this change has undoubtedly led to more rapid transplantation for these children, there may be a decrease in mean graft survival rates related to this shift [22].

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

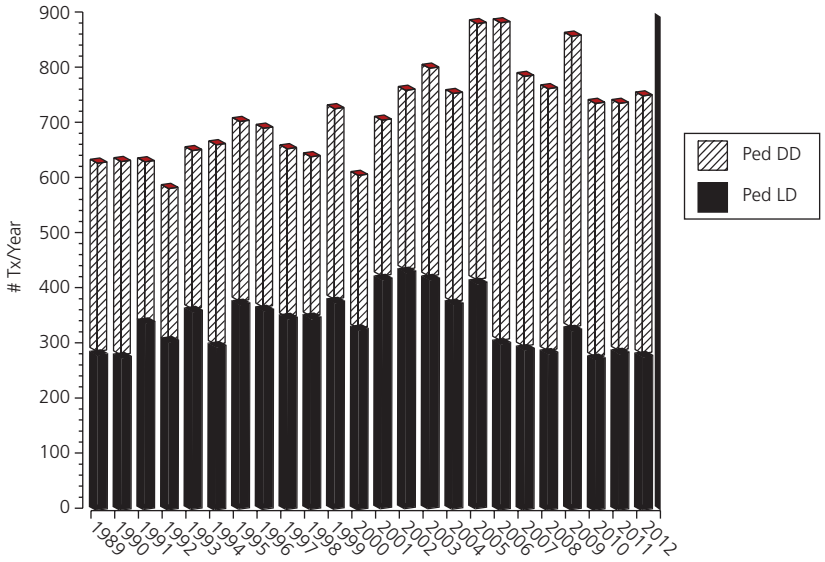

Figure 113.1. Number of living donor (LD) and deceased donor (DD) kidney transplants in children younger than 18 years of age by year between 1989 and 2010 (adapted from UNOS data: www.optn.org).

Parents comprise the majority of LDs. Mothers comprise the majority of parent donors; fathers account for 46%. Since there are more boys than girls who receive kidney transplants, it should not be surprising that fathers donate to sons 64% of the time and mothers to sons 60%. There is no outcome advantage to either parent, with the possible exception that infants less than one year of age seem to have fewer rejections if the mother is the donor [23,24]. Due to the fact that children most often have siblings who are too young to donate (less than 18 years), there are few transplants between siblings. NAPRTCS has identified150 grafts were from donors less than 21 years of age. A review of the NAPRTCS registry identified only 12 living donors under 18 years of age, of which 11 were transplants between siblings and one was from parent to an infant. It is quite clear that most programs are very reluctant to use minor donors [25,26]. However, a review of United Network for Organ Sharing (UNOS) data revealed that from approximately 40 000 LDs in the US between 1987 and 2000, 60 were from donors less than 18 years of age [27]. Twenty-four of the recipients were children and 36 were adults; only seven of the transplants were between identical twins. In recent years there has been a substantial interest in living-unrelated donation in adult transplant literature since the outcome of the grafts has been shown to be better than that of DD kidneys [28]. NAPRTCS identified 123 instances of living-unrelated donation between 1987 and 2001. In a preliminary analysis of the first 38 living-unrelated recipients, 23 (61%) were male, 30 (79%) were Caucasian, eight were younger than six years old, and 20 were older than 12 years [29]. This was the primary transplant for 29 of the 38 recipients. Of the 38 donors, 22 were non-biologic parents, and a family friend was the donor in ten of the cases. In 2008, UNOS documented 293 pediatric LD kidney transplants: 189 (68%) were from parents, 24 from siblings and 30 from other biologically related. Thus 83% of LD kidney transplants in children came from biologically related donors.

The majority of DD kidneys for children are recovered from adult donors. In the 1980s there was a tendency to preferentially place kidneys recovered from infants into infant recipients, with disastrous consequences for patient and graft survival [30]. As a result of widespread dissemination of these data [31,32], there has been a marked change in the practice. From 1987 through 1990, the percentage of DDs older than ten years ranged from 59–68%. From 1991 through 1994, these percentages ranged from 78–88% and has continued to rise to greater than 90%. Prior to 1991, children younger then two years of age comprised 3.2% of DDs. In 1991, no pediatric recipient received a kidney from a DD less than two years of age; and in 1995 and 1996, there were no such kidneys utilized in children [33]. The early change in allocation of kidneys from young donors led to improvement in graft survival [30]. More recently there has been improvement in outcomes of kidney transplantation using young donors [17,34,35], but many programs transplant grafts from very young donors into older recipients [36,37].

Patient selection and indications for transplantation

Etiology of ESRD in children

Generally ESRD in children is due to congenital or inherited diseases. In reviewing 10 632 index transplants in the NAPRTCS database, the most common congenital diagnoses are obstructive uropathy and aplastic/hypoplastic/dysplastic kidneys, each representing about 16% of the patients [3] (Table 113.1). Among glomerular disorders, focal segmental glomerulosclerosis (FSGS) is the most common with 1246 children receiving a renal transplant for FSGS between 1987 and 2011. The primary diagnosis also varies with the race of the recipient. Overall in the NAPRTCS registry, Caucasian children account for 64% of all recipients; however, Caucasian children account for less than 50% of the children transplanted for FSGS. The data regarding the role of FSGS in leading to ESRD can be better appreciated by observations from the dialysis section of the registry, in which the two most common diagnoses are FSGS and aplastic/dysplastic kidneys at 14% each. Of 733 children with FSGS on dialysis, Caucasian children account for only 34%, with African-American and Hispanic children accounting for 62% of the patients. Twenty-four percent of African-American children on dialysis and 30% of those >12 years old have FSGS. The information regarding primary diagnosis is critical in predicting graft survival as well as recurrence of the original disease, as discussed below.

Table 113.1. Pediatric kidney transplant gender and race distribution by primary diagnosis

	N	%	% Male	% White	% Biopsied

Adapted from Smith et al. [3].

Indications for renal transplantation in children

There has been a substantial change in long-term renal allograft outcome for children during the past decade [3,38–40]. Previously, young children were thought to have poor short- and long- term graft survival related to several factors, most prominently a proposed heightened immune response, especially in infants [41,42]. The most recent comprehensive registry reviews have clearly demonstrated a dramatic reversal in outcomes with marked improvements in patient and kidney graft survival for infants and young children [16,21,38,39,43]. Indeed, several analyses have identified these very young recipients as now having the best long-term survivals of all age groups [16,23,38,44] (Figure 113.2). Thus, children of all ages are excellent transplant candidates. By the time the child has reached chronic kidney disease (CKD) stage 4–5 planning for kidney transplantation and pretransplant preparation should have begun. There are very few contraindications to kidney transplantation in children. Perhaps the only two are another otherwise-fatal condition with a short projected survival, such as metastatic Wilms' tumor; and, severe neurological compromise. About 75% of children are treated with a course of chronic dialysis prior to renal transplantation, but unless there is a need for specific pretransplant preparation, there is no advantage to pretransplant dialysis. Preemptive renal transplantation, indeed, has a survival advantage [45–49].

Recipient age at transplantation

Kidney transplantation prior to six months of age, or in a recipient who weighs less than 6 kg is exceptional. Since 1987, UNOS has recorded 111 transplants performed in children younger than 12 months compared to about 3500 performed in children 1–5 years of age. Of these, seven transplants were performed in children between 3–5 months, 22 were performed in children between 6–8 months, and 63 were performed in children between 9–11 months of age. Only 31 infants have been reported since 2000. Since infants and adolescents have different risk factors for both patient and graft survival, children frequently have been grouped into five age categories: 0–1, 2–5, 6–12, 13–17 and 18–21 years of age. In 1987, 119 children 1–5 years old received kidney transplants whereas in 2012 the same age group received 187 transplants. Early on, excellent results were obtained is very young patients in some individual centers [44,50] but the concept of a heightened immune response in young recipients suggested that they were a high-risk group [51–53]. The unique problems associated with transplantation in young recipients may have been related to infections, technical issues and differences in pharmacokinetics [23,54–58] rather than their immune response.

There has been a substantial change in long-term renal allograft outcome for children during the past decade [38–40]. Previously, young children were thought to have poor short- and long- term graft survival related to several factors, most prominently a proposed heightened immune response, especially in infants [41,42]. The most recent comprehensive registry reviews have clearly demonstrated a dramatic reversal in outcomes. Improvements in surgical technique [59–63], donor selection [64], immunosuppression practices [65–69], and the enhanced experience of specialized pediatric transplant teams [70], as well as the development of

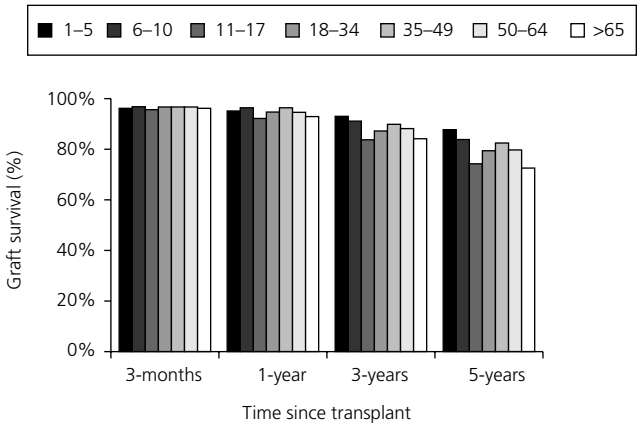

Figure 113.2. Living donor kidney transplant survival by recipient age at the time of transplantation. Reprinted from Magee JC, Krishnan SM, Benfield MR, et al. Pediatric transplantation in the United States, 1997-2006. American Journal of Transplantation. 2008;8(4 Pt 2):935–945.

multi-center research consortia have all led to marked improvements in patient and kidney graft survival for infants and young children [38,39,43]. Indeed, several analyses have identified these very young recipients as now having the best long-term survivals of all age groups [16,23,38,44,71]. In fact, young recipients of adult-sized kidneys who have immediate graft function have been reported as having the longest projected graft half-lives, exceeding even those of adult recipients of 2-haplotype matched living donor (LD) transplants [72].

Pediatric recipients under age 11 who receive LD kidney transplants have three-year graft survival rates that are as good or better than older age groups (93% for those aged 0–5 years, and 92% for those aged 6–10 years) [16]. The results of young recipients of DD kidney transplants are similar to those seen in adults, with recipients aged 1–5 years and those aged 6–10 years having three-year graft survival rates of 82% [16]. Unfortunately, this excellent outcome is not seen in adolescents [73,74] whose three-year graft survivals for both LD (85%) and DD (76%) grafts are worse than all other age groups (Figure 113.2).

Management of the transplant list

Recipient preparation

Before a child can undergo renal transplantation, the problems caused bychronic renal insufficiency (CRI) must be addressed and repaired if possible. In those cases where ESRD is due to urologic abnormalities, corrective reconstructive surgery should be undertaken, especially to the lower urinary tract, prior to transplantation. Two of the major consequences of CRI are anemia and growth retardation both of which should be addressed prior to transplantation. A recent report of final adult height in pediatric renal transplant recipients suggests that the current improvement in final adult height post-transplanttransplantation is more related to improving height deficits prior to transplant than to any net gains achieved after transplantation [10,12,75]. Uremia also leads to wasting and malnutrition in the child, and this can compromise the success of the procedure. For example, prophylactic native nephrectomy and reversal of protein wasting and malnutrition improves the outcome of transplantation in children with congenital nephrotic syndrome [76–78]. Careful preparation is particularly important in children undergoing pre-emptive transplants. Since live-viral vaccines are generally not indicated or effective in chronically immunosuppressed patients, children should receive all appropriate vaccines pretransplantation. There are various reports concerning the efficacy of immunization protocols for children pretransplantation [79–82].

Urological preparation

Children with urologic causes of ESRD require a thorough urologic evaluation prior to transplantation and they frequently require pre-transplant reconstructive urological surgery [83–86]. In a NAPRTCS report, 1878 of 7651 (25%) pediatric transplant recipients were identified as having lower urinary tract abnormalities [43]. For all such patients, a history of voiding pattern prior to development of renal failure is most helpful. Preliminary investigations consist of measurement of urinary flow rate and ultrasound estimation of the post-transplant micturition urine volume. Urinary flow rate should be at least 15 ml per second [87], and the residual volume should be less than 30 ml. Further investigations would consist of urethrocystoscopy in patients suspected of a urethral stricture, and a voiding cystometrogram is essential for complete assessment of bladder function [88]. This provides information about bladder capacity, pressure rise, and the efficiency of voiding. Still more information can be obtained by combining the urodynamic studies with radioisotope imaging. Routine voiding cystourethrogram is not indicated in older patients with no symptoms related to the urinary tract [89].

A bladder with a very small capacity may not be adequate for a functioning transplant. Occasionally a small capacity bladder may be seen in patients with prolonged oligoanuria. However if the bladder is distensible and the bladder wall compliant, such a bladder may be used safely for kidney transplantation. Other criteria for a useable bladder are an end-filling pressure less than 30 cm of H_2O, and a good flow rate. In patients with a poor flow rate, if urethral and bladder outlet obstruction are ruled out, the problem may be due to detrusor malfunction [87]. When a bladder fails to empty completely, infection and obstruction are potential complications that may shorten graft survival. Intermittent, clean, self-catheterization, which is widely used in urologic practice, can be safely used post-transplanttransplantation in patients where the primary abnormality is inefficient and uncoordinated detrusor function. Most pediatric patients have a urinary bladder that will adapt to the new kidney. Although the bladder may not appear to have the capacity, especially in patients on long-term dialysis prior to transplantation, it will most often distend with usage [90]. However in patients with a truly low capacity or high pressure, bladder augmentation may be necessary prior to transplantation [91–94].

The goal of modern reconstructive pediatric urology is to have a competent low-pressure urinary reservoir which can be emptied by voiding or at least by intermittent catheterization. Augmentation cystoplasty consists of adding bowel or gastric wall to the bladder, whereas substitution cystoplasty is performed when most of the bladder is excised and replaced with bowel. Gastric remnants have been popular for augmentation, however they do tend to cause excessive loss of acid in the urine, leading to discomfort and metabolic alkalosis. Early attempts to reconstruct bladders with bioengineered material are ongoing. There are promising reports of "bio-engineered" bladder material, although these have not yet been tried in transplant recipients [95–97]. Urologic reconstruction, including augmentation cystoplasty, typically occurs prior to

transplantation [85,86,93,94,98–102]; although some programs have reported successful reconstruction after transplantation also [84]. In those patients in whom augmentation has been performed, long-term antibiotic therapy and intermittent catheterization may have to be carried out to prevent urine stasis and infection. In general, the incidence of urinary tract infection and other complications is higher in these recipients, their course is generally no worse than pediatric recipients without urologic abnormalities [94]. If native kidneys in children with ESRD are causing hypertension, chronic infections or excess losses of protein, urine or other substances, there should be consideration for nephrectomy prior to or at the time of transplantation [103]. About 25% of children have native nephrectomies prior to index transplants [104].

Donor preparation

Donor selection

The selection of the appropriate donor is an integral part of the transplantation procedure and may be a limiting factor in the long-term outcome of kidney transplantation for any individual child. The use of living donors has generally been more common in pediatric kidney transplantation than in adults [3,16,32,33,38,43,104,105]. On average, graft survival can be twice as long when a LD is used compared to a DD [22,38,104,105]. There are limitations to the use of living donors however, such as donor suitability, blood group incompatibility and age; and, thus, not every child may have a suitable living donor. Moreover, there is concern about using living donors when there is a substantial risk of early graft failure or recurrent disease [106,107]. When DDs are used for children, careful attention should be paid to utilizing low-risk donors since the mortality risk for children after kidney transplantation is low and children are expected to require the grafts for long periods of time [18,64,108–110].

Living donor

The first successful kidney transplants utilized living donors and the use of living donors has been a mainstay of pediatric kidney transplantation since that time. Importantly, as the donor shortage has become more acute, considerations about donor safety have also become apparent [111]. Recently, the transplant community has examined this issue and has reached consensus on the appropriateness of the use of living donors, their evaluation process and the appropriate follow-up and care of those donors [1,112]. The donor should never be put at physical, emotional or psychological risk for the benefit of the recipient. Included in this principle was the agreement that children less than 18 years of age should not be considered as living donors, although that has not been universally observed [27,113]. The LD pool has been increased by the use of genetically unrelated donors, which initially included spouses, but has expanded to include other genetically unrelated family members, friends or even anonymous non-directed ("good Samaritan") donors. Importantly, the outcomes of these unrelated donors appear to be comparable to related donors [114–121]. There have even been proposals that non-directed living donors be compensated for the donation, leading to a commercial system to expand the donor pool [122,123]. Although commercial systems using paid donors have existed in many parts of the world, most countries have declared such practices illegal and the broad transplant community has condemned them [124,125]. The use of non-directed living donors have also played an important role in expanding the donor pool through the practice of donor exchange. These programs have allowed living donors to donate to an unrelated recipient in exchange for that recipient's incompatible donor to donate to the former's family member [126–128]. These programs have included simple two-recipient exchanges, multiple domino-style exchanges and exchanges with the DD waiting list [129–139]. In depth treatment of the ethics of living donation can be found in Chapter 138, and specific coverage of Pair Exchange donation is found in Chapter 27.

The work up for a donor proceeds as described in detail in Chapter 23. In general, all living donors are evaluated for ABO blood type, human leukocyte antigen (HLA) histocompatibility typing and some type of cross-matching with potential transplant recipients. Parents predominate as living kidney donors for children, accounting for about 80%. Unrelated donors, siblings and occasional non-directed donors make up the balance [105]. Thus, there are few 2-haplotype donors for pediatric kidney transplantation, with most donors being 1-haplotype HLA matched, or less. Although there may be some disadvantage to the lack of any HLA-B matching [105], overall the lack of histocompatibility matching for pediatric recipients, especially infants, does not seem to compromise long-term outcomes [23,72].

As noted above, donors are carefully evaluated in order to assure that they are not being paid, coerced or that they might be injured in any way as the result of the donation procedure. The components of an appropriate donor evaluation have been published [140,141]. Much of the evaluation is performed to assure donor safety, but also it is designed to assure that the donor does not transmit infectious or other diseases to the recipient and that the donor organ will provide sufficient function for the recipient. In general, donor candidates are excluded if they are too young (<18 years of age), too old (as individuals age, they lose glomerular filtration rate (GFR) and the potential for cancer, cardiovascular and other diseases increases) or have medical problems that may be exacerbated by the donation surgery or living with only one kidney [112]. Conditions such as hypertension, diabetes and a history of metastatic cancer typically exclude donors. Also, chronic infections such as HIV, or hepatitis B or C are exclusionary because of the likelihood of transmission. Although cytomegalovirus (CMV), human papillomavirus (HPV) and Epstein Barr Virus (EBV) may also be transmitted, these are typically not exclusionary, since they can be treated in the recipient.

Deceased donor

The majority of kidney transplants currently come from DDs. While living donors were more common for children in the past, changes in allocation policy in the US has led to a predominance of DD transplants for children since 2006 (Figure 113.1) [4,16,18]. The consequences of this change in donor selection will not be known for years; but, on average, the long-term outcomes of LD kidney transplants in children are superior to those obtained from DDs (Figure 113.3) [3,16,18,104,105], indicating that the short term benefit of having rapid access to the DD list may be counterbalanced by shortened graft survival.

For many years there was a tendency to utilize kidneys recovered from infants and young children for transplantation into young recipients [30]. Early studies showed that 25% of all DD transplants performed in children were recovered from children under ten years [41]. A special study of the NAPRTCS [64], demonstrated that the preferential placement of small kidneys into infants and very young children had disastrous consequences for graft survival and this was subsequently confirmed by a larger study [142]. As a result,

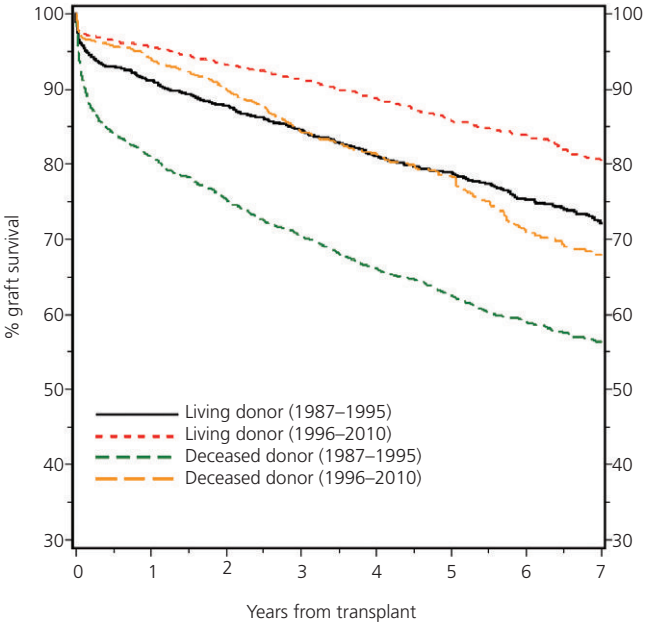

Figure 113.3. Seven-year graft survival of living and deceased donor pediatric kidney transplants from two eras. Reproduced from NAPRTCS 2010 Annual Report: www.naprtcs.org. https://web.emmes.com/study/ped/annlrept/2010_Report.pdf. [December 19, 2013].

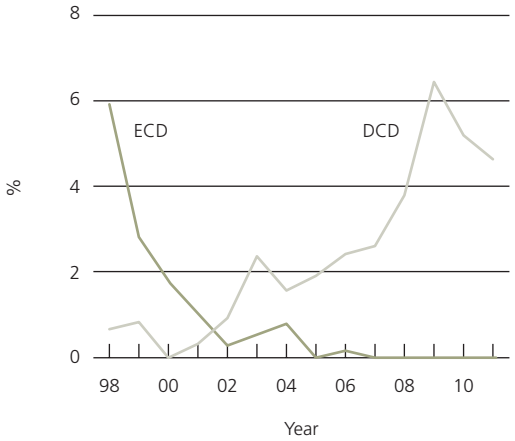

Figure 113.4. Frequency of extended criteria donors (ECD) and donors after cardiac death (DCD) as source of deceased donors for pediatric kidney transplantation 1998–2010. SRTR 2012 Annual Report: http://www.srtr.org/ [accessed December 19, 2013].

DD allocation policies for pediatric recipient were changed resulting in improved outcome [30]. More recent information shows that this practice has now undergone substantial change [43]. Since 1991, less than 1% of DD kidneys for pediatric recipients have come from donors younger than two years old. And, during the same time, the percentage of kidneys recovered from donors over the age of ten years increased from 78% to 88%. Importantly, the kidneys from young donors have not been discarded, but have been utilized for transplantation via the en bloc technique into adult recipients [36,142,143]. Single centers have reported better success with young donors, utilizing carefully controlled protocols [34,35]. Advanced donor age is also associated with diminished long-term graft survival [144,145] and likely should be avoided for young recipients [64,146,147].

The influence of matching on transplant outcome used to be substantial, but it has diminished significantly since the introduction of improved immunosuppression [148–151]. Pediatric DD kidney transplant outcomes are influenced very little by donor histocompatibility matching [18,104,105]. ABO blood type compatibility and cross matching are still necessary, however. In general, transplant candidates who have preexisting antibodies or who develop antibodies after transplantation are at higher risk of early rejection and should have enhanced immunosuppression protocols [152–156].

Deceased donors are typically evaluated to assure that the graft will provide sufficient function for the recipient and that the donor does not transmit infectious or metastatic cancer diseases to the recipient. In the past, the standard for determining the donor eligibility rested on the determination of brain death. However in efforts to expand the donor supply, recent advances have been made in recovering organs from donors whose death has been determined on the basis of cardiac death, so-called donation after cardiac death (DCD). Children are receiving these grafts at an increasing frequency (Figure 113.4). Although there is a substantially higher incidence of delayed graft function when such donors are used, the short term outcomes of kidney transplants from DCD donors is equivalent to that from brain-dead donors [118,128,157,158] but there is some concern about late graft loss [159].

Most countries with national organ allocation systems have provided some sort of preference for pediatric deceased-donor transplant candidates. In the US, a recent change of the Organ Procurement and Transplant Network (OPTN) allocation system gives children under18 years of age at the time of listing, preference over most other candidates, resulting in much shorter waiting times than adult candidates [18]. The use of elderly or extended criteria donors (ECD) has continuously been associated with poor outcomes [119,128,145,160]. Children rarely receive organs from elderly DDs or from extended criteria donors (Figure 113.4) [104].

The transplant procedure

Technical issues in transplantation

The operative technique differs based on the weight of the child. For small children, less than 15 kg, the transplant is frequently done through a midline incision and the larger vessels are utilized for anastomosis with the donor kidney [90]. After reflection of the cecum and the right colon, the anterior wall of the aorta and the inferior vena cava are exposed and dissected [161]. The aorta is mobilized from above the inferior mesenteric artery to the external iliac artery on the right side. After ligating and dividing the lumbar branches, the iliac arteries and the inferior mesenteric are encircled. Next the inferior vena cava is mobilized from the left renal vein to the iliac veins. After ligating the lumbar veins the iliac veins are encircled. The donor renal vein is anastomosed to the recipient vena cava in an end-to-side technique [162]. The donor renal artery is then anastomosed to the recipient aorta in an end-to-side fashion. Careful attention needs to be paid to the recipient hemodynamic response upon clamping and unclamping of the major vessels, and it is desirable to maintain a central venous pressure of 15–18 cm H_2O prior to unclamping [90,161].

The filling of the transplanted kidney may be slow due to the fact that a large adult kidney will take up a significant portion of the normal pediatric blood volume. Hemodynamic studies suggest

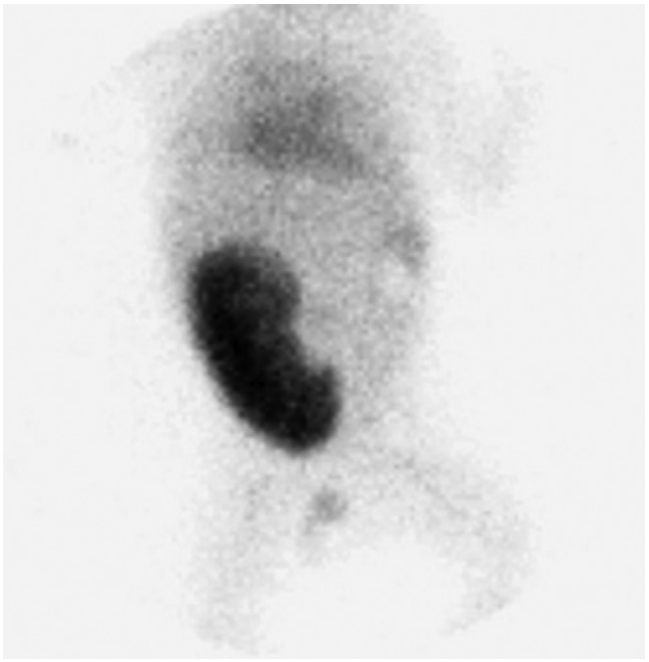

Figure 113.5. ^{99M}Tc-MAG3 radionuclide renal scan in a nine-month-old infant who received a living donor (LD) renal transplant from his father. The graft is intraperitoneal and occupies most of the right side of the peritoneal space. Note the relative sizes of the graft and the heart. Reprinted from [315] Harmon WE. Pediatric kidney transplantation (Chapter 75). In: Avner ED, Harmon WE, Niaudet P, et al., editors. Pediatric Nephrology, 6th ed. Springer; 2009: Oxford University, UK: 1867–1901.

that the cardiac output of infants must double in order to perfuse the adult donor kidney adequately [163]. Thus volume replacement is critical (Figure 113.5). The ureteral anastomosis is done by implanting the donor's ureter into the recipient's bladder using either a Ledbetter-Politano procedure or a modification of it to assure non-refluxing anastomosis. However, most surgeons now prefer a non-refluxing extravesical rather than transvesical approach for ureteroneocystostomy (see Chapter 55) because it is faster, a separate cystotomy is not required and less ureteral length is necessary, thus assuring a distal ureteral blood supply [164–166].

The transplantation technique utilized in children with a body weight greater than 15–20 kg is similar to that employed in adults described in Chapter 55. Unlike the transperitoneal approach necessary in younger children, this transplant is extraperitoneal, with the renal vein anastomosed to the common iliac or the external iliac vein [161]. The arterial anastomosis can be to either the common iliac or internal iliac artery. The ureterovesicular anastomosis is done utilizing the techniques described above.

The use of a laparoscopic technique to remove the LDkidney has become very popular recently, because it tends to shorten the hospitalization and rehabilitation time for the donors. The procedure does require substantially longer time in the operating room and the rate of delayed graft function is slightly higher. Although most programs indicate that the procedure is safe, a review of 10 000 living organ donations identified three deaths or serious complications; all three followed laparoscopic procedures [167]. Although some studies suggest more complications in the pediatric recipients [168,169], most reports demonstrate good outcomes when the donor has a laparoscopic nephrectomy [170–175].

Evaluation of graft dysfunction

At the completion of the vascular anastomosis and release of the vascular clamps immediate function of the transplanted kidney is demonstrated by the production of urine. Various causes however, may prevent initial function, and evaluation of immediate non-function and the differential diagnosis of this condition is a critical component of the transplant physician's role.

Delayed graft function (DGF)

A well-functioning kidney graft should lead to normal renal function within two–three days. The lack of attainment of normal renal function, as demonstrated by a fall of the serum creatinine to normal levels, is termed delayed graft function (DGF). There is no consensus concerning the definition of DGF [176]. In some settings, DGF is used only to distinguish recipients who require dialysis after transplantation, which is a stringent but commonly-used definition. Acute tubular necrosis (ATN) represents the most frequent cause of immediate graft non-function. The risk of early ATN is related to factors such as prior transplants, prolonged cold ischemia, absence of prophylactic antibody therapy and the use of more than five pretransplant blood transfusions. If recovery of graft function is delayed, however, a transplant biopsy may be necessary since other diagnostic tests cannot distinguish between ATN and rejection or sudden recurrence of primary disease [177–179]. Importantly, early acute rejection can mimic ATN or coexist with it [180]. The presence of ATN does not auger well for the transplant, particularly for recipients of DD grafts since graft failure and death are more common among patients with ATN [181,182]. DGF is an independent risk factor for graft loss and death [183–185]. Importantly, although the incidence of DGF is increased when a DCD donor is used, the detrimental affect of DGF on long-term outcomes in this setting does not appear to be as severe as when it occurs after living donation or after transplantation from brain-dead DDs [157,158,176].

Graft thrombosis

Graft thrombosis is an almost unique complication of pediatric transplantation. Although usually a major cause of immediate graft non-function, it can be seen later on in the course, and has been recorded to occur as late as 15 days post-transplanttransplant following initial engraftment and function. Graft thrombosis has been the third most common cause of graft failure in pediatric renal transplantation, accounting for about 10% of graft losses [3,43]. It is irreversible in most cases and necessitates removal of the graft. Graft thrombosis should be suspected in cases where there has been immediate function followed by the development of oligoanuria. The diagnosis is established by a radionucleide scan using diethylenetriamine pentaacetic acid (DTPA) or MAG3 [186], which reveals a photopenic defect with no uptake by the transplant kidney (Figure 113.6).

Since the outcome of graft thrombosis is uniformly dismal, numerous studies have been conducted in an attempt to understand and anticipate this complication. The etiology of graft thrombosis is multifactorial, but it is more commonly seen in young recipients [110]. In a special study of 2060 LD and 2334 DD kidneys [187], the NAPRTCS has shown that a history of prior transplantation increases the risk, whereas increasing recipient age has a protective effect for LD kidneys. The prophylactic use of

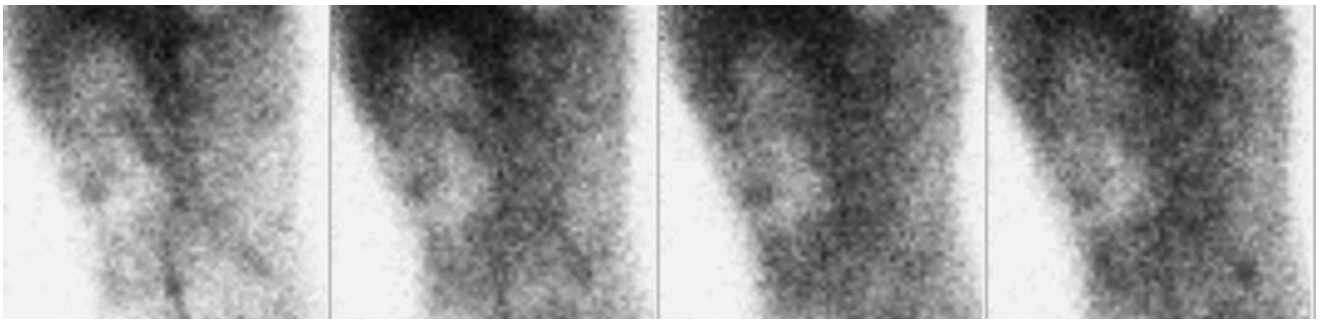

Figure 113.6. ^{99M}Tc-MAG3 radionuclide renal scan in a six year old girl with focal segmental glomerulosclerosis (FSGS) who received a living donor (LD) renal transplant, performed 16 hours postoperatively. Note the photopenic area in the right abdomen, indicating thrombosis of the graft with no perfusion. Reprinted from [315] Harmon WE. Pediatric kidney transplantation (Chapter 75). In: Avner ED, Harmon WE, Niaudet P, et al., editors. Pediatric Nephrology, 6th ed. Springer; 2009: Oxford University, UK: 1867–1901.

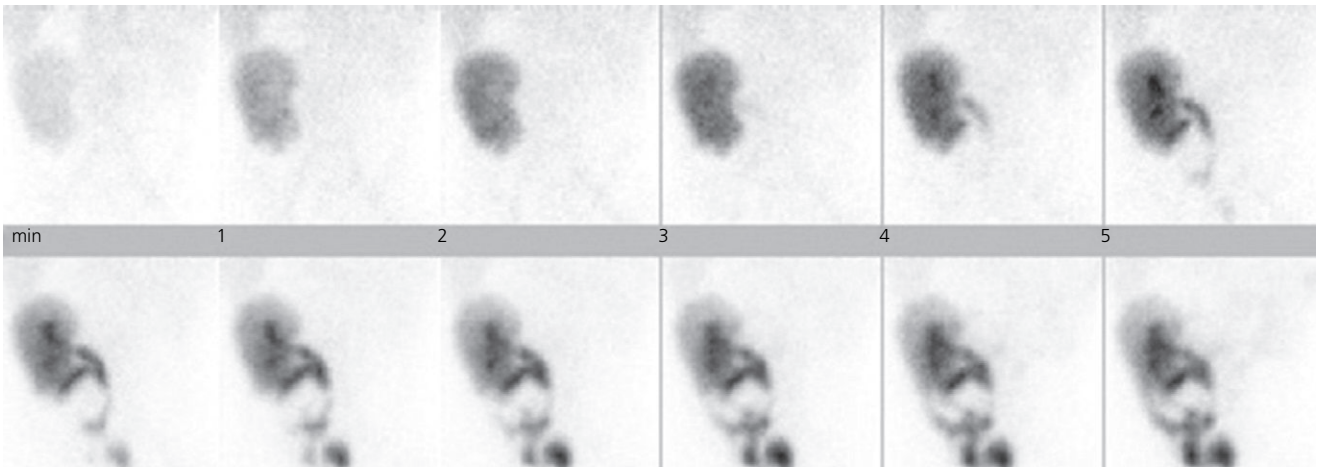

Figure 113.7. ^{99M}Tc-MAG3 radionuclide renal scan in an eight year old girl who received a deceased donor renal transplant, performed 12 hours postoperatively. Note the good perfusion of the graft and the rapid concentration and excretion from the kidney. Tracer, however, rapidly accumulates in the right lower quadrant, outside of the bladder. Investigation demonstrated a traumatic bladder rupture. Harmon WE. Pediatric kidney transplantation (Chapter 75). In: Avner ED, Harmon WE, Niaudet P, et al., editors. Pediatric Nephrology, 6th ed. Springer; 2009: Oxford University, UK: 1867–1901.

antilymphocyte antibody also decreases the risk and this may be particularly true for the monoclonal IL2r antibodies [188]. For DD kidneys, a cold ischemia time longer than 24 hours increases the risk of thrombosis. The use of antibody induction therapy, the use of donors greater than five years of age, and increasing recipient age were factors that decreased the risk of thrombosis. A heightened thrombotic state has also been implicated [186,189,190]. One study showed that centers that performed fewer infant transplants had higher rates of graft thrombosis [70]. Other studies suggested that pretransplant use of peritoneal dialysis increased the risk of thrombosis [191,192], but a later study disputed that relationship [46]. Some centers routinely administer anticoagulants to pediatric recipients at high risk of graft thrombosis, but no clinical studies of their effectiveness have been performed and its use is not without complications [193].

Obstruction, urinary leak, urologic complications

An uncommon but correctable cause of immediate graft dysfunction is obstruction of the urinary flow, which presents as decreasing urine output and the development of hydronephrosis. An ultrasound or radionuclide scan with a furosemide washout enables the clinician to establish this diagnosis. Obstruction can be due to kinking of the ureter, to edema or blockage of the implantation site of the ureter or to development of a lymphocele. A more ominous cause of immediate non-function is the rare case of urinary leak due to disintegration of the distal ureter or rupture of the bladder. This condition is extremely painful due to the extravasation of urine into the pelvis or peritoneal cavity and is established by radionucleide scan (Figure 113.7). The appearance of the tracer in the peritoneal cavity or in the scrotal, vulvar, or inguinal area clinches the diagnosis and immediate surgical correction is necessary.

Immunosuppression strategies

Immunosuppressive strategies are consistent with those described for adults throughout this text. One-half of pediatric kidney transplant recipients receive antibody-based induction therapy following kidney transplantation, with about half of these receiving lymphocyte-depleting agents [3,194–198]. At day 30 post-transplanttransplant, majority of children receive "triple" maintenance immunosuppression with tacrolimus, mycophenolate mofetil and steroids [3,108], but an increasing percentage are no longer receiving chronic steroids. As shown in the NAPRTCS annual report, the "typical" immunosuppression protocols have changed frequently over the past two decades (Figure 113.8). However, it

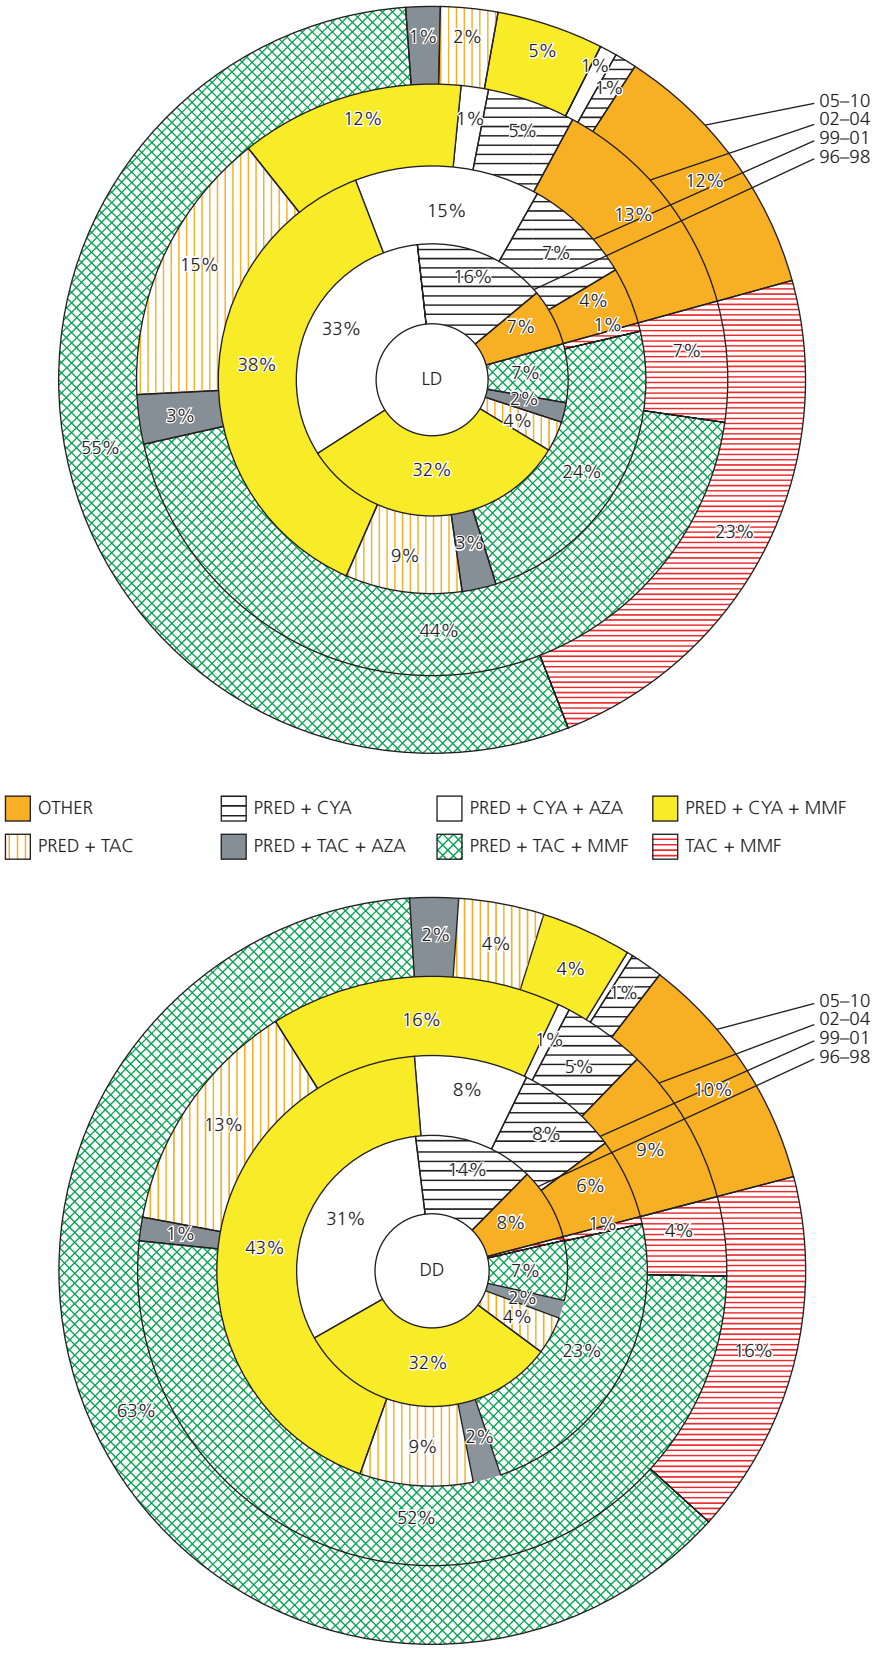

Figure 113.8. Maintenance immunosuppression at Day 30 posttransplant in pediatric living donor (LD) and deceased donor (DD) renal transplant recipients by three-year cohorts:1997–2010; adapted from NAPRTCS 2010 Annual Report: www.naprtcs.org. https://web.emmes.com/study/ped/annlrept/2010_Report.pdf. [December 19, 2013].

also appears as if children who begin treatment under one combination stay on that regimen. Several recent multi-center research efforts have been directed to attempt to decrease the number of types of chronic immunosuppression, with corticosteroids and calcineurin inhibitors being the most common medications targeted for removal [199]. Several single center [175,199–201] and multicenter trials [202–204] have reported success in avoiding or withdrawing corticosteroids, although some of these have had substantial side effects [202,205,206]. There have also been reports of avoidance of calcineurin inhibitors in children designed to prevent nephrotoxicity. At least one of these trials resulted in excellent long-term graft function, but had a high rate of early acute rejections [207]. A subsequent trial with enhanced antibody induction may have better short-term results [195].

Post-transplant transplant management

Hyperacute rejection

Hyperacute rejection is the result of specific recurrent antidonor antibodies against HLA, ABO or other antigens [208]. Irreversible rapid destruction of the graft occurs. Histologically there is glomerular thrombosis, fibrinoid necrosis, and polymorphonuclear leukocyte infiltration. In the early years of transplantation, when the HLA matching techniques were not well developed, hyperacute rejection was more common. In most centers, it occurs very rarely. The latest data from the NAPRTCS shows only19 cases over the last 24 years [3]. The only treatment is surgical removal of the allograft.

Acute rejection

Information regarding the incidence and outcome of acute rejection in pediatric renal transplantation is difficult to standardize since there are multiple different definitions. A common definition of a rejection episode is based upon the circumstance of a patient having been treated with anti-rejection therapy although biopsy confirmation is becoming more common. In a recent review of pediatric kidney transplantation, the biopsy confirmation rate was 95% and the one-year cumulative acute rejection rate was reported to be 15% [3]. A remarkable decrease in the incidence of acute rejection has occurred over the past two decades (Table 113.2). Risk factors for DD transplants include the absence of prophylactic T cell antibody therapy, donor age less than five years, black race, and no Dr matches. Risk factors for LD transplants are the absence of T-cell antibody and one or two Dr mismatches, black race and ATN. There are conflicting data about whether infants and small children have a "heightened" immune response and an increased incidence of acute rejection episodes. Indirect evidence suggested a more vigorous immune response especially in infants [42]. Also, data from the UNOS registry demonstrated a higher rate of acute rejections in young children after both LD and DD transplantation, although adolescents were noted to have a higher rate of late acute rejections [23]. On the other hand, data from surveillance transplant biopsies suggest equivalent rejection responses in all groups [52]. Data from one large pediatric transplant program demonstrated that infants have a lower rate of acute rejection than older children [54]. A recent SRTR report demonstrated that infants and young children now have the best outcomes of all age groups [15]. Thus, either the proposed heightened immune response has been overcome by improved immunosuppression or the cause previously poor outcome was related to other factors.

Table 113.2. 12-month probability (%) of first rejection, by transplant year

Transplant year	Living donor		Deceased donor	
	%	SE	%	SE
1987–1990	54.2	1.7	68.9	1.5
1991–1994	44.9	1.5	60.3	1.6
1995–1998	33.0	1.4	40.5	1.7
1999–2002	21.9	1.3	26.6	1.8
2003–2007	12.8	1.3	17.1	1.5
2007–2010	8.6	1.8	16.6	2.1

Adapted from Smith et al. [3].

Diagnosis of acute rejection

Rejection is suspected when there is decreasing urinary outflow and a rising serum creatinine. In the past, classical signs of acute rejection included fever and graft tenderness. Under calcineurin inhibitors and prophylactic antibody therapy however, these signs are rarely seen; thus early evidence of graft dysfunction even without other signs, should initiate concern. The differential diagnosis consists of ureteral obstruction, renal vascular compromise from stenosis, urinary leak and an infectious process. When rejection is suspected, a urinalysis and urine culture should be performed to assess the possibility of infection. The urinalysis is also helpful if it suggests intra-graft inflammation or immune response as evidenced by proteinuria and the presence of leukocytes and other cells in the sediment. An ultrasound is performed to rule out anatomical obstruction. Obstruction can be the result of perirenal fluid collection, a large lymphocele, hematoma, or rarely, an abscess. The ultrasound can also provide information about intragraft blood flow and pressure [177]. A radionuclide renal scan, using a tracer such as MAG3, is a very helpful tool in establishing some diagnoses (Figures 113.6 and 113.7) [209]. Rejection is suggested by rapid uptake of the tracer by the kidney but a delayed excretion. Unfortunately radionucleide scans cannot distinguish among various causes of intragraft dysfunction, such as rejection, cyclosporine toxicity and ATN. Thus, a definitive diagnosis of rejection requires a transplant biopsy.

Pediatric renal transplant biopsy

The renal transplant biopsy procedure is very easy and safe when conscious sedation and ultrasound guidance are utilized. Data evaluating over 150 pediatric renal transplant biopsies, including some in intraperitoneal kidneys and many performed during the first week post-transplanttransplantation, have demonstrated a very low risk [178]. A major factor in reducing post-transplantbiopsy bleeding is the use of a automated biopsy "guns" using a small (18 gauge) rather than the standard (15 gauge) needle. Biopsies should be performed in pediatric renal transplant recipients whenever the diagnosis of rejection is in doubt.

Treatment of acute rejection

Standard treatment of an episode of acute rejection is intravenous methylprednisolone in a single daily dose of 10–20 mg/kg (maximum dose: 0.5 Gm), for three consecutive days. Most Grade I and II rejections will respond to steroid therapy. Steroid resistant rejection episodes are treated with T cell antibody, such as the polyclonal antithymocyte globulin Thymoglobulin. Thymoglobulin is given in a dose of 1.5–2 mg/Kg /dose for a total of 10–14 days. It may be advisable to monitor CD3+ cells during treatment and restrict the frequency of dosing only to days when the count is

greater than 20 cells/mm^3 [210]. All antibodies have several side effects. Precaution against the potential anaphylactic reaction related to polyclonal antibodies consists of using 500 mg of methylprednisolone with the infusion of the antibody and administration of an antihistamine, such as diphenhydramine (Benadryl), one-half hour prior to drug administration.

Chronic allograft nephropathy

The gradation from acute to chronic rejection is gradual; however many biopsies may show features of both, and some characteristic vascular changes of chronic rejection may be seen as early as ten days post-transplant-transplant [211]. The clinical picture is that of gradually declining renal function together with varying degrees of proteinuria and hypertension [212]. The clinical condition may be referred to as transplant glomerulopathy, chronic rejection, chronic allograft dysfunction (CAD), chronic allograft nephropathy (CAN) or interstitial fibrosis and tubular atrophy (IFTA) [213]. The succession of names reflects lack of clarity of the etiology, clinical course, or treatment of this disorder. Nonetheless, this process, which will be referred to as CAN in this chapter, is the leading cause of graft loss following kidney transplantation in children.

An ongoing controversy exists as to whether the changes seen in chronic rejection are immune mediated, secondary responses to infection, ischemic in nature, or non-immunological injury due to hyperfiltration [214–217]. Data in children have shown clearly that acute rejection is a predictor of chronic rejection [40]. In a study of 1699 LDs and 1795 DD recipients NAPRTCS noted acute rejection was a relative risk (RR) factor for chronic rejection (RR = 3.1), and multiple acute rejections increased the RR to 4.3. Late acute rejections are also clinical correlates of chronic rejection [218]. Even if acute rejection is the most critical element in the genesis of chronic rejection, other immune mechanisms may mediate its progression, such as antibodies directed against the donor, MICA, endothelial cells and B lymphoblasts [156,219]. Gene expression profiles in graft biopsies of patients with established CAN demonstrate upregulation of profibrotic and growth factors [220].

Recurrent kidney disease

As described in depth in Chapter 77, some diseases will recur in a transplanted kidney, and the recurrent disease may lead to loss of the graft, as it had done to the native kidneys previously. Recurrence of the original disease is the cause of 7% of all pediatric kidney graft losses [3]. The five-year graft survival for children with FSGS is 71% and for children with glomerulonephritis it is 77%; in contrast to all other causes of ESRD in which five-year graft survival is greater than 83%. In the DD group, five-year graft survival rates for children with FSGS, glomerulonephritis and congenital nephrotic syndrome are below 64%; hemolytic uremic syndrome (HUS) and familial nephritis have rates of 66%; and all other causes have a rate of 70%. Several publications have reviewed the course of recurrent disease in pediatric kidney transplantation [106,221,222]. In some cases, recurrence of some features of the disease without affecting graft survival up to recurrence of the full disease with substantial reduction in graft survival. Unfortunately, there has been very little change in frequency of recurrent disease in pediatric grafts, despite substantial changes in immunosuppression during the past two decades [3,223].

Focal segmental glomerulosclerosis is the most common cause of steroid resistant nephrotic syndrome leading to ESRD and is the most common acquired cause of ESRD in children. Reports of recurrence of FSGS vary from 15–50% and about 50% of the recurrences lead to graft loss [221–223]. The genetic diseases do not seem to recur in a graft. Risk factors for recurrence include early onset of nephrotic syndrome, rapid progression to ESRD, resistance to treatment, white or Asian race, recurrence in a previous transplant, and possible presence of a circulating "glomerular permeability factor" [179,223]. Recurrence can occur immediately after transplantation and result in massive proteinuria, acute tubular necrosis and even graft failure related to small vessel thrombosis [179]. In general, children with active nephrotic syndrome are not candidates for pre-emptive transplant because of the heavy proteinuria and consequent risk of graft thrombosis and delayed diagnosis of recurrence [221]. Many programs will perform native nephrectomy and will maintain the children on chronic dialysis for some period of time, certainly to improve nutritional status and to normalize the serum albumin. There is no benefit to LD transplantation in children with recurrent FSGS: although graft loss due to rejection is lower in recipients of LD transplants, graft loss due to recurrence is higher, leading to equivalent graft survivals in living and DD transplants [179,224]. Plasmapheresis is often used prophylactically prior to transplantation or immediately after it to attempt to prevent or treat recurrence of FSGS [225–228] and some programs report complete remission in up to 60% treated in that manner. Although no specific immunosuppression protocol has demonstrated clear efficacy in treating or preventing recurrent FSGS, there is some evidence that high dose cyclosporine may be effective in doing so [227,228]. Whether the high dose is needed to counteract the effect of high serum levels of low-density lipoprotein which binds free cyclosporine, or whether the beneficial effects are due to direct action on podocytes is not clear [106,229]. Rituximab has also been used to treat recurrent FSGS in children, with mixed results [230–233].

Hemolytic uremic syndrome in children is most commonly caused by enteropathic bacteria and the disease typically does not cause ESRD or recurrence in a kidney transplant [234]. On the other hand, children with atypical or "non-Shiga toxin-associated" HUS have a much higher incidence of progression to ESRD and recurrence of the disease after transplantation [107,235,236]. Although calcineurin inhibitors have been associated with de novo HUS in a few kidney transplants, their use in recurrent disease seems to have no effect [106]. In patients with factors H, I or B mutations, the recurrence rate appears to be high but recent reports of prophylactic or rescue treatment using a monoclonal antibody that binds to complement factor protein C5, eculizumab, are very promising [237–239].

Both forms of MPGN can recur in transplants, with variable frequency from 30–60% [106]. Type II seems to be more severe, and neither form seems to be treatable after recurrence [240].

Primary oxalosis recurs almost immediately and universally after kidney transplantation and was once considered a contraindication to kidney transplantation. However, treatment with intensive pre and post-transplant dialysis to lower the body burden of oxalate and the use of combined kidney-liver transplantation has led to substantially better outcomes [241–246]. If liver transplantation is being considered, however, careful consideration must be paid to determining whether the child has a variant that might be responsive to lifelong treatment with pyridoxine rather than liver transplantation [106]. Methylmalonic acidaemia may be partially ameliorated by kidney transplantation, but full treatment may require liver transplantation in select recipients [106]. ESRD is typically the earliest organ failure in children with cystinosis and often accounted for the bulk of deaths from this disorder. However, the

use of kidney transplantation and cystine-depleting therapy with cysteamine has extended their life expectancy to the fifth decade [247–250]. Although cystine may accumulate in the interstitium of renal grafts, it does not cause graft failure. However, the unremitting accumulation of cystine results in substantial non-renal morbidity and mortality [249,251].

Outcomes and risk factors

In order to obtain a proper population mix representing gender, age, and racial diversity, multi-center registry results such as SRTR and NAPRTCS annual reports have been used to accurately report kidney graft outcomes [3,16,21].

NAPRTCS has recorded a total of 11 603 kidney transplants in 10 632 pediatric recipients between 1987 and 2010. Of the 2920 graft failures, about 9% were deaths with a functioning graft, 13% were due to acute rejection and 36% were due to chronic rejection. Vascular thrombosis remains a major cause of failure, and 13.5% were attributed to primary non-function, vascular thrombosis, or miscellaneous technical causes. These data show that such problems occur in about 4% of all pediatric transplants [70,110,187,189, 191,192,252]. Recurrence of original disease as a cause of graft failure accounted for 7% of graft failures. The specific diseases include: focal segmental glomerulosclerosis accounted for 44% of these graft losses, membranoproliferative glomerulonephritis Type II 9%, HUS 9%, oxalosis 5%, chronic glomerulonephritis 4%, others 28%.

Overall ten-year LD graft survival curves by recipient age are shown in Figure 113.2 and seven-year graft survival rates by donor source and era are shown in Figure 113.3. Expected graft survival for index transplants performed in the last decade at one, three and five years for LD kidneys is 97, 92, and 84% respectively, and for DD kidneys it is 95, 84, 78% [3,21]. There has been a continuous improvement in short and mid-term graft survival rates, mostly due to marked improvements in early graft survival rates. This may be related to the decreased frequency of acute rejection rates and the decreased incidence of acute rejection as a cause of graft loss. It is notable, however, that as shown in Figure 113.3, the slope of the graft survival curves have not changed significantly over the past two decades. These important trends in improved graft survival in pediatric LD and DD renal transplant outcome have been reported frequently over the past decade [3,15,21,32,105].

Table 113.3 shows relative hazards for graft failure for selected transplant characteristics for both living and deceased kidneys.

Table 113.3. Relative hazard analysis for graft failure in pediatric kidney transplantation

	Living donor		Deceased donor	
	RH	*P* Value	RH	*P* Value
Recipient age (>2)	1.23	NS	0.67	0.0040
Prior transplant	1.50	<0.0001	1.45	<0.0001
Induction antibody	0.84	0.0050	0.92	NS
>5 Lifetime transfusions	1.22	0.0160	1.25	0.0006
No HLA-B mismatches	1.32	0.0183	1.15	0.0170
No HLA-DR mismatches	0.82	NS	1.13	0.0333
Black race	1.94	<0.0001	1.58	<0.0001
Prior dialysis	1.16	0.0375	1.23	0.0326
Cold storage time >24hours	–	–	1.15	0.0200
Transplantyear (1987–2010)	0.95	<0.0001	0.94	<0.0001

Adapted from Smith et al. [3].

Relative risks of graft failure are derived using Cox proportional hazards regression models. For recipients of LD grafts, the most influential prognostic variables of graft survival are race (African American vs. non-African American), prior transplant, lack of induction antibody treatment and transplant year. For DD recipients, the important prognostic factors include: African-American race, prior transplant, age older than two years and transplant year. A history of prior dialysis, lack of HLA-B and -DR matches and prolonged cold-storage time may be slight relative risks. Male recipients seem to have improved risk compared to females for both LD and DD transplants. Also for both LD and DD transplants, a history of more than five lifetime blood transfusions seems to be associated with worse graft survival rates, but the significance of this finding in the modern era is not clear. Also, the interpretation of the use of induction antibody treatment is hampered by selection factors that motivate its usage; the size and direction of these biases cannot be quantified and the evaluation of this factor cannot be considered definitive. Importantly, the improvement in graft survival rates in very young recipients is strongest in the LD recipients and the overall improvement in this age group may be related to the high percent of living donors used for them.

Growth following transplantation

A major distinguishing feature of pediatric from adult recipients is the need for children to grow. The growth failure commonly observed in children at the time of transplantation is multi-factorial; however the most important cause is the reduced response to endogenous growth hormone [253], related to several mechanisms. For several years it has been suggested that a functioning transplant would enable the child to achieve catch-up growth [9]. Unfortunately, long term data from registry studies has shown a more disappointing outcome.

NAPRTCS data shows that the mean height deficit at the time of transplantation is −1.75. Males (−1.78) and younger recipients have greater height deficits at the time of transplantation [43]. The deficit has been improving steadily, with a mean deficit of −2.43 in 1987 improving to −1.23 in 2009 [3]. Younger children generally show early catch-up growth [3,9] with complete inversion of Z-score up to 0.60 at two years for those <5 years of age at transplant. Older children may grow at a normal rate, but rarely show catch-up growth. Final adult height for children with ESRD is improving, but all of the improvements seem to be related to the gains achieved during treatment for CKD rather than after transplantation [10,12]. The final adult height of children transplanted more recently is much better than those transplanted years ago. The Z-score for children transplanted in 1987–1991 who have reached their terminal height was −1.93 as compared to −1.08 for those in the 1997–2001 cohort.

Adherence to chronic immunosuppression treatment

Non-adherence is often cited as a cause of long term graft loss in pediatric renal transplant recipients, especially adolescents [254]. This is covered in depth in Chapter 120. A major reason for non-adherence is thought to be the alteration in appearance that accompanies immunosuppressive medications, including the cushingoid facies and growth retardation related to long-term daily corticosteroid administration and the hirsuitism and gingival hypertrophy associated with cyclosporine. However, the true incidence of non-adherence is unknown. Non-adherence rates of 22% [255], 43% [256] and as high as 64% in adolescents [257] have been reported.

Some factors, such as young age, adolescence, poor socio-economic status, and family stress have been associated with increased levels of non-adherence [255,257–259]. Importantly, however, healthcare workers are not able to identify a significant proportion of non-adherent patients [260]. Treatments such as educational programs [256] and family-based therapy [261] have been proposed, but these types of programs have not been universally successful in changing motivation [254]. An alternative proposal for improving non-adherence would be to change the type or frequency of immunosuppressive medications so that the recipients do not have to adhere to rigid schedules; but these proposals are currently only hypotheses [175,262].

Hospitalization

The re-hospitalization rate has fallen substantially between 2000 and 2010. Living donor recipients have decreased from 49 to 39% with the stay has decreased from eight to six days. For DD recipients, the rate has fallen from 57 to 42% and from ten to six days [3]. The most common reason for hospitalization used to be for treatment of rejection. However, a recent analysis supports that treatment of viral and bacterial infections are the next most common reasons for hospitalization [3,263]. Treatment for hypertension is the cause for hospitalization in the first six months in 5–8% of recipients, and falls to ~1% five years after transplantation [33].

Post-transplant transplant lymphoproliferative disease and malignancy (PTLD)

Although PTLD has been reported as a complication of pediatric organ transplantation for many years [264], the number of published reports seem to be increasing [265]. It is not clear whether this indicates that the incidence of this potentially lethal complication of immunosuppression is increasing or if it is just more readily recognized. If the incidence is increasing, it may be the unfortunate consequence of "improved" immunosuppression [266]. In a review of UNOS data age <18 years, Caucasian race, and male gender are significant risk factors [267]. Current incidence appears to be 1–2% of all pediatric renal transplants with some reports being much higher [206].

This complication is specifically covered in Chapter 96. PTLD often presents within lymph nodes, but it can be extra-nodal, frequently occurring within the gastrointestinal tract [268], proximate to or within the graft [269], or distant from it [270]. Presentation of PTLD within the central nervous system is often devastating and rapidly fatal. PTLD is generally thought to emanate from an EBV infection [268,271,272]. Thus, the pretransplant EBV status of the donor and recipient may be an important determinant of the disease and may explain why the disease is more common in children than in adults [273,274]. In several reports, the incidence rate of PTLD for EBV-seronegative recipients was many times higher than for EBV-seropositive recipients [275–277] and in others, the source was the donor in most of the cases [278]. However, EBV seropositive recipients may be at risk for later onset and more lethal disease [279]. Concomitant primary infection with CMV may increase the risk of PTLD five-fold [275]. The intensity of immunosuppression may also predispose the child to PTLD [277,280]. Treatment with anti-lymphocyte antibodies, such as OKT3, as either induction or anti-rejection therapy, may increase the risk of developing PTLD substantially [275,276,279,281]. Although it has been reported following both cyclosporine and tacrolimus treatment, programs that have used both drugs have suggested that the incidence was higher in tacrolimus-treated recipients [266,273,282]. However, a recent registry report suggests that neither mycophenolate mofetil (MMF) nor tacrolimus were independent risk factors for PTLD; rather, the intensity of immunosuppression was most important [267].

The diagnosis of PTLD has generally been made on the basis of characteristic pathologic findings and the diagnosis cannot be made without biopsy material. Advances in detection of EBV DNA [283–287] and in the outgrowth of transformed lymphocytes [288–290] have permitted early detection of patients at high risk to develop PTLD. Surveillance of blood and prospective adjustment of immunosuppression has been proposed, but there are no universally-accepted standards in this area [291]. Similar tests have been used also to guide treatment [283] but their absolute value for this function is not established.

The mainstay of treatment of PTLD is the reduction or discontinuation of immunosuppression [278,292,293]. Of interest, in many of these cases, the graft is not rejected despite the marked lowering or discontinuation of immunosuppressive medications. Interferon-α and intravenous γ globulin [294,295], ganciclovir [296,297], and even chemotherapy have been suggested, but their efficacy has been variable. Prophylaxis of high-risk patients may be useful [298]. Treatement with the monoclonal antibody Rituximab has shown promising results [299–303].

Other infections

Immunosuppression renders both adult and pediatric recipients susceptible to numerous viral and bacterial infections. These are covered as they relate temporally to the transplant procedure in Chapters 92–94. Infections account for the majority of complications post-transplanttransplantation in children and are the principal cause of morbidity. Prophylactic therapy against the more common infections seen in the context of a renal transplantation is employed by most centers.

Cytomegalovirus infection in immunocompromised allograft recipients may cause serious or even fatal disease, especially when the recipient is sero-negative and the donor is positive. Prophylaxis with oral valganciclovir for 3–12 months post-transplanttransplantation is routinely practiced in pediatric kidney transplant programs [297,304,305]. Similarly, prophylaxis against pneumocystis jirovecii pneumonia using trimethoprim-sulfa, pentamidine, dapsone or atovaquone.

Varicella can be very serious or even fatal in immunocompromised individuals [306,307]. Children should receive varicella vaccine prior to transplantation [308,309] and should be repeated as necessary to assure sero-conversion prior to chronic immunosuppression [81]. The use of varicella vaccine post-transplanttransplantation has been reported in only a small series [309], but it is likely safe, although not uniformly successful. BK virus nephropathy is an increasingly recognized complication of renal transplantation and its incidence in children is similar to what is seen in adults [310–313]. As is done with EBV, the typical approach is preventative, with careful screening for viremia and selective reduction of immunosuppression when it occurs. Some patients may benefit from treatment with leflunomide [314].

Mortality

Mortality rates for children receiving kidney transplants is remarkably low. Patient survival has improved for both LD and DD recipients (Figure 113.9) [3] and current five-year patient survival is now 97% and 96% respectively. Survival for infants, especially those

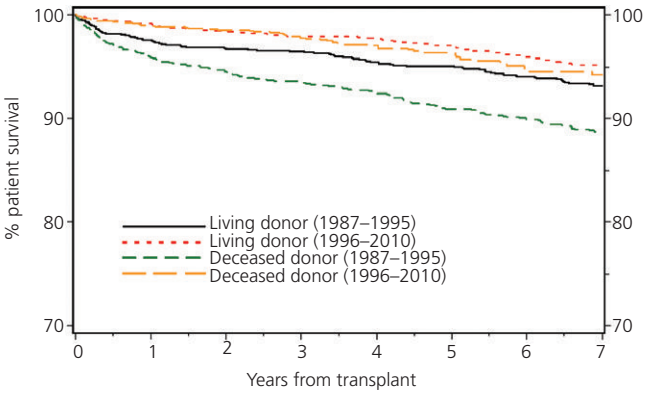

Figure 113.9. Seven-year actuarial patient survival in children from living donor (LD) and deceased donor (DD) renal transplantation from two eras; adapted from NAPRTCS 2010 Annual Report: www.naprtcs.org. https://web.emmes.com/study/ped/annlrept/2010_Report.pdf. [December 19, 2013].

receiving DD grafts, was not as good as older children, but the current rates are now comparable. The major cause of death for children is infection, followed by cardiopulmonary problems, malignancy and dialysis-related problems. About half of the deaths occurred with a functioning graft [3].

Summary

In general, pediatric transplantation has improved through the implementation of therapies designed for adults and then adapted post-transplant hoc to the specific needs of children. Surgical techniques relate to the size of the child and the congenital anomalies that often are found in this population. Outcomes are outstanding and significantly better than those achieved through dialysis, although this remains suboptimal in adolescents. Immune management is similar to adults transplant recipients, although this is largely a product of the development pathways for drugs, with the small population of children commanding limited attention from pharmaceutical companies. Future opportunities in the field include specific immunosuppressive approaches that specifically consider the dynamic, developing immune system in children (see Chapter 112), and begin providing therapies uniquely responsive to the needs of children.

Introduction

Although the basic principles of evaluation and selection for liver transplantation are the same for children as for adults with acute or chronic liver disease, clearly the candidate populations are divergent. Pediatric recipients are distinct from adult recipients not only with respect to age but also with respect to the spectrum of liver diseases, increased penetration of technical variant grafts, decreased risk of disease recurrence, protracted exposure to immunosuppression medications, and remarkable potential for life years gained [1].

Deceased donor organ allocation

Allocation of deceased donor (DD) livers to pediatric candidates is based on the regulatory framework of the Final Rule established in 2000 and implemented by the US Department of Health and Human Services in 2002. The pediatric end-stage liver disease (PELD) and Mayo end-stage liver disease (MELD) scoring systems use objective measures to estimate disease severity and medical urgency. Ethical considerations involved in the allocation of organs can be found in Chapter 137, and national allocation policies are considered in Chapter 128. The PELD score is calculated from age, serum albumin concentration, total serum bilirubin concentration, international normalized ratio (INR) and the presence or absence of growth failure [2] while the MELD score is calculated from total serum bilirubin concentration, INR, and serum creatinine [3]. Organs are allocated to children under age 12 years based on the PELD score and to adolescents aged 12 to 18 years based on the MELD score. Providers may request additional exception PELD/MELD points from a regional review board if the calculated PELD/MELD score is believed to inadequately reflect the severity of the patient's disease [4–6].

Indications for liver transplantation for pediatric patients

The indication data depicted here are retrieved from the Studies of Pediatric Liver Transplantation (SPLIT) Registry and represent over 2000 pediatric liver transplants done in North America (Table 114.1). Biliary atresia is the most common underlying condition for liver transplantation, accounting for approximately 37% of the cases. Acute liver failure, retransplantation, and primary liver tumors including hepatoblastoma account for 13.5, 10, and 9% of transplants, respectively. Approximately 21.5% of the pediatric liver transplants are performed for inherited gene defects that be categorized into (1) disorders of cholestasis (4.5%); (2) disorders of metabolism refractory to medical therapy, without cirrhosis (6%) and (3) disorders of metabolism that lead to structural liver injury with cirrhosis (11%). The remaining cases comprise a heterogeneous group of chronic conditions including cryptogenic cirrhosis, autoimmune hepatitis, sclerosing cholangitis and mitochondrial hepatopathy. Disease recurrence is rare, occurring only in patients with autoimmune disease and in a subset of recipients with inherited disorders of cholestasis [7]. As a result, liver disease distribution differs distinctly between children and adult as the latter is dominated by hepatitis C cirrhosis, alcoholic and non-alcoholic steatohepatitis, and hepatocellular carcinoma.

Biliary atresia

For children with biliary atresia, there is no doubt that liver transplantation improves survival. Left untreated, all patients with biliary atresia die by two years of age; more than 70% ultimately require liver transplantation [8–10]. Transplantation offers the only option for patients with failed portoenterostomy. With improved immunosuppression and operative techniques, adjusted five year post-transplant patient survival for biliary atresia is 92.3% after living donor (LD) liver transplantation and 85.8% after DD liver transplantation (2009 OPTN/SRTR Annual Report 1999–2008. HHS/HRSA/HSB/DOT; UNOS; Arbor Research Collaborative for Health). The decision is more complex for older patients who develop complications of portal hypertension after successful portoenterostomy in whom survival benefit is less well-defined [9,11–14].

Acute liver failure

Decision-making relative to liver transplantation for children with acute liver failure (ALF) is complicated as the disease is characterized by rapid clinical changes. Moreover, the increased risk of early and late post-transplant mortality compromises survival benefit [15–17]. Children with indeterminate ALF, compared to those with an established cause of ALF, are 2.5 fold more likely to require liver transplantation. For the latter, which include children with acute acetaminophen toxicity, herpes simplex, and hemophagocytic lymphohistiocytosis [16,18–21], targeted treatment alternatives can be life-saving without transplantation. Existing acute liver failure scoring systems including the Kings College Hospital Criteria (KCH) [22], the Clichy score [23,24], MELD/PELD [24–26] fail to

Table 114.1. Indications for pediatric liver transplantation. Derived from the SPLIT Registry (Patients with first transplant between June 1, 2005 and May 31, 2009)

Primary Diagnosis	%Primary Transplant
Biliary atresia	41.2%
Alagille syndrome	3.1%
Acute liver failure	14.5%
Liver tumor	5.2%
Metabolic liver disease without cirrhosis	11.2%
Other	15.8%

Table 114.2. Indications for liver transplantation for children with metabolic liver disease. Derived from the SPLIT Registry (Patients with first transplant between June 1, 2005 and May 31, 2009)

Primary Diagnosis	N
α1-Antitrypsin deficiency	71
Wilson's disease	28
Tyrosinemia	24
Primary hyperoxaluria	6
Cystic fibrosis	37
Urea cycle defects	58
Crigler-Najjar	15
Glycogen storage disease	18
Neonatal hemachromatosis	13
Inborn error in bile acid metabolism	2

reliably distinguish between those who will spontaneously survive and those who require transplantation [16,21]. The pressing clinical questions faced when managing children with ALF are:

1 Does the child have a condition that is medically treatable?
2 What is the risk of deterioration or improvement for each successive day that the child remains alive with his/her native liver?
3 Is transplantation necessary for patient survival?
4 Is full recovery possible without transplantation?
5 Are associated morbidities recoverable or irreversible?

Liver tumors

Hepatoblastoma is the most common primary liver tumor in children, accounting for approximately 70% of transplants for hepatic malignancy and 5% of all pediatric liver transplants performed. Primary curative resection yields outstanding results with >90% event-free survival. Unfortunately, only one third present with resectable disease. For the remainder, neoadjuvant chemotherapy is administered. For children deemed unresectable even after chemotherapy, liver transplantation is required for long-term survival [27–29]. The main predictors of clinical outcome are the presence or absence of metastatic disease, histology, and tumor resectability as determined by PRETEXT staging [27,30–32]. Current US allocation policy stipulates assignment of status 1B at listing.

Metabolic disease

Transplantation corrects the expression of mutated proteins by the liver and any co-existing structural damage [33] (Table 114.2). For the sub-group of metabolic diseases with structural liver damage, the decision to proceed with transplantation is based on survival benefit and medical urgency as determined by PELD/MELD score. However, for the subgroup without structural liver disease, the goal of liver transplantation is not only to correct the gene defect but to prevent damage to extra hepatic organ(s) occurring consequent to the gene defect. Urgency therefore reflects the risk of irreversible damage to the central nervous system or the kidneys, rather than the risk of death. Transplant decision-making must balance the risk of transplantation against the likelihood that transplant will prevent extrahepatic disease progression and requires a multi-disciplinary approach inclusive of relevant specialists.

Retransplantation

The main indications for retransplantation are primary non-function, hepatic artery thrombosis, chronic rejection, and late vascular or biliary complications. Primary non-function and early hepatic artery thrombosis are medically urgent, usually occurring within days after transplantation. Patient and graft survival after retransplantation are lower than for primary transplant [34]. Donor age less than one year, use of a technical variant graft, and INR at time of retransplantation are independent predictors for survival; INR likely acts as a surrogate marker of liver failure.

Transplant evaluation

Evaluation for liver transplantation should be initiated when a child is determined to have irreversible, potentially life-threatening liver disease. The timing of evaluation depends on the child's clinical status along with an understanding of the primary disease process. For instance, an asymptomatic six-month-old child with biliary atresia and a serum bilirubin of 8 mg/dl will require liver transplantation by age 24 months to ensure survival. In contrast, a six-month-old child with Alagille Syndrome and the same laboratory profile in the absence of cardiac disease will not likely require transplantation. The evaluation process seeks to: (1) estimate the survival benefit offered by transplantation [35]; (2) identify progressive and irreversible non-hepatic disease that may negate the benefit of transplantation; (3) determine if psychosocial support is sufficient to optimize outcome.

The impact of liver transplant on quality of life remains a critical part of the evaluation and discussion with the patient and family. Nevertheless, given limited data on quality of life over time after liver transplantation and the DD organ shortage, quantity of life supercedes quality of life [4,36]. An interdisciplinary transplant team comprised of surgeons, hepatologists, coordinators, psychologist, social worker, financial counselor, and any other relevant consultants should participate in the assessment of any candidate for liver transplantation. General considerations for the preoperative evaluation of transplant candidates can be found in Chapter 29.

Survival benefit

On many occasions, there is insufficient data to make evidence-based decisions on the presence and magnitude of the survival benefit offered by liver transplantation for children. As with the adult population, short-term survival benefit is strongly driven by liver disease severity. For children with a PELD score of 17–27, liver transplantation yields survival benefit after one month. In contrast, for patients with PELD scores of 7–16, survival benefit does not begin to accrue until ten months after transplantation [37].

Is there irreversible and progressive non-hepatic disease that compromises transplantation outcome? Liver transplantation is generally contraindicated by uncorrectable multi-system failure, extra-hepatic malignancy, active infection outside the hepatobiliary system or advanced and/or irreversible cardiopulmonary or central nervous system disease. There are however exceptions. A single, surgically resectable hepatoblastoma metastasis does not preclude

transplantation [27,28]. Often, the distinction regarding irreversible, extra-hepatic disease may be ambiguous. Arguably, liver transplantation should not be considered if futility is likely. However, the definition of futility is elusive as it depends on a complex interaction of factors including primary diagnosis, transplant center skill, and the availability and quality of organs. Moreover, the definition of futility for children may differ from adult, considering the greater potential for life years gained and the lower burden of medical co-morbidities? Are we, as a society, willing to accept more risk for children given the potential for greater survival benefit return? Analysis of SRTR data has delineated survival benefit during the first year after liver transplantation from time of listing for children [38]. Using the PELD score as an estimate of disease severity, a futility threshold could not be identified. Given the lack of a defined threshold, an effective interdisciplinary team to promote good decision-making is critical for cases in which a substantial concern for futility has been raised.

Is there psychosocial support sufficient to optimize outcome? Psychosocial evaluation does not focus solely on suitability of the candidate but on identifying and mitigating psychosocial risk which might diminish post-transplant outcomes [39]. A structured assessment should aim to determine if: (1) there is evidence of child abuse; (2) the child or parent is depressed or has evidence of post-traumatic stress; (3) the family can support the child through the transplantation process. None of these factors should be considered contraindications to transplantation but challenges to be addressed by the liver transplant team.

Pretransplant care

The pretransplant period is a time of significant risk. Mortality risk on the waiting list is highest for children with acute liver failure and for those who are less than one year old [21,37] (Table 114.3). The outcome of transplantation reflects an interaction of multiple processes: (1) the primary disease; (2) pretransplant care; (3) organ allocation; (4) donor/graft quality; and (5) operative and peritransplant care [40]; also covered in Chapters 20 and 38.

Care during the pretransplant period impacts early patient and graft survival. In order for a pediatric candidate to be medically and psychosocially optimized at the time of transplantation, the transplant team must develop processes to:(1) address patient and family education; (2) maximize access to a suitable organ, living or deceased; (3) optimize nutritional status; (4) prevent infection; and (5) prevent and/or treat complications of portal hypertension.

Hepatopulmonary syndrome

Hepatopulomonary syndrome (HPS) is defined by the presence of severe liver disease, hypoxemia on room air, intrapulmonary vascular dilatation [41,42] in the absence of underlying primary cardiopulmonary disease. HPS is a risk factor for poor prognosis in patients with cirrhosis [43]. However, HPS is reversible after liver transplantation, particularly if transplant occurs prior to the development of severe hypoxemia [44,45]. While data in children are limited, liver transplantation has been shown to improve survival for adults with HPS [45]. As a result, current allocation policy recognizes HPS as an exceptional indication for transplantation. Adults who satisfy predetermined criteria receive a MELD score equivalent to a 15% mortality risk at three months. MELD score then increases by a 10% mortality equivalent every three months. No standard criteria have been established for children with HPS.

Table 114.3. Prevalence of specific symptoms as the primary indication for pediatric liver transplantation. Derived from the SPLIT Registry (Patients with first transplant between June 1, 2005 and May 31, 2009)

Primary Indication for Transplant	N	%
Failure to thrive	255	26.6
Ascites	308	32.1
Spontaneous bacterial peritonitis	31	3.2
Hepatic encephalopathy	130	13.6
Portal hypertensive bleeding	80	8.3
Intractable pruritus	99	10.3
Other	56	5.8
Total	959	100.0

Variceal hemorrhage

The efficacy of primary and secondary prophylaxis for variceal bleeding is established for adult patients but unknown for children. Management of acute variceal bleeding should parallel that for adult patients, beginning with hemodynamic stabilization, diagnostic and therapeutic endoscopy followed by a defined for plan secondary prophylaxis.

Malnutrition

Maintenance of adequate nutrition is a challenge given the effect of chronic liver disease on intake and endocrine function, the latter including diminished response to growth hormone [46]. Based on the data from the SPLIT Registry, 40% of transplant candidates less than two years old are more than two standard deviations below norms for weight and height at evaluation, and even more are greater than two standard deviations below norms at time of transplant. It is likely that an even larger proportion suffer milder degrees of nutritional deficiency. Optimizing nutritional status for children with moderate or high liver disease severity (MELD/PELD score >15) requires thorough, serial assessments on a monthly basis. In-depth diet history, evaluation of anthropometrics and growth, review of medication and vitamin/mineral supplementation, determination of energy, protein, macronutrient and/or micronutrient intake, and fluid requirements should be reviewed. Nutritionally replete children on the waiting list suffer fewer infections that may delay or complicate transplantation. After transplantation, a favorable nutritional status is associated with fewer infections, improved wound healing, and decreased risk of intractable ascites [12,47].

Ascites and spontaneous bacterial peritonitis

Ascites management should be directed towards maintaining a patient's intravascular volume status, serum sodium greater than 130 meq/l, and adequate nutritional and respiratory status. A sudden, marked increase in ascites may reflect portal vein thrombosis that should be assessed using Doppler ultrasonography. Guiding principles and management strategies for adults are outlined in several reviews but are also applicable to children [48,49].

Spontaneous bacterial peritonitis (SBP) is defined as bacterial infection of ascites not due to specific intra-abdominal pathology. Registry data indicate that SBP occurs in 10% pediatric patients awaiting liver transplantation. Fever, worsening encephalopathy, abdominal pain, and essentially any clinical change in a patient with ascites should be investigated with diagnostic paracentesis. SBP is most frequently diagnosed by increased neutrophils in the ascitic fluid (>250 cells/mm^3), with or without a positive culture. Broad-spectrum anti-microbial therapy should be initiated on the basis of a positive cell count. Cefotaxime has been the most widely studied antibiotic, and covers the three most common isolates: *Escherichia coli*, *Klebsiella pneumoniae* and *Streptococcus pneumoniae* [48,49].

Repeat paracentesis is not needed unless symptoms persist or response to treatment is atypical. Studies in pediatric patients are limited. Even so, primary and secondary prophylaxis for children with cirrhosis and ascites is likely to improve outcomes and, as such, is often prescribed.

Transplant procedure and surgical techniques

Historically, children have been instrumental in the initial establishment of and subsequent innovation in liver transplantation. Both the first attempted liver transplant in 1963 [50] and the first three successful liver transplants in 1967 involved young children [51]. Later, during the late 80s as the field of liver transplantation burgeoned, it became clear that waitlist mortality rates of 25–46% (compared to 8% for adults) secondary to the insufficient supply of size-matched organs demanded innovation [52–54]. The liver's segmental anatomy inspired surgeons to transplant partial grafts of a size suitable for the specific candidate [55,56]. Initially, whole livers underwent size reduction into a right lobe, left lobe, or left lateral segment graft through formal resection on the back table to accomplish transplantation of one child with outcomes comparable to whole liver transplantation [53,57,58]. Shortly thereafter, innovation progressed to divide whole livers into two transplantable grafts accomplishing transplantation of either two children or one adult and one child [58–60] (Figure 114.1). Initially, complication rates for split grafts were higher than whole or reduced grafts, reflecting the increased surgical complexity of dividing the critical structures optimally for the two recipients [59]. These difficulties were quickly overcome, paving the way for a final innovation, transplantation of a partial graft procured from a LD [61,62]. With the rapid development and dissemination of a deep menu of options to achieve transplantation for children, that waitlist mortality dropped precipitously [54,63], thereby maturing the field of pediatric liver transplantation. Technical details of the whole liver transplant procedure can be found in Chapter 56 and of the segmental and live donor liver transplant procedures in Chapter 57. The prevalence increased steadily from two transplants in 1989 (0.4%) to 120 transplants (20.4%) in 2000 (Figure 114.2). Coincident with a major change in allocation policy for deceased donor organs in February 2002, the trend reversed such that living donors currently accounts for 9–12% of all pediatric liver transplants. Figure 114.3 shows that the frequency of living donor transplantation varies by candidate age. Perhaps not surprisingly, living donor transplants consistently account for the largest percentage of transplants for infants (<1 year) followed by toddlers (1–5 years). However, interestingly, older children (6–17 years) comprise a larger percentage of LD transplant recipients in the past few years, perhaps a consequence of the maturation of adult to adult LD liver transplantation.

Early post-transplant surgical complications

Vascular complications

The substantial technical challenge of pediatric liver transplantation is reflected by the observed rates of surgical complications in the early post-transplant period. Hepatic artery thrombosis (HAT)

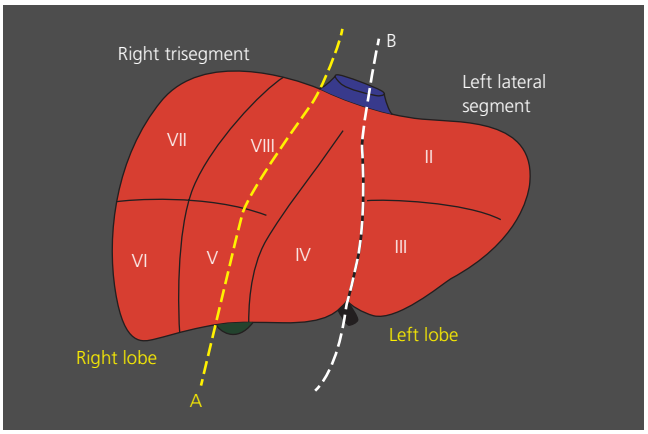

Figure 114.1. Splitting a deceased donor liver. For transplantation of one child and one adult, the liver is typically divided into two grafts as indicated by the white dashed line "B": (A) left lateral segment (Couinaud's segments II and III) accounting for approximately 20–25% of the liver mass, and (B) right trisegment graft (Couinaud's segments I, IV–VIII) accounting for approximately 75–80% of the liver mass. The left lateral segment typically comes with the left hepatic vein, the left portal vein, the celiac axis with Carrel aortic patch, and the left hepatic duct. The right trisegment graft typically comes with the inferior vena cava, the main portal vein, the right hepatic artery, and the common bile duct. An alternative splitting approach is to divide the liver into the right lobe (Couinaud's segments V–VIII) and the left lobe (Couinaud's segments I–IV) as indicated by the yellow dashed line "A".
Reproduced from Renz JF, Yersiz H, Reichert PR, Hisatake GM, Farmer DG, Emond JC et al. Split-liver transplantation: a review. Am J Transplant 2003;3(11):1323–1335, with permission from John Wiley and Sons.

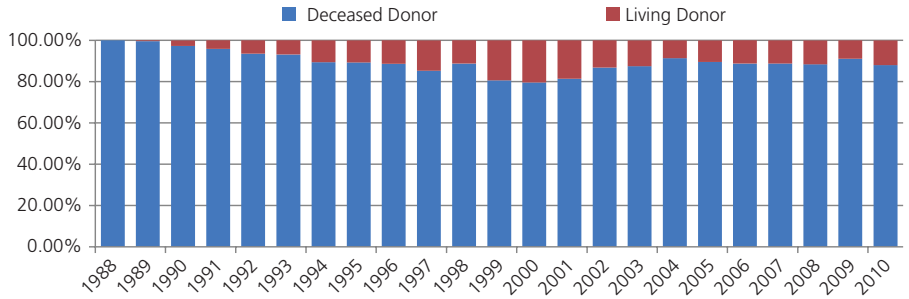

Figure 114.2. Annual proportion of deceased versus living donor liver transplants for children (<18 years). Since the first pediatric living donor liver transplant in 1989, their proportion increased steadily through the 1990s. However, coincident with implementation of the MELD/PELD liver allocation policy in February 2001, the national volume of living donor liver transplantation decreased and currently accounts for approximately 10% of pediatric liver transplants.
Based on OPTN data as of January 12, 2012.

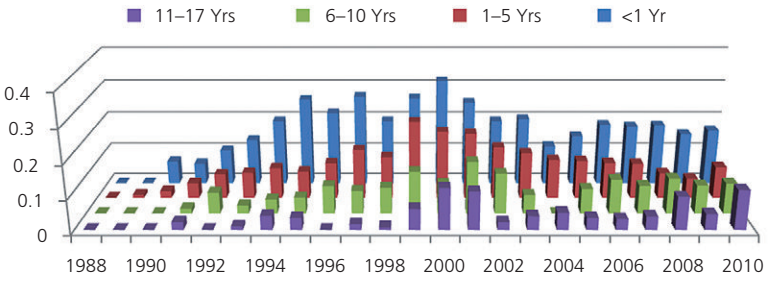

Figure 114.3. Proportion of living donor transplants according to recipient age. The proportion of living donor transplants varies significantly with donor age and year of transplantation. Although living donor transplants have predominantly served infants and toddlers (0–5 years of age), there appears to have been a relative increase in the percentage of pediatric liver transplants. Based on OPTN data as of January 12, 2012.

looms as a serious, potentially life threatening complication after pediatric liver transplantation. Although HAT can be clinically silent, it can also lead to acute allograft failure with massive hepatic necrosis or subacute problems with abscess formation or ischemic biliary complications of leak or stricture. Historically, thrombosis rates reached as high as 38% but, more recently, many centers have reported rates of less than 10% [64–70]. Similar to portal vein complications, demographic factors that likely translate into small recipient and/or donor vessel size such as age less than three years, weight less than 15 kgs, use of a whole graft, and multiple/arteries requiring reconstruction and/or separate anastomoses have been implicated risk factors [67,68,70–72].

Substantial thrombosis rates led to exploration of alternative surgical techniques and additional medical therapies. Early on, in the setting of DD whole or partial liver transplantation, aortic revascularization either directly or with an interposition graft and the use of an interrupted suture technique was tauted as an advance [67,68,70,73]. However, with the emergence of LD transplantation, adaptation of microvascular surgical techniques with high magnification (greater than 10×) afforded by an operative microscope led to dramatic reduction of hepatic artery thrombosis rates [66,74–77]. More recently, several reports suggest that high power loupe magnification (3.5 to 6×) may be sufficient [64,65,78]. Medical maneuvers to mitigate risk of HAT center on anti-coagulation strategies. Aspirin, heparin, and/or low molecular weight dextran are frequently employed but are of unproven efficacy [65,71,79,80].

Considering the frequency of HAT and the knowledge that successful intervention depends upon early diagnosis, many pediatric transplant centers perform daily or even twice daily Doppler ultrasounds for one or two weeks after liver transplantation [65]. Suspicious findings are typically confirmed by angiography although some centers recommend proceeding immediately to exploration [72,81,82]. In the operating room, thrombectomy with or without thrombolysis is performed with reassessment of the original anastomosis and revision as necessary. Full anti-coagulation may also be instituted.

Patient and graft outcomes of HAT are mixed. Many reports indicate that HAT does not impact post-transplant patient survival [69,72,81]. Graft survival, however, is clearly compromised as 60–75% of recipients with HAT require retransplantation [69,82,83]. Urgent revascularization has a success rate of 30–50% [69,82]. However, even after successful revascularization, many children with HAT suffer biliary complications [69,72,84].

Portal vein complications, most often stenosis or thrombosis, are the second most common vascular complications after pediatric liver transplantation. Reported frequencies range from 4 to 16% although higher rates, upwards of 35%, were observed in early series [85–94]. Potential risk factors for portal vein complications include recipient demographic variables, anatomic and functional characteristics, as well as anastomotic technique. Demographic characteristics including age less than or equal to one year and weight less than 10 kgs have been variably found to be associated with portal vein complications as they are associated with a diminutive portal vein diameter [86,87,92,94]. Moreover, a subgroup of children with biliary atresia has co-existent structural abnormalities that complicate portal venous reconstruction. These abnormalities include visceral heterotaxy (left isomerism), splenic anomalies (usually polysplenia), preduodenal portal vein, portal vein hypoplasia, absent portal vein, absent inferior vena cava, or intestinal malrotation [95–99]. Finally, unfavorable functional characteristics including low portal flow or non-hepatopetal (fluctuant, absent, or hepatofugal) flow has also been correlated with increased post-transplant portal venous complications [86,87,94].

The most commonly used approach is an end to end anastomosis of the donor to recipient portal vein. However, if the recipient portal vein is unsuitable, more complex strategies must be employed. One option is complete resection with end-to-end anastomosis to the confluence of the splenic and mesenteric veins or end-to-side anastomosis to the superior mesenteric vein. A second option is portoplasty or reconstruction of the native segment typically with a venous patch. On balance, the use of a conduit or interposition graft appears to be associated with higher rate of portal venous complications [87,90,91].

Early portal vein complications have been treated with surgery for thrombectomy and revision of the portal anastomosis, interventional radiology with clot fragmentation/lysis and stenting, or a combination procedure [97,100–102]. The literature, dominated by small single center case series, generally indicates good long-term patency.

The third type of vascular complication after pediatric liver transplantation is venous outflow obstruction. As in adults, the frequency of this complication is lower when the allograft is implanted using a caval replacement rather than a piggyback technique. Therefore, particularly early in the days of partial liver transplantation for children, rates of outflow obstruction ranged between 17–28% [62,103]. Rates are more modest in later series, ranging between 4.5–10.5% [103–106]. It is widely believed that a simple end-to-end anastomotic approach is a risk factor for graft torsion that can obstruct outflow resulting in allograft dysfunction with fluid retention and ascites accumulation or even acute allograft failure. Several have proposed alternative anastomotic geometries with an emphasis on creating a wide and short outflow tract. Options include a triangulated anastomosis using the confluence of the native hepatic veins further opened onto the the inferior vena cava or a site fashioned directly onto the inferior vena cava [62,103,107,108].

Clinically, compromised venous outflow can present dramatically early after transplantation with acute allograft failure. More

commonly, presentation is dominated by the development of ascites and/or peripheral edema, with or without biochemical evidence of allograft dysfunction. Diagnosis is often suggested by Doppler ultrasonography showing hepatic venous waveforms without the typical phasicity and confirmed by transjugular venography. Surgical intervention is typically reserved for acute presentations in the immediate peritransplant period. Otherwise, venous outflow obstruction is addressed with percutaneous endovascular approaches to resolve the pressure gradient [103,104,109,110]. Balloon dilatation is first attempted, with high rates of both initial success and recurrence. Persistence of a gradient or recurrence strongly merits consideration of stent deployment. Long-term outcomes are generally excellent with clinical resolution and graft preservation.

Biliary complications

The typically small bile ducts of both the allograft and the recipient have led to the dominance of Roux en Y hepaticojejunostomy over choledochocholedochostomy as the preferred anastomosis strategy for pediatric liver transplantation. Unlike vascular complications which occur with higher frequency in children over adults, biliary complications occur at a similar frequency ranging between 10–33% [111–116]. Complications are usually either leak or stricture. Biliary leaks typically present early after transplantation. Although most commonly anastomotic, leaks can also emanate from the cut edge of partial grafts. Biliary strictures can present either early or late after transplantation. Similarly, the most common are anastomotic strictures as diffuse intrahepatic strictures are rare. Risk factors for biliary complications after pediatric liver transplantation include hepatic artery thrombosis resulting in biliary ischemia, multiple ducts, and ABO incompatible transplantation [112–114,116]. Graft type — whole grafts or partial grafts from deceased or living donors — has not been consistently identified as correlated with biliary complications. More recently, a few reports have explored choledochocholedochostomy with an external stent as an anastomotic strategy [117–120]. Conversion to Roux en Y was frequently necessary for complications, particularly with infant recipients.

Although non-invasive approaches such as ultrasonography or biliary scintigraphy can suggest the presence of a biliary complication, percutaneous transhepatic cholangiography is required for definitive diagnosis. If a diagnosis is made, it is critical to assess the hepatic artery prior to treating the biliary complication. In the immediate peritransplant timeframe, surgical intervention is generally undertaken. However, later after transplantation, percutaneous and, occasionally, endoscopic approaches are more frequently exercised [121–125]. Although biliary complications certainly result in morbidity, they typically do not compromise graft or patient survival.

Early post-transplant management considerations

Immunosuppression strategies

In the early days of transplantation, when the immunosuppression armamentarium comprised solely of corticosteroids and azathioprine, and even after the emergence of cyclosporine, induction immunosuppression was commonly utilized in both adult and pediatric liver transplantation. With the gradual development and increasing penetration of more potent immunosuppression agents such as tacrolimus followed by mycophenolate, induction was essentially abandoned. However, as the toxicity profile of corticosteroids and calcineurin inhibitors in children has been better delineated, there has been a resurgence of interest in induction immunosuppression. Rather than using induction to augment overall immunosuppression and reduce rates of acute rejection, induction immunosuppression is now used to facilitate minimization or even complete avoidance of corticosteroids and/or reduction of exposure to calcineurin inhibitors while maintaining stable rates of acute rejection, graft, and patient survival [117,126–132]. Currently, induction is administered to 31% of pediatric liver transplant recipients. The dominant choice for induction has been anti-interleukin-2 (IL-2) receptor antibodies, over anti-thymocyte globulin [133]. Historically, two anti-IL2 receptor antibodies have been available, basiliximab and daclizumab, but the latter is no longer available. In general, the IL-2 receptor antibodies have had an excellent safety profile with no increases in hemodynamic, metabolic, nephrologic, neurologic, infectious or malignant adverse events including post-transplant lymphoproliferative disease [127–130,132].

Maintenance immunosuppression regimens have evolved tremendously over the past two decades, and are covered in detail in Chapter 66. Although it is widely recognized that the calcineurin inhibitor, cyclosporine, brought transplantation into the modern era, it has long been displaced by tacrolimus as the dominant maintenance immunosuppression agent. In randomized control trials, tacrolimus proved superior to cyclosporine with significantly lower rates of acute and chronic rejection albeit no improvement in patient or graft survival [134–136]. The toxicity profile of tacrolimus compared to cyclosporine was mixed. Tacrolimus was associated with significantly higher rates of diabetes and post-transplant lymphoproliferative disease (PTLD) but significantly lower rates of hirsutism and gingival hyperplasia [137–141]. Over time, the penetration of tacrolimus has steadily increased such that currently, greater than 90% of pediatric liver transplant recipients are discharged from the transplant hospitalization on tacrolimus [142].

Similar to tacrolimus and cyclosporine, mycophenolate mofetil has largely replaced azathioprine as the anti-metabolite of choice for maintenance immunosuppression. The first report of incorporating mycophenolate mofetil into a de novo maintenance immunosuppression regimen with microemulsion cyclosporine and corticosteroids appeared in 1999 [143]. When compared to a historical cohort treated with azathioprine, oil-based gel-encapsulated cyclosporine, and prednisone with anti-T-cell antibody induction therapy, the authors concluded that the new regimen was safe, well-tolerated, and eliminated the need for intravenous induction immunosuppression. Utilization of mycophenolate increased as reports of its use to improve renal function through reduction of calcineurin inhibitor exposure [144–150] and as rescue therapy for refractory rejection emerged [148,151–153]. Mycophenolate is now prescribed as maintenance immunosuppression for approximately 40% of de novo pediatric liver transplant recipients.

With the widespread use of tacrolimus, with or without mycophenolate, there has been substantial interest in exploring corticosteroid minimization or avoidance strategies. The first trial compared a prospective cohort of 20 recipients treated with basiliximab induction and tacrolimus with a historical cohort of 20 recipients treated with corticosteroids and tacrolimus [131]. Recipients in the steroid free regimen enjoyed superior one year rejection free survival and exhibited significant linear growth. Subsequently, additional studies have confirmed that basiliximab supported complete steroid elimination with a significantly lower incidence of acute

rejection [129,132], overall infection [132] or viral infection [129]. Moreover, steroid elimination reduced anti-hypertensive use and improved catch-up linear growth [129]. Currently, in the US, approximately 20% of children undergo liver transplantation with complete steroid avoidance. Although the majority of children still receive corticosteroids at the time of transplantation, there has been a strong trend of minimization through discontinuation, particularly in the interest of optimizing (catch-up) growth [154–160]. One year after transplantation, approximately 40% of pediatric liver transplant recipients remain on corticosteroids.

Diagnosis and management of acute cellular rejection

The diagnostic and therapeutic algorithms for early acute cellular rejection (within the first six months) for pediatric liver transplant recipients parallel those for adult liver transplant recipients, covered in Chapter 70. In light of the increased technical difficulty and higher rate of surgical complications for pediatric liver transplantation, ultrasound and Doppler examination is an important first step in the assessment of allograft dysfunction that is typically manifest by elevated liver tests. If there is no evidence of hepatic arterial, portal venous, or biliary complications, then liver biopsy should be obtained. The most common approach to liver biopsy is percutaneous, with ultrasound guidance. A transjugular approach performed by an interventional radiologist has gained popularity as any associated bleeding is typically contained within the intravascular space [161,162].

The histological diagnosis and grading of acute rejection are according to the Banff Classification [163] that is presented in detail in Chapter 82. In the immediate peritransplant timeframe, the primary differential diagnoses for allograft dysfunction are acute cellular rejection, ischemia/reperfusion or preservation injury or pericholangitis suggesting biliary stricture. Currently, the incidence of early acute cellular rejection approximates 40–45% with the vast majority of episodes occurring within six weeks of transplant (Figure 114.4) [164]. Analysis of the SPLIT database showed that

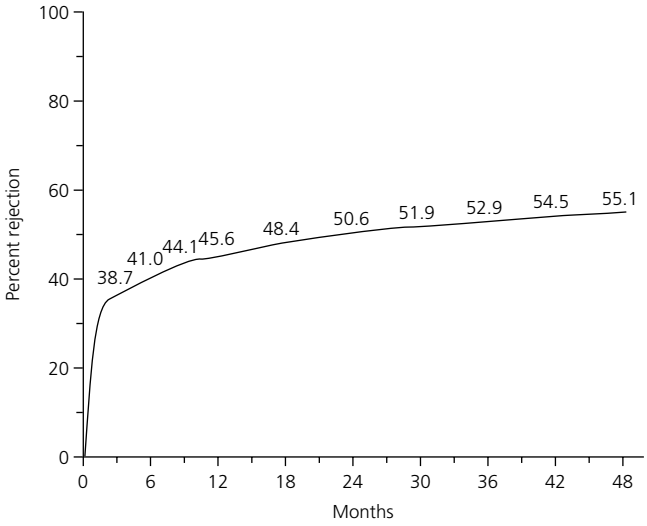

Figure 114.4. Probability of rejection according to time after transplantation. Kaplan-Meier plot showing the probably of rejection over time in 2291 primary pediatric liver transplant recipients registered in the SPLIT database between 1995 and 2006. Reproduced from [164] Shepherd et al. with permission from John Wiley and Sons.

independent factors that negatively associated with acute rejection included age at transplant of 0–5 months compared to all other age categories, cholestatic, metabolic, or other etiology of liver disease compared to biliary atresia, ABO incompatible compared to ABO identical transplantation, tacrolimus compared to cyclosporine primary immunosuppression, and transplantation after 2002 [164].

Early acute cellular rejection after pediatric transplantation is most commonly treated with intravenous bolus corticosteroids. Follow-up biopsy may be necessary to assess treatment efficacy, particularly if there is suspicion of incomplete response. An episode of acute cellular rejection that does not resolve with corticosteroid bolus is termed steroid refractory rejection and often requires more intense therapy with a monoclonal or polyclonal antibody. In addition to the immunosuppression bolus administered to treat acute rejection, augmentation of maintenance immunosuppression is often considered. Options include intensification (dose increase), conversion [137] (change from less to more potent agent, typically in the same class), or addition (adding an agent) [153,165–168]. In special circumstances, these options, in and of themselves, may represent viable treatment approaches [169]. While it is always desirable to choose the least intense option that will be effective in reversing the rejection process, inadequate treatment risks potential evolution to chronic rejection, a more serious and difficult condition to treat and reverse.

Management of infection risk after transplantation

While improvements in surgical technique, immunosuppression medications, and general medical care have undoubtedly coalesced to revolutionize pediatric liver transplantation, advances in the prevention, detection, and treatment of infections also deserves substantial credit for dramatically improving post-transplant patient survival. The achievements in controlling infection are particularly notable when considered within the context of increasingly potent and efficacious immunosuppression regimens that heighten patients' vulnerability. Pediatric liver transplant recipients are susceptible to infection as the majority enters transplantation as infants and toddlers, lacking immunity to many pathogens. Moreover, chronic liver disease and its frequent companion, malnutrition, weaken cellular immune defense mechanisms and predisposes to specific infections such as spontaneous bacterial peritonitis and biliary sepsis [170–172]. Finally, at the time of transplantation, immunosuppression is administered. Therefore, it is not surprising that, in spite of substantial progress, infectious complications continue to compromise both quality and quantity of life for children after liver transplantation [17,164,173–175].

Profile of infection according to time after transplantation

It is widely accepted that uncontrolled infection is a contraindication to transplantation. Although some children come to transplantation without any particular infectious issues, many may have had recent infection, current infection controlled by treatment, and/or additional vulnerabilities such as indwelling catheters/drains. Like every patient who undergoes major surgery, children undergoing liver transplantation are prone to infections involving the surgical site(s) particularly if there are unfavorable anatomical or technical factors and infections related to indwelling devices such as foley catheters, vascular catheters, and/or endotracheal tubes. Pathogens most frequently encountered within the first month of transplantation are bacteria, both gram positive and gram negative, and candida species [164,175–178]. While anti-microbials and anti-fungals are

important therapies, durable resolution requires correction of any underlying anatomic or technical problem, if present. Otherwise infection will recur and potentially involve resistant organisms reflecting previous treatment with anti-infective agents. Data from SPLIT indicates that 38% of pediatric liver transplant recipients experience a culture proven bacterial or fungal infection during the first month after transplantation [164].

Between one and six months after transplantation, assuming resolution of anatomical and technical issues that may have been present, opportunistic infections reflecting the effect of immunosuppression emerge, along with (seasonal) community acquired infection [174,175]. Routine prophylaxis against candida and pneumocystis has had their intended effect. Although viral infection or reactivation has been the dominant problem, these have receded with the advent of effective prophylactic and/or preemptive treatment as discussed further on in this chapter. As additional time passes after transplantation, the burden of infection generally diminishes, particularly for those with good allograft function on standard maintenance immunosuppression. Exceptions are children who have required aggressive treatment for rejection, those with some sort of chronic, often viral, infection, and those whose allograft function is not optimal.

Important viral infections: Cytomegalovirus

Cytomegalovirus (CMV) is a DNA virus in the herpes family that is a well-known pathogen for immunosuppressed liver transplant recipients. A spectrum of clinical scenarios can result, ranging from an asymptomatic infection to a self-limited febrile illness to a serious tissue-invasive disease of the lungs, the liver, the gastrointestinal tract, or, very rarely, the central nervous system [174,175,178–181]. In the setting of documented viral replication, infection refers to asymptomatic cases, while disease refers to symptomatic cases. The main risk factor for CMV infection and/or disease, the lack of previous infection and therefore the lack of immunity, affects the majority of pediatric liver transplant recipients who are predominantly infants and toddlers at the time of transplantation. This vulnerability is accentuated by exposure to the graft and blood products from donors with previous history of infection. Primary infection is widely considered to be more virulent than reactivation infection. The second most important risk factor is receipt of a potent antibody preparation such as rabbit thymoglobulin or OKT3 [178,180,182,183]. Among pediatric liver transplant recipients, these medications are typically prescribed for steroid refractory rejection and therefore, affect only a small minority of patients.

Recognition of the potential for morbidity and mortality posed by CMV has led to two dominant strategies for patient management beginning at the time of transplantation when immunosuppression is initiated. Many centers prescribe anti-viral medications at a prophylactic dose to all transplant recipients, often with different duration based on risk profile [184–189]. Ganciclovir is often administered intravenously during the transplant hospitalization with conversion to oral therapy to complete a predetermined course. This approach is arguably the simplest to implement but does expose all patients to anti-viral medications for months with attendant side effects. Moreover, data has shown that infection/disease often emerges after prophylaxis is discontinued [181], leading programs to extend the course thereby further increasing toxicity. The alternative approach is preemptive therapy whereby serial determinations of CMV DNA copy-numbers are obtained and treatment is initiated when the titer exceeds a predetermined threshold [185–187]. While this approach minimizes drug exposure, it is essentially individualized care and, as such, is more resource intensive. As a result, many transplant centers have designed various hybrid strategies. Possibilities include risk stratification with prophylactic treatment for high risk recipients and preemptive treatment for low risk recipients or prophylaxis for a time period followed by preemptive monitoring.

The diagnosis of CMV infection and disease has also evolved substantially over the past several decades. Today, detection and quantification of circulating CMV DNA is the mainstay, having replaced assays for pp65 antigenemia and viral cultures of blood, urine, or other secretions [190–192]. Positive viral DNA titers must be interpreted in the context of the patient's clinical condition. CMV DNA may be detected in the absence of or prior to any evidence of clinical disease. Depending on the titer, treatment may be initiated or follow-up testing performed. Moreover, CMV DNA may not be detected in the presence of tissue-invasive disease most commonly of the gastrointestinal tract. Tissue biopsy should be obtained for histological examination as dictated by clinical suspicion.

The primary therapeutic agent for CMV infection and disease is intravenous ganciclovir, a nucleoside analog that has myelodepression as its primary toxicity. Oral ganciclovir or valganciclovir, a prodrug with improved bioavailability, are typically prescribed for prophylactic or preemptive treatment although use of the latter as a therapeutic for established disease is being explored [181,182,184,186–189,193]. Alternative medications include CMV hyperimmune globulin as adjunctive therapy and foscarnet, or cidofovir as second line drugs with less favorable side effect profile [189]. Finally, consideration should be given towards immunosuppression reduction for serious CMV disease.

Important viral infections

Epstein-Barr virus, including post-transplant lymphoproliferative disease

Epstein Barr virus (EBV) is a lymphotrophic herpes virus. As the etiologic agent of a wide spectrum of disease ranging from infection to malignancy, EBV causes substantial morbidity and mortality after pediatric liver transplantation [178,194–198]. A detailed consideration of PTLD is found in Chapter 96. Like CMV, primary infection produces more serious clinical syndromes than reactivation infection. Infants and toddlers are particularly vulnerable, as they typically undergo transplantation in a naïve state without previous exposure or immunity. Primary infection typically occurs in the peritransplant period, transmitted through the graft itself and/or transfused blood products although the routine incorporation of leukocyte depletion has diminished the importance of the latter. Acute infection can be entirely asymptomatic or result in a mild, non-specific viral illness evidenced after the fact by seroconversion. Alternatively, acute infection can produce a more serious viral syndrome with a variety of generalized symptoms including fever, malaise, anorexia, and myalgia. There can also be signs or symptoms of organ inflammation including pharyngitis, lymphadenopathy, splenomegaly, hepatitis, pneumonitis, and gastroenteritis. The inflammation signals EBV-driven proliferation of lymphocytes [predominantly (>85%) B cells] and is thereby termed post-transplant lymphoproliferative disease (PTLD). In addition to an EBV-naïve immune state, the intensity of overall immunosuppression is well recognized as the other dominant risk factor for the development of PTLD [195,199–203].

There are significant parallels between the management of CMV and EBV risk, infection, and disease, particularly since the same

anti-viral agents are thought to be effective for both viruses [184]. Some centers administer prophylaxis, either to all recipients or to high-risk recipients — those who are EBV naïve receiving an organ from a donor with previous infection. Others use a preemptive strategy, following peripheral blood EBV titers. Because the development of PTLD has been associated with variably defined "high" EBV DNA copy-numbers, immunosuppression reduction is often practiced to augment anti-viral therapy. Several reports suggest that this strategy has reduced the incidence of PTLD [204–213]. The modern incidence of PTLD ranges has decreased to <5% while historically, incidence upwards of 20% had been reported [199,200,207,214–216].

Thorough clinical, laboratory, and radiographic assessment should be carried out to delineate extent and burden of disease. Definitive diagnosis of PTLD requires biopsy of involved tissue(s). The pathology is classified according to the criteria of the World Health Organization. In children, most are EBV driven and of polymorphic histology. Complete details of the spectrum of pathology, clinical findings and range of therapies are described in Chapter 96. As for other organs, treatment of biopsy proven PTLD has historically followed a sequential approach, ascending a hierarchy of therapeutic modalities. At the base of the pyramid is immunosuppression reduction, which is often sufficient for patients with "early lesions" and polymorphic disease, and even for some children with monomorphic disease. Some centers have advocated complete cessation of immunosuppression [217]. Surgical or radiation therapy may also be a front-line approach for symptomatic relief or localized disease. The next therapeutic in the modern armamentarium is rituximab, a monoclonal antibody against a cell surface antigen expressed by all B cells that is present in the majority of PTLD cases, CD20. Since the first reported use for PTLD in children in 2002, there have been several subsequent reports that have solidified its role for PTLD with positive CD20 staining [218–221]. At the top of the pyramid is the standard chemotherapy regimen that is administered to non-transplant patients diagnosed with lymphoma. Many reports have shown that these regimens result in prohibitive rates of morbidity and mortality, motivating the design of less intensive, and therefore, less toxic regimens that have yielded improved toxicity profiles while maintaining adequate efficacy [222,223].

The outcomes of pediatric liver transplant recipients with PTLD illustrate the delicate balance that must be achieved to emerge with a healthy recipient and a healthy allograft. Primary causes of mortality after the diagnosis of PTLD is either the PTLD itself or toxicities related to its treatment (infection/sepsis/multi-system organ failure or severe allograft dysfunction). The latter is the dominant etiology of graft loss, typically resulting from immunosuppression reduction that precipitates acute and subsequently chronic rejection [207,209,217]. Reported mortality rates have varied widely over the past one to two decades, from 12% to as high as 60% [195,199,215–217,224,225].

Late post-transplant challenges

Late mortality and graft loss are infrequent among pediatric liver transplant recipients. Late mortality is predominantly attributable to complications of immunosuppression such as infection (sepsis or multi-system organ failure) or malignancy (PTLD or hepatoblastoma recurrence) [17,226]. However, late graft loss is often attributable to inadequate immunosuppression resulting in chronic rejection or technical complications such as hepatic artery thrombosis and/or biliary obstruction. Common predictors of late death and late graft loss are transplantation for tumor and greater than five admissions during the first post-transplant year. Additional independent predictors for late death are transplantation for fulminant hepatic failure, weight deficit at transplantation, and hepatic artery thrombosis. Additional independent predictors for late graft loss are early reoperation and steroid resistant acute cellular rejection [17]. Children face substantial risk of morbidity from non-immune complications of immunosuppression given their longer potential life span and greater cumulative exposure. Current immunosuppression medications increase risk for diabetes, hyperlipidemia, hypertension, obesity, and the metabolic syndrome. In addition to these critically important medical outcomes, chronic immunosuppression likely compromises growth and functional outcomes including health related quality of life, issues considered in greater depth in Chapter 118. Presently, only one third of 10 year survivors have stable allograft function defined by normal liver tests while on immunosuppressive monotherapy, with normal growth and absence of complications of immunosuppressive medications [227].

Late surgical complications

Vascular and biliary complications can develop or be diagnosed late (more than one year) after transplantation, resulting in considerable morbidity and potential graft loss [17,226]. The true prevalence of late hepatic artery thrombosis is unknown as the condition can be clinically silent. If the diagnosis is made incidentally in the setting of preserved liver function and the absence of any symptoms, then intervention may not be either necessary or advisable. Late hepatic artery thrombosis can, however, be the cause of refractory biliary complications and thereby necessitate retransplantation. Late biliary complications occur in up to 13% of pediatric liver transplant recipients and are dominated by strictures [111,116,228]. Common presenting signs and symptoms are elevated liver tests, particularly in a fluctuating pattern, or a frank episode of cholangitis. Patency and adequacy of hepatic arterial flow must be assessed and considered when planning therapy. Percutaneous or endoscopic intervention is typically the first-line approach to treat late strictures, particularly if hepatic artery thrombosis is present, to maximally preserve collateral circulation [111,115,123]. Retransplantation may be necessary for recurrent biliary sepsis and/or secondary biliary cirrhosis. Approximately 15–20% of late graft loss has been attributed to biliary complications [17,226,229,230].

Late venous complications occur less frequently than biliary complications [85,89,231]. Presenting symptoms of portal vein stenosis or thrombosis typically reflect the development of portal hypertension and include gastrointestinal bleeding, ascites, and/or splenomegaly [85]. Outflow obstruction most often presents with ascites, with or without peripheral edema, First line therapy for a portal or hepatic vein stricture is balloon dilatation. Initial success is high but recurrence is common, frequently necessitating repeat dilatation or stent deployment [89,104,105,110,231]. Portal vein thrombosis necessitates standard management of the complications related to portal hypertension as they develop.

Late allograft dysfunction

Allograft rejection

Late allograft rejection, defined as acute cellular rejection occurring more than 90 days after transplantation, is not common, occurring in about 10% of pediatric transplant recipients between 3–12 months after liver transplant and less frequently thereafter (Figure 114.4) [164]. Allograft rejection is usually associated with a change

in immunosuppression; either a scheduled change according to the center's management protocol or non-adherence to treatment regimen [232–234]. Non-adherence is particularly relevant in pediatric transplantation and is covered in-depth in Chapter 120. The latter may be detected by excessive variation of calcineurin inhibitor blood levels [235,236]. Clinically, acute rejection is usually asymptomatic, often suspected as a result of elevated liver tests compared to baseline and evaluated by biopsy. Allograft biopsy is the gold standard to diagnose and grade acute and/or chronic rejection. Biopsies should be interpreted according to the Banff global assessment criteria [163] (see Chapter 82). If the biopsy does not demonstrate rejection, other causes of liver dysfunction should be thoroughly considered.

The treatment strategy for acute rejection should take into account the clinical and histological severity, any objective evidence of non-adherence, and potential to precipitate new or exacerbate preexisting co-morbidities such as renal dysfunction or diabetes. Mild or moderate acute rejection (rejection activity index less than six) can be treated with intensification (dose increase, most frequently, of a calcineurin inhibitor), conversion to a more potent agent, addition of a new medication, or some combination of the above. If liver tests do not stabilize or improve within two weeks, corticosteroids can be given. Moderate to severe acute rejection can be treated with bolus corticosteroids, either intravenously, orally, or both. If liver tests normalize or return to baseline, then rejection is considered resolved. Failure to see improvement in liver tests may require a repeat liver biopsy to determine whether the rejection process is ongoing and therefore, resistant to corticosteroids, necessitating administration of potent antibody preparations such as rabbit thymoglobulin or OKT3. Chronic rejection is uncommon, occurring in less than 2% of pediatric liver transplant recipients [17]. Even so, chronic rejection accounts for approximately 40% of late graft loss [17]. Chronic rejection occurs less frequently in transplant recipients who receive primary immunosuppression with tacrolimus compared to cyclosporine-based regimens [136,237]. Diagnosis is based on liver histology according to the Banff criteria [163,238]. Enhanced immunosuppression is indicated for children with chronic rejection, particularly if diagnosed at an early stage when the process might still be reversible. However, with the exception of early studies of conversion from cyclosporine to tacrolimus [137,239], reliable treatment strategies other than retransplantation are not well-defined.

Chronic hepatitis and fibrosis

Chronic inflammation and fibrosis are prevalent among pediatric liver transplant recipients more than five years after transplantation even in the face of normal aminotransferases [240–243]. Fibrosis is of variable severity occurring in as many as 75% of the population by ten years after transplant. The pathobiology of chronic hepatitis and/or fibrosis is not defined and may reflect late complications of technical variant allografts, atypical rejection, chronic viral hepatitis or de novo autoimmune hepatitis. For patients with clinical, serologic, and histological features of de novo autoimmune hepatitis, treatment with azathioprine, corticosteroids, and/or sirolimus may be effective [244,245].

Non-immune complications of immunosuppressive agents

Post-transplant renal disease

Estimates of chronic renal dysfunction in pediatric liver transplant recipients range from 24% to >70% [246–248]. Recipients with inborn errors of metabolism, Alagille syndrome, congenital hepatic fibrosis, and those exposed to nephrotoxic agents (chemotherapeutic agents, aminoglycosides) prior to transplantation are at increased risk of chronic renal dysfunction [246,247,249]. Indirect evidence also suggests that acute kidney injury in the peri-transplant timeframe contributes to development of chronic renal dysfunction [250,251]. Strategies to preserve renal function during this critical period include close monitoring of serum creatinine, maintenance of adequate intravascular volume, avoidance of nephrotoxic medications and early recognition and mitigation of acute kidney injury [252]. Immunosuppressive medication treatment strategies can decrease risk of renal dysfunction especially for patients with preexisting renal disease and/or those who have decreased glomerular filtration rate (GFR) at transplant. Observational and controlled studies in adults and children with decreased GFR more than one year after transplantation have demonstrated improved renal function in association with lowering the calcineurin inhibitor dose by 25–50% and adding mycophenolate mofetil [147].

Diabetes

De novo post-transplant diabetes occurs in 10–15% of pediatric liver transplant recipients and is therefore less common than in adults [253–255]. The mean duration of post-transplant diabetes is 75 days, suggesting that it may be due to the high doses of corticosteroids often administered in the peri-transplant timeframe [253]. Risk factors include Hispanic ethnicity, adolescent age at transplantation, cystic fibrosis etiology of liver disease, corticosteroid and tacrolimus administration [141,254]. As with adult liver transplant recipients, minimization or early discontinuation of corticosteroids may improve glycemic control, particularly in children with diabetes prior to transplantation or those at increased risk.

De novo malignancy

Increased risk of cancer over time has been convincingly demonstrated in adult solid organ transplant recipients but the data in children is less substantial [226,256–258]. Anecdotal experience suggests that skin cancer is rare during the first 10–15 years post-transplant among pediatric transplant recipients [259,260]. In a Swedish study that linked all solid organ transplant pediatric recipients between 1970 and 2007 (n = 536) to the National Cancer Registry, two cases of non-melanoma skin cancers were identified [261]. However, given the longer life expectancy of children, strategies towards prevention of skin cancers are critical. Other cancers have been reported but the relative risk compared to the general population has not been determined. Risk factors, screening guidelines, and optimal treatment have not been established for pediatric transplant recipients.

Health-related quality of life

Health-related quality of life (HRQOL) refers to those aspects of QOL that are directly related to health and are potentially affected by the health care system. There are five aspects of health that comprise HRQOL as defined by the World Health Organization: (1) physical health; (2) mental health; (3) social functioning; (4) role functioning; and (5) general health perception [262–264]. A large, cross-sectional, multi-center study of pediatric liver transplant recipients in North America demonstrated that all aspects of HRQOL including school function were decreased in pediatric liver transplant recipients compared to population norms but that the largest effect size was in school functioning [265]. A more detailed study showed that the mean intelligence quotient for liver transplant recipients at least two years after transplantation was decreased

compared to the normal population [266] (see Chapter 119). In the same cohort, learning disability and reduced executive function were also more common among liver transplant recipients than in the normal population [265]. These observations have significant implications for education strategy, management of non-adherence, and transition to adult care.

Transition to adult care

The transition of a child transplant recipient to an adult-oriented care model is a complicated issue covered in depth in Chapter 121. For successful transition to the adult care system, the adolescent or young adult must understand his/her cause of organ failure and need for transplantation. The patient should recognize behaviors which promote good outcomes including adherence to medical regimens and avoidance of risk taking behavior and have accumulated knowledge of the health care system [233,267–271]. Medical adherence is considered a critical factor in the transition process and may decline after the transfer to adult care. To ensure a safe transfer of care, a strategy for transition of responsibility from the parent to the adolescent or young adult should begin several years before the actual transfer of care.

Summary

Pediatric liver transplantation has evolved into the preferred treatment for children with end stage liver disease, and in doing so has developed many practices that are distinct from adult liver transplantation. These include technical, pharmacological, and social nuances that must be understood for the clinician to engage in this highly complicated but immensely rewarding practice.

CHAPTER 115

Pediatric Heart Transplantation

Steven A. Webber
Department of Pediatrics, Vanderbilt University School of Medicine, Nashville, TN, USA

Introduction

Pediatric heart transplantation has been an integral part of heart transplantation in general since the earliest days of the field. During its development, pediatric heart transplantation has led to substantial insights important not only to the technical aspects of cardiac replacement, but also to the understanding of immune development and tolerance. Today, cardiac transplantation is an established option for children with anatomical or functional heart disease. This chapter will cover the development of heart transplantation in children, and provide an overview of the indications, preparations, conduct, and follow-up for this procedure, highlighting pediatric-specific issues to be contrasted with similar topics for adult transplantation covered elsewhere in this textbook.

Historical notes

On December 3, 1967, the first cardiac allotransplantation procedure was performed by Christian Barnard at the Groote Schuur Hospital in Cape Town, South Africa [1]. The first pediatric heart transplant followed only three days later, in the early morning hours of December 6. The procedure was performed by Kantrowitz and colleagues at the Maimonides Medical Center in Brooklyn, New York [2]. A previous attempt at infant heart transplantation had been abandoned by the same team the prior summer (June 1966). The new recipient was felt to have tricuspid atresia, although in fact was later found to have severe Ebstein's malformation with functional pulmonary atresia. A systemic-to-pulmonary shunt had been performed on the third day of life, but the infant developed severe heart failure and pulmonary edema. On November 24th, it was decided to offer the family the option of orthotopic heart transplantation using the heart from an ancephalic infant when it became available. A consent form for the operation was signed by the parents over a week before Barnard's first transplant in South Africa. Both donor and recipient were blood group A, and the "irradiated hamster test disclosed no evidence of major incompatibility". In the early hours of December 6, an ancephalic child was identified as a potentially suitable donor and both infants were brought to the operating room where external cooling was begun by immersion in iced water (Figure 115.1). Donor cardiac activity ceased at a temperature of 27 °C and the transplant proceeded (this was prior to agreed upon criteria for brain death). The implantation essentially used the technique of Lower and Shumway (Figure 115.2), though the procedure was performed under circulatory arrest. Initially the infant appeared to do well and was moving all limbs spontaneously. However, after several hours metabolic and respiratory acidosis ensued and after approximately six hours cardiac arrest occurred. Attempts at resuscitation failed. Autopsy revealed a good surgical result with appropriate hemostasis from the suture lines. However, the aortopulmonary shunt had been incompletely closed. These first heart transplants in South Africa and New York were performed following many years of laboratory experimentation with heterotopic and orthotopic transplantation in small and large animals. The race to be the first may well have been part of the driving force behind the timing of these first transplants, though there is also evidence to suggest that these pioneering surgeons believed that successful thoracic transplantation was feasible in both children and adults by the end of the 1960s.

Following Barnard and Kantrowitz, a large number of surgeons attempted heart transplants in 1968. By the end of that year some 102 procedures were recorded from 17 countries. Mean survival for these early transplants was only 29 days [3]. Over the next decade enthusiasm for human heart transplantation declined worldwide, as it became apparent that the therapeutic armamentarium for controlling allograft rejection was inadequate for achieving allograft and patient survival [4]. Surgeons at a small number of centers, most notably Stanford University, persevered with attempts at heart transplantation in selected adults. The Stanford group also started to transplant a few adolescents, performing seven procedures between 1974 and 1980. Although only corticosteroids and azathioprine were used for immunosuppression, four of these patients survived greater than ten years from transplantation [5]. In addition, donor organ availability improved as the concept of brain death became accepted [6,7].

The favorable impact of the introduction of cyclosporine on survival of adult heart transplant recipients was immediately apparent [8,9] and led to renewed interest in pediatric heart transplantation in Stanford, at the University of Pittsburgh (1982) and subsequently at a number of other centers around the world. The earliest recipients were older children and adolescents, but it was not long before infants and younger children were also considered to be suitable recipients. Bailey and colleagues, as a result of extensive work in the animal laboratory, suggested that the neonate might make an excellent solid organ recipient [10,11]. Their first attempt at neonatal transplantation was a baboon-to-human xenotransplant in a 2.2 kg 12-day-old infant with aortic and mitral atresia [12]. The infant only survived for 20 days but the surgical feasibility of newborn

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

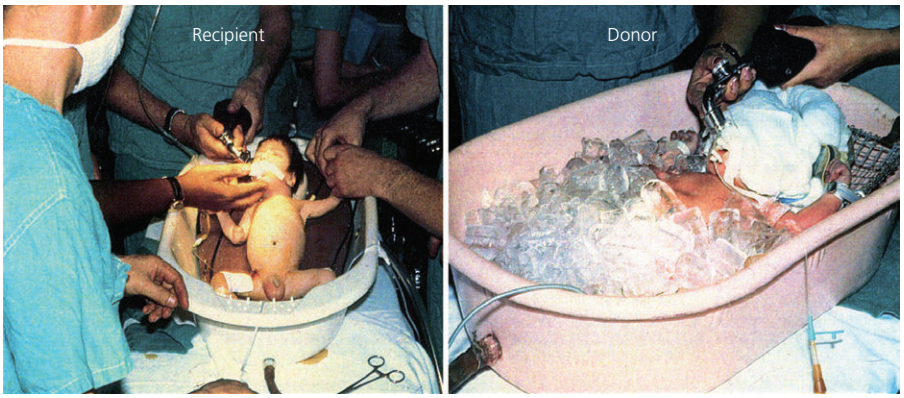

Figure 115.1. The first pediatric heart transplant was performed on December 6th, 1967. Hypothermia was induced by placing both the ancephalic donor (right panel) and the recipient (left panel) in baths of iced water. When donor cardiac activity ceased, the transplant procedure commenced.

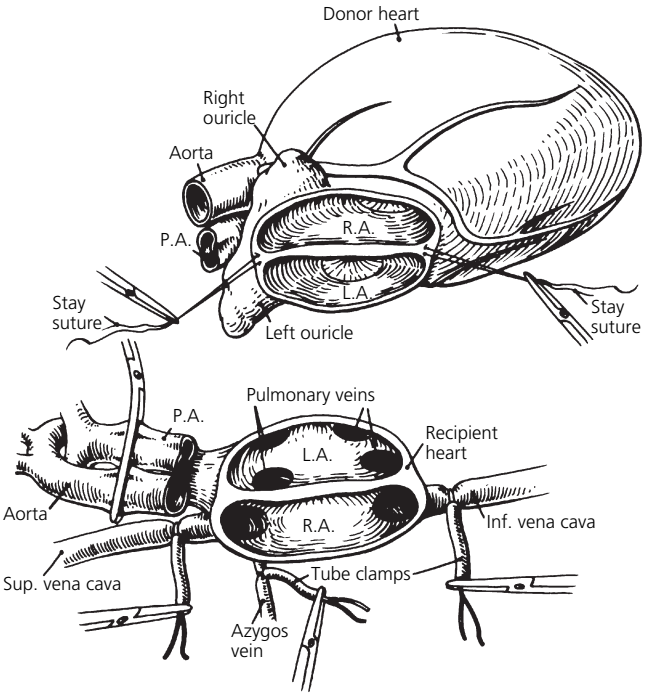

Figure 115.2. Surgical technique of the first pediatric heart transplant. The drawing was made shortly after the procedure. Reproduced from [87] Fine R, Webber SA, Harmon W, et al. (2007). Pediatric Solid Organ Transplantation, Second Edition, with permission from John Wiley and Sons.

transplantation for hypoplastic left heart syndrome (HLHS) had been demonstrated. Orthotopic newborn heart transplantation was introduced at Loma Linda, in November 1985 [13]. The first recipient was a four day old infant with HLHS, a condition generally considered to be lethal at that time, despite the recent introduction of a palliative operation by Norwood [14]. During the 1990s, transplantation for HLHS became the fastest growing area of pediatric heart transplantation. More recently, improved results of staged surgical palliation for HLHS and the long wait times for donor organs for neonatal candidates have led many centers to abandon transplantation as the primary procedure of choice for infants with this condition.

Many other challenges have been overcome, and milestones achieved, in the field of pediatric heart transplantation over the last 15 years. Early results with transplantation for previously palliated complex congenital heart disease were disappointing [15]. However, with improved patient selection and increased surgical experience, results similar to transplantation for cardiomyopathy can now be achieved in experienced centers [16].

The shortage of donor organs remains a critical issue, and death on the waiting list remains highest in the infant heart candidate population, especially for children receiving mechanical circulatory support with ECMO [17]. The use of ABO incompatible transplants has recently been advocated by the Toronto group for neonatal and infant candidates, since antibodies to the major blood group antigens are not produced until later in infancy (discussed in more depth in Chapter 112) [18]. Such a strategy may improve survival for select infants with high wait-list mortality [19]. No comprehensive solution to the donor shortage will occur unless xenotransplantation can be shown to be safe, efficacious and socially acceptable.

Indications for transplantation and candidate evaluation

Indications for transplantation in childhood

Transplantation of the heart is generally considered indicated when expected survival is less than two years, and/or when there is unacceptable quality of life. Cardiomyopathy (predominantly dilated forms) and complex congenital heart defects remain the primary indications, and together account for approximately 90% of transplantations undertaken in children [20]. Transplant activity has remained approximately constant over the last decade reflecting the limited number of donor organs. Diagnoses leading to transplantation are age dependent, with congenital heart defects accounting for over half of transplants in the infant age group, and cardiomyopathy accounting for almost two-thirds among adolescents [20]. Of note, the proportion undergoing transplantation in infancy and for a diagnosis of congenital heart disease (CHD) are significantly higher in North America than the rest of the world [20].

The appropriate indications for heart transplantation in childhood were summarized in a 1999 report from the Pediatric Committee of the American Society of Transplantation [21]. More recently, a consensus group of the American Heart Association has addressed the same topic [22]. In general, there is broad consensus in the pediatric cardiology community as to when transplantation is indicated. Perhaps the most controversial indication for heart

transplantation is HLHS and related pathologies in the newborn. Survival rates in excess of 80% at one year may be achieved in experienced centers with either Norwood reconstruction or primary transplantation for this condition. Median waiting times for newborn heart transplant candidates are approximately two months in the US (and longer in some countries), resulting in very high costs of care prior to transplantation, significant pretransplant morbidities, and a wait-list mortality as high as 30% [23]. In light of these observations, most centers have moved away from transplantation, and towards staged reconstruction, for neonates with HLHS. This strategy increases availability of organs for other infants with cardiac disease unsuitable for surgical palliation.

Relative and/or absolute contraindications for heart transplantation include chronic infection with either hepatitis B or C, or human immunodeficiency virus (HIV), prior non-adherence with medical therapy, recent or current treatment of malignancy with inadequate follow-up to ensure likely cure, active acute viral, fungal or bacterial infections, excessive and fixed pulmonary vascular resistance (above 10 IU), inadequate intraparenchymal pulmonary vascular bed, diffuse pulmonary vein stenosis, and major extracardiac disease felt to be non-reversible with heart transplantation (e.g. severe systemic myopathy). Inevitably, some centers consider specific contraindications absolute, whereas others may feel they are relative. Decision-making is based on consensus discussion among all team members and with consultation with the family and referring physicians.

Evaluation of the candidate

The evaluation process broadly follows the principles laid out for evaluation of the adult potential cardiac candidate (see Chapter 30). The evaluation includes the assessment of expected survival without transplantation, current quality of life, the potential for alternate surgical or medical therapies, as well as the inherent risks of the transplant surgery itself.

Anatomic and hemodynamic considerations

The most complex anatomy may be successfully transplanted provided the lung vasculature is adequately developed and pulmonary vascular resistance is acceptable. Anatomic points of most interest to the surgeon include abnormalities of cardiac and visceral situs (especially anomalies of the systemic and pulmonary venous return), as well as the size and anatomy of the main and branch pulmonary arteries, including the presence of stenoses, distortions and non-confluence. Intracardiac anatomy is less important since the bulk of the cardiac mass will be explanted. Abnormalities in the relation of the great arteries usually pose few problems. Attention must also be given to the relationship of key structures such as right ventricular-pulmonary artery conduits or giant right atria (after Fontan procedure) to the posterior aspect of the sternum. Computed tomography and/or magnetic resonance imaging are well suited to delineating cardiac anatomy, but cardiac catheterization is usually indicated pretransplantation to assess pulmonary vascular resistance. Excessive fixed resistance may result in acute donor right ventricular failure and an inability to wean the patient from cardiopulmonary bypass.

In general, children with indexed pulmonary vascular resistance (PVRI) $\leq$9 IU are considered low risk for acute donor right heart failure and early death. PVRI in excess of 9 IU is considered as high risk [24] and should be a contraindication to isolated heart transplantation unless there is a major fall with pulmonary vasodilator therapy. In borderline cases, restudy of hemodynamics after several days of inotropic and vasodilator therapy may be indicated, as pronounced falls in PVRI are occasionally seen. It should be noted however, that rapid fall in pulmonary resistance can lead to acute elevation in left atrial pressure in patients with very poor left ventricular function, even precipitating pulmonary edema. The role of ventricular assist device (VAD) therapy as a strategy to unload the left ventricle and reduce excessive PVRI to prepare children for orthotopic transplantation is unknown at this time but recent case reports suggest that short-term VAD support can lead to significant fall in PVRI in selected cases with subsequent successful transplantation.

Laboratory investigations

Blood typing is necessary to assure ABO compatibility with the transplanted organ, though infants and young children with absent or low anti-A and anti-B isohemagglutinin titers may be safely transplanted across traditional ABO barriers. This strategy was introduced by West and colleagues in Toronto [18,19] and is based on the principle that isohemagglutinins against blood group antigens do not normally develop until the latter part of infancy. Transplantation across blood group barriers prior to the development of naturally occurring anti-A and anti-B isohemagglutinins appears to result in outcomes comparable to ABO compatible transplants [25,26]. Furthermore, most of the transplanted infants did not form antibodies against donor blood group antigens during long-term follow-up [27], possibly due to the development of B cell tolerance [28]. Even when antibodies do develop, outcomes have still been reported to be excellent [27]. This strategy has important implications for pretransplant care, since use of blood products pre and post-transplant must be carefully planned to avoid transfusion of blood products containing inappropriate anti-A and anti-B antibodies. Acceptable products should be summarized in collaboration with the blood bank and posted at the child's bedside. These restrictions will apply indefinitely and information on acceptable blood products must be provided to the family prior to hospital discharge.

Evaluation for the presence of preformed anti-HLA antibodies ("sensitization") was traditionally performed using panel reactive antibody (PRA) testing. Today, almost all centers use solid phase assays, in particular the Luminex platform with or without cell based (PRA) assays. The solid phase platforms are highly sensitive and data (unpublished) from the Clinical Trials in Organ Transplantation in Children (CTOT-C) show that approximately half of all pediatric heart candidates have preformed anti-HLA antibodies. Many are at low titer and the significance of this observation (even when donor specific) remains to be determined. Most centers perform recipient molecular HLA typing as part of the evaluation process. This is essential if "virtual" cross-matching is to be performed in sensitized candidates (covered in more depth in Chapter 89).

Infectious disease evaluation includes serologic testing for cytomegalovirus (CMV), Epstein–Barr virus (EBV), varicella, herpes simplex virus, T. gondii, HIV, measles and hepatitis viruses A, B, C and D. Serologic status for these agents may guide prophylaxis as well as the diagnostic evaluation of post-transplantation fever. Very rarely, it may lead to exclusion of candidacy of the child for transplantation. The infectious disease evaluation should also include review of immunization history. Those candidates in whom transplantation is not likely to be imminent should undergo an update of appropriate immunizations on a regular basis. In addition, re-evaluation of antibodies against infectious agents for which

the patient was naïve at the time of the transplant evaluation should be repeated at the time of transplantation since this will influence CMV prophylaxis and assessment of risk for PTLD post-transplantation.

Consultations

A multidisciplinary team that includes the transplant cardiologist and surgeon, social worker, transplant coordinator, and infectious disease experts evaluates each candidate. A screening psychiatric/psychological examination of the child and their family is also very beneficial. The primary purpose of this evaluation is to identify patients and families at high risk for poor psychosocial outcome while waiting for transplantation and after transplantation. Evaluation of past history of non-adherence to medical therapy is critical. Additional consultations may be required from specialist services such as hematology-oncology (when there is past history of malignancy), child development, genetics, neurology and feeding/nutritional specialists. Patients with Fontan circulation require evaluation of the liver for evidence of cirrhosis and may require formal hepatology consultation.

Wait-list management and outcomes

Patients and families are interested in the chances of survival once a decision has been made to proceed with listing for transplantation. Despite this, emphasis is rarely given to pre-transplant mortality, risk factors for wait-list mortality and the optimal timing of transplantation. Premature transplantation results in exposure of the recipient to the hazards of transplantation and long-term immunosuppression. Excessive delay may result in death without transplantation or the development of co-morbidities that may increase operative risk. These co-morbidities include progressive end-organ dysfunction (especially renal), malnutrition associated with advanced heart failure, and progressive rise in pulmonary vascular resistance.

Data from the US Scientific Registry of Transplant Recipients (SRTR) reveal that children in all age groups have substantially shorter waiting times for heart transplants than do adults, but they have a greater risk of death while waiting (www.ustransplant.org). The highest death rate is among infants less than one year of age, and this rate is dramatically higher when the underlying diagnosis is congenital heart disease. The use of ABO incompatible heart transplants may decrease wait-list mortality in infant heart transplant candidates [19].

Several analyzes of the Pediatric Heart Transplant Study (a multi-institutional research database focusing on outcomes following listing for transplantation and after transplantation in over 40 centers world-wide since 1993), have focused on understanding risk factors for survival after listing for transplantation, and for defining the optimal timing of transplantation. Children awaiting transplant at the lowest urgency status (UNOS Status 2 in the US) have a very low risk of sudden death while waiting if the underlying etiology is dilated cardiomyopathy. This contrasts with the high risk of sudden death in adults with ischemic etiology on the transplant waiting list. These data suggest that routine use of automatic implantable cardioverter defibrillators (AICD) in all children who are awaiting transplant is not indicated, though certain subpopulations may benefit [29]. Despite these observations, one study has suggested a survival advantage with transplantation for patients listed as Status 2 out to at least four years [30].

Detailed analyses of outcomes for children with cardiomyopathy after listing have been performed using the Pediatric Heart Transplant Study (PHTS) database [31–33]. For dilated cardiomyopathy, the commonest indication for transplantation in children, competing outcomes show that waitlist mortality by one year is 10% with 74% achieving transplantation and 16% remaining alive waiting [31]. Risk factors for mortality while wait-listed included a history of mechanical ventilation, extracorporeal membrane oxygenation (ECMO) and arrhythmias.

By contrast, patients with congenital heart disease fair less well on the waiting list, especially those who are Status 1A and those who are listed in infancy. Wait list mortality for certain diagnostic subgroups is as high as 30% in infancy [23], perhaps reflecting the inability to support certain groups of patients to transplantation with current medical and surgical therapies. Although there has been a dramatic increase in the use of VAD support in children over the last 15 years, outcomes are far inferior for patients with CHD when compared to cardiomyopathies [34]. Almost all children are supported by paracorporeal pumps, and although the introduction of the Berlin Heart [35,36] in children has led to successful bridge to transplant for children less than 30 kg (the approximate limit of use of adult devices), the outcomes for infants are still disappointing [35,36]. None-the-less, the alternative mechanical support used most often in infants is ECMO, and this usage is associated with both very high pretransplant mortality and also high post-transplant mortality [17,36]. Because the median wait time in most centers exceeds the time that most children can be supported on ECMO, the latter is being increasing used as a bridge to VAD support when urgent mechanical support is required [35]. However, for most infants with CHD, anatomical considerations severely limit the successful applicability of this technology [34].

Donor evaluation, surgical techniques and early post-transplant management

This section focuses on evaluation of the donor for pediatric heart transplantation, surgical techniques (with focus on modification for patients with CHD) and early post-transplant management during the intensive care period/initial hospitalization. The technical aspects of the procedure described here are focused on specific issues common in the pediatric population and should be considered in concert with the more general technical aspects of heart transplantation presented in Chapter 58.

Evaluation of the cardiac donor for the pediatric recipient

Evaluation of the donor heart begins with a careful review of the history. This includes donor age and gender, body size, cause of death, presence of any chest trauma, need for cardiopulmonary resuscitation, length of resuscitation and evaluation of the hemodynamic status of the donor (including blood pressure, heart rate and central venous pressure if available). The amount of inotropic support, and trends in usage over time, are also noted. A history of cardiopulmonary resuscitation is not, in itself, a contraindication to cardiac donation for pediatric recipients [37,38]. It must be recognized that brain death results in dramatic physiological disturbances in the donor. These include temperature instability with hypothermia, circulatory volume changes (most commonly depletion) and neuro-endocrine dysfunction. There is depletion of circulating thyroxine, cortisol, insulin, glucagon and antidiuretic hormone (ADH).

To rule out structural abnormalities and to evaluate cardiac function, a complete echocardiogram should be performed. Most centers avoid the use of donor hearts whose systolic function is more than mildly impaired after treatment with inotropic agents or thyroid hormone (e.g. shortening fraction less than 26%, ejection fraction less than 50%). Some degree of atrioventricular valvular regurgitation is common after brain death and mild degrees do not constitute a contraindication to organ donation. Pericardial effusion may be indicative of myocardial contusion. A twelve-lead electrocardiogram should be performed. Mild non-specific ST and T wave changes are commonly present, and usually reflect central nervous system effects, electrolyte disturbances or hypothermia. These do not contraindicate organ donation. Interpretation of cardiac enzymes may be difficult in the setting of generalized trauma. It has been suggested that elevation in cardiac troponin I levels in donor serum is a useful predictor for acute graft failure after infant heart transplantation [39]. However, a recent analysis using the SRTR database concluded that troponin I elevation before procurement is not associated with increased graft failure or hospital length of stay among pediatric heart recipients [40].

Evaluation of adult donors for coronary artery disease by selective coronary arteriography is commonplace in adult transplantation. Use of older donors (e.g. above 35 years of age) for pediatric recipients is associated with high risk of post-transplant coronary disease and poor long-term survival [41]. Such donors are generally avoided for pediatric candidates and thus coronary arteriography is rarely requested on the donor for pediatric recipients.

Size matching is a critical issue in the selection of potential donors. Most centers avoid under-sizing the donor below 75–80% of recipient weight. Below this, cardiac output of the donor may be insufficient to meet the needs of the recipient. None-the-less, a recent report from the SRTR database suggests that donor-recipient mismatching as low as 60% of recipient size is not associated with worse graft outcomes [42]. This retrospective analysis was not able to look at the complex interaction of donor size, cold ischemic time and preprocurement donor organ function. Therefore, it cannot be concluded that severely undersized organs can be safely used on a routine basis.

Use of oversized donors is common in children, and indeed is a necessity for infant candidates since there are so few donors available that are well matched for recipient size. Most candidates with cardiomyopathy will have marked cardiomegaly, leaving ample room within the chest for an oversized donor heart. Use of donor:recipient weight ratios of 2.5 : 1 is common in pediatric practice, and ratios of 3 : 1 and greater have been successfully used [43], especially in newborn and infant candidates. Marked over-sizing often results in delayed sternal closure and in infant recipients, donor: recipient weight ratios of greater than two have been associated with a more prolonged ventilator course and increased risk of primary graft failure [44]. Oversized donor hearts may also give rise to a postoperative syndrome characterized by high output state associated with systemic hypertension, raised intracranial pressure and even mental status changes. Although widely recommended, it is unclear if over-sizing of donors may improve outcome when there is significant preoperative pulmonary hypertension in the recipient. Most authorities would agree that significant undersizing should be avoided in the presence of recipient pulmonary hypertension.

All donors should be screened for CMV, EBV, HIV 1 and 2, human lymphotropic viruses 1 and 2 (HTLV-1, HTLV-2), and hepatitis viruses A, B and C. Donors are also screened for syphilis and for antibodies to *Toxoplasma gondii*. Presence of antibodies to CMV, EBV or *T gondii* do not constitute contraindication to transplantation but helps guide post-transplantation therapy and surveillance. Evidence of donor retroviral infection (HIV or HTLV) is considered an absolute contraindication to heart transplantation. The presence of donor hepatitis B surface antigen is also usually considered an absolute contraindication to heart donation. The usage of hepatitis C positive donors remains controversial.

Surgical techniques of graft implantation

Detailed review of surgical techniques is outside the scope of this text and has recently been reviewed [45]. In 1960, Lower and Shumway enumerated the basic surgical principles of orthotopic heart transplantation, initially in dogs, and several years later in humans [46]. The pioneering efforts led to the adoption of the *biatrial anastomosis* for cardiac transplantation. This technique has been applied to thousands of patients, of all ages, with excellent results.

Despite the great success of the biatrial technique, this is nonetheless a non-anatomic technique that results in large atrial cavities. The resulting abnormal atrial geometry is thought to contribute to tricuspid valve dysfunction. Sinus node dysfunction, from surgical trauma or ischemia, has also been described. For these reasons, many centers now perform *bicaval anastomosis* in children of all ages undergoing orthotopic heart transplantation. Some specific forms of congenital heart disease lend themselves particularly well to the bicaval technique. For example, patients who have previously undergone Mustard or Senning operations, and those with a Glenn anastomosis. The bicaval technique may be associated with superior caval vein stenosis, especially in infants [47]. This can generally be successfully treated with interventional catheter techniques beyond the first few weeks after transplantation when wound healing is complete [47].

Transplantation for congenital heart disease is often performed after multiple palliative procedures, and may present formidable surgical challenges. The anatomic substrate can be broadly classified as abnormalities of the systemic venous return, abnormalities of the pulmonary venous return, and abnormalities of the great vessels, including HLHS. Surgical modifications of the two basic techniques, atrial and bicaval anastomoses, are required for transplantation of these anatomic variants. In general, abnormalities of great arterial positions pose few challenges. Abnormalities of systemic venous return are among the most challenging anatomic variants to transplant. Fashioning unobstructed connections in patients undergoing heart transplantation with left sided cavae (for example in dextrocardia with situs inversus or in heterotaxy syndromes), requires special consideration and planning. A variety of techniques have been devised to overcome these difficult anatomic arrangements (Figure 115.3) [16,45]. Of key importance is procurement of generous sections of donor caval veins including the innominate vein. When there are bilateral superior caval veins without a connecting vein, the donor innominate vein can be used with an end-to-end anastomosis to the recipient left cava. When there is recipient complete mirror image arrangement (situs inversus with dextrocardia), resection of the interatrial septum may be performed with rerouting of superior venae cava and inferior venae cava flow to the right side using atrial flaps as tunnels.

Often times, prior cardiac operations have involved the pulmonary arteries in the form of systemic-to-pulmonary shunts, cavopulmonary anastomoses, or other procedures. In all cases as much donor pulmonary artery as possible should be harvested.

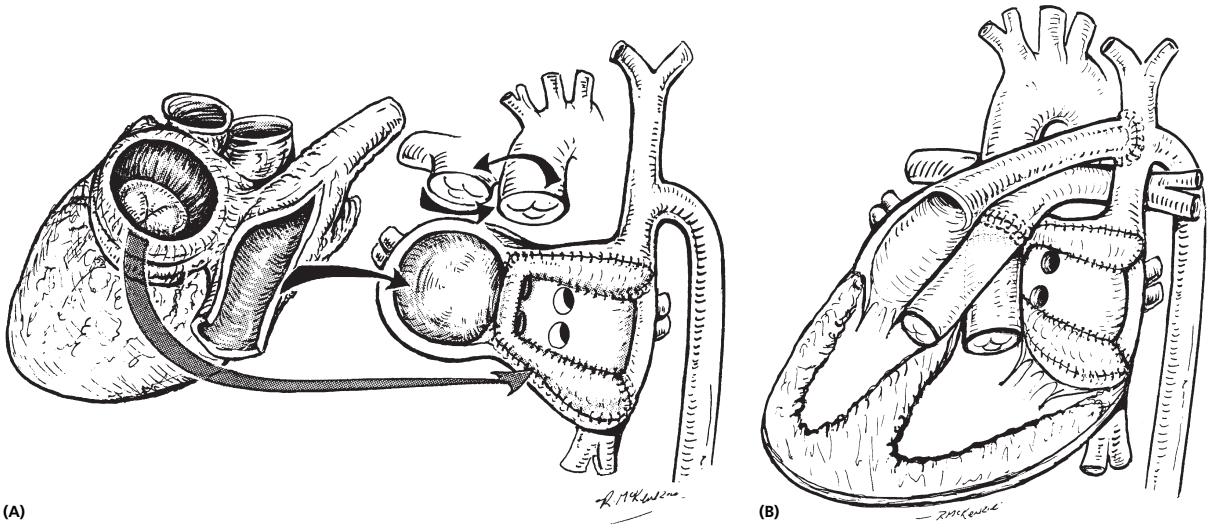

Figure 115.3. Transplantation for previously repaired transposition of the great vessels with mirror image arrangement ("situs inversus") following prior mustard (atrial baffling) procedure. (A) The mustard baffle was preserved to direct left-sided systemic venous return to the donor right atrium. (B) Because of stenosis of the superior caval baffle, the donor superior caval vein was anastomosed to the recipient superior caval vein proximal to the baffle.

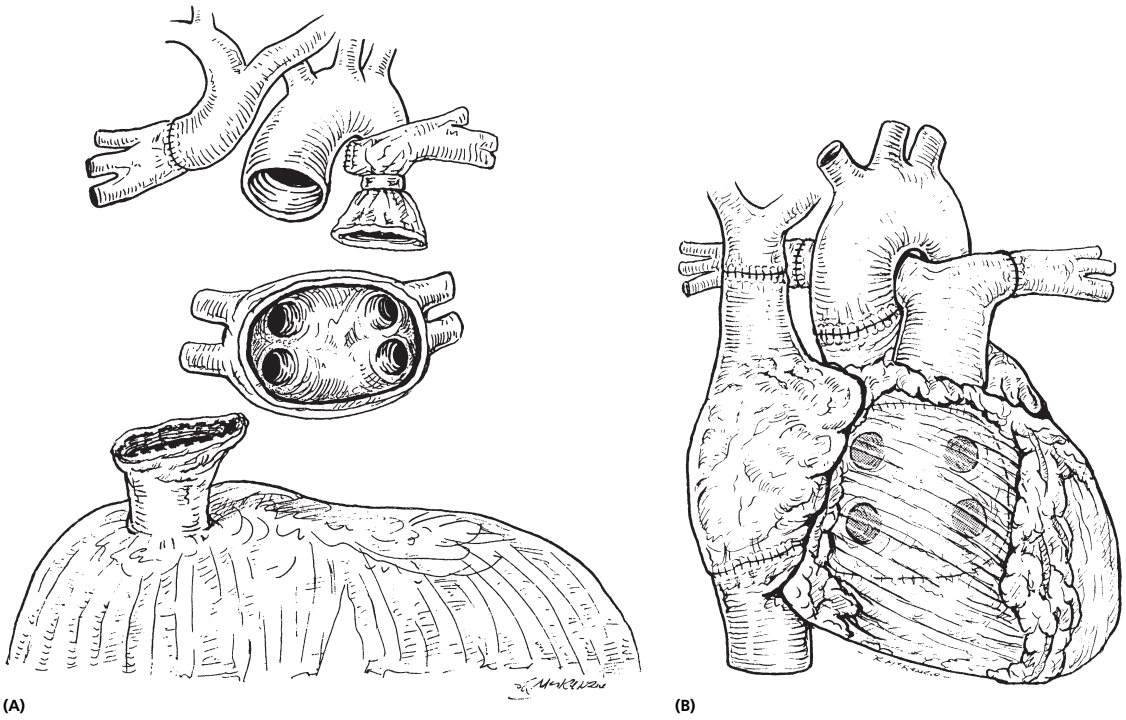

Figure 115.4. Bicaval heart transplantation in a child with discontinuous pulmonary arteries following prior right classical Glenn shunt and pulmonary artery banding. (A) After recipient cardiectomy, inferior cavo-atrial cuff and left atrial button were prepared and the classic Glenn shunt was taken down. (B) The donor organ was procured with both branch pulmonary arteries and an extended segment of the superior caval vein. Bipulmonary and bicaval anastomoses were performed.

Most commonly, as is the case in bidirectional Glenn or Fontan operations, the cavopulmonary anastomosis is taken down, the pulmonary arteries are patched, and bicaval anastomoses are performed. Patch material may take the form of bovine pericardium, homograft, or donor or recipient discard. Repair is best accomplished after recipient cardiectomy and before organ implantation.

In the case of discontinuous pulmonary arteries, the donor organ should be procured with the pulmonary bifurcation and pulmonary arteries intact (Figure 115.4). Direct left and right pulmonary artery anastomoses are then performed. Alternatively, excess donor aorta can be used to connect the right and left pulmonary arteries prior to implantation. Transplantation to a single lung is feasible when there

is unilateral absence or severe hypoplasia of a pulmonary artery [48]. This should only be performed when the dominant pulmonary artery is well developed with very low pulmonary vascular resistance. Otherwise the risk of acute donor right heart failure is high.

Few centers currently perform primary transplantation for HLHS. Because of the extensive arch hypoplasia, the donor surgeon must procure the entire transverse and proximal descending aorta en bloc with the organ. Surgical reconstruction of the arch is performed under deep hypothermic circulatory arrest.

Postoperative management and early complications

Many of the fundamental principles of early postoperative management after heart transplantation are similar to those for pediatric patients undergoing other procedures with cardiopulmonary bypass. This section focuses on aspects of care that are specific to the transplant recipient.

Cardiovascular considerations

Low cardiac output

Abnormalities in cardiac function are inevitable due to the obligatory hypoxic/ischemic insult that the donor heart endures. Recovery of systolic function is usually rapid. Abnormalities in diastolic function, however, may persist for many weeks. Most heart transplant recipients will benefit from low dose inotropic support in the immediate postoperative period, though often this is only required for 2–3 days. The choice of inotrope will reflect both physician preference and hemodynamic factors such as heart rate, pulmonary vascular resistance and blood pressure. Low dose dobutamine and isoproterenol are common choices. The latter is sometimes recommended because of its combined properties of chronotropy, inotropy and pulmonary vasodilatation. The addition of a combined vasodilator/inotropic agent such as milrinone is logical when there is low cardiac output and evidence of high systemic vascular resistance. In infants with markedly oversized donors, the simplest way to improve cardiac function is to leave the chest open at the end of the transplant procedure. Occasionally, there is failure to wean from cardiopulmonary bypass, or early postoperative graft failure in the first 24 hours. This primary graft failure is a serious complication associated with high mortality. The term primary graft failure is often reserved for the finding of acute left ventricular or biventricular failure not due to high pulmonary vascular resistance. Poor donor selection, very prolonged ischemic time, poor preservation technique and hyperacute rejection should all be considered. When primary graft failure occurs (not due to hyperacute rejection), recovery is frequently possible if the circulation can be supported. This is usually achieved with extracorporeal membrane oxygenation (ECMO) [49]. Retransplantation for early graft failure is generally associated with very poor outcomes [50], and many consider this a contraindication to retransplantation [51].

Systemic hypertension

In contrast to the non-transplant cardiac surgical patient systemic hypertension is common. Many factors contribute including vigorous function of an oversized donor organ and use of high dose corticosteroids. It is not unusual to observe quite severe systolic hypertension within 24 hours of a successful transplant procedure. If good ventricular function is confirmed by echocardiogram, rapid wean of inotropic support is performed. Where systemic resistance appears high, intravenous vasodilators are a logical choice. In the case of a vigorous oversized organ, some have advocated beta blockade.

Pulmonary hypertension

The importance of pulmonary vascular resistance as a risk factor for acute donor right ventricular failure is discussed above. If there is a concern about elevated pulmonary vascular resistance, on the basis of preoperative evaluation, additional precautions should be taken. Nitric oxide is begun in the operating room and is used to wean from cardiopulmonary bypass. Acidosis must be avoided and high levels of inspired oxygen are provided. Hyperventilation is performed and generous sedation is provided in the early postoperative period. The right heart may require significant inotropic support, and sometimes epinephrine may be required in addition to milrinone and dobutamine, despite potential negative effects on pulmonary vascular resistance. If right ventricular dysfunction persists with poor cardiac output despite this level of support, then mechanical assistance should be provided. If pulmonary vascular resistance is moderately elevated pretransplantation, (or if there is an acute elevation in resistance following bypass in a child with previously low resistance), then 24–48 hours of support will often enable the right ventricle to recover enough to support the circulation, despite elevated pulmonary pressures. If acute donor right heart failure reflects poor candidate selection (e.g. indexed pulmonary resistance greater than 9 IU after vasodilator challenge), then recovery of right heart function is unlikely.

Cardiac rate and rhythm

Postoperative tachy- and bradyarrhythmias have been observed in children following heart transplantation. The commonest rhythm abnormality (other than sinus tachycardia) is sinus node dysfunction leading to sinus bradycardia, with or without an atrial or junctional escape rhythm. The denervated sinus node responds appropriately to exogenous chronotropic agents and isoproterenol is useful in this respect. A simpler approach is atrial pacing, and all transplant recipients should have temporary pacing wires placed in the operating room. Sinus node dysfunction reflects ischemic and/or traumatic injury, but usually recovers in a few days. Ventricular ectopy and non-sustained ventricular tachycardia are also quite common in the first week or two after transplantation. These presumably relate to the obligatory ischemia-reperfusion injury, and rarely require treatment. The fresh cardiac allograft has limited ability to increase stroke volume, and therefore establishing an adequate heart rate is important for maintaining cardiac output. Atrial pacing is most commonly used to control the heart rate.

Respiratory support

The principals of respiratory support do not differ from those of other pediatric open heart procedures. Early extubation should be the goal. The patient who has required prolonged preoperative mechanical ventilation will usually need more prolonged ventilatory support postoperatively as retraining of respiratory muscles will be required. Infants with long-standing cardiomegaly will often have significant tracheobronchomalacia and persistent or recurrent pulmonary atelectasis is not unusual, especially of the left lower lobe.

Renal function

The combination of chronic heart failure, cardiopulmonary bypass and use of cyclosporine or tacrolimus all contribute to postoperative renal dysfunction. This is exacerbated if there is low cardiac output state postoperatively. Oliguria is common. Fortunately,

acute renal failure is rare in children and dialysis is seldom required. Persisting oliguria is managed with loop diuretics and low dose dopamine (e.g. 3–5 mcg/kg/minute). Low output is managed with inotropic agents as discussed above. Administration of a continuous furosemide infusion (up to 6 mg/kg/day) may be helpful. These maneuvers are usually successful in stimulating an adequate urine output (>1 ml/kg/hour). When urine output remains low, it may be necessary to withhold calcineurin inhibitors (tacrolimus or cyclosporine) for several days. This can be facilitated by the use of intravenous induction agents as part of the early immunosuppressive regimen (see further in this chapter).

Gastrointestinal considerations

Gastrointestinal complications are quite common early after pediatric heart transplantation [52]. All patients should receive intravenous, and subsequently oral, H_2 antagonists to decrease the risk of stress ulcers in the early post-operative period. These are usually continued until corticosteroids have been weaned to low doses or discontinued. The nasogastric tube is removed as soon as the patient is extubated and able to take oral feeds and medications. Attention is paid to providing optimal calories without use of excessive volumes since most patients will tend to retain fluid in the early postoperative period. Pancreatitis is not uncommon following transplantation and should be sought when there is abdominal pain or unexplained feeding intolerance. Immunosuppressive regimens that avoid the use of azathioprine and corticosteroids may reduce this complication. Symptoms of gastrointestinal perforation may be subtle in small children on immunosuppressive medications, especially if corticosteroids are being used. Many children with chronic heart failure have gastroesophageal reflux disease. This should be aggressively managed, but with knowledge that there are many drug interactions between immunosuppressant medications and drugs used for gastroesophageal reflux disease including antacids, antihistamines and prokinetic agents.

Infectious precautions

Infections are a leading cause of death and morbidity in the first year following pediatric heart transplantation [20]. Most severe infections occur during the initial hospitalization. During the first week after transplantation, invasive lines and drains are removed as soon as possible. A short course of antibiotics (e.g. 72 hours) is given as prophylaxis against mediastinal and wound infection. Usually a first generation cephalosporin will suffice. Broader staphylococcal coverage (i.e. vancomycin) is given if the patient has had a prolonged ICU stay and has long-standing lines in place. Such lines are usually replaced in the operating room. Patients colonized with MRSA are also covered with vancomycin. Oral nystatin is started in the intensive care unit, along with ganciclovir, if recipient or donor are seropositive for CMV. Patients at high risk for yeast infections (e.g. patients on pretransplant ECMO) are frequently given prophylaxis with fluconazole. However, it should be noted that all "azole" antifungals have a profound effect on calcineurin inhibitor metabolism (via the cytochrome P450 system). A marked reduction in tacrolimus or cyclosporine dosing (50–90% reduction) is required during concomitant use of an azole antifungal agent. Initiation of prophylaxis against *Pneumocystis jiroveci* can follow nearer to the time of hospital discharge.

Immunosuppression and early acute rejection

High dose intravenous methylprednisolone (e.g. 15–20 mg/kg) is given in the operating room. A tapering course of corticosteroids is often given over the next 1–2 weeks, with the majority of centers discharging patients on maintenance corticosteroid therapy [2]. Some centers attempt to wean patients off steroids if the rejection course has been benign [53]. However, there is increasing use of steroid avoidance immunosuppressive regimens in pediatric practice [54]. This likely requires induction therapy to be successful. Cyclosporine or tacrolimus is commenced generally within 24–48 hours of surgery once good urine output has been established. Both agents can be given intravenously or enterally. If anti-T cell induction therapy is used (most commonly polyclonal rabbit antithymocyte globulin; less often with an interleukin-2 receptor antagonist), then there is less urgency to introduce a calcineurin inhibitor (CNI) in the immediate (first 1–2 days) post-transplant period. Cyclosporine or tacrolimus can then be commenced by the oral route rather than intravenously. Delay in commencement of these agents for several days (under coverage of induction therapy) may be particularly useful when urine output is low or renal function is deteriorating. Of interest, use of induction therapy has progressively increased over the last decade in children reaching 70% in 2010 [20]. This trend has not been mirrored in the adult population. This may reflect the desire to avoid corticosteroids in low immunologic risk cases, as well as delay the need for invasive endomyocardial biopsy (EMB) in pediatric recipients.

Careful daily assessment is performed for signs of rejection, though severe rejection before 7–10 days is rare (except in the sensitized patient). Rejection is generally delayed with use of induction therapy. Infants and young children experience less acute rejection than adolescents. Pallor, increasing tachycardia, abdominal pain, gallop rhythm and oliguria all are suggestive of severe rejection. Ideally, rejection is identified by echocardiography and/or surveillance biopsy before such signs develop. The electrocardiogram may show reduced precordial voltages. The tempo of rejection can be quite abrupt in the early post-transplant period and any deterioration in the patient's condition after initial recovery from surgery must be taken very seriously. If there is unequivocal evidence of new graft dysfuction, empiric treatment (usually consisting of bolus intravenous corticosteroids), or immediate EMB, should be performed. Biopsy generally shows lymphocytic infiltrates (predominantly T cells) with varying degrees of edema and myocyte damage. Endomyocardial biopsies are graded according to an internationally agreed classification system developed by the ISHLT [55].

Post-transplant management and long-term complications of transplantation

The long-term management of pediatric heart recipients is aimed at maximizing long-term survival, minimizing complications of immunosuppressive therapy, and improving quality of life. A detailed discussion of all complications of heart transplantation that occur beyond the immediate postoperative period is outside the scope of this chapter and are covered elsewhere in this text. This section focuses on how specific complications impact the pediatric cardiac transplant recipient and the strategies that are employed to prevent and manage these complications.

Maintenance immunosuppressive therapy

Immunosuppressive therapy aims to prevent or minimize any damaging immune response of the host to the donor organ, while avoiding complications of therapeutic immunosuppression. Immunological complications of transplantation fall into two main

groups: (1) allograft rejection and graft dysfunction (both acute and chronic) reflecting inadequate or ineffective immunosuppression and manifestations of non-specific immunosuppression, including infections and malignancy. (2) non-immune side effects of immunosuppressive therapy (i.e. tissue and organ toxicities) are an important cause of morbidity, and occasionally mortality, after heart transplantation in children.

As discussed previously, most children currently receive some form of induction therapy in the perioperative period, most commonly with rabbit anti-thymocyte globulin. As with adults, almost all children receive a CNI with an anti-metabolite/anti-proliferative agent. Presently, the combination of tacrolimus and mycophenolate mofetil is the most commonly used combination of agents, with approximately 66% use of tacrolimus and 70% use of mycophenolate mofetil (MMF) or mycophenolic acid (MPA) at one year after transplantation [20]. Use of MMF/MPA has fallen to approximately half of patients by five years [20], perhaps reflecting the relatively high intolerance of MMF/MPA in children [56]. Use of corticosteroids is highly variable, though internationally, 64% are still receiving corticosteroids at one year after transplantation falling to 39% at five years [20]. However, as discussed previously, many centers have experience with complete steroid avoidance beyond the first few days after transplantation in non-sensitized children after heart transplantation [54]. This offers many obvious advantages to pediatric recipients. Further work is needed to identify which patients are most suitable for steroid avoidance regimens.

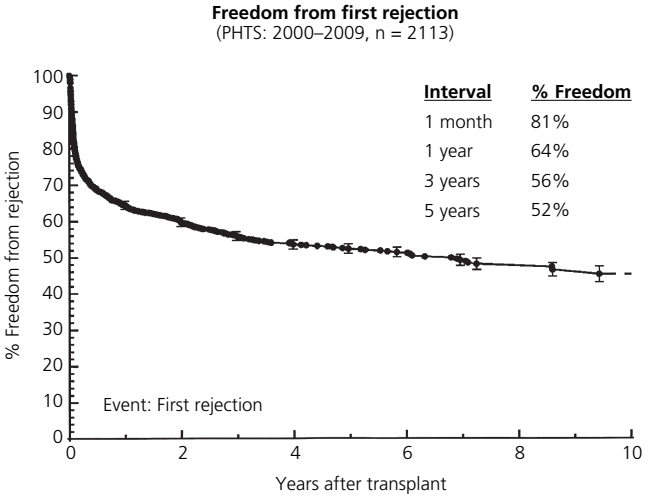

Figure 115.5. Freedom from first acute rejection event in patients transplanted within the Pediatric Heart Transplant Study (PHTS) database from January 2000 to December 2009. Published with permission of PHTS.

Acute rejection

Patients remain at risk for acute rejection indefinitely, though it is clear that the hazard declines over time. There is no evidence that heart transplant recipients become truly tolerant to their allograft. The importance of acute rejection episodes becomes evident when causes of death after heart transplant are examined. Data from the ISHLT show that acute rejection is the commonest cause of death between 30 days and three years after heart transplantation [20]. During this time period, 20% of deaths are identified as being due to acute rejection with another 31% attributed to "graft failure". The peak hazard, or instantaneous risk, for first rejection is between one and two months after transplantation. By one year after transplantation, approximately 64% of pediatric heart recipients are free of acute rejection [23] (Figure 115.5). Late acute rejection episodes (occurring beyond the first year after transplantation) appear to carry a particularly poor long-term prognosis especially if associated with graft dysfunction [57,58]. When there is any degree of systolic dysfunction with acute rejection, rapid deterioration is common, even when the patient appears well and free of heart failure at presentation. Thus, it is prudent to admit all patients with acute graft failure to the intensive care unit for initiation of therapy. If systolic failure is more than mild, intravenous milrinone should be initiated and the patient should be monitored for arrhythmias. Unless graft failure is known to be due to coronary artery disease, treatment for acute rejection/graft dysfunction should be initiated with intravenous methylprednisolone 10–15 mg/kg (maximum 1 g) daily for 3–5 days. Unless the patient is unstable, it is optimal to obtain an EMB since acute graft dysfunction maybe associated with "acellular rejection" (which carries a worse prognosis) or with clear histological evidence of antibody mediated rejection (AMR). Additional therapies may then be required, including urgent plasmapharesis. It should be emphasized that treatment of severe acute rejection should not be delayed while waiting for EMB to be performed or results to be obtained. Acute rejection with hemodynamic compromise can rapidly lead to graft failure. Unless there are specific contraindications, such patients should receive full hemodynamic support, including use of mechanical support since the condition is generally reversible in nature. ECMO is most commonly used in this setting [59]. Retransplantation should be avoided in the setting of active acute rejection since outcomes are poor [51].

Three recent analyses from the PHTS have investigated the presence of era effects for acute rejection [58,60,61]. There have been significant reductions in acute rejection events from 1993 to the current era both during the first year after transplantation [60], as well as reduction in first and recurrent episodes of late rejection (occurring more than one year after transplantation) [57,58]. This is important since late rejection episodes have been shown to be associated with high risk for subsequent development of moderate to severe graft vasculopathy, death and need for retransplantation [57,58]. Of particular note, the incidence of acute rejection with severe hemodynamic compromise has not changed over time within the PHTS, despite the overall fall in frequency of all acute rejection events [61]. Furthermore, survival has not improved for acute rejection associated with severe hemodynamic compromise with similar survival across eras at one and five years after the rejection event (63% at one year and 49% at five years) [61].

Risk factors for acute rejection have also been extensively investigated with the PHTS. Risk of first rejection is associated with earlier era of transplantation, older age at transplantation and positive donor-specific cross-match [60]. Of note, race was not a risk factor in the recent era for first acute rejection, but has remained a risk factor for late rejection episodes and for episodes of rejection with severe hemodynamic compromise [58,61].

Antibody mediated rejection is also observed after pediatric heart transplantation, as for adults. Most episodes occur in patients transplanted across a positive donor-specific cytotoxicity cross-match [62,63]. Sensitization is common in the pediatric age group

due to the high frequency of prior surgical procedures, including previous use of aortic and pulmonary homografts for repair of congenital heart defects. These cryopreserved allografts have a profound sensitizing effect [64]. Some children have such broad sensitization that wait-list times are very long, and wait-list mortality high, due to inability to find a compatible donor with acceptable HLA antigens [65]. Pretransplant desensitization regimens do not appear effective in this population. In some cases ("100% PRA"), it is apparent that an acceptable donor will never be found. Some centers have attempted to transplant these patients knowing that the donor-specific cross-match will be positive. Typical perioperative regimens include intraoperative plasma exchange, short-term post-transplant plasmapharesis, T cell depleting antibody induction therapy, triple drug immunosuppression (tacrolimus, MMF, steroids) and serial infusions of intravenous immunoglobulin. A trial is under way to evaluate the success of such a strategy [66]. The role of rituximab, bortezomib and other experimental agents in this setting is unknown. All these agents have also been used for the treatment of established AMR in pediatric heart recipients [67], though no prospective, randomized trials have been performed.

Chronic rejection or cardiac allograft vasculopathy

The terms chronic rejection and cardiac allograft vasculopathy (CAV) are generally used synonymously. Coronary disease subsequent to transplantation is an accelerated vasculopathy that is the leading cause of death among late survivors of pediatric heart transplantation [20,41]. It accounts for at least 25% of deaths in the period beyond three years after transplantation [20]. Details of CAV pathophysiology are found elsewhere in this text. Suffice it to say that pediatric recipients are not immune from this complication, though freedom from CAV appears superior to adults at any given time point after transplantation, especially in young children [41]. Intriguing data have recently been published showing that persistence of viral genome of various viruses (especially adenovirus) detected in the myocardium of heart biopsy samples by polymerase chain reaction predicts the development of coronary disease and late graft loss in children [68]. Use of older donors, late acute rejection episodes, and older recipient age are all risk factors for the development of post-transplant CAD in children [41]. The role of cytomegalovirus serostatus and infection in CAV in children is not entirely clear and is less well studied than in adults [69].

Symptoms of ischemia are often absent, though some children will experience episodes of abdominal pain and/or chest pain, despite operative denervation of the heart [70]. Syncope and sudden death are also common presentations of CAV in children. In the current era, the diagnosis is most often made during surveillance selective coronary angiography. Intravascular ultrasound has much greater sensitivity for this diagnosis, though experience in children is much more limited than adults [71,72]. Assessment of coronary flow reserve is also feasible in children, but has rarely been utilized due to the technical challenges involved and uncertainly about interpretation of the findings [73].

Unfortunately, no curative treatment exists for established coronary arterial disease. Diastolic dysfunction tends to develop early and may be observed even when there is little evidence of epicardial coronary artery narrowing [74]. This may be a reflection of diffuse small vessel disease in many patients. Once overt systolic failure ensues, survival is poor and consideration should be given to retransplantation. Outcomes for late retransplantation (beyond six months from primary transplant) are similar to those for primary transplantation [50]. Children with ischemic-induced syncope should receive automatic implantable cardioverter-defibrillators (AICD) if they are to be discharged from hospital while awaiting retransplantation. Beta blockers may be given for their anti-ischemic benefits if heart failure is not advanced and beta agonists are not required. Stenting and bypass grafting may play a limited role in bridging to retransplantation, but are limited by the diffuse nature of CAV. Graft loss was reported in 52% of children within one year of a percutaneous revascularization procedure, emphasizing the limited role of these interventions [75].

Infections

An increased prevalence of all forms of infection is seen compared to the general population of children. Most infections are caused by pathogens that also cause infection in the non-immunocompromised host. Common examples include respiratory viruses, *Streptococcus pneumoniae*, and varicella virus. All infections that occur in non-immunocompromised patients can cause greater disease severity in the recipient of a transplanted heart. Of particular note in this respect are infections due to cytomegalovirus (CMV) and Epstein-Barr virus (EBV), which only rarely cause severe disease in the immunocompetent host. More rarely, opportunistic infections are seen such as that due to *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*) [76]. Although most infections are well tolerated, infection is second only to graft failure as the leading cause of death in the first 30 days after transplantation, and remains an important cause of death during the remainder of the first post-transplant year [20].

Broad spectrum antibiotic coverage is required in any septic appearing child after heart transplantation until an organism has been identified. *Streptococcus pneumoniae* infections occur with increased frequency and choice of antibiotics must include coverage of this agent. When there is clinical and radiographic evidence of pneumonia and deteriorating clinical status, there should be a low threshold for performing bronchoalveolar lavage in order to obtain deep cultures for viruses, fungi and bacteria. *Pneumocystis jiroveci* should be ruled out when there is hypoxia and characteristic chest X-ray changes [76]. Respiratory viral pathogens (e.g. RSV, influenza, parainfluenza, adenovirus) should be sought when there is evidence of severe respiratory infection in a heart transplant recipient. While viral respiratory disorders tend to be well tolerated in older children and later out from transplantation, acquisition of one of these respiratory viruses in the first few weeks after transplant can occasionally cause devastating disease, especially in infants. Invasive fungal infections make up approximately 7% of serious post-transplant infections in children, and are most commonly due to *Candida* and *Aspergillis* spp [77]. These are associated with incremental numbers of invasive pretransplant procedures (e.g. ECMO, prior surgery, VAD) and are associated with high mortality, predominantly within the first six months after transplantation [77].

Primary CMV infection is less problematic in heart transplant patients than in lung transplant recipients, but can still cause serious morbidity and occasionally fatality. In heart recipients, pneumonitis is quite rare, whereas it is a common site of disease in lung and heart-lung recipients who develop primary infection post-transplantation. By contrast, gastroenteritis, hepatitis and bone

marrow suppression are relatively common findings. Diagnosis is facilitated by evaluation of peripheral blood by PCR or antigenemia (pp65) testing. Diagnosis of CMV *disease* remains a tissue diagnosis. When the diagnosis is made early, treatment with intravenous ganciclovir and/or oral valganciclovir is usually very effective. Prophylaxis strategies generally do not differ from adults (see Chapter 94).

Infection from EBV in the immunocompromised pediatric recipient can be asymptomatic, or may cause a non-specific viral syndrome, mononucleosis, fulminant "viral sepsis" or a post-transplant lymphoproliferative disorder (PTLD). The strongest risk factor for the development of PTLD is the development of primary EBV infection post-transplantation, though children who are seropositive for EBV at the time of transplant are not completely protected from this complication. Two analyses of the PHTS database provides the most comprehensive analysis of PTLD in the pediatric heart population [78,79]. PTLD was diagnosed in 147 of 3170 primary heart transplants between 1993 and 2009 among 35 institutions, with probability of freedom from PTLD being 90% at ten years after transplantation. Rebound rejection during therapy for PTLD remains a major concern, and graft failure (in contrast to PTLD disease progression) accounts for approximately half of all deaths after a diagnosis of PTLD is made [78]. Further details of the pathobiology, epidemiology, treatment and prognosis of PTLD are given in Chapter 96.

Non-immune complications

In addition to the consequences of over or under-immunosuppression, transplant recipients experience a wide array of non-immune toxicities of immunosuppressive therapies. Toxicities of immunosuppressive agents in children have been previously reviewed [80,81]. In contrast to adults, growth failure is a unique problem in children and contributes to the desire for steroid minimization and avoidance regimens in many pediatric transplant centers. One complication worthy of particular attention is that of progressive renal dysfunction due to calcineurin inhibitor renal toxicity. This is becoming increasingly problematic as larger numbers of children survive long-term after heart transplantation. Some have already developed end-stage renal failure requiring renal transplantation [82]. It should be noted that estimates, and direct measures, of creatinine clearance overestimate glomerular filtration rate (GFR) in this population and that the severity of renal disease is generally greater than perceived [82]. In a recent analysis of renal dysfunction within the PHTS, late renal dysfunction was found to be associated with earlier era of transplant, black race, rejection with hemodynamic compromise in the first year and lowest quartile estimated GFR at one year post-transplantation [83]. Another recent multi-institutional study in children was unable to confirm earlier reports that common genetic variations might influence post-transplant renal function under CNI-based immunosuppression [84]. Of note, clinical trials of CNI avoidance from the time of transplantation have not been performed in the pediatric heart transplant population.

Post-transplant survival and risk factors

Data from the registries of the ISHLT [20], the SRTR and the Pediatric Heart Transplant Study [23] all demonstrate important trends in post-transplant survival over the last two decades. Importantly, there have been significant improvements in outcome

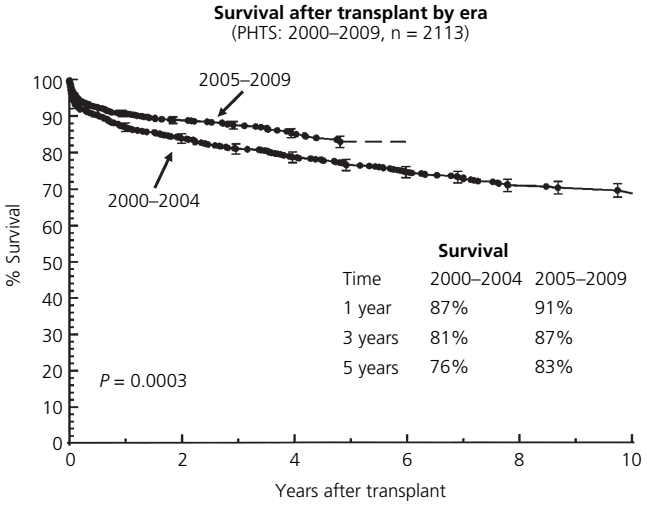

Figure 115.6. Overall survival in patients transplanted within the Pediatric Heart Transplant Study (PHTS) database from January 2000 to December 2009 stratified by era. Published with permission of PHTS.

in recent years; the improved survival being most evident in the infant age group and in smaller volume centers. Of note, there has been significant improvement in outcome even between the first and second halves of the first decade of the new millennium (Figure 115.6). Most of the improvement appears to be due to reduction in early mortality. One-year survival is now approximately 90% in many centers, with only a relatively small drop over the next 1–4 years. The PHTS and the ISHLT databases continue to show a slightly higher perioperative and early mortality for infant recipients, but interestingly, these youngest recipients have a patient half-life that now approaches 20 years, and the conditional half life for infants surviving to one year is superior to all other age groups [20]. By contrast, patient half-life for adolescents is only 11.9 years [20]. It is likely that this reflects a lower incidence of post-transplant coronary artery disease in very young recipients and a degree of immune privilege. The higher graft loss and mortality rates in older children likely reflects, at least in part, inferior adherence in this age group. Use of induction therapy, choice of initial CNI (cyclosporine or tacrolimus) and use tacrolimus versus cyclosporine at one year post-transplant have not been associated with differences in survival after pediatric heart transplantation [20].

The results of transplantation for congenital heart disease still lag behind those of transplantation for cardiomyopathy; this difference is due to higher perioperative mortality. This difference is most notable in infant recipients and least noticeable in adolescents. ISHLT reports a 12% superior survival at ten years for infants with cardiomyopathy compared to CHD; the difference is entirely due to increased early mortality. The difference did not reach statistical significance for the adolescent age group.

Importantly, there remains evidence of reduced survival among black pediatric recipients compared to other racial groups [85,86]. This difference is primarily due to increased graft loss beyond the first year after transplantation. Lower socioeconomic status has also been associated with increased graft loss beyond the first year [86].

In the most recent analysis of the ISHLT registry, risk factors at transplant for death at one year included the following: ECMO,

retransplantation, congenital diagnosis, dialysis, mechanical ventilation, prior sternotomy, donor age, pretransplant creatinine level and total ischemic time [20]. Donor cause of death was also found to be a risk factor with cerebrovascular events having higher relative risk for one-year mortality compared to head trauma, and anoxia being protective compared to head trauma. The significance of these latter observations is unclear, since a recent analysis of the PHTS database (3122 donors) did not reveal traditional donor risk factors to influence post-transplant outcomes including donor cause of death, donor CPR and high donor inotropic requirements (prior to procurement) [37]. In infants less than six months of age, no donor-related factors influenced post-transplant survival. Longer ischemic time and greater donor-recipient age difference did influence survival in recipients over ten years of age.

Summary

Excellent outcomes are now being achieved after pediatric heart transplantation, with five-year survival now exceeding 80%. The improved outcomes appear to be limited primarily to the early postoperative period, and this improvement is most apparent among infants and those with congenital heart disease. Infants surviving the first year have the best long-term outcomes with conditional graft half-lives in excess of 20 years. Pretransplant wait-list mortality also appears to have improved and likely reflects multiple factors including better medical care for critically sick candidates, extension of VAD support as a bridge to transplantation in children, and perhaps changes in allocation policy. Despite these advances, heart transplantation remains palliative and all transplant recipients are at risk for the adverse effects of non-specific immunosuppression, including infections, lymphoproliferative disorders and non-lymphoid malignancies. In addition, current immunosuppressive agents have narrow therapeutic windows and exhibit a wide array of organ toxicities. This poses special challenges for the young patient who must endure life-long immunosuppression. New immunosuppressive regimens have lowered the rates of acute rejection (but not rejection with severe hemodynamic compromise) but appear to have had relatively little impact on the incidence of CAV, the principal cause of late graft loss.

CHAPTER 116

Pediatric Lung Transplantation

Albert Faro and Stuart C. Sweet
Division of Pediatric Allergy, Immunology and Pulmonary Medicine, Washington University School of Medicine, St. Louis, MO, USA

Introduction

In 1963 Dr. Hardy performed the first successful human lung transplant into a convicted felon serving a life sentence. Immunosuppression consisted of azathioprine, prednisone and radiation therapy. The patient died 18 days later from renal insufficiency. Despite an ABO mismatch, no rejection was found on autopsy. Dr. Cooley and his team performed the first human heart-lung transplant on a two-month-old infant with complete atrioventricular canal defect and pulmonary hypertension in 1968. The patient survived for only 14 hours [1]. Outcomes such as this relegated lung transplantation mostly to the laboratory until surgical techniques, preservation solutions and immunosuppressive regimens improved or became available. Reports of successful heart-lung and lung transplantation in adults in the early 1980s [2,3], allowed for the expansion and application of this procedure to the pediatric population. Between 1986 and June 2010, 1664 lung and 653 heart-lung transplantations, in patients less than 18 years old, had been reported to the Registry for the International Society for Heart and Lung Transplantation (ISHLT) [4].

The decision to transplant a child presents unique challenges. For all the experience gained in the field of adult lung transplantation, the indications, approaches, complications, immunosuppressant pharmacokinetics, and monitoring are often very dissimilar for children. Therefore, lung transplantation in the pediatric population must be treated as a distinct entity and studied as such. This chapter will attempt to highlight some of the unique features of pediatric lung transplantation. Chapters 31, 45, 59, 72, 80, 84, and 106 cover general and adult-specific aspects of lung transplantation. Special considerations in children relate to size and growth of the child, complications of airway anastomoses, increased exposure to infections in daycare or school settings, non-adherence to immunosuppression, transitioning to adult healthcare providers, and obstacles related to monitoring the allograft.

Patient selection and indications for transplantation

Lung transplantation should be considered in selected children with end-stage or progressive lung disease or pulmonary vascular disease for which there is no other therapy. The diagnoses that commonly bring a child to a lung transplant center for evaluation are often different than those in adults (Chapter 31). Chronic obstructive pulmonary disease (COPD), emphysema, and idiopathic pulmonary fibrosis are the three most common adult pretransplant diagnoses. Indications for lung transplantation in children have undergone considerable change in the last two decades as experience with this procedure even in infants has grown [5,6]. The most common diagnoses for which children are transplanted are listed in Figure 116.1 according to the age in years at time of transplantation. In children younger than one year, the most common indications are pulmonary hypertension, usually associated with congenital heart disease, other pulmonary vascular diseases, primarily pulmonary vein stenosis, and rarely alveolar capillary dysplasia. Disorders of surfactant metabolism include surfactant protein B (SPB) and C (SPC) deficiencies, ATP binding cassette A3 (ABCA3) transporter and NKX2.1 mutations [6–9]. Less common indications include interstitial lung disease, bronchopulmonary dysplasia and pulmonary hypoplasia [10]. In the 1–5 years age group, disorders leading to pulmonary hypertension remain a common indication. In patients 6–11 years of age, cystic fibrosis (CF) becomes the most common indication. The relative percentage of children with primary pulmonary hypertension coming to lung transplant has diminished significantly during the past decade, largely because of the introduction of effective medical therapies including prostaglandins (epoprostenol), phosphodiesterase-5 inhibitors (e.g. sildenafil) and endothelin receptor antagonists (e.g. bosentan) [4]. In adolescents, CF accounts for almost three quarters of the population that receives a lung transplant. In other words, it is more likely that pediatric lung transplant candidates, in contrast to their adult counterparts, will present with septic lung disease and continue to harbor organisms in their upper airways after lung transplant.

Historically, timing of referral for lung transplant has been predicated on matching predictions of mortality with the anticipated waiting time for donor lungs. Before committing a child to lung transplant, given imperfect disease specific criteria, most pediatric centers carefully consider multiple factors beyond lung function including trajectory of the underlying disease process, growth and nutrition status, frequency of hospitalizations, psychosocial factors, and potential for improvement in overall quality of life (QOL).

Absolute contraindications encompass situations that would clearly put the child at risk for a poor outcome after transplant, are similar between pediatric and adult patients and include systemic disease such as malignancy or multi-organ failure. Relative

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

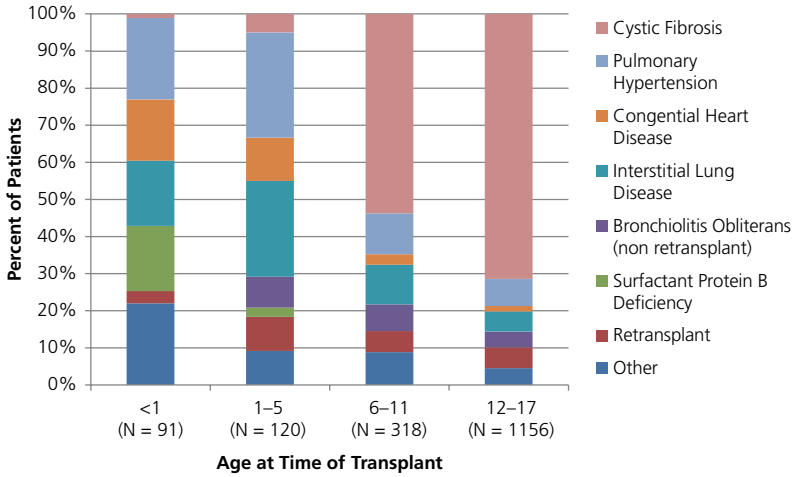

Figure 116.1. Distribution of pediatric lung transplants by age and indication. Data adapted from [4] with permission.

contraindications increase the risk of transplant but are weighed on a case-specific basis. In general contraindications are not static and can change over time with the emergence of new information, therapies or techniques. Contraindications are also center-specific based on that center's individual experience. For example, many centers will not consider patients requiring veno-arterial extracorporeal support (VA-ECMO).

One challenging concern that all pediatric transplant programs must address at times is a history of documented non-adherence to medical management. This is more problematic for pediatric programs than adult centers because the responsibility for providing the child their medications or for bringing them to clinic appointments belongs to the parents and not to the minor. A detailed discussion of this can be found in Chapter 120. In these situations the referring center and the transplant center must share the responsibility of working with the family to identify and address any barriers to care. This may take the formulation of a contract between the referring physician and family that outlines the need for strict adherence to a treatment program over a three to six month period prior to listing for transplant. In general, concerns about non-adherence become an absolute contraindication at some transplant centers when it is refractory to intervention. Although in some centers this may serve as an impetus to involve legal authorities to place the child in foster care, many centers will view temporary placement in a foster home as an absolute contraindication to transplant.

The transplant evaluation itself consists of a number of laboratory and radiographic studies as well as consultation with multiple services (Table 116.1). The evaluation is multi-disciplinary in nature, involving both medical and psychosocial components.

Table 116.1. Recommended evaluation for pediatric lung and heart-lung candidates

Bloodwork:
Blood type (ABO)
Complete blood count
Coagulation studies (PT, INR, PTT)
Complete biochemistries including electrolytes and renal and liver function tests
Lipid profile
Serologies including CMV, EBV, HIV, hepatitis B and C, measles, varicella, herpes simplex, *Toxoplasma gondii*
Anti-HLA antibody screen
Arterial blood gas
Autoimmune screen (ANA, ANCA, rheumatoid factor, quantitative immunoglobulins)
Thyroid profile
Pulmonary function testing:
Six minute walk test
Sputum or deep throat culture and susceptibility testing
Tuberculin testing
Electrocardiogram
Cardiac catheterization (in select patients)
Imaging:
Chest radiograph
Chest CT
Sinus CT (in patients with CF or immunodeficiency)
Echocardiogram
Bone densitometry
Consultations with:
Cardiothoracic surgery
Cardiology (in select patients)
Infectious diseases
Social services
Psychology
Nutrition
Physical therapy
Child life

Disease specific evaluation

Cystic fibrosis

Cystic fibrosis (CF) is a highly variable disease in which end stage lung disease is the most common cause of death. Improvements in care have led to better median survival, but there are still children with CF who progress to respiratory insufficiency. Liou et al. used a proportional hazards model to determine if lung transplantation provided a survival benefit to children with CF and concluded that it did not [11]. Their model however had several flaws [12]. It was derived using data obtained at the time of listing and not at the time of transplant. Their study was done prior to 2005 at a time when lungs were allocated in the US based on time spent on the waiting list and not by the Lung Allocation System (see further in this chapter). Patients were typically listed two and three years prior to their actual transplant to allow them to survive to transplant. Clinicians were astutely taking into account that the date of listing was not going to be the date of transplant, but rather acknowledged that if patients were going to survive to transplant, they would need to accrue time on the list. This flaw, in and of itself, impacts the calculated survival benefit

of the procedure. Other studies [13] have found a benefit and lung transplantation remains the only treatment option available to patients with CF and end stage lung disease with the potential to extend life [14].

Specific indications

Early studies in CF led to recommendations for referral for lung transplantation once the forced expired volume in one second (FEV_1) declined below 30% predicted [15]. Although more recent studies have attempted to add to these criteria [16], none have improved significantly on the ability to predict waiting list mortality. Even in the best model, the positive predictive value is less than 50% [17].

Specific contraindications

Individual transplant centers have specific microbiologic contraindications to transplantation; most commonly chronic infection with *Burkholderia cenocepacia*. Case reports suggest that outcomes for patients chronically infected with *Mycobacterium abscessus* may be worse [18], but other investigators have demonstrated successful outcomes in these patients [19]. The presence of severe liver disease may be a contraindication in some centers, but may be an indication for combined lung-liver transplantation at other centers. Pleurodesis is not an absolute contraindication to transplant, but may prolong the ischemic time because of excessive intra-operative bleeding.

Surfactant processing abnormalities

Patients with SPB deficiency typically present with respiratory failure shortly after birth. Children with SPC deficiency, ABCA3 transporter mutation, or NK2.1x mutation can have variable presentations [20]. Lung biopsy may show diffuse alveolar type II cell hyperplasia, alveolar septal thickening, and alveolar proteinosis. Diagnosis is confirmed by genetic analysis.

Specific indications

Once a decision to pursue transplant has been made, patients with SPB deficiency should be transferred as soon as a possible to the transplant center, as many of these patients ultimately require high frequency oscillator ventilation or ECMO. For the other surfactant processing abnormalities lung transplantation is indicated for refractory respiratory failure or progressive respiratory insufficiency unresponsive to medical interventions.

Specific contraindications

As noted above in many transplant centers VA-ECMO dependence is an absolute contraindication to transplantation. Significant cerebral hemorrhage or other severe neurologic injury associated with a significant likelihood of developmental delay is also a contraindication.

Pulmonary vascular disease

There are multiple potential etiologies for pulmonary vascular disease in children including idiopathic pulmonary hypertension (IPH), congenital heart disease and pulmonary vein anomalies. These entities must be carefully distinguished to allow for appropriate management. Therapeutic advances have dramatically improved outcomes for children with IPH and they should only come to transplant when medical therapy has failed. Determining when to proceed with transplantation for patients with Eisenmenger syndrome continues to be challenging. Many of these patients can live for years, if not decades after diagnosis.

Specific indications

A decreased cardiac index of less than 2 L/min/m^2, elevated pulmonary vascular resistance, right atrial pressures of greater than 7.4 mmHg, and right ventricular end diastolic pressure of more than 10.4 mmHg portend poor survival and are indications for lung transplantation. Other factors that may correlate with survival include von Willebrand factor levels of more than 240%, elevated uric acid levels, and plasma levels of brain natriuretic peptide (BNP) greater than 180 pg/mL.

In patients with Eisenmenger syndrome and progressive disease, including severe hypoxia, syncope, or a very limited QOL, heart-lung transplantation must be considered. Patients with simple cardiac lesions may be candidates for cardiac repair at the time of bilateral lung transplantation [21,22].

As in patients with SPB deficiency, once the decision to transplant is made patients with alveolar capillary dysplasia (ACD), pulmonary veno-occlusive disease or pulmonary vein stenosis should be referred as soon as possible as these entities are poorly responsive to medical or surgical interventions.

Specific contraindications

In this population, the presence of extensive aorto-pulmonary collateral circulation (often seen in pulmonary atresia with diminutive or absent central pulmonary arteries), coupled with multiple prior thoracotomies has been associated with poor outcome [23,24]. In addition, patients who have undergone multiple thoracic surgeries or who have had implantation of homograft valves or vessels have in increased likelihood of developing allosensitization and subsequent risk of antibody medicated allograft injury. These risk factors are a relative contraindication in many centers.

Management on the waiting list

In the US listing practices for children >12 years of age and adults are driven by the "Lung Allocation System" (LAS) adopted in 2005 by the Organ Procurement and Transplantation Network (OPTN) [25] (see Chapter 31). The LAS allocates donor lungs based on models of waiting list mortality and post-transplant survival, in order to maximize the one-year transplant survival benefit. Factors in the models include diagnosis, age, height/weight, need for supplemental oxygen, pulmonary arterial pressures, six minute walk distance, and lung function. Waiting time and waiting list mortality have decreased in the US coincident with the LAS adoption [26]. However, an effect of the double contribution of the waiting list mortality to the LAS (LAS = post-transplant survival – 2 * waiting list survival, normalized to a 0–100 scale), has been an increased number of sicker patients receiving transplant and an overall poorer survival of those patients transplanted with high LAS scores (primarily those requiring mechanical ventilation) [27]. An important aspect of the LAS is the potential for serially collected data from patients listed for lung transplant to be used for refinement of the underlying models that generate the priority score; a proposal for LAS updates was released for public comment in early 2012. Although sufficient data has not been available to create a LAS type system for children younger than 12 years of age, since 2010 lung allocation for this group has been based on two urgency tiers and broader geographic sharing (Table 116.2) [28].

The goal of preoperative management is to maintain a state of health that will maximize the patient's likelihood of a successful post-transplant outcome and to address deficiencies discovered during the evaluation. Therefore many of the interventions during this time period are the same no matter the underlying diagnosis.

Table 116.2. Priority status for children under 12 years of age awaiting lung transplantation in the US

Respiratory failure, defined as:
• requiring continuous mechanical ventilation; ***or***
• requiring supplemental oxygen delivered by any means to achieve FiO_2 greater than 50% in order to maintain oxygen saturation levels greater than 90%; **or,**
• having an arterial or capillary PCO_2 greater than 50 mmHg, or a venous PCO_2 greater than 56 mmHg.
Pulmonary hypertension, defined as:
• having pulmonary vein stenosis involving three or more vessels; ***or***
• exhibiting any of the following, in spite of medical therapy: suprasystemic PA pressure on cardiac catheterization or by echocardiogram estimate, cardiac index less than 2 L/min/M^2, syncope, or hemoptysis.

Strategies will include: maximizing the child's nutritional status; allowing the child to participate in physical and occupational therapy and therefore minimizing muscle relaxation; minimizing infectious exposures; providing appropriate vaccinations; and if there have been issues in regards to adherence, working with the family to establish routines that will benefit them later with the complex post-transplant regimen.

Other specifics of preoperative management will vary by disease state. In patients with CF, continuation of aggressive airway clearance, nutritional supplementation, antimicrobial therapy and physical rehabilitation is vital. In patients with pulmonary vascular disorders, depending on the specific etiology, use of pulmonary vasodilator therapy, diuretics, anticoagulation, supplemental oxygen, and/or atrial septostomy may prolong life. In children with interstitial lung disease steroids may be of some benefit.

It is worth noting that although mechanical ventilation is a risk factor for a poor outcome in adult lung transplant recipients that does not seem to be the case for infants and toddlers. Graft survival at one and three years in mechanically ventilated children under three-years-old was not different compared to nonventilated patients [29].

In patients who remain difficult to manage despite mechanical ventilation, the Interventional Lung Assist device (Novalung® iLA), a pumpless venovenous membrane ventilator, has been shown to be an efficient remover of carbon dioxide and may be a useful bridge to transplant. Additional detail regarding artificial lung devices can be found in Chapter 50 [30]. The device has been used successfully in a child as young as two years of age [31]. At our center we have also utilized the Maquet® Quadrox-iD membrane oxygenator in an attempt to provide adequate gas exchange while avoiding muscle relaxation. These devices carry similar risks for anticoagulant related complications to ECMO; therefore their role in long term support remains to be clearly defined.

Transplant procedure and surgical techniques

Potential donor lungs for children are evaluated in a similar fashion to adult patients. In contrast to adult lung transplantation (chapter 59), most procedures in children are performed while on cardiopulmonary bypass. The surgical approach still uses the bilateral anterolateral trans sternal ("clamshell") incision providing optimal access to both pleural spaces and visualization. Most procedures involve bilateral sequential lung transplantation with end-to-end rather than telescoping bronchial-to-bronchial anastomoses to reduce the likelihood of stenosis [32]. To provide optimal blood supply to the anastomosis and reduce the risk of extension of infection from the airway to adjacent vascular structures, the anastomosis is generally covered with pericardial or peribronchial lymphatic tissue from either the donor or recipient [32,33]. In patients with CF, vigorous washing of the recipient trachea and bronchial stumps with an antibiotic solution prior to implantation is used to reduce the likelihood of transmission of airway organisms to the donor allograft.

Heart-lung transplantation is a relatively rare event in pediatrics [4]. Although in the past, pulmonary hypertension with significant right ventricular dysfunction was considered an indication for heart-lung transplant, resolution of even marked right ventricular hypertrophy and dysfunction can be seen with successful bilateral lung transplantation [34,35]. When a congenital heart defect requiring repair is part of the clinical picture, intracardiac repair may take place at the time of, or after, the bilateral pneumonectomies and prior to implantation of the donor lungs, obviating the need for heart-lung transplantation [22]. Because of the high prevalence of septic lung disease in pediatrics, and concerns about lung growth, single lung transplantation is used rarely among children [4].

Living donor lung transplant has virtually disappeared in the US since the introduction of the LAS. Nonetheless, the procedure, where a right lower lobe from one healthy donor and a left lower lobe from another (generally family members) are implanted in the recipient [36] is still used in Japan where access to donor organs suitable for children has been restricted. Other surgical techniques used in children include donor downsizing using linear stapling devices or lobectomy and lobar transplant [37]. These are typically used to increase the scope of organs available for transplant in infants and small children.

Post-transplant management

The post-transplant management in pediatrics differs from the adult regimen in a few important ways that we will highlight. Specifics regarding adult management can be found in Chapter 80. Certain post-transplant management issues are identical to both pediatric and adult lung transplant recipients such as the approaches to primary graft dysfunction or rejection and these will only be briefly mentioned or not be explored in further detail here.

Immunosuppression

Pediatric transplant physicians must consider not only the efficacy of the immunosuppressive regimen, but also how immunosuppression affects normal growth or causes cosmetic side effects that may promote non-adherence to the medical regimen. Almost 80% of pediatric lung transplant recipients are on tacrolimus and 65% are on MMF at the end of the first year [4]. Because lung transplant recipients have a higher risk for rejection episodes than other solid organ transplant recipients, more intense immunosuppression regimens have been developed. For example, the initial targets for trough levels for tacrolimus are typically in a range of 10–20 ng/mL. Initial dosing for prednisone is typically 0.5–1.0 mg/kg/d with the goal of 0.25–0.5 mg/kg/d by three to four months after transplant. Few patients are weaned from prednisone by five years post-transplant [4]. Induction immunotherapy is used by the majority of pediatric lung transplant centers; recent registry data showed that over 60% of patients received either a polyclonal agent (anti-lymphocyte or anti-thymocyte globulin) or an IL-2 receptor antagonist (i.e. basiliximab) [4].

The use of steroids in children deserves special mention because of the potential for adverse impact on a child's linear growth. There

are data in other pediatric solid organ recipients that steroid avoidance strategies can lead to successful immunologic outcomes but no systematic study in pediatric lung transplant recipients [38]. Further study is warranted in this area.

Antimicrobial regimen

Most patients receive prophylactic intravenous antibiotics before and after lung transplantation to cover common airway pathogens as well as the organisms known to colonize their airways. The antibiotic regimen may be modified based on donor cultures. Patients without CF generally receive a single antibiotic with broad Gram positive and Gram negative coverage. In recipients with CF, their pretransplant sputum flora cultures help guide therapy; typically, such antimicrobial therapy is chosen to cover Gram negative organisms such as *Pseudomonas aeruginosa* and occasionally *Achromobacter* spp. Vancomycin is often included to cover Methicillin resistant *Staphylococcus aureus* (MRSA), which has recently become more prevalent in children with CF and advanced lung disease. Most centers now use voriconazole or anidulafungin prophylaxis for patients in whom *Aspergillus fumigatus* has been isolated prior to transplant. In some circumstances, aerosolized amphotericin, oral itraconazole or oral voriconazole has also been used [39]. Prophylaxis against *Pneumocystis jiroveci* is begun shortly after transplant with three times weekly trimethoprim/sulfamethaxozole (TMP/SMX), (alternatively nebulized pentamidine, oral atovaquone or dapsone). Oral nystatin is given as prophylaxis for candidal disease.

Although ganciclovir prophylaxis has significantly reduced the incidence of CMV pneumonitis in lung transplant recipients, CMV remains a serious potential risk for mortality [40,41]. The approach to CMV prophylaxis in the pediatric lung transplant recipient varies considerably across transplant centers. In general when both recipient and donor are CMV seronegative, no prophylaxis is given [42]. When the donor or recipient is seropositive for CMV, 4–12 weeks of ganciclovir or valganciclovir is administered. Recently some centers have extended the duration of prophylaxis (with IV ganciclovir or oral valganciclovir) to six months or longer, based on studies suggesting benefit [43,44]. Although based on adult experience some pediatric centers use CMV hyperimmune globulin (CMVIg) in addition to ganciclovir [45], the benefit of CMVIg remains unclear [46].

Monitoring of the allograft

Measurement of lung function in children is more challenging, particularly in children less than six years of age because spirometry is generally not available/reliable in that age group. For older children, as in adults, spirometry is essential for the clinical diagnosis of bronchiolitis obliterans syndrome (BOS). For infants, using thoraco-abdominal compression techniques, pulmonary function testing can identify the presence of airflow obstruction, but requires specialized equipment and experience and cannot be done once the child's length is greater than 90 cms [47,48]. In addition, because they require sedation, infant pulmonary function testing cannot be performed as frequently as conventional spirometry. Moreover, criteria for BOS using infant pulmonary function testing are not included in the most recent BOS definition [49]. Some pediatric transplant centers therefore routinely perform high resolution CT scanning of the chest along with ventilation/perfusion scans to aid in the early identification of air trapping indicative of BO.

Impulse oscillometry (IOS) is a validated technique to assess the presence of airflow obstruction in children as young as two years old [50,51]. The technique requires that the subject breathe normally into a mouthpiece (or a special face mask for young children unable to close their lips around the mouthpiece) for a short period of time. It does not require active co-operation and probably deserves more intensive study in the post-transplant pre-school aged child.

Obtaining surveillance biopsies in infants and toddlers is also more challenging. Although smaller transbronchial biopsy forceps that will fit in the suction channel of pediatric bronchoscopes have been available for some time, they typically produce much smaller pieces of tissue. Therefore, obtaining sufficient tissue for the reliable diagnosis of rejection in infants is often quite challenging [52].

Outcomes and risk factors

Survival

Survival after pediatric lung transplantation for patients transplanted between January 1990 and June 2009 is comparable to adult survival (Figure 116.2). See Chapter 106 for additional discussion of lung transplant outcomes. Overall, pediatric recipients have a median survival of four and a half years, which is not statistically

different from the adult experience. One-year survival rates for pediatric recipients have improved significantly, from 67% in the era between 1988 and 1994 to 83% in the recent era (2002–2009). (Figure 116.3) There is, however, no significant improvement in five-year survival when comparing eras, suggesting that improvements in early mortality are primarily responsible for the era effect. Kaplan-Meier survival analysis also demonstrated significantly better survival in children transplanted between the ages of 1–11 years compared to those between 12–17 years (Figures 116.4a and 116.4b). In the most recent ISHLT report, the two most common causes of death within the first year post-transplant were infection and graft failure. By one to three years after transplant, bronchiolitis obliterans becomes the leading cause of death, accounting for nearly 40% of the mortality. Infection and graft failure remain an important cause of death throughout the follow-up period.

It is important to note that although outcomes remain poorer for retransplantation (overall 37% five year survival) than for primary transplantation, retransplantation has become a more frequent occurrence in the recent era [4,26], perhaps due in part to increased access provided by the LAS for children 12 years and older as well as reports of improved survival for selected recipients [53]. Appropriate selection of pediatric candidates for lung retransplantation will remain an important priority.

Complications

Airway complications

Dehiscence at either the vascular or bronchial anastomoses is a rare but emergent complication requiring reoperation. Most transplant centers assess the integrity of the airway anastomoses via flexible bronchoscopy during the first 24–48 hours after transplantation. Cultures from the lower airways are also obtained. The development of techniques to cover the anastomosis with vascularized tissue has significantly reduced the frequency of this complication [3,33,54]. Perhaps surprisingly, airway complications including fibrotic strictures, excessive granulation tissue or airway collapse at the site of the anastomosis occur at a frequency comparable to that seen in adult lung transplant recipients [55,56]. Stenosis of the airway lumen, when clinically significant, is treated via balloon dilatation by bronchoscopy. Most centers avoid placement of metallic expandable stents because of their limited ability to expand to the degree necessary to accommodate for maximal growth of the child's airway, requiring eventual removal. Unfortunately removal of these stents is fraught with potentially fatal complications [57]. In addition, the formation of granulation tissue may cause severe airway obstruction. At our institution, silicone rubber stents were used in 12 bronchial anastomoses and four were responsible for complications including dislodgement or obstruction [56]. Newer biodegradable stents have the potential to relieve the stenosis, but still allow for subsequent growth of the airway [58] and are deserving of further study.

Vascular complications

As the majority of pediatric lung transplant procedures are performed on cardiopulmonary bypass, bleeding, particularly in the pleural space or at the site of the vascular anastomoses, is a not infrequent problem, particularly in patients who have had prior thoracotomy [10]. Vascular anastomotic complications are often associated with hypotension and radiographic abnormalities. Thrombus formation in the pulmonary veins or left atrial anastomotic suture line may occur in the early postoperative period [59]. Perfusion scans and echocardiography should be used to assess the anastomoses.

Immunologic complications

The risk of developing acute cellular rejection and BOS appears to be lower in the infant population [29]. Otherwise the diagnostic and treatment approaches for immunologic complications are the same as in adult transplant recipients. Antibody mediated rejection is a more recently recognized immunologic complication of lung transplantation and seems to effect children and adults in a similar fashion. Although there is debate regarding the specific criteria for treatment, identification of circulating donor specific antibodies (identified using solid phase flow cytometry techniques), alveolar capillary complement (C4d) deposition, and capillaritis in the setting of allograft dysfunction is usually considered sufficient evidence [60]. Treatment of humoral rejection is also quite variable among pediatric centers. Most centers use some combination of steroids, plasmapheresis, intravenous immunoglobulin and B cell

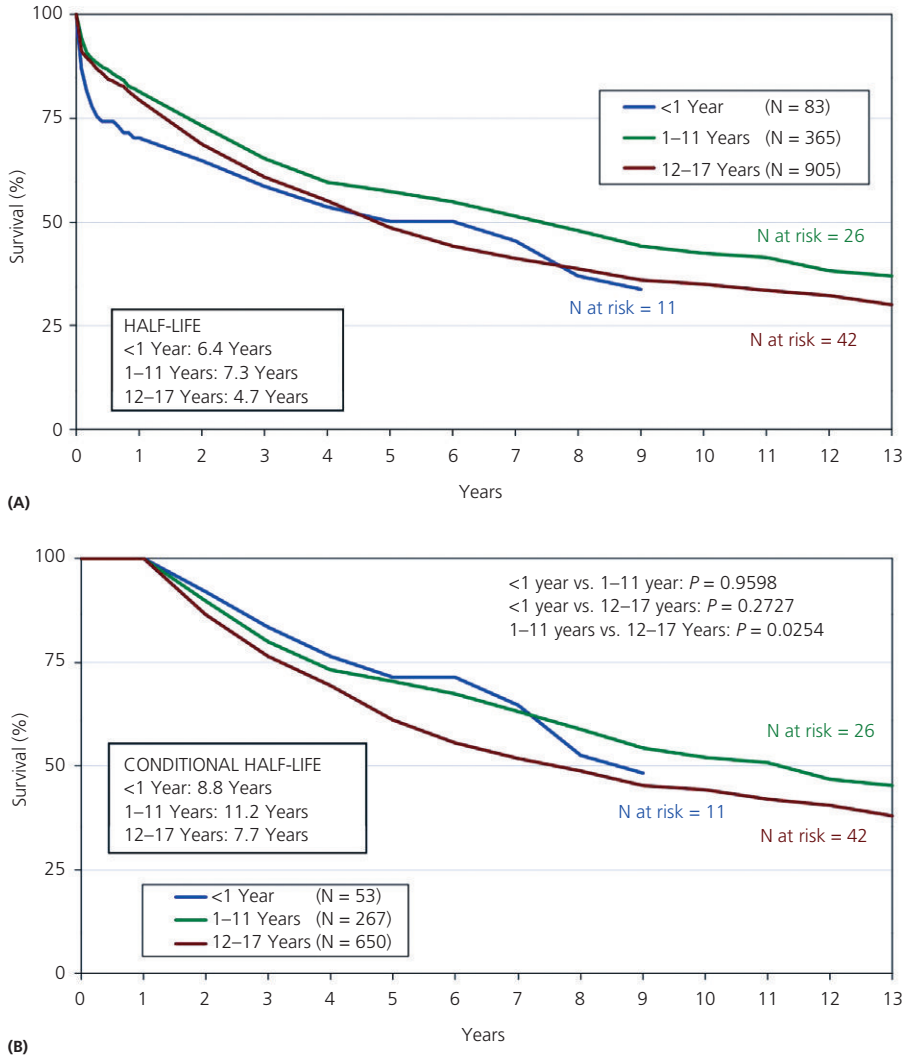

Figure 116.4. (A) Comparison of lung transplant survival between different age groups. (B) One year conditional survival between different age groups. reduction (cyclophosphamide or rituximab) [61]. Newer agents such as bortezomib, a proteosome inhibitor targeted at plasma cells or complement inhibitors such as eculizumab are increasingly being used [62,63].

An important complication of immunosuppression is the development of malignancy. The incidence of malignancy after lung transplantation in children is 5.9% and 13.1% at one and five years post-transplant, respectively; post-transplant lymphoproliferative disease (PTLD) is by far the most common malignancy [4]. In immunosuppressed pediatric patients, PTLD is typically an EBV driven, B cell lymphoproliferation with highly variable histology [64,65]. PTLD is more common in lung transplant recipients (than other solid organ recipients), in patients with CF, and in children as compared to adults [66]. These findings are probably explained by the intensity of immunosuppression in lung transplant recipients and the fact that many pediatric patients are EBV seronegative at the time of transplantation [65]. PTLD often presents with an unanticipated finding of a single or multiple round or ovoid pulmonary nodules on chest imaging without other symptoms [67]. The incidence of extrapulmonary PTLD increases after the first post-transplant year. Sites include the GI tract, the skin, and other lymphatic tissue including lymph nodes and the nasopharynx [68,69]. Most centers monitor quantitative measurements of EBV by PCR, a sensitive and somewhat specific marker for PTLD [70]. Positron emission tomography (PET) can be a sensitive and specific test [71]. Histologic diagnosis of PTLD is critical for prognostic purposes as CD20 positive tumors may be more amenable to antibody therapy and monomorphic PTLD has a worse prognosis [72].

Although some adult centers respond to the presence of elevated EBV PCR by reducing immunosuppression [73], a recent study suggests caution with this approach in children [74]. Although it can be successful in some patients, reduced immunosuppression carries a significant risk for the development of acute rejection. In many cases additional therapy is needed to induce remission. Many centers now follow the Children's Oncology Group protocol ANHL 0221 (ritixumab, an anti-CD20 monoclonal antibody shown to be effective in non-Hodgkin's B cell lymphoma, low dose cyclophosphamide and prednisone), which has shown promise as an approach to therapy for PTLD in pediatric solid organ transplant recipients [75].

Community acquired respiratory viruses

Children tend to have greater exposures to respiratory viral infections because of daycare, school, or the presence of siblings. These infections can be particularly problematic post-transplant. Adenovirus [76] and paramyxoviruses including parainfluenza and respiratory syncytial virus (RSV) can cause significant lung injury or mortality [77,78]. Many centers treat these viruses aggressively with cidofovir and ribavirin respectively [78–80]. Respiratory viral infections are also associated with the later development of BOS [81].

Transplant benefit, functional outcome and quality of life

Although QOL and survival in adult lung transplant recipients was better than candidates who remained on the waiting list [82–84], extrapolation of these findings to children and adolescents must be approached cautiously. Although registry report data indicate that more than 80% of lung transplant survivors report no activity limitations at one, three and five years post-transplant [4], there are limited well-controlled studies of QOL in pediatric lung transplantation. One small study showed a 24% improvement in quality of well-being in thoracic transplant recipients [85]. In another study, a group of 47 thoracic organ recipients (six lung transplant recipients) reported lower health status compared to a normal population but had similar health status as children with asthma, juvenile rheumatoid arthritis and intractable epilepsy [86]. It is important to note that assessments of QOL may be affected by the child's baseline capabilities prior to transplant and their expectations after transplant [85]. Moreover, consideration of the child's development level must also be included in QOL studies. It will be important to include systematic assessment and developmental impact of transplant in future longitudinal studies of pediatric QOL lung transplant recipients.

Lung growth

Successful lung transplantation in infants and young children raised concerns whether the lung allograft would grow with the child [87]. Allogeneic lung transplantation in animal models is associated with an increase in lung volumes and airway size with age [88]. In humans, spirometry and lung volume measurements have been reported to be normal in infants [89] and older children [24]. However, these measurements may reflect increased alveolar volume rather than increase in alveolar number and thus surface area for gas exchange. Ro and co-workers reported serial CT scan data supporting growth of intrathoracic airways over time [90]. However, a single center study of the diffusing capacity of carbon monoxide (DLCO) among pediatric recipients of cadaveric and living donor transplants suggested that no growth occurred [91]. Although DLCO provides a better estimate of gas exchange surface area, it is not easily measurable in infants. Further study is needed to clarify the extent of lung growth in infant and toddler lung transplant recipients.

Child development

Predictions of neurocognitive outcome are difficult to make. Infants possess some degree of neurocognitive plasticity that serves them well in the face of altered environmental interactions, circulatory compromise, infection, and abnormal nutrition and growth states. Infants who receive solid organ transplants are at risk for the development of learning disabilities, visual and spatial deficits, and motor delays [92]. However, transplantation in children in chronic renal failure actually allowed for significant improvement in development to occur. Measurements of head circumference, motor skills, and cognitive functioning all showed improvement post-transplant, with most children normal or near normal [92]. It is vital that transplant programs caring for infants have in place a protocol that assesses a child's neurodevelopment so that interventions may be implemented early. This is an area deserving of further study to better define the pertinent risk factors associated with developmental delay.

Adolescence

Adolescent transplant recipients deserve special mention. Adolescence is an emotionally fragile stage of life in which individuals struggle with self-identity, cognitive development, and emerging autonomy. Teenage transplant recipients have the added potential for risk-taking behavior which may manifest itself as non-adherence with medical therapy. At a time when they feel well, the importance of the immunosuppression regimen may be underestimated and may result in a poorer clinical outcome in terms of an increased incidence of late acute rejection, graft failure, and mortality [93,94]. There is little doubt that the adolescent transplant population requires an even more intense effort than other populations to establish a strong relationship with the transplant team in order to provide regular education, encouragement, and open communication. Because adolescents require such an intensive effort from the team, the authors recommend that programs considering offering lung transplants to adolescents include on their team dedicated pediatric practitioners with experience dealing with the unique and special needs of this population.

Eventually, however, the goal for all pediatric practitioners is to have our patients "outgrow" us. Unfortunately, rather than being viewed as a victory, oftentimes, the transition period is greeted with great apprehension by all involved. For the young person preparing to transition their care to an adult transplant provider, it is a time when they are expected to be fully responsible for managing their own healthcare yet they are moving to an adult healthcare and insurance system they have no experience navigating. For the parents, it is a time where they must relinquish control of managing every detail to their children. It is therefore no surprise that medical outcomes during this period can be poor [95]. Transition warrants a concerted effort to improve communication between the pediatric and adult centers and specifically between the providers [96,97]. How to best approach the process of transition needs to be an area of active study as this is a challenge that will only increase in scope as we become more successful in managing pediatric lung transplant recipients [98,99].

Summary

Pediatric lung transplantation presents unique challenges and numerous opportunities. It is clear that lung transplantation can be successfully performed in infants and children with end-stage pulmonary parenchymal and vascular disease providing some with prolonged survival and improved QOL. However, long-term outcomes for many fall far short of our expectations. Critical obstacles like donor graft shortage and effective approaches to bronchiolitis obliterans are shared with the adult lung transplant world. However, some issues encountered in the field of pediatrics distinguish themselves and warrant approaches specifically designed as such.

CHAPTER 117

Pediatric Intestinal and Multivisceral Organ Transplantation

Douglas G. Farmer
Dumont-UCLA Transplant Center, David Geffen School of Medicine at UCLA, Los Angeles, CA, USA

Introduction

The origins of intestinal transplantation are closely associated with intestinal and liver diseases in children. It is these diseases that drove the early transplantation attempts. Several important milestones are worth noting. First, the foundations for liver inclusive intestinal type transplants were laid in the first successful pediatric liver transplant cases performed in 1967 by Thomas Starzl [1]. Concomitantly, there were several attempted pediatric intestinal type transplants without success [2]. With the clinical introduction of parenteral nutrition in the late 1960s [3], no other clinical intestinal cases were performed for nearly 20 years. Then in the mid-1980s, spurred by several reports of successful adult intestinal transplants [4–6], pediatric intestinal transplantation was re-attempted [7]. In fact, the longest survivor received her intestinal transplant in 1988 in Paris France [8]. Soon thereafter, case series were published [9] thus ushering in the modern era of pediatric intestinal transplantation.

Pediatric intestinal transplantation has changed dramatically over the ensuing two decades. Herein we will review some of the major advancements, surgical techniques, outcomes and complications of the procedure. General features of intestinal and multivisceral transplantation, and adult specific aspects are covered in Chapters 33, 42, 62, 86, and 109.

Indications and patient selection

The major indication for intestinal transplantation is irreversible intestinal failure: a clinical condition in which the fluid/electrolyte, caloric, macro- and micronutrient needs of a patient cannot be maintained by the gastrointestinal tract. Less common secondary indications are usually technical issues such as unresectable tumors involving the root of the mesentery or pan porto-mesenteric-splenic vein thrombosis not amendable to standard surgical therapies. Additional treatment of this topic is found in Chapter 33.

Intestinal failures are broadly grouped into three categories, which may have overlapping syndromes/diagnoses: surgical, functional, or mucosal (see Table 117.1).

Children who develop intestinal failure are first stabilized with parenteral nutrition management. In general, the initial goal is enteral adaptation thus avoiding the need for transplantation. The specific management of these patients at this stage of intestinal failure/rehabilitation is beyond the scope of this chapter and the reader is referred elsewhere [10,11]. Several prognostic factors are assessed in an effort to establish the likelihood of adaptation in contrast to the irreversibility of intestinal failure. Many of these factors (Table 117.2) have been shown in large studies to predict adaptation, although none are absolute [12].

Patients with a poor prognosis and/or those not demonstrating early evidence of enteral adaptation should be referred to a transplant center for assessment. Other medical and surgical means to assist with adaptation can be considered. However, the indication to proceed with transplantation is the presence of irreversible intestinal failure and one or more life-threatening parenteral nutrition related complications. These complications commonly include:

1 Loss of central venous access.
2 History of multiple central venous catheters.
3 History of multiple blood stream infections.
4 Presence of intestinal failure associated liver disease.
5 Chronic pain syndromes associated with intestinal failure.
6 Difficult fluid/electrolyte/nutrition management.

There is a subset of patients with an extremely poor prognosis for adaptation that consideration for transplantation should be given prior to the onset of the common parenteral nutrition related complications. This standard was set forth in a position paper published by the American Society of Transplantation in 2001 [13] and continues to be used today.

Wait-list issues

A major obstacle to successful pediatric intestinal transplantation has been wait list mortality. This was first exposed in a study of the UNOS database from 1993–2001 [14] where wait-list mortality rates for children listed for liver intestine or multivisceral grafts far exceeded that for child listed for isolated liver grafts. In retrospect, these findings were not surprising as liver-intestine and multivisceral candidates are basically waiting for size-matched pediatric donors while candidates waiting for liver only grafts have several options including size-matched pediatric donors, adult cadaveric split grafts, or living donor grafts. In addition, it was retrospectively discovered that the end-stage liver disease and pediatric end-stage liver disease (MELD/PELD) scoring system did not accurately predict three month survival in patients with intestinal failure

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Table 117.1. Common pediatric causes in each category are:

Surgical	Functional	Mucosal
gastroschisis	pseudo-obstruction	microvillous inclusion disease
jejunoileal atresia	Hirschsprung's disease	tufting enteropathy
midgut volvulus	–	congenital neuroendocrinopathy
necrotizing enterocolitis	–	–

Table 117.2. Assessed prognostic factors to establish the likelihood of adaptation in contrast to the irreversibility of intestinal failure

Factor	Positive predictor	Negative predictor
Age	younger	older
Length of remnant bowel	long	short
Ileocecal valve	present	absent
Colon	present	absent
Enterostoma	absent	present
Time since onset	short	long
Underlying intestinal disease	absent	present
Small bowel segment	ileum	jejunum

associated liver disease. Therefore, significant changes in the US intestinal allocation system including the addition of 23 PELD/MELD points to children awaiting liver-intestine or mutivisceral grafts as well as the allocation of pediatric organs to pediatric recipients first over a wider geographical region. These changes have resulted in a dramatic decrease in wait-list mortality for these candidates [15].

Graft options and surgical techniques

The type of intestinal transplant offered to children is tailored to the underlying disease. In general, four types of intestinal transplants are considered – isolated intestine grafts, combined liver-intestine grafts, multivisceral grafts, and modified multivisceral grafts. Technical details of these operations are covered in Chapters 62 and 63.

Bear in mind, significant controversy exists over the exact nomenclature used [16]. The reader is referred to other related chapters in this text for further information. For the purposes of this chapter, the following definitions will be used:

1 Isolated intestinal transplant — transplantation of part or all of the donor jejunoileum into the recipient. This is reserved for patients with irreversible intestinal failure, early or no liver disease, and the absence of foregut (stomach, duodenum, pancreatic) disease. Arterial inflow is commonly established from either the infra-renal aorta or the superior mesenteric artery. Venous outflow is common performed into the mesenteric veins or the inferior vena cava.
2 Liver-Intestine transplant — transplantation of part or all of the donor liver, pancreas, and jejunoileum. Note, the donor pancreas is now commonly included in this organ complex as a technical modification to simplify both the donor and recipient procedure [17]. The recipient liver and remnant jejunoileum is removed. However, the recipient pancreaticoduodenal complex remains in situ. This transplant is reserved for patients with irreversible liver disease and irreversible intestinal failure in the absence of foregut disease. Arterial inflow is generally established with vascular conduits off the aorta. Venous outflow is via the transplanted liver into the suprahepatic inferior vena cava.
3 Multivisceral transplant — transplantation of part or all of the donor liver, pancreas, and jejunoileum with or without inclusion of the donor stomach. This transplant is reserved for patients with irreversible liver disease, intestinal failure, and foregut disease. The major difference between this type of transplant and the liver intestine type is that the recipient foregut is removed along with the liver and remnant jejunoileum. Otherwise vascular inflow and outflow are similar.
4 Modified multivisceral — transplantation of all or part of the pancreas and jejunoileum with or without the stomach. Importantly, the liver is not included in this graft. This option is reserved for patients with irreversible foregut disease and intestinal failure. As before, the recipient foregut is removed. This graft is arterialized from the aorta using vascular conduits with venous outflow via the portal vein.

Most of these graft types can be modified, again based on patient specific needs, to include the stomach, colon, and/or kidney(s).

Immunosuppression and rejection

One of the major advances in intestinal transplantation has been in immunosuppression. Conceptually, the intestine is the only organ transplanted that relies on itself to absorb critical medication to prevent its own immune mediated destruction. Therefore, the development of highly absorbable and potent immune suppressants and/or intravenous formulations of immunosuppressants have been crucial to the advancement of the field. Without question, the first breakthrough came with the discovery [18] and clinical introduction [19] of tacrolimus (Prograf®; Astellas Pharma; Deerfield, IL). Prior to the clinical use of this agent, successful intestinal transplantation was rare; afterward, it became commonplace as noted above.

The next major breakthrough in this field was the use of induction immunotherapy. Prior to its routine use, the short-term survival after intestinal transplantation was commonly reported at 25–50% [20]. In 1999–2000, most centers began using induction therapies with either an interleukin-2 receptor antagonist (daclizumab; Zenapax®; Roche Pharma, Nutley, NJ) or basiliximab; Simulect®; Novartis Pharma, East Hannover, NJ) or an antithymocyte product (rabbit antithymocyte gobulin/rATG; Thymoglobulin®; Genzyme Corp, Cambridge, MA). More recently, alemtuzumab (Millenium and Ilex Partners, LP, Cambridge, MA) has also been used for induction therapy with improved results. All agents led to a marked increase in short-term survival rates as high as 75–90% [21–24].

Outcomes

Survival

General outcomes following intestinal transplantation are discussed in detail in Chapter 109. To review outcomes after intestinal transplantation, there are several different data sources. The standard multicenter data set remains the Intestinal Transplant Registry [25]. This data set is believed to have captured nearly all intestinal type transplants performed worldwide since 1985. The other available registry data set is the United Network for Organ Sharing/Organ Procurement and Transplant Network (UNOS/OPTN) data which is reported through the Scientific Registry of Transplant Recipients (SRTR) [26]. As with all registry type data, there are limitations as to the number of data points collected per patient, the completeness of the data points entered, and the variability in

interpretation of entered data from the different centers. The other major source of outcome data is single center reports. Few reports are dedicated to children alone. The experience reviewed herein is contained within the Table 117.3 [20,21,22,24–31].

The UNOS/OPTN data set indicates that between 1988–2011, 2138 intestinal transplants had been performed in the US with 56% occurring in children [26]. At three and five years post-transplant, the patient survival was 51–79% and 33–76%, respectively while the corresponding graft survival was 44–64% and 30–69%, respectively. Examining the 2009 ITR report on pediatric intestinal transplantation indicates that, worldwide, 1151 patients received 1236 transplants [32]. Five-year survival improved with each era analyzed whereby after 2000, a 70% patient survival was reported. The most common causes of patient death were sepsis (46%) and multiorgan failure (35%).

The single center reports are shown in Table 117.3. In general, similar trends are seen. That is, patient and graft survival improve in the more recent time intervals analyzed with three year patient and graft survival between 56–72% and 53–92%. The most common causes of death and graft loss are infection, rejection, and post-transplant lymphoproliferative disorders (PTLD).

Acute rejection

Acute rejection is the most formidable obstacle to successful intestinal transplantation. Historically, rejection has occurred almost universally after intestinal transplantation and has been the leading cause of graft loss. Single center reports remain the optimal source for assessing rejection rates. Unfortunately, there is no unified system for reporting with rates reported by transplant era, immunosuppression group, total rejections per graft, and patients with and without rejection. From these reports, the lowest rejection rates are with alemtuzumab induction combined with sirolimus (Rapamune®, Wyeth Pharma, Philadephia, PA) maintenance therapies (36% and 17%, respectively).

One of the most detailed reports on this subject is from the University of Miami [33]. Two hundred and nine patients including 128 children underwent intestinal transplantation during the study interval. Thirty-two percent did not have a rejection episode while the rest had 290 episodes for an average of two episodes per patient. The median time to first rejection was 18 days. Statistical analysis showed that transplant era before 2001, lack of alemtuzumab induction, the lack of donor spleen inclusion, and a longer cold ischemia time all predicted rejection with the transplant era being the strongest predictor.

These data indicate that while rejection is still a major obstacle to successful intestinal transplantation, the rates and severity have improved over time. Rigorous endoscopic monitoring protocols have been implemented at most centers which helps detect rejection at early stages. Induction immunotherapy of any kind appears to help reduce the incidence of rejection. Noninvasive tests that predict rejection need to be developed to aid with this problem.

Cytomegaloviral disease

Tissue invasive cytomegaloviral disease (CMV) disease is a problem after intestinal transplantation. This should not be a surprise as this virus is trophic to the gastrointestinal tract and thrives in immunoincompetent patients. Reports from earlier in 2000, indicates rates as high as 26% [34]. However, more recent reports indicate reduction in this infection to 11–24% see Table 117.3. A recent review at the University of California, Los Angeles, indicates an overall rate of CMV disease down to 5% [35]. Progress has been made due to the institution of prophylactic and preemptive therapeutic protocols targeted against this virus. The UCLA protocol includes weekly monitoring of blood for viral DNA as well as prophylactic treatment with intravenous ganciclovir [36].

Post-transplant lymphoproliferative disorders

Similar to the CMV virus, the Epstein Barr Virus (EBV) with associated infection and malignant viral transformation is another major problem after intestinal transplantation. Again, this virus thrives in immuno-incompetent patients. The actual incidence of EBV infection is not clear in the literature. In contrast, the incidence of PTLD is clearly reported. However, not all PTLD are EBV-associated/driven and therefore there is a lack of uniformity in the literature. From single center reports, the historical incidence of PTLD (EBV related or not) is between 23–44% (see Table 117.3). In more recent studies, these rates have decreased to 11% from 24%. At UCLA, the incidence of PTLD is 8% [35]. The improvement in the rate of PTLD would appear to be largely related to the same pre-emptive and prophylactic strategies used against CMV, although causality is hard to determine. Detailed discussions of PTLD are found in Chapter 96.

Renal failure

The extent of the problem with kidney function after intestinal transplantation was first elucidated in a report from the OPTN/SRTR in which the incidence of chronic renal failure in 228 recipients was 21 $\pm$ 3.4% at five years [37]. This finding has spurred several important single center studies on the subject. In a study of 44 children after intestinal transplantation, Ueno and colleagues found that while the pretransplant estimated glomerular filtration rate (eGFR) was 138 $\pm$ 42 mL/min/m2, by 24 months post-transplant, the corresponding eGFR had dropped to 81% of baseline [38]. This decrease was correlated with high trough levels of tacrolimus in the first 12 postoperative months. At UCLA, an analysis of 45 children and 23 adults after intestinal transplantation was undertaken to assess postoperative renal function [39]. Multiple time points were assessed and renal function was reported as eGFR/normal GFR as reported in standardized tables. Prior to transplant, the eGFR was 83–91% of normal. After transplant, the eGFR ranged from 64 to 95% of normal. Several factors were found to predict an eGFR of $<$75% normal including a low pre-transplant eGFR, ICU status prior to transplant, long time period on TPN prior to transplant, high dose tacrolimus, and age $>$18 years. From these studies, we can conclude that renal dysfunction/failure is a major problem after intestinal transplantation and that high tacrolimus levels are an important contributor to this problem.

Nutrition

The ultimate goal of intestinal transplantation is enteral nutritional autonomy. Surprisingly, there are few studies on this subject. To address this issue, Venick and colleagues performed a detailed assessment of nutritional outcomes in 33 children after intestinal transplantation [40]. Enteral nutrition was initiated a median of eight days after transplantation and parenteral nutrition was discontinued a median of 31 days after transplant. Improvement was seen in the median Z scores for both height and weight at 48 months post-transplant when compared to pretransplant (Weight: -1 to 0; Height: -3 to -2.4). Similar improvements were noted in the serum albumin and prealbumin (albumin: 2.7 to 3.7 g/dL;

prealbumin: 15 to 25.1 mg/dL). However, micronutrient deficiencies were commonly seen especially with iron and zinc. Nevertheless, this study provided specific evidence over a prolonged postoperative time period that intestinal allografts can support nutritional autonomy.

Summary

Outcomes after intestinal transplantation have markedly improved over the past decade. The reasons behind this progress are no doubt multifactorial. However, advances in surgical technique, center specific experience, induction immunotherapy, and anti-infectious drugs have played a role. Successful intestinal transplantation appears to be associated with nutritional autonomy. However, major obstacles still remain. Rejection, viral infections, and deterioration in renal function are particularly relevant problems that need to be addressed. Despite these issues, patients undergoing intestinal transplantation now have outcomes nearly equal to those seen after other solid organ transplants.

CHAPTER 118

Growth and Development after Organ Transplantation

Franz Schaefer
Division of Pediatric Nephrology, Hospital for Pediatric and Adolescent Medicine, University of Heidelberg, Germany

Introduction

The realization of a patient's genetic growth potential is one of the key objectives of organ transplantation in children and adolescents. In principle, the restoration of full organ function should permit catch-up growth and a normal onset and progress of puberty. However, the recovery of growth and development following organ transplantation is usually incomplete. To date, final adult height is below target in a major proportion of patients who received an allograft during childhood. This chapter will detail the factors affecting post-transplant growth and the current strategies to improve growth and development following solid organ transplantation. Chapters 119 and 121 will provide additional insights into the related topics of cognitive development, and developmental issues influencing the transition from pediatric to adult care.

Growth retardation and delayed pubertal development in chronic organ failure

Chronic organ failure in children leads to alterations of growth and maturation. Consequently, retarded growth and delayed puberty are common in pediatric solid-organ recipients at the time of grafting. Skeletal maturation and the onset of puberty is commonly delayed commensurate with the retardation of growth.

Registry and large single center surveys have provided information about the average growth deficit at time of transplantation in solid organ recipients. The natural history of growth in children end-stage renal disease (ESRD) is characterized by a gradual deviation from the normal growth channel by 0.2–0.5 standard deviation score (SDS) per year in infancy and mid-childhood, a marked deceleration of growth in the late prepubertal period and a pubertal growth spurt which is delayed by 1.5 to 2 years and is of subnormal size and duration, resulting in a 50% reduction of cumulative pubertal height gain compared to healthy children (see [1] for review). Fortunately, growth failure in chronic renal insufficiency and ESRD can be prevented and treated by aggressive nutritional management and recombinant human growth hormone (rhGH) therapy. The intense therapeutic attention to growth failure has resulted in improved growth patterns in the pretransplant phase. In the North American Pediatric Renal Transplant registry (NAPRTCS), mean standardized height at the time of first kidney transplantation has increased from −2.4 SDS in 1987 to −1.5 SDS in 1999, with only slight further improvement (0.25 SDS) between 1999 and 2009 [2] (Figure 118.1).

Since pediatric liver diseases most commonly occur in infancy, severe malnutrition and rapid growth failure are common sequelae of liver failure. Indeed, failure to thrive is considered one of the indications for elective liver transplantation in patients suffering from disorders such as biliary atresia or Alagille syndrome. The mean pretransplant height SDS of 569 patients enrolled into the SPLIT registry was −1.3 [3]. Single-center studies from UCLA [4], the University of Chicago [5], and the UK [6] comprising 236 294, and 107 pediatric recipients, respectively, reported mean baseline height SDS of −1.7, −1.6, and −1.2.

In children with end-stage liver disease, growth retardation is usually inversely correlated with age, supporting the notion that liver failure is more critical to the nutrition-dependent growth phase of infancy. The crucial role of nutrition is also underlined by the severe growth retardation observed in the majority of infants with short bowel syndrome requiring isolated small bowel or combined liver-small bowel transplantation [7]. In contrast, patients acquiring end-stage liver disease in the post-infantile period more commonly undergo rescue liver transplantation due to acute conditions such as fulminant hepatitis or intoxications, without preceding growth failure. A third group of patients with liver failure is comprised of syndromic disorders with hepatic involvement. In these children, chronic liver failure may be one of several factors contributing to severe growth retardation. A genetic disposition for small stature has been suggested in Alagille or Byler syndrome; intrauterine growth retardation occurs in 50% of patients affected with these disorders and normalization of liver function by transplantation does not appear to induce catch-up growth [8–10].

Growth is also suboptimal in patients with severe cardiac disease awaiting transplantation. Impaired tissue oxygenation can cause impaired intestinal motility and nutrient malabsorption, acidosis, increased energy expenditure and even ischemic injury to the hypothalamo-pituitary axis with resultant insufficiencies of one or more of the endocrine systems promoting growth and development [11]. The overall degree of growth failure appears to be moderate. In the most recent large single-center reports, median height SDS at time of transplantation was −0.7 in 46 prepubertal children from UCLA and −1.3 in 130 children from Toronto [12,13].

Factors affecting post-transplant growth and development

Kidney transplantation

Post-transplant growth and development has been studied most systematically in renal allograft recipients. While a wide variety of growth patterns after kidney transplantation has been reported by individual centers, ranging from progressive growth failure to almost complete catch-up growth [14–28], most reports are in agreement about the main determinants of post-transplant growth. These are the age and the degree of stunting at time of transplantation [17,18,28–31], the level of allograft function and the modalities of glucocorticoid treatment.

The potential for post-transplant catch-up growth appears to be inversely related to the 'age at transplantation'. Excellent catch-up growth is usually observed in infants [17,29–32]. The critical age beyond which significant improvements in height SDS were no longer observed ranged from two to twelve years in different studies [17,27,29–31,33]. Pubertal growth seems to benefit least from renal transplantation. As in dialyzed patients, the onset of puberty and the pubertal growth spurt are delayed in renal allograft recipients by approximately two years. Although a distinct acceleration of height velocity occurs, total pubertal height gain is subnormal due to a shortened duration of the pubertal growth spurt [34]. An inverse relationship between pubertal peak height velocity and cumulative glucocorticoid intake has been observed [34,35].

In addition to the impact of age, the change in standardized height following renal transplantation is closely correlated to the 'height at time of grafting' [32,36]. Hence, the general principle of catch-up growth 'by demand', that is: the tendency of an organism to return to a predetermined growth channel after removal of growth-inhibitory conditions, holds also true for renal allograft recipients.

Post-transplant growth appears to be very sensitive to the 'function of the allograft'. Whereas native kidney function only affects linear growth when glomerular filtration rate (GFR) is consistently decreased to less than 30 mL/min/1.73 m^2, post-transplant growth velocity is significantly reduced at any GFR below 60 mL/min/1.73m [2,16,29]. Multivariate analyses have confirmed that the growth-suppressive effects of poor renal graft function is independent of glucocorticoid dosage [24,27].

In view of the profound growth-suppressive endocrine and metabolic effects of glucocorticoids (see further on), there is little doubt that this component of immunosuppressive medication plays a major role in post-transplant growth. Results from clinical trials using modified steroid administration, complete steroid withdrawal or even primary steroid avoidance protocols have provided some evidence that glucocorticoids affect catch-up growth in renal transplant recipients. On the other hand, surprisingly few studies found a consistent correlation between steroid dosage and the post-transplant change in standardized height [14,35]. The lack of a consistent correlation between glucocorticoid dose and post-transplant growth may be explained by a non-linear 'threshold' relationship, and by the large interindividual variability of glucocorticoid resorption and pharmacokinetics. Indeed, the area under the serum methyl-prednisolone concentration curve was superior to the administered glucocorticoid dose in predicting post-transplant growth rates [37].

Conflicting findings have been reported with respect to a possible growth inhibitory effect of mTOR inhibitors. On the cellular level, this class of immunosuppressive agents has profound antiproliferative properties by interfering with key anabolic signaling pathways [38]. In experimental studies rapamycin induced growth retardation via an antiangiogenic effect at the growth plate [39,40]. After a clinical case report first suggested growth failure induced by sirolimus [41], a retrospective analysis compared growth in 34 children switched from calcineurin inhibitors (CNI) to sirolimus due to CNI toxicity, acute or chronic rejection or malignancy, compared to 34 controls matched for age, gender, renal function and steroid dose [42]. Catch-up growth was observed over time in the children on CNI, but not in those receiving sirolimus. In a subset of prepubertal children with excellent GFR and very low steroid doses, the difference was even more marked with a mean two-year change in height SDS of −0.22 in the patients receiving sirolimus versus +0.77 in the CNI-treated controls. By contrast, a single-center study comparing 25 children receiving sirolimus, MMF and prednisone with 23 matched children treated with tacrolimus, MMF and prednisone from the time of transplantation did not find any adverse impact of sirolimus on growth rates during the first two post-transplant years, with unchanged mean height SDS in both groups [43].

After more than three decades of pediatric renal transplantation, several thousand patients worldwide have achieved 'final adult height'. This provides the opportunity to assess the ultimate completeness of post-transplant catch-up growth, and to analyze the eventual impact of the modulatory factors mentioned above on the ultimate endpoint of longitudinal growth. Final height has been assessed in single-center studies and registry reports [2,34,36,44,45]. Short adult height was found in 25–41% of all patients who developed end-stage renal disease and underwent kidney transplantation during childhood. Average final heights have substantially increased over time; the NAPRTCS Registry

reported mean SDS of −1.93, −1.51, −1.05, and −0.94 for patients achieving adult height in 1987–1991, 1992–1996, 1997–2001, and after 2002 respectively [2]. However, this increase appears to be entirely related to improved growth management prior to transplantation. In 237 children reported to the NAPRTCS registry who had received a graft at age ≤12 years, mean final height SDS was identical to standardized height at the time of transplantation, indicating a lack of catch-up growth in the pediatric renal transplant population as a whole [45]. As found for early post-transplant growth in the studies cited above, final height was inversely related to the age at transplantation; significant catch-up growth was limited to prepubertal patients. The most severely stunted patients exhibited the most marked post-transplant growth improvement, and renal graft function was an additional independent predictor of final height. In addition, an average prednisone dosage in excess of 0.15 mg/kg/day was independently associated with a retarded final height [45].

Liver transplantation

Post-transplant catch-up growth is observed in 40–50% of liver allograft recipients [5,8,46]. As in kidney transplantation, age and the degree of stunting at time of transplantation are important predictors of post-transplant catch-up growth [5,46], with young infants usually exhibiting most rapid and complete catch-up growth [4,5,46,47].

The 'primary hepatic diagnosis' might also impact post-transplant growth potential. McDiarmid et al. noted an increase in height SDS-score of +0.7 at five years post-transplant for recipients with biliary atresia compared to a decrease by −1.0 for those with fulminant hepatic failure, and −0.9 in those whose primary disease was a tumor [47]. Lack of catch-up growth was also noted in recipients with Alagille syndrome and familial cirrhosis [6,47]. This variation could either be due to persistent differences in post-transplant growth conditions or simply reflect differences of the age at which end-stage liver disease typically occurs.

Long-term growth outcome appears to be favourable in liver allograft recipients. McDiarmid et al. noted an improvement in standardized height from −1.7 SDS at baseline to −1.4 SDS at five years post-transplant in 236 children, Viner et al. an increase from −1.2 to −0.8 SDS at seven years in 107 recipients, and Fouquet et al. an increase from −1.4 to −0.5 SDS ten years post-transplant in 80 children with biliary atresia [4,6,47]. In 121 children followed in the North American SPLIT registry, mean height SDS ten years post-transplant was −0.5 [48]. Hence, the majority of pediatric liver allograft recipients reaches a height in the normal range.

Long-term growth performance of liver allograft recipients appears to be crucially determined by maintenance steroid administration (see further on in this chapter) and graft function [4,5,49,50]. In immunologically low-risk patients with good liver function who can be weaned off steroids entirely, nearly complete catch-up growth is common [4,51,52]. These findings were confirmed in a long-term growth analysis of 237 Japanese liver allograft recipients followed for 15 years [53]. Mean standardized height increased from −1.70 to −0.64 SDS in the first post-transplant year, followed by a plateau phase with slight further catch-up to −0.33 SDS at ten years post-transplant. Children transplanted before two years of age showed late growth deterioration beyond the tenth post-transplant year, which was mainly related to graft dysfunction. Mean height SDS at 15 years was −0.47. Long-term growth failure was strongly associated with steroid therapy; at ten years post-transplant, height was below the tenth percentile in 43% of patients still receiving steroids as compared to 11% in the steroid-free patients.

Heart transplantation

Varying growth patterns have been observed in cardiac allograft recipients. In patient cohorts on steroid-based immunosuppressive protocols, standardized height did not change or slightly decreased up to six years after transplantation [12,13,54–57].

Early propagation of steroid-free immunosuppressive protocols in heart transplantation has provided evidence that maintenance glucocorticoid therapy is the most important determinant of the long-term growth performance in pediatric cardiac allograft recipients.

A small group of heart transplant recipients in Newcastle, UK, followed for >1 year without maintenance corticosteroid therapy exhibited an increase in standardized height from a mean of −2.15 at baseline to −1.15 [58]. Similarly, in 77 infants transplanted at <6 months of age maintained on a steroid-free protocol catch-up growth was almost universally observed during the first post-transplant year [59]. Factors predicting subnormal height at five years post-transplant in patients with steroid-free immunosuppression included prolonged hospitalization during the first post-transplant year, frequent late rejection, and below-average parental stature.

Lung transplantation

Although more than 1500 pediatric lung transplants have been performed worldwide to date, the still limited long-term survival of children undergoing this procedure has precluded the analysis of post-transplant growth patterns [60]. It would be expected that these children have significant pre-existing growth retardation at time of transplantation due to the high incidence of malnutrition, infection and steroid treatment in this population. Catch-up growth after transplantation is unlikely since patients are still universally treated with steroid-based immunsuppressive protocols, and steroid withdrawal appears an option only in very few selected cases. A single paper in 1997 reported height data on 88 pediatric lung transplant recipients [61]. Mean patient height was '72% of normal' at the time of transplantation, and 64% at last observation.

Intestinal transplantation

Two reports describe the post-transplant growth performance in children undergoing intestinal, with or without liver, transplantation [7,62]. In a cohort of 46 children, 35 retained a functioning small-bowel graft for an average of three years without any need for additional parenteral nutrition [7]. Immunosuppression was maintained with tacrolimus and prednisone. Despite usually young age at transplantation (median 3.7 years), no catch-up growth was noted. Median height SDS was stable around −1.8 during the first two post-transplant years. The Paris group followed 31 children with a mean height SDS of −1.2 at transplantation for 2–15 (mean 7) years [62]. Height SDS remained stable in 25 children whereas growth velocity was impaired in five. Only a single child with severe pretransplant growth failure exhibited catch-up growth after transplantation.

Endocrine mechanisms of glucocorticoid-induced growth failure

In the postinfantile period, longitudinal growth is mainly driven by the hormones of the somatotropic and, during puberty, of the

gonadotropic hormone axis. These endocrine systems appear to be affected to a major degree by glucocorticoid immunosuppression in pediatric allograft recipients.

In children after renal transplantation, growth plates appear responsive to stimulation via the somatotropic axis as suggested by a positive correlation between growth hormone (GH) pulse amplitudes and height velocity [63]. However, pituitary GH secretion is variably reduced, most likely due to a stimulatory effect of chronic glucocorticoid therapy on hypothalamic somatostatin synthesis and release [64]. Hence, some children receiving post-transplant glucocorticoid medication appear to be partially GH deficient. During normal puberty, augmented pulsatile gonadotropin secretion stimulates sex hormone secretion. The increase of circulating sex steroid concentrations elicits the pubertal growth spurt, both by direct action on the growth plate and by stimulating pulsatile GH secretion. In kidney transplant recipients, the pubertal surge of gonadotropin secretion appears intact but, at least in boys, sex steroid levels rise insufficiently [64]. This is associated with a blunted augmentation of GH pulses and a subnormal pubertal height gain [20,64]. A recent report of Finnish patients transplanted at a mean age of five years reported more normal sex steroid patterns at puberty, suggesting that the use of low steroid doses and transplantation early in childhood may preserve the normal endocrine events during puberty [65].

In addition to suppressing GH secretion, experimental and clinical evidence suggests that glucocorticoid exposure may suppress GH action on the target organ level. Hepatic GH receptor expression is dose-dependently reduced by growth-suppressive doses of methylprednisolone treatment in rats [66,67] and circulating GH binding protein, reflecting hepatic GH receptor content, is low in pediatric kidney allograft recipients [20,68,69]. The steroid-induced alterations of GH secretion and action would imply reduced availability of IGF-1, the principal downstream mediator of GH. Indeed, reduced IGF-1 gene transcription has been demonstrated in glucocorticoid treated animals [67,70]. Surprisingly however, plasma IGF-I levels in glucocorticoid-treated renal allograft recipients are in the normal range [20,68,69]. This discrepancy may be explained by additional steroid-induced alterations of IGF-1 mRNA stability, post-trancriptional processing and secretion of IGF-1 peptide or increased plasma half-life by altered IGF-1 binding protein composition [70]. In contrast to the normal immunoreactive plasma IGF-1 concentrations, IGF 'bioactivity' was found significantly suppressed in patients on glucocorticoid treatment [68,71]. It has been suggested that glucocorticoids may induce the production of IGF inhibitors [71]. These putative IGF inhibitors appear to have a molecular weight of 12–20 kD, but have not been characterized any further to date.

In addition to these endocrine effects, glucocorticoids interfere with growth and endochondral ossification by multiple mechanisms on the level of the growth plate chondrocyte. They inhibit proliferation, suppress autocrine/paracrine IGF-1 synthesis, downregulate chondrocyte GH and IGF-1 receptor expression and interfere with the sulfation and mineralization of epiphyseal cartilage matrix [72,73].

Strategies to optimize post-transplant growth

Glucocorticoid treatment has profound effects on endocrine functions and growth performance in pediatric allograft recipients, but also on multiple other systems including body composition, lipid metabolism, bone mineralization and blood pressure regulation. The severe consequences of steroid-related side effects for long-term health and quality of life have stimulated the search for alternatives to daily methylprednisolone therapy in pediatric organ transplant recipients [74].

Modification of steroid therapy

Registry results and evidence from clinical trials suggest that improved longitudinal growth can be achieved without any risk for long-term graft function when the same total dose of corticosteroids is applied in an alternate-day rather than a daily fashion [22,27]. In the NAPRTCS registry, alternate-day steroid dosing (performed in 17% of all transplant recipients) predicted a positive change in height SDS during the first two post-transplant years independently of the absolute corticosteroid dose. In both studies, a gain in standardized height by 0.5 SD was observed with alternate day steroid dosing, contrasting to an unchanged height SDS observed on daily steroids. An analysis of long-term (five to seven years) growth performance in 30 young renal allograft recipients receiving alternate day steroids demonstrated nearly complete catch-up growth, from −1.9 to −0.4 SDS, in children aged two to five years at time of transplantation and with stable growth observed in children who received a graft at age <2 years (height SDS of −1.1 at time of transplant and at seven years post-transplantation) [32]. Due to its well established safety, alternate-day administration is the preferred mode of steroid therapy in many experienced centers beyond the first post-transplant year in allograft recipients with low immunological risk. In the 2010 Annual Report of the NAPRTCS registry, 34% of allograft recipients received alternate-day steroid treatment four years post-transplantation [2].

Steroid withdrawal

In the first two decades of pediatric 'kidney' transplantation, complete steroid withdrawal was problematic since steroid-free immunosuppressive protocols based on cyclosporin A (CsA)and azathioprine alone resulted in deterioration of renal function in at least 50% of children [21,75]. Nonetheless, several uncontrolled small scale studies suggested that if successful, steroid withdrawal may result in significant catch-up growth [76,77]. In the past 15 years the introduction of more powerful immunosuppressive agents, in particular the nearly complete replacement of CsA by tacrolimus and of azathioprine by mycophenolate-mofetil, has increased the therapeutic window for steroid withdrawal in kidney transplantation [78]. In the latest Annual Report of the North American Pediatric Renal Transplant Study (NAPRTCS) Registry the proportion of steroid-free patients three years post-transplant is 17% for cadaveric and 25% for living-related allograft recipients over the whole observation period 1996–2009 [2]. The fraction of patients receiving steroids 30 days after transplantation has steadily decreased from 95% in the 1990s to 49% in 2009.

Both late and early steroid withdrawal protocols have been evaluated in the past decade:

'Late steroid withdrawal' appears to be possible in at least 70% of pediatric allograft recipients receiving tacrolimus. In 52 children weaned off steroids six months post-transplant, mean height SDS had increased from −2.41 to −1.31 after three years [79]. Using a CsA and MMF based protocol, Höcker et al. successfully discontinued glucocorticoids in the second post-transplant year in 20 selected patients with major side effects of steroid therapy, stable graft function and not more than one preceding rejection episode [80]. After four years of follow-up, height SDS had increased from

−1.6 to −1.0, compared to an unchanged standardized height in a matched control group on continued daily methylprednisolone. Catch-up growth was limited to six prepubertal children who improved from −2.24 to −0.77 SDS, whereas pubertal patients had no significant benefit from steroid withdrawal with respect to growth. Other sequelae of steroid therapy such as obesity and hypertension were considerably improved.

The growth promoting efficacy of 'early steroid withdrawal' has been assessed in the randomized controlled TWIST trial, in which tacrolimus and MMF was administered to all 196 patients and randomization was made for either ongoing daily steroids or induction therapy with the monoclonal antibody daclizumab and steroid withdrawal on post-transplant day five. A significant improvement in standardized height was seen in the steroid withdrawal arm after six months (0.16 vs. 0.03 SDS, $P = 0.005$), along with significant improvements in metabolic and blood pressure control. Graft survival and rejection incidence did not differ at six months follow-up [82]. Extended outcome results of this trial have not been published to date. Several smaller studies exploring early steroid withdrawal with poly- or monoclonal antibody induction therapy with historical control groups obtained similar results during one to two-year follow-up periods, with excellent safety records and improved growth [82–85]. It seems, however, that the growth benefit of early steroid withdrawal may attenuate over time. In a prospective comparative trial evaluating the effect of early steroid withdrawal in 95 children on tacrolimus/MMF based protocols, mean height SDS improved from −2.4 at transplantation to −1.5 and −2.2 at one year, −1.3 and −1.9 at two years and −1.0 and −1.2 at five years in the steroid-treated and steroid-free patient groups respectively [85].

Steroids are still a cornerstone of immunosuppression in many pediatric 'liver' transplantation programs. Several uncontrolled [86] and one controlled study [87] evaluated the concept of steroid withdrawal in pediatric liver allograft recipients. In five uncontrolled studies attempting steroid withdrawal at 3–58 months post-transplant with concomitant CsA therapy, acute rejection episodes occurred in 7–27%, chronic rejection in 4–13% and graft loss or patient death in 3–13% of the recipients. In contrast, McDiarmid et al. [87], weaning steroids with very rigid inclusion criteria in 23 patients at a mean interval of three and a half years post-transplant, noted a 6% acute rejection rate and no resultant chronic rejection, graft loss or patient death. Unfortunately, no significant benefit of steroid withdrawal on linear growth compared to a control group on continued steroid therapy was observed. In three studies attempting steroid withdrawal within the first post-transplant year using concomitant tacrolimus immunosuppression, the incidence of acute rejection varied from 14 to 29% [86]. Reding et al. compared the impact of steroid withdrawal on linear growth in recipients receiving either CsA or tacrolimus [86]. Within 12 months of steroid discontinuation, standardized height slightly worsened with CsA (−0.2 to −0.4) compared to a modest improvement in the tacrolimus (−0.2 to +0.3) group. The observed difference could be due to the much shorter steroid exposure in the patients receiving tacrolimus (weaned on average 1.2 years post-transplant) compared to those treated with CsA weaned five to six years post-transplant.

In many pediatric 'heart' transplantation programs steroids are discontinued early in the post-transplant period; more than 50% of heart allograft recipients are on steroid-free maintenance immunosuppression 12 months post-transplant [88]. In an analysis of 25 infants who underwent heart transplantation at <3 months of age, growth performance was compared in 18 patients weaned off steroids seven months post-transplant versus eight patients continued on steroid therapy [89]. There was no difference in standardized height at follow-up between the eight patients maintained on low-dose steroids and the 18 who underwent steroid withdrawal. However, the overall post-transplant growth performance in this group of cardiac allograft recipients was rather poor. The mean standardized height worsened from −1.08 at transplant to −1.8 at four years post-transplant.

Steroid avoidance

With the increasing number of new potent and selective immunosuppressive agents, complete steroid avoidance has become a realistic option in pediatric organ transplantation. In addition to the advantage of preventing all side effects of glucocorticoid treatment from the beginning, animal data have suggested that the steroid avoidance strategy may even facilitate the induction of tolerance against allogenic tissue.

Steroid avoidance protocols have been pioneered in 'cardiac transplantation'. Almost universal catch-up growth has been observed in pediatric heart transplant recipients. In one large series, only 12% of recipients were below the fifth height percentile five years after transplantation [59].

In 'kidney transplantation', the Stanford group first reported favorable early results with entirely steroid-free immunosuppression in 50 children who received a combination of tacrolimus and MMF or sirolimus, complemented by IL-2 receptor blockade during the first 6 post-transplant months [90,91]. After a mean of 22 months follow-up, acute rejection had occurred in only 8% of the children, as compared to 32% in historical matched control patients on a steroid-based regimen. Growth was superior in the steroid-free group. This was most marked in children younger than five years, who gained 1.7 ± 0.8 SDS within the first 12 post-transplant months compared to an unchanged mean standardized height in the steroid-treated controls. This promising preliminary experience stimulated a three-year multicenter trial in which 130 children undergoing primary kidney transplantation were randomized to steroid-free or steroid-based immunosuppression, with concomitant tacrolimus, mycophenolate and standard dose daclizumab in the steroid-based and extended dose daclizumab in the steroid-free group [92].

Disappointingly, no significant difference for linear growth was observed at three years in those patients who still had growth potential at transplantation, with −0.92 ± 2.29 height SDS change in the steroid-free versus −0.96 ± 1.16 SDS in the steroid based study arm ($P = 0.732$). Only among children younger than five years those on steroid-free immunosuppression tended to display a superior change in height SDS, but this effect was lost at one and three years after transplantation. There were no differences in the rates of biopsy-proven acute rejection (16.7 vs. 17.1%; $P = 0.94$) or graft survival (95 vs. 90%) at 3 years follow-up. The steroid-free group showed lower systolic blood pressure and lower cholesterol levels.

Steroid-free immunosuppression has first been applied at the pediatric 'liver transplant' program in Brussels, Belgium. Twenty children receiving combined tacrolimus and basiliximab were compared with 20 matched historical controls treated with tacrolimus and steroids. The tacrolimus-basiliximab group exhibited higher rejection free survival rates and significantly better growth rates in the first year after transplantation. The slight growth retardation (−0.57 SDS) at time of transplantation was completely caught up

within six months post-transplant in the steroid-free patients, whereas growth recovered at a slower pace in the steroid-treated children [93]. After this positive initial experience, the same protocols were compared in two prospective trials including 72 and 84 pediatric liver allograft recipients respectively [94,95]. Both trials found similar patient and graft survival rates in the study arms but significantly longer rejection-free intervals, lower infection rates and reduced need for antihypertensive agents in the basiliximab-tacrolimus treated patients. Within three years, the steroid-free patients showed complete normalization of standardized height (mean −1.16 SDS at baseline, 0.21 SDS at three years) while the patients on maintenance steroids showed incomplete catch-up growth (−1.15 SDS at baseline, −0.42 at three years, $P < 0.001$) [95].

Growth hormone treatment

Chronic administration of rhGH has proven remarkably successful in the treatment of growth failure in children with chronic renal insufficiency, and resulted in a steady increase of height SDS at the time of transplantation in pediatric allograft recipients over the past 15 years. Hence, rhGH treatment has been considered as an alternative to modification or withdrawal of steroid treatment in growth retarded renal allograft recipients who do not exhibit post-transplant catch-up growth.

Experimental support for this concept has been provided by animal studies showing that the growth-depressing effects of glucocorticoid treatment are compensated by rhGH administration [96], mediated in part by stimulation of circulating or local IGF-I synthesis [97–99].

Numerous uncontrolled trials have suggested a growth-promoting effect of rhGH in children with renal allografts with up to three years of therapy [68,69,100–106], with a median annual standardized height increment of 0.5 SDS during the first two treatment years. Four randomized controlled trials confirmed the short term efficacy of rhGH in renal allograft recipients [107–110]; in the two larger trials one-year growth velocity increased to 7.7–9.0 cm/yr as compared to 4.2–4.6 cm/yr in the control groups. A long-term growth assessment in 513 pediatric post-transplant patients and 2263 untreated controls followed in the NAPRTCS registry suggested increased cumulative height gain and superior final height (−1.83 ± 0.14 vs. −2.63 ± 0.05 SDS) associated with rhGH treatment [33].

Successful growth stimulation was also achieved by rhGH treatment in seven liver allograft recipients on prednisolone. In the first treatment year, annual growth velocity increased from 3.9 to 8.2 cm, and median height SDS from −2.7 to −2.1 [111].

It has been argued that rhGH may not only antagonize the growth-inhibitory, but also the immunosuppressive effects of glucocorticoids. Two large controlled trials and the registry analysis of pediatric renal allograft recipients were powered to evaluate any changes in the risk of rejection and graft failure during rhGH treatment. While none of the studies found an increase in the overall incidence of rejection episodes or the rate of renal function decline, the prospective trials noted an increased risk of subsequent rejection episodes in those patients who had more than one rejection prior to treatment.

Summary

In conclusion, while large individual variation of growth and pubertal development exists in solid organ transplantation, many pediatric allograft recipients still grow up to become undersized adults. Major determinants of post-transplant growth and development are the age and the height deficit attained at time of transplantation, long-term graft function, the nature of the underlying disorder and the choice of maintenance immunosuppressive therapy. Complete withdrawal or even primary avoidance of steroids appears possible in the majority of children undergoing solid organ transplantation. However, the early growth-promoting efficacy and immunological safety of minimized steroid exposure awaits confirmation in long-term trials. Growth hormone treatment may be an alternative to steroid withdrawal in patients with high-immunological risk. The transduction of these approaches into routine clinical practice should allow improved catch-up growth and a normal final adult height in many, if not most, allograft recipients.

CHAPTER 119

Cognitive Development and Functional Outcomes after Organ Transplantation

Estella M. Alonso, Saeed Mohammad, and Lisa G. Sorensen
Northwestern University Feinberg School of Medicine; Ann & Robert H. Lurie Children's Hospital of Chicago, Chicago, IL, USA

Introduction

Solid organ transplantation is expected not only to prolong life and reverse the consequences of end-stage organ failure, but also to result in a health state that is desirable and a marked improvement from the pretransplant condition. In considering all aspects of health in children, physicians must examine not only physical outcomes but also psychosocial outcomes, including cognitive development and scholastic function. However, considerable gaps in this area of research exist in pediatric heart, kidney, liver and intestinal transplantation. In this chapter, we will review recent reports examining cognitive function in pediatric solid organ transplant recipients and discuss their findings in the context of present knowledge.

Assessment of cognitive development is complicated by the need to use age appropriate methods that investigate emerging skills. In assembling groups of children who have survived uncommon medical interventions, such as organ transplantation, the resulting samples are often small and include a heterogeneous mixture of patients with a wide array of ages. Thus, investigators find themselves testing these patients with different tools geared for different ages and attempting to collapse the results to form meaningful conclusions. To this point, many studies of cognitive development in children who have received solid organ transplantation have been limited to single center studies of relatively small samples. However, during the past few years some important studies have been published that help broaden our understanding of developmental outcomes and rehabilitation in these patients.

Cognitive function

Developmental outcomes can be measured in several ways dependent upon the age at testing. Measurement of infant development focuses on motor function, social and environmental interaction and language development and adaptive skills while older children can be tested for intelligence, academic achievement, behavior and more specific cognitive domains such as attention, executive function, language, visuospatial processing, learning and memory. Abnormalities that are observed later in childhood are more predictive of deficits that are likely to persist into adulthood. Many forms of chronic disease in childhood can have a negative impact on cognitive development. Children that experience solid organ failure during infancy may be at particular risk for cognitive delay since they experience the onset of their illness during a period of rapid neurologic maturation. The relative contributions of pretransplant versus post-transplant neurodevelopmental injury have not been carefully studied. Likewise, longitudinal studies of neurocognitive outcomes and developmental rehabilitation following solid organ transplant are limited.

Across the multiple organ recipient groups neurocognitive studies have included some of the same measures. One of the most commonly studied areas is intelligence, which is most frequently measured by intelligence quotient (IQ). IQ is most frequently measured with the Wechsler scales. Current versions for children are the Wechsler Preschool and Primary Scale of Intelligence, 3rd edition (WPPSI-III) and the Wechsler Intelligence Scale for Children, 4th edition (WISC-IV), which are standardized to a score of 100 with a standard deviation of 15 [1,2]. Developmental delay can be categorized as "mild to moderate", typically a "full scale intelligence quotient" (FSIQ) of 71–85, and "serious", patients with a FSIQ $\leq$ 70, which is two standard deviations below the normative population. Patients in the seriously delayed category have IQ scores typically indicative of mental retardation while those in the mildly to moderately delayed category have intellectual functioning that is in the borderline deficient to low average range [3]. Learning disability (LD) is also an outcome that has been frequently studied, but the definition of LD has evolved over time. In some studies, the operational definition of LD is a discrepancy of 15 points or more (one standard deviation) between intellectual ability as measured by IQ and academic achievement in reading and/or math computation [3]. Learning disability can also be measured by parental report of an established diagnosis, which is expected to be accurate, especially if the patients have been tested to support special education services within their school systems.

Kidney recipients

Chronic renal failure has been demonstrated to have a negative impact on neurocognitive development, which may be alleviated by renal transplantation. Intelligence levels in children following kidney transplant are usually in the normal to low normal range with one study reporting a mean FSIQ of 87 [4] (normative mean 100, standard deviation 15) and a more recent study reporting a median FSIQ of 97 in 27 recipients with only 22% having a FSIQ $<$ 85 [5]. It has been suggested that renal transplant recipients have lower verbal compared to non-verbal performance, shorter

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

attention spans and difficulty with memory, especially those who have had renal disease since birth [4]. In children who are older at the time of transplant, significant deficits have been observed in performance IQ, which measures intellectual ability that is less dependent upon one's fund of knowledge, vocabulary and basic knowledge and more dependent on fluid mental abilities [5]. Motor skills are also significantly delayed in renal transplant recipients as compared to norms with deficits observed in multiple areas of function including pure motor tasks $P < 0.001$, adaptive fine motor tasks $P = 0.01$, adaptive gross motor tasks $P < 0.001$, and static balance $P = 0.001$) [5]. Altered motor skills can play a pivotal role in peer relationships, and academic tasks such as drawing and handwriting.

Few longitudinal studies measuring cognitive function before and after renal transplantation have been conducted. A recent study assessed six children with chronic kidney disease (CKD) before and after transplantation and compared their outcomes to 28 children with moderate to severe CKD and 23 healthy controls [6]. The renal transplant recipients had on average a 12 point increase in FSIQ, even though they were tested relatively early in the first post-transplant year (mean six months post-transplant). Neither the CKD group nor healthy controls demonstrated this same trend.

Risk factor analysis for determinants of lower cognitive outcomes has been attempted in multiple groups of renal transplant recipients despite small sample sizes. Early onset of renal disease, longer duration on dialysis, pretransplant morbidity (e.g seizures) [4], and lower socio-economic status are believed to have a negative impact on developmental outcome [7–9]. Yet, other studies [5] have shown no relationship between medical factors and cognitive outcomes. However, it is generally accepted that avoiding prolonged dialysis may mitigate some of these deficits. Prolonged exposure of the developing brain to the complications of end stage renal disease including hypertension and uremia are hypothesized to have a negative effect on neuronal myelination and synaptic development. In fact, early transplantation has been shown to improve head circumference from a standard deviation score (SDS) of -1.4 to -0.9 ($P = 0.02$) and significantly improve gross motor, social and language development quotients ($P = 0.02$–0.0006) in infants one year post transplant [10].

Following renal transplantation, approximately 70% of patients receive routine classroom instruction while the remainder require some special educational support or have a history of serious neurological morbidity such as stroke [4,7]. There are a number of long-term studies that have reported final education levels that are lower than national averages [11,12]. While others have revealed education levels that were similar to the general population and their sibling controls [13].

Liver recipients

Even from the earliest experiences in pediatric liver transplantation clinicians have been particularly interested in neurocognitive outcomes in these recipients. Multiple studies have shown that children who have survived liver transplantation are more likely to have significantly lower intelligence than healthy children [14–18]. Onset of liver disease in infancy is thought to increase the risk of neurocognitive delay, which may persist even after successful liver transplantation. There are several unique aspects of the pediatric liver recipients that could theoretically place them at risk for cognitive deficits. Since approximately half of pediatric liver recipients are less than two years of age at transplant, it has been particularly important to study neurocognitive function in this infant population. Patients with chronic liver disease resulting in portal hypertension may develop clinical signs of chronic hepatic encephalopathy (HE). Serum levels of neuro-inhibitory substances, including ammonia may not only alter mental processes during periods of elevation, but may also contribute to altered function after successful transplantation by causing irreversible injury. Finally, calcineurin inhibitors may cause significant neurotoxicity and pediatric liver recipients appear to be at higher risk for this complication than other solid organ transplant recipients [19–21].

A series of studies in the early experience of liver transplantation were conducted at the University of Texas and examined patients with end stage liver disease and biliary atresia, finding that their IQ and developmental functioning ranged from borderline low to average. Early disease onset, liver function, and growth parameters (especially in younger children) were highlighted as important correlates of intellectual deficits. Younger patients (0.5–5 years) fared worse; overall cognitive functioning on the Bayley or Stanford-Binet fell in the borderline range with extremely low motor skills. Infants' "mental and motor" development were associated with growth parameters whereas developmental outcomes in older children were more closely related to liver function [22]. A small, recent study (n = 15; age 4–20 months) of infants with Biliary Atresia confirms these earlier findings, demonstrating significant delays particularly in very young patients [23]. In this study, all scales on the Mullen test were below norms, with the weakest performance apparent in "gross motor and expressive language skills". Modest associations were found with liver function, growth parameters, and age at Kasai procedure. Of note, nearly half the sample was primarily Spanish speaking and required an interpreter for testing, so the language results should be interpreted cautiously.

The University of Texas group also conducted two small studies examining neuropsychological outcomes after transplant by comparing pediatric liver transplant recipients to controls with cystic fibrosis (CF). Both studies reinforced and expanded on earlier findings in patients with end stage liver disease suggesting that deficits noted prior to transplantation were not reversible [24,25].

Historically, there have been very few studies successful in examining cognitive function before and after liver transplantation. The most important of which was a longitudinal study of infants with biliary atresia. While awaiting transplant, these patients had mental and motor developmental scores that are within the low average range [26]. Follow-up testing after transplantation revealed that scores dropped further in the immediate post-transplant period and only recovered to pretransplant levels at 12 months after the procedure. This observation suggests that infant recipients do not exhibit developmental "catch-up" until after the first post-transplant year. This study also demonstrated that infants with longer hospitalizations and those with growth impairment at transplant had more significant delays.

The most recent studies examining cognitive function in liver transplant recipients have mostly reinforced earlier findings. IQ has nearly universally fallen below published norms [15,27,28]. Pediatric LT patients clearly have a downward shift in IQ, with mean IQ scores typically in the mid-80s to low-90s and an increased prevalence (up to 27 vs. 2% expected) of scores falling below 70 [14,16,28,29]. Of note, the only multicenter study to examine IQ in pediatric LT patients, and the largest sample (n = 144; age 5–6), found the smallest proportion of patients with a FSIQ at or below 70 (4%), although FSIQ, verbal IQ (VIQ), and

performance IQ (PIQ) were all significantly below norms (FSIQ = 94.7 ± 13.5; VIQ = 95.0 ± 13.8; PIQ = 94.9 ± 13.5) and twice as many as expected (26 vs. 14% expected) had mild to moderate IQ delays (IQ = 71–85) [28]. Preliminary analysis of follow-up of this cohort suggests that IQ does not improve within a two-year interval.

Learning disability and school performance have also been examined in LT recipients. One study of long-term recipients, age three to nine years, revealed that almost 20% had an IQ of less than 70 and that 26% had a discrepancy between IQ and academic achievement thus meeting the definition of learning disability [30]. In that study, many of the children with low IQ and learning problems had not been identified by their school systems. A recent survey of school outcomes conducted by the studies of pediatric liver transplantation (SPLIT) network revealed that 40% of patients have required some type of special educational services, with 8% having been classified as learning disabled and 5% having a reported IQ of less than 70 [31]. Missed school days may also contribute to compromised school function. Data from the SPLIT network suggests that 30–40% of patients in long-term follow-up miss more than ten days of school per year, with teens having the highest rate of absences [31].

Heart and lung recipients

Studies performed in children with cyanotic heart disease consistently show that chronic cyanosis is associated with progressive cognitive impairment and that earlier correction of cyanotic heart disease leads to more favorable cognitive outcomes [32–34]. Other factors including circulatory arrest, cardiopulmonary bypass and embolic events have also been associated with lower than expected developmental outcomes [32–38]. Research findings examining developmental status of pediatric heart recipients, primarily infants, are detailed in a review by Chinnock et al. [39]. In general, reports describing developmental outcomes in children who have received cardiac transplantation suggest that the majority of these patients have intelligence in the low-normal range which is comparable to other children with surgically corrected congenital heart disease. However, a significant percent, perhaps as high as 40%, have intelligence scores in the low to borderline range (FSIQ < 85) and up to 10% may have significant neurological injury, frequently related to ischemic events which could preclude testing. Freier et al. in 2004, reported the longitudinal neurodevelopmental assessment, using the Bayley scales, of 39 patients transplanted as young infants (median age at transplant 53 days) [40]. Patients were tested four to six weeks after transplant and then every 6–12 months thereafter. The mean mental developmental index (mdi) of the group was within normal limits and the mean psychomotor developmental index (PDI) was in the mildly delayed range. Wray et al. in 2006 reported a longitudinal assessment of 34 older patients who received heart and lung transplants spanning a wide age range from 1.3–15.3 years [41]. Cognitive function and academic achievement were tested at 12 and 36 months following transplant. Mean scores of intelligence and academic achievement were within the normal range and appeared stable over the testing period with the exception of a drop in arithmetic scores for younger children. Several studies have examined risk factors for lower cognitive outcomes finding that circulatory arrest, birth head circumference, prolonged hospital stay, cardiopulmonary bypass, embolic events, waiting time to transplant and pretransplant diagnosis are all potentially associated with variability in developmental outcomes in this patient group [35–39,41]. Studies that have examined the impact of primary diagnosis suggest that patients transplanted for cardiomyopathy typically have higher scores than those with a history of cyanotic congenital heart disease. One such recent study included 18 recipients age 6–16.5 years and identified that mean FSIQ, VIQ and PIQ were all significantly lower than test norms with 26% scoring in the range of mental retardation (<70) [42]. When patients were grouped by history of neurological injury, such as abnormal neuroimaging results prior to transplant, it was clear that this high risk group was driving the mean difference, with all other patients scoring within the normal range. In this study, abnormalities on brain imaging were associated with the number of cardiac surgeries before transplant and with having congenital heart disease.

Another study of 21 heart recipients median age of two and half years (range 14 months to ten years) identified not only lower global intelligence, but also deficits in expressive language ($P = 0.01$, 46% >1 SD below norms), adaptive behavior ($P < 0.005$) and visual-motor ($P = 0.01$), and fine-motor skill ($P < 0.005$). Authors suggested that some aspects of adaptive behavior might have been influences by delays in the ability to use spoken language and poor coordination of motor skills [43].

Despite the encouraging results of studies examining intelligence in this patient group, the school performance of cardiac transplant recipients appears to be lower than healthy children and the prevalence of behavior problems may increase with time after transplantation [44]. Ikle et al. studied 26 children who had received cardiac transplants for hypoplastic left heart syndrome using the Vineland scales. The analysis found that many scored greater than 1 SD below the mean for measures of daily living skills (39%), socialization (29%), communication skills (48%), and overall adaptive behavior (52%) [45]. These findings suggest that interventions that target improvement in these skill areas might improve functional outcomes, including school performance in this population.

Lung transplant recipients have not been studied as extensively as cardiac recipients. A study that focused on a cohort of 18 infants and 11 toddlers who underwent lung transplantation found that 40–50% of infants and 20–30% of the toddlers had severe developmental delay. Of note, two of the infants with severe delay had significant hearing impairment. Patients were also tested relatively early in their postoperative course; more than 50% tested within the first year [46].

As mentioned above, Wray et al. [41] have reported mean scores for intelligence and academic achievement in the normal range. These same authors, studied a group of 99 patients, aged three to 17 years, consecutively listed for heart, lung or heart/lung transplantation to determine differences in cognitive delay between differing diagnostic groups. The study included 56 patients with congenital heart disease (CHD; 34% listed for heart/lung), ten patients with cardiomyopathy (CM), 15 patients with cystic fibrosis (CF; 100% awaiting lung) and nine with primary pulmonary hypertension (PPH; 100% awaiting lung). The mean scores for the group for all aspects of intelligence and academic achievement were significantly lower than the normative values. Ten percent (eight patients with CHD, one with CM) had an IQ of less then 70 and 23 % of the overall group had academic achievement that was more than two standard deviations below the norm. Underachievement or learning disability, defined as standardized scores for academic achievement that are more than one standard deviation below IQ,

was observed in 23% (22% in math and 14% reading). In general, the CM and PPH patients exhibited better performance than the CHD and CF groups. Bivariate analysis suggested associations between diagnosis, cumulative time spent in hospital since birth and age at assessment of IQ. However, in multivariate analysis, only time spent in the hospital accounted for a significant proportion of the variance (13%) in both IQ and academic achievement. These findings further highlight the impact of the duration of chronic disease on cognitive outcomes in children who will undergo transplantation. This effect may not be fully reversible following successful organ replacement.

Intestine recipients

Intestinal Transplant patients have been reported to have a high prevalence of cognitive delay [47–49] and patients may display worsening developmental delay in the first two months after transplant, similar to what has been reported in liver transplant recipients. Among pediatric patients with intestinal failure, the most studied group is premature infants with necrotizing enterocolitis (NEC). Several studies have found a higher prevalence of neurodevelopmental impairment (NDI) among those with NEC versus those without, even when groups have similar gestational age and birth weight. More serious NEC (Bell's Stage III) and NEC requiring surgery have been found to be associated with higher risk for NDI compared to NEC that can be managed medically or absence of NEC. However, it is unclear whether this association reflects severity of disease or factors related to surgery and complications (e.g., proinflammatory cytokines, transient blood pressure changes, more serious nutritional deficits, and more episodes of sepsis). Multivisceral transplant recipients are also more delayed than infants receiving liver only transplantation. These patients generally recover more slowly and have undergone a more extensive surgical procedure than patients receiving liver, heart or kidney transplantation. Some patients may have an ostomy, which necessitates repeat surgery for closure. Many continue to require parenteral nutrition while the transplanted intestine adapts to its new environment. Thus, intestinal recipients have a relatively larger burden of chronic disease than other solid organ recipients that may contribute to the slower developmental rehabilitation. Common risk factors experienced by infants with end stage liver disease compounded by chronic malnutrition and prolonged hospitalization and prematurity likely play an important role.

Cognitive function summary

The existing body of literature examining neurodevelopmental outcomes in pediatric solid organ transplant recipients is growing. The need to use different scales to measure cognitive ability in different age groups coupled with the small sample sizes available to study make it difficult to reach comprehensive conclusions. Children that receive heart transplantation may have better cognitive outcomes than expected considering the results of older studies of children with cyanotic congenital heart disease. The cognitive outcomes of both liver and kidney transplant recipients may also be improving, but many still require special educational resources. Infants requiring intestine or liver and intestine transplant are probably at the highest risk for cognitive delay, but longitudinal studies that affirm that these delays are not recoverable are lacking. In all cases neurologic co-morbidities increase the risk of delay. Despite recent advances, a significant proportion of both liver and heart recipients have serious developmental delay and/or neurological injury. Risk factors for developmental delay are still being examined, but strategies that limit the duration of unsupported organ failure and chronic malnutrition, especially during infancy, are likely to have a positive impact.

Solid organ transplant recipients display a wide range of developmental outcomes which include both patients with normal development and those with significant delays, see Table 119.1. While the exact mechanisms that contribute to these delays are not fully elucidated, factors such as long-term hospitalization, chronic malnutrition in the pretransplant period, and a history of surgical complications likely all play a role, see Figure 119.1. The primary care physician is an important partner in assisting in the early diagnosis of developmental delay and in facilitating appropriate evaluation and intervention within the patient's community. Early intervention with physical and occupational therapy can curtail physical disabilities. Prompt recognition of cognitive delay and abnormal school function can aid in securing special educational resources early in their academic experience. Again, setting expectations for the family and school system regarding cognitive outcomes is an important aspect of their anticipatory health care.

Functional outcomes

Children who survive organ transplantation are faced with multiple hurdles during the process of rehabilitation and, even when recovery from the transplant process is deemed complete, their health status often more closely resembles that of children with chronic diseases than that of their healthy peers. These patients struggle with co-morbidities that can include both physical and developmental deficits. These deficits become even more apparent when these patients, who were transplanted as children, grow into young adulthood and endeavor to live independently and find their place in society.

Assessment of functional outcomes includes measurement of health related quality of life (HRQOL) and specific measures of everyday living skills. Direct patient testing of physical skills and cognitive status can also be incorporated into functional outcomes assessments. Few pediatric solid organ recipients have obvious chronic physical disabilities, unless they have end stage graft failure or suffer a severe neurological injury during the transplant process. However, as detailed above, many have obvious cognitive deficits. Direct patient testing, such as neurocognitive testing or exercise/strength testing, allows investigators to gather specific information regarding functional skills that contribute to a patients' physical and psychosocial HRQOL. This information is essential to plan appropriate rehabilitation service and to assess the patient's ability to meet age appropriate expectations. Rehabilitation following transplant should focus on both physical and cognitive function and ongoing outcomes assessment should be sensitive to changes in both of these domains. Understanding deficits across this spectrum is vital to anticipatory guidance for education in intermediate follow-up during childhood, and also in job placement as these children mature to adulthood.

Health related QOL has been defined as an individual's subjective experience of their illness, and the impact that illness and its treatment has on the individual's functioning. Transplantation often leads to improved physical health. However, the impact of the medications, hospitalizations, clinic visits and invasive procedures, as well as the impact of living with the uncertainty of graft survival and long-term health status may all affect an individual's HRQOL.

Table 119.1. Intelligence testing in pediatric solid organ transplant patients

Publications	Sample size	Age range	Intelligence quotient (IQ)	Low or borderline IQ
Kidney				
Qvist et al [76]	33	7–12 yrs	Mean Verbal IQ 87.5 ± 13.4 Non-verbal IQ 87.5 ± 14.9	9% IQ < 70 42% IQ ≥ 70 < 90
Falger et al [5]	27	6–17 yrs	Median (range) FSIQ 97 (49–133) Verbal IQ 104 (50–146)	4% IQ < 70 19% IQ ≥ 70 < 85
Liver				
Adeback et al [14]	21	4–16 yrs	Mean Overall IQ 86.6 Verbal IQ 90.6 Non-verbal 84.5	15% FSIQ < 70 35% FSIQ ≥ 70 < 85
Sorensen et al [28]	134	5–7 yrs	Mean FSIQ 94.7 ± 13.5 Verbal IQ 95.0 ± 13.8 Performance IQ 94.9 ± 13.5	4% FSIQ ≤ 70 26% FSIQ > 70 ≤ 85
Heart/Lung				
Wray et al [41]	22 Heart and Heart-Lung	Mean age 7.88 ± 5.1 yrs	Mean Overall IQ 103.7 ± 13.3 (12 months post-transplant) Overall IQ 100.2 ± 12.9 (3 years post-transplant)	100% IQ ≥ 85
Haavisto et al [42]	18 Heart and Heart-Lung	6–16 yrs	Mean FSIQ 85.6 ± 18.8 Verbal IQ 89.8 ± 22.7 Performance IQ 82.2 ± 18.9	26% IQ < 70 16% IQ ≥ 70 < 85
Uzark et al [43]	21 Heart	1–10 yrs	Mean Overall IQ 86.7 Verbal IQ 88.4 Non-verbal IQ 87.5	43% Overall IQ < 85

All tests standardized to a score of 100 with a standard deviation of 15. Normative population expectations 14%, IQ > 70, ≤85, and 4% IQ < 70.

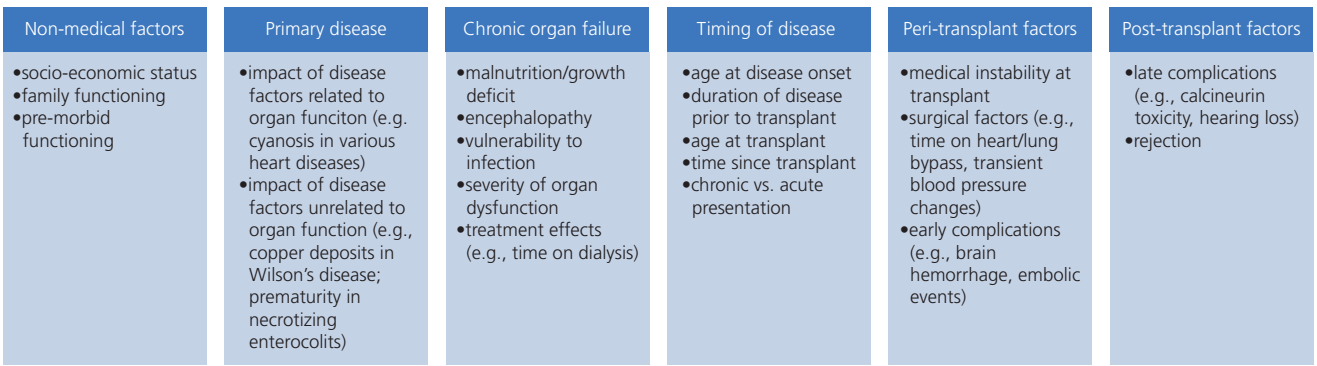

Figure 119.1. Factors impacting cognitive function in solid organ transplant recipients.

Health related QOL can be measured from either a generic or disease specific perspective. It can also be measured from the parent or child's perspective, and instruments must be developmentally sensitive, with age-appropriate versions. Assessment of HRQOL facilitates the evaluation of patient outcomes by providing a more thorough understanding of the child's and family's experience of solid organ transplant and its treatment.

Surveys of generic HRQOL include general questions such as: "Do you have trouble lifting something heavy?" or "Does your child have a low energy level?" — questions that are relevant for any child regardless of their health status. Assessing HRQOL from this generic perspective allows us to compare transplant recipients to both healthy children and to those with other chronic diseases. However, these questions may not tap into some of the real issues for children living with a transplant since many of these issues are unique. Disease specific HRQOL measurements help us understand these more subtle changes in health status over time and are likely more sensitive to changes in treatment and graft function. Most studies of HRQOL following solid organ transplantation have utilized only generic instruments, but now as new disease specific tools are available [50], data regarding disease specific HRQOL is emerging.

To measure HRQOL in young children parents must serve as proxies to report their child's status. However, older children, age five and above, may be able to accurately report their own status. Correlation between parent and child report in adolescents is reasonable, except for domains that are related to mostly internalized symptoms, such as pain or anxiety. Parent reports for school function and peer relationships are frequently well correlated, since these are issues older children frequently discuss with their family. Assessment of both parents' and the child's perspective are likely complimentary and inclusion of both respondents creates a fuller representation of the child's outcomes. Likewise, generic and disease specific measurements provide complementary information and inclusion of both in study designs is optimal.

We will briefly review functional outcomes assessment individually across all the solid organ groups, but it is important to note that these recipients experience very similar issues. Focus group discussion and individual interviews with recipients and their parents consistently identify medication and treatment related issues as highly important [51,52]. Measurements of disease specific HRQOL have identified treatment anxiety, recurring pain and discomfort, and concerns related to medication side-effects as significant issues across age groups and from both the child and parent perspective [50]. Immunosuppressive management strategies are evolving to reduce medication related physical side-effects such as weight gain and short stature. Evaluations of how these aspects of HRQOL change with differing treatment regimens are yet to be conducted. Likewise, analysis of predictors of lower HRQOL have been limited and have not consistently identified intervention targets. However, it is clear that demographic variables such as markers of socio-economic status are key determinants.

Kidney recipients

In general, physical and psychosocial HRQOL are considered to be good for pediatric kidney recipients and far better than that of patients remaining on dialysis. Pediatric kidney transplant recipients experience a higher level of HRQOL as compared to patients who continue hemodialysis or peritoneal dialysis with moderate effect size [53–56]. However, several studies comparing kidney transplant recipients to healthy controls reveal lower levels of HRQOL [53,56–58]. Patients report distress regarding their physical appearance and physical symptoms, difficulty with peer and family interactions, and school disruption as significant concerns [59]. Primary caregivers report a significant negative impact on their emotional state and limitations on family activities due to their child's health [58,59]. Significant discordance exists between child and parental reports of HRQOL with parents tending to report lower physical and psychosocial function [53,58]. Although the large majority of pediatric kidney transplant recipients who have transitioned into adulthood appear to be satisfied with their QOL and report successful interpersonal relationships [59–61] up to 83% report they suffer from anxiety, depression or both [13]. They are more likely to be unemployed and less likely to live independently when compared to the general population [11–13]. An interesting correlation has also been noted between final adult height and measures of functional outcomes including educational level, paid activity, marital life, and independent housing [11].

Liver recipients

Children that have survived liver transplantation have weathered multiple physical and psychological insults which have the potential to impact HRQOL in both short-term and long-term follow-up. Initial studies reporting HRQOL in children following liver transplantation suggested that survivors have few physical restrictions and general QOL that is good [62–64]. However, in subsequent studies using validated instruments it became clear that pediatric liver transplant recipients have a level of HRQOL that is significantly lower than healthy children and more on par with pediatric chronic disease populations [65–67]. In one of the few studies exploring changes in HRQOL before and after pediatric LT, Cole et al. [68] performed a longitudinal assessment of children under age five years which demonstrated significant improvement in all domains of function with the largest change observed in the first six months. A multi-center study that examined HRQOL at one time point two years after transplant included 102 children of two age groups; younger ($n = 7$) and older ($n = 35$) than five years [65]. Results differed by age, with parents reporting that older children had HRQOL that was significantly lower than both a normative group and younger recipients, age two up to five years. These younger patients experienced both physical and psychosocial HRQOL that was similar to a control group that was collected in parallel. Univariate analysis among the sub-scales identified demographic, but not clinical variables as significant predictors of HRQOL across all age groups.

The SPLIT Functional Outcomes Group (FOG) recently conducted a large cross-sectional analysis of generic HRQOL in 873 (363 self-report) pediatric liver transplant recipients between the ages of 2–18 years with a median interval from transplant to survey of 3.1 years [69]. Outcomes were compared to a sample of healthy children randomly matched by age group, gender, and race/ethnicity. The physical and psychosocial function of the liver transplant recipients compared favorably with children with other chronic pediatric illnesses, see Figure 119.2, but were not equal to the healthy sample. The Total Scale Score and subscales of the PedsQL™ 4.0 Generic Core Scales were all significantly lower than those of healthy children with effect sizes in the small (emotional functioning) to moderate range (school functioning). In considering survey questions that assessed school function, questions that related to missing school had the largest impact on score in this domain.

Demographic as well as medical variables may predict levels of HRQOL in this population [67,68]. The SPLIT/FOG cross-sectional data set was analyzed to examine the impact of age at testing on parent report of HRQOL. Results suggest that age at testing may indeed have an important impact on HRQOL with younger children having the highest scores and younger adolescents having the lowest scores. In fact, the impact of age at testing appears to be more significant than interval from transplant. Initial results from multivariant analysis examining the impact of various factors on parent reported HRQOL in the SPLIT/FOG study identified single parent household, length of initial hospitalization after transplant, older age, history of seizures, lower height z score at transplant and days hospitalized in recent follow-up as negative predictors.

The relationship between the patient's HRQOL and family dynamics bears further consideration. Studies that have included assessment of the impact of the child's health state on the parents have shown a considerable negative influence on parental emotional state and family life [14,58,65]. However, when family function was formally measured at two years post-transplant, family function was found to be equal to that reported by a reference population [65]. These preliminary results suggest that services that support the parents' ability to cope with their child's health

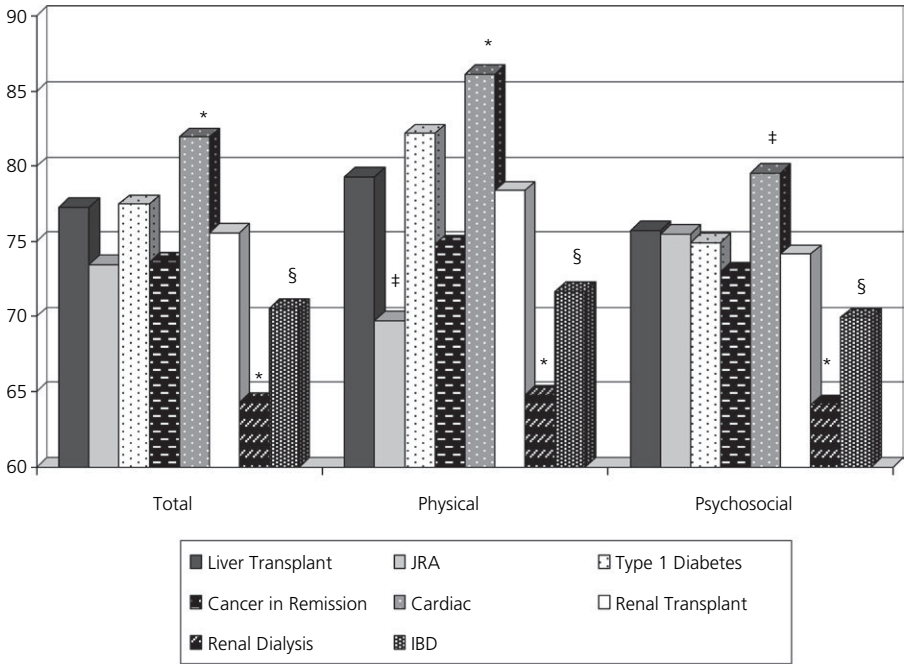

Figure 119.2. Parent proxy-reported PedsQL™ scores for liver transplant sample and chronic disease groups. Reproduced from Limbers et al. Health-related quality of life in pediatric liver transplant recipients compared with other chronic disease groups. Pediatric Transplant. 2011;15(3):245–253, with permission from Wiley.

condition would likely improve the child's HRQOL. This strategy is especially important since patients levels of HRQOL have been linked to adherence behaviors and possibly long-term maintenance of graft function [70].

Heart and lung recipients

Although it is reported that the majority of patients adjust well after transplant, HRQOL has not been systematically studied. A recent study of 23 adult patients who received heart transplants as children reported physical and mental health scores using the SF-36 (QualityMetric) that were similar to the general US population [71]. Seventy percent lived with a parent or family member and had private medical insurance and all had completed high school. Among lung transplant recipients there appears to be a significant percentage that have behavior problems at home, and decreased social competence with their peers, most commonly in male patients. The prevalence of depression has been explored with reported rates of 23% at one year and 13% at the three year follow-up [41,72].

Intestine recipients

Assessment of QOL after intestinal transplant has been limited by small sample sizes and is confounded with issues related to feeding and ongoing gastrointestinal symptoms. Scores for QOL often deteriorate over time in patients on parenteral nutrition, particularly as complications such as liver disease emerge. Conversely, after intestine transplantation, QOL is reported to improve with time [73]. After the initial postoperative course, assessed QOL was similar between parenteral nutrition-dependent patients and intestinal transplantation (IT) patients. In longitudinal follow-up, IT patients reported significant improvement in anxiety, sleep, and impulsiveness and control, which reflected a progressive adjustment to post-transplant status [73]. Parents of intestinal recipients have reported significant limitations in the physical and psychosocial well-being of their children, while the patients themselves reported little impact in most domains compared with other normal school children [74]. These authors concluded despite differences in life relative to peers, these children do not find that these differences impact their functioning.

Function outcome summary

The HRQOL and functional outcomes of children that have received solid organ transplantation are lower than a normative population and appear to be most comparable to that of children with other chronic diseases. Parents of pediatric solid organ transplant recipients experience stress related to their child's illness and tend to report functional outcomes that are lower than that reported by the children themselves. Age at the time of testing may have an influence on reporting of HRQOL with parents of younger children reporting better functional outcomes. It appears that demographic factors have a significant impact on HRQOL and interventions that provide support and education for families caring for organ transplant recipients may improve outcomes for these children.

Health related QOL is a global measure of how well patients feel, how they see themselves in relationship to others and how they function within their environment. Despite good long-term patient and graft survival in solid organ transplantation, many recipients struggle with diminished HRQOL and sub-optimal or incomplete rehabilitation. Data regarding long-term HRQOL in these pediatric

Table 119.2. Suggested screening methods for annual assessment of developmental delay by age

Age	Functional domain	Screening method		Referral***
		Tool	Mode of administration	
1–5 years	Adaptive behaviors: Socialization, motor, communication, daily living skills	Adaptive Behavior Assessment System, Second Edition (ABAS-II) [77] * or Vineland Adaptive Behavior Scales, Second Edition (Vineland-II) [78]*	Parent completed survey (15–20 minutes)	Developmental evaluation (psychologist)
	Developmental milestones: Social, motor, language	Denver-II [79]	Screening in clinic (10–20 minutes)	Developmental evaluation (psychologist)
	Language	Preschool Language Scale, Fifth Edition (PLS-5) Home Communication Questionnaire [80]	Parent completed survey (10–20 minutes)	Developmental evaluation (psychologist) and speech/language evaluation
	Hearing	Audiology screen**		Comprehensive audiology evaluation
6–13 years	General physical and psychosocial function	PedsQL-4.0 Generic Core Scales [81]*	Parent and child completed surveys (5–10 minutes)	Psychological diagnostic evaluation (pediatric medical psychologist)
	Executive function	PedsQL-CF Scale [75]*	Parent and child completed surveys (5 minutes)	Neuropsychological evaluation (neuropsychologist)
		Behavior Rating Inventory of Executive Function (BRIEF) [82]	Parent and teacher completed surveys; child self report survey (age 11+) (10–15 minutes)	
	Attention	ADHD Rating Scale IV [83]*	Parent and teacher completed surveys (10–15 minutes)	
	School performance	Medical clinicians and/or social service support team should assess for school concerns: Does the parent report academic delays? Does the child receive special education services, such as an Individualized Educational Plan (IEP) or 504 plan? Are the child's grades below average, highly variable, or lower than in the past? Does schoolwork require more effort, help, or time to complete than for peers? Is the child excessively frustrated by schoolwork? Does child avoid/resist schoolwork and/or become distressed about going to school? How many days of school have been missed due to illness or medical visits?	Parent interview (10–15 minutes)	
	Hearing	As above at age 1–5 years		
14–18 years	General physical and psychosocial function Executive function Attention School performance	As above at age 6–13		
	Transition planning	Medical clinicians and/or social service support team should discuss plans for advanced education or job placement within context of cognitive function and history of school performance. Cognitive function, especially intellectual and executive function should be considered in developing plans for self-management of medical care/self care.	Parent/patient interview (10–15 minutes)	Transition planning for self management of medical care/self care: Psychological diagnostic evaluation (pediatric medical psychologist). Transition planning for continued education or vocational development: School

* Available in English and Spanish

** Audiology screen is recommended at least once following transplantation. If concerns are noted on screening, refer for comprehensive audiology evaluation. No further screening is needed unless clinical concerns are suspected and/or prior audiology testing indicated problems.

*** Comprehensive neuropsychological, developmental, speech/language, and psychological diagnostic evaluations do not need to be completed annually. If child has already had one evaluation, consult relevant specialist for follow-up recommendations, or refer for re-evaluation if new concerns arise or concerns become more serious following initial evaluation.

groups is lacking and would be best served by a multi-center study design. The primary care provider, through their relationship with the family and other siblings is well poised to assist families in determining needs for rehabilitation and social support. By facilitating evaluation and laboratory monitoring in the community, the primary provider may help to reduce the need for school absences and interruption of family activities. The primary provider can also help the family place their concerns within the context of those of parents of children with other chronic diseases and share intervention strategies that have improved functional outcomes for children with other more common diseases, such as asthma or diabetes.

Summary and implications for long-term follow-up

As we review the various aspects of developmental outcomes in pediatric solid organ transplant recipients some common themes emerge. Although many recipients have completely normal cognitive function and perform well in school, a disproportionate number have below average intelligence, learning difficulties and problems meeting expectations in the classroom. Subtle physical deficits such as delays in fine motor skills and high frequency hearing loss can make it even more difficult for them to keep up with their peers. The stress related to coping with these differences

increases significantly as academic tasks become more complex and children progress through adolescence. The duration and severity of the chronic disease, be it dialysis, portal hypertension or congestive heart failure, clearly impacts outcomes. Socioeconomic and environmental factors likely have an influence as well and factors that limit a family's ability to secure special resources for their child may compound the impact of medical risk factors. For most transplant families, their strongest connection to the medical system is through their transplant team. However, even with input from transplant social service professionals, transplant teams may not always elicit a history of cognitive delay or school problems during routine post-transplant follow-up. Special attention to these aspects of the medical history should be incorporated into follow-up care with both their transplant physician and primary care provider.

Developmental testing is both expensive and labor intensive and thus difficult to justify for all transplant recipients. Yet, patients that would benefit from more rigorous testing to pinpoint deficits can be identified through systematic screening programs embedded into routine post-transplant care. Some suggestions for screening measures and appropriate referrals are included in Table 119.2. If concerns are found, referral for more comprehensive evaluation by the appropriate clinician as indicated is recommended.

Questions regarding physical and social developmental milestones and language acquisition should be routinely included in follow-up evaluation of children less than age four years. The older child, age five and above, should be assessed for difficulties in the classroom and frequency of school absence. In liver transplant recipients, age five to seven years, the question "PedsQL™4.0 Cognitive Function Scale" questionnaire correlates well with more extensive measures of executive function and can easily be administered in a clinic setting [75]. For more comprehensive assessment of executive function, the BRIEF can be used. Adolescents that have required special educational support while in the primary grades may struggle with many of the tasks required for self-management as cognitive function is a vital consideration in individualized transition of care plans. The ultimate objective for pediatric recipients is that they grow into healthy and productive adults. Interventions to help these children circumvent cognitive weaknesses would be expected to improve their functional status as young adults. Likewise, identifying specific problems such as borderline intelligence or diminished executive skills helps patients and their families set realistic expectations for career choices and long-term functional outcomes.

CHAPTER 120

Nonadherence, Psychosocial Adaptation and Its Effects in Pediatric Transplantation

Robert Ettenger[1,2] and Margaret L. Stuber[2]

[1] Mattel Children's Hospital, UCLA, Los Angeles, CA, USA
[2] David Geffen School of Medicine at UCLA, Los Angeles, CA, USA

Introduction

The World Health Organization defines medication adherence as "the extent to which a person's behavior (taking medications, following a recommended diet and/or executing life-style changes) corresponds with the agreed recommendations of a healthcare provider [1]". As this definition implies, there are numerous recommendations with which a chronically ill transplant patient is expected to comply, including attendance at medical appointments, having blood tests performed, and avoidance of alcohol or illicit drugs. In this chapter, we focus on non-adherence with immunosuppressive medications, with the understanding that if a family or recipient is not following other facets of the recommended care program, this could also have deleterious effects on the recipient's health or well-being. It will be apparent that non-adherence remains a major cause of late graft loss and patient death, and thus remains a critical target for acquisition of new knowledge and for trials of interventions to enhance adherence.

The burden of medication non-adherence on the health of transplant recipients

A Cochrane review, "Interventions for enhancing medication adherence" concluded that improving medication taking may have a far more profound impact on clinical outcomes than any discreet improvement in treatments [2]. Since there are currently no practical, reproducible ways to assure consistent transplant success without immunosuppressive medication, it stands to reason that medication adherence is a critical component of solid organ transplantation success. Indeed, in the overwhelming number of adult organ transplant recipients, medication adherence has been shown to be critical in the prevention of allograft rejection [3,4].

The success of transplantation in the modern era is due in large part to the more potent immunosuppressive agents available to combat rejection. Nevertheless, these advancements in immunosuppression come at a price. All of the currently available maintenance agents are administered orally, and need to be taken for the lifetime of the allograft. Transplant recipients who forgo taking their medication, even if it is only for a few days, run the risk of acute rejection and allograft loss, consigning the patients to the difficult life of dialysis [5–8] or death, in the case of other life-sustaining organs such as the heart.

In addition to the human costs, there are huge financial costs associated with medication non-adherence. It is estimated that the cost of non-adherence in solid organ transplant recipients ranges between $15 million to $100 million annually [9]. The median annual cost of maintaining a functioning kidney transplant is approximately $8500, while the cost after a failed transplant is about $51 000 [9]. Moreover, based on average costs, it takes approximately two and a half years of transplant function for the cost of transplant to be offset by the avoided costs of dialysis [10]. Similar analyses in Europe have come to essentially the same conclusions [11]. Further time of transplant function is a large economic gain to the healthcare system. In this time of concern about healthcare finances, improvements in medication adherence can have an important impact on healthcare spending.

Under-appreciation of the incidence and impact of non-adherence

The frequency and impact of medication non-adherence in solid organ transplant recipients is frequently underappreciated. Only a 2% non-adherence rate was reported in a group of pediatric liver transplant recipients to United Network for Organ Sharing (UNOS) [12]. However, a retrospective review found that 35% of graft loss was attributable to non-adherence [12]. There are other examples of the lack of recognition of medication non-adherence [9], yet scant attention has been paid to improvement in adherence [13,14]. Even the pediatric renal transplant community has been late coming to an acceptance of the impact of medication non-adherence. In the 2010 Annual Report of the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS), almost 50% of grafts that failed did so because of "rejection". Yet, graft loss due to patients discontinuing their medicines was recognized in only 4.5% of graft losses [15].

Unique pediatric implications

Solid organ transplantation is widely accepted as the therapy of choice for children and adolescents with end stage organ failure. For example, kidney transplantation yields remarkable improvements in health and cognitive function that far surpass those seen with any form of dialysis [16,17]. The United States Renal Data

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

System (USRDS) data show that kidney transplant recipients live markedly longer than those on dialysis and this effect is most pronounced in pediatric patients, with gains in expected lifetime years of approximately 20 to 30 years [18]. The benefits of successful transplantation include improvement in growth and sexual development [19,20] and the ability to adopt the roles of a "well" person instead of the role of the chronically ill individual. In pediatrics, this translates into the chance to negotiate and enjoy the roles and responsibilities that come with maturation [21–23].

Despite all of these positive results, the incidence of medication non-adherence is estimated to be high in pediatric renal transplant recipients, particularly adolescents [24]. While renal allograft survival at one year is excellent for all children over one year of age, patients who are transplanted as adolescents, or who survive to be adolescents, show a greater decline in renal graft function and allograft survival over three to five years than younger recipients. At five years after transplantation, patients who are transplanted as adolescents have the worst allograft loss rate of any age group, including all adult groups [17]. The increased rate of graft loss in the adolescent transplant recipient appears to be due, in large part, to medication non-adherence.

Definitions of non-adherence

The WHO definition of adherence mentioned previously fails to address a number of issues that underpin failure to take prescribed medication. Non-adherence should not be seen as solely a willful defiance or careless behavior on the part of the patient. Rather, non-adherence represents a limitation in the delivery of healthcare. This may be the result of a failure between the medical provider and the patient to fully agree about the prescription in the first place, or it may represent a lack of identification and provision of the educational, emotional, or financial support that the patients need [25]. Thus, there are nuanced definitions of medication adherence that stress not only the patients' responsibilities, but also the caregivers' approaches.

Compliance

This designates the situation wherein the patient follows the medical team's dictated orders without necessarily buying into the reasons for these orders. This is the situation in which the adolescent transplant recipient often finds himself/herself.

Adherence

Adherence describes a situation in which the patient understands the reasons for the medical teams' orders and participates in their execution by following these orders. In pediatric and adolescent solid organ transplantation, this is often the best situation that is obtained.

Concordance

This is the theoretical goal in the adherence literature. With concordance, the patient's desires and incentives are aligned with those of the medical team. Thus, the conclusion is that the patient wants to do those things that the medical team believes will benefit him/her.

Operational definition of non-adherence in organ transplantation

The issues that surround medical adherence or compliance in solid organ transplant recipients are often difficult for patients and families to appreciate. On the other hand, those issues are more starkly drawn for the healthcare team. Chapman offered the following useful definition: "Non-adherence is the covert failure to take prescribed medication used for the prophylaxis of allograft rejection, which potentially results in impaired graft histology or function [26]". This definition has two important clinical features: (1) The non-adherence must be covert, and in the majority of cases of adolescent non-adherence, this condition is met. Occasionally, however, the adolescent is overtly expressing defiance through refusal to take the prescribed medication. Usually, however, the pediatric transplant physician and medical team cannot accurately identify when an individual is non-adherent;(2) The non-adherence should have a measurable effect on the clinical outcome of the graft for the behavior to be meaningful non-compliance [26].

There are a number of issues that make the literature in pediatric transplant non-adherence difficult to interpret. Matas and Nevins [8] asked pertinent questions: What is a robust, clinically useful definition of medication non-compliance [non-adherence]? How much compliance is enough? What about dosing delays [8]? Is there a true "threshold-effect", beyond which graft damage will occur? Because of individual differences in immune reactivity, organ immunogenicity, histocompatibility matching, drug metabolism and countless other factors (many of them undefined), it is sometimes difficult to apply hard-and-fast definitions.

As an example, consider the various definitions in the peer-reviewed literature about what comprises the quantitative aspect of "medication non-adherence". Greenstein and Siegal defined non-compliance as missing, forgetting, altering or delaying a dose at least once per month (2% of doses assuming twice daily dosing) [27]. Nevins et al. defined non-compliance as missing at least 10% of drug doses, that is, six doses per month [28]. Chisholm et al. and Blowey et al. defined non-compliance as missing at least 20% of doses, or 12 doses per month [29,30]. If taking doses of medications "late" is defined as non-adherence, what is the cutoff for appropriate timing [31]? In recognition of this conundrum, a recent consensus conference defined non-adherence in organ transplantation as "any deviation from the prescribed medication sufficient to influence adversely the regimen's intended effect" [9]. There is no doubt that all clinicians would strive for 100% compliance. Failing that, a clinician must fall back on the operational definition of organ pathology as a true marker of non-adherence and subsequent under-immunosuppression leading to acute or chronic rejection.

Prevalence of non-adherence with immunosuppressive medications in pediatric transplantation

According to a recent meta-analysis [32], approximately 50% of studies dealing with non-adherence in pediatric transplantation were performed in renal transplant recipients. Thirty percent of such studies were performed in pediatric liver allograft recipients, while 13% were reported in heart recipients. Thus, studies in kidney transplantation are by far the most frequent. Across all transplant types, the immunosuppression non-adherence rate was six cases per 100 patients per year. There was no significant difference between immunosuppressive medication non-adherence rates in different organ types [32].

It is difficult to compare the incidence/prevalence of immunosuppression medication non-adherence between adult and pediatric populations. Much of this involves the different methodologies and definitions of non-adherence from study to study. As a result,

meta-analyses containing the sum and substance of "all" the studies in the literature will often come to different conclusions. For example, as noted above, Dew et al. [32] found that the pediatric immunosuppressive medication non-adherence rate was only six cases per 100 patients per year, while in adults, the rate was between 19–25cases per 100 patients per year [33]. Other meta-analyses have come to different conclusions [24,34,35]. Prevalence rates vary greatly from study to study, ranging from 5% to almost 80% [36], reflecting variations in study quality, study methods, and definitions of non-adherence, among other factors. In pediatric kidney transplantation, the weighted mean prevalence across 16 studies dealing with immunosuppression non-adherence was 30.7% [34]. A previous study by the same authors compared the weighted mean prevalence of medication non-adherence over different solid organ types. This study reported a weighted mean prevalence of 32% for pediatric kidney transplant recipients, 30.8% for liver recipients, and 15.9% in cardiac recipients [24].

Numerous studies have identified adolescence as a prime age for non-adherence. The systematic review by Dobells et al. identified adolescence as the most worrisome time for medication non-adherence in pediatric transplantation. There is a significant difference between adolescents and younger children, with weighted rates of 43.2% and 22.4% respectively [24,32,34]. In the review by Dobells et al., adolescence was defined as age $\geq$10 years, unless otherwise designated. Other analyses have also identified that older pediatric transplant recipients (i.e. adolescents) are at higher risk for medication non-adherence [37]. High rates of medication non-adherence are also reported in adolescents with other conditions that require chronic medication such as asthma, HIV infection, rheumatoid arthritis and diabetes [38,39].

Well over 50% of pediatric renal transplants are performed in adolescents, especially when one extends the lower age limit to $\geq$10 years old [15,40]. In most studies, patients are characterized by the age at which they received their kidney transplant [15]. Thus, when patients are transplanted in adolescence, it has been impossible to know at what specific age medical complications occurred that might be due to medication non-adherence.

New data appear to clarify this. Foster et al. [41] have more precisely identified the ages at which adolescents experience graft loss. Using the USRDS database, and controlling for time post-transplant in their analysis, the authors demonstrated that beginning at approximately nine years of age, adolescent patients experienced year to year graft loss at an ever increasing rate until it peaked at an age of 19–20 years. They also demonstrated that in children less than 12 years old the rate of graft loss increases dramatically over the late post-transplant period, that is, when the patients reach late adolescence. The greatest incidence of graft failure occurred in patients aged 17–24 years of age. Foster et al. found that for children who were very young at the time of transplant, the highest rate of graft failure occurred some 13–17 years post-transplant, whereas higher failure rates were found in the years immediately following transplant among those transplanted during adolescence. Taken together, these data strongly suggest that adolescence, in and of itself, is a specific risk factor for graft loss. The reasons underlying these findings are by no means straightforward because the process of graft loss in pediatric transplantation is complex. None-the-less, the most obvious explanation of the findings of Foster et al. is medication non-adherence. Other immunobiological processes, including enhanced alloreactivity with older age in childhood and infection with environmental pathogens, particularly viruses [42–45], may also play an important role in allograft rejection and loss.

Psychosocial and developmental adaptation in pediatric and adolescent transplant recipients

Issues of non-adherence to medication after transplantation vary with the age and developmental status of the transplant recipient [32]. To understand how to facilitate adherence, the transplant team must consider not only the cognitive developmental stage of the recipient but also the developmental tasks for that age group.

Early childhood

Generally, issues of non-adherence for children under the age of seven are considered to be due to parental or social factors and have less to do with the child's level of understanding or co-operation [32]. Children below the age of three live in the moment, and express their pleasure or displeasure with the physical sensations they are experiencing. They do not understand why they need to see doctors or take medication, and can be very resistant. Most parents are comfortable making infants and toddlers take medication, and many are skilled at doing this. These very young children can be traumatized, however, if they have the experience that the adults on whom they depend are emotionally out of control, frequently angry, or physically overpowering for any reason, even if it is ostensibly for their own good [46,47]. Secure attachment (which predicts future emotional stability) is dependent on a predictable, responsive adult. Insecure attachment does not bode well for later adherence, as will be discussed further.

Children between the ages of three and about seven are in what Piaget termed the preoperational stage of cognitive development [48]. Although they are now able to understand relatively complex language, they do not have a good sense of cause and effect and they are unlikely to understand the need for medication. They are developing a sense of their own autonomy, and developing the interpersonal skills they will need for school. Very anxious parents of preschool- age children may understandably view transplant recipients as "vulnerable" and be extremely protective and overly vigilant [49]. Anxiety or even post-traumatic stress disorder (PTSD) on the part of the parents may be (at least temporarily) beneficial in terms of medication adherence [50]. However, the child who is kept in this dependent role when it is no longer medically or developmentally appropriate will be less able to participate in their care in the future. They may be non-adherent in a deliberate attempt to establish independence.

School age

Children ages 7–11 are more able to think logically and to understand the reasons for medication [51]. Piaget called this cognitive stage "concrete operational thinking". Clinicians and parents must be careful in the way they explain things, as school age children do not understand anatomy and tend to take instructions and explanations literally and view guidelines as rules [52]. School-age children can follow instructions, but do not have very good independent judgment, and are generally not well organized or responsible. Studies examining the role of school age children in post-transplant care have found that children under the age of 11 are generally starting to have some responsibility for their medications, but this is limited and often with supervision [53,54]. This supervision is quite appropriate.

Adolescence

Adolescents have the worst transplant outcomes, and much of this has been attributed to non-adherence [41]. This is interesting, because from a purely cognitive developmental standpoint, one would expect recipients over the age of 11 to be the most adherent. They are in what Piaget called the Formal Operational Stage, able to understand multiple causations of events and to reason abstractly [55]. However, the three most prominent characteristics of adolescent behavior are an increase in risk taking, increased sensation seeking, and a move away from parents to greater peer affiliation [56]. These behaviors set the stage for the post-transplant behavioral problems we term as "non-adherence".

Three major themes have emerged based on cumulative neuroimaging research on the developing brain of adolescents [57]. First, there appears to be an increase in associative cognitive activity as various areas of the brain become increasingly integrated [58]. The second structural theme is a general pattern of childhood peaks (such as synaptic proliferation) followed by adolescent declines (known as pruning). Thus the brain becomes "refined" [57]. The third, and perhaps the most important for our discussion, is a changing balance between competing neuronal networks as different cognitive and emotional systems mature at different rates [57]. There appears to be an increase in executive functioning, which encompasses a broad array of abilities including attention, response inhibition, emotional regulation, organization and long range planning. These functions appear to lie in the prefrontal lobe circuitry that is relatively late in maturing [57]. Over time, there appears to be an increasing proportion of frontal as opposed to limbic system activity for a number of cognitive tasks [59].

An additional contribution to non-adherence is the major developmental tasks of adolescence of separation and individuation [60]. Adolescents are even more attuned to what is acceptable to their peers than school-age children. They experiment to see which of their parents' values and expectations they wish to retain and what to reject. People in authority, like doctors and teachers, are questioned as a part of this discovery of what the teens believe and who they are [61]. An adolescent who questions the necessity of daily medication may try to see what happens if they skip a dose here and there. They find that stopping medication, whether deliberately or because they "forgot", has no immediate negative consequences. By the time rejection is detected it is often too late.

Young adults

The developmental tasks of young adulthood can also present challenges for adherence [62]. This is the age when young people are deciding on advanced education, careers, life-partners, housing and parenting. Limitations in any of these areas, perceived or real, may feel devastating to a young person. There is some suggestion, based on data from childhood cancer survivors, that people who were not symptomatic with PTSD as children or adolescents may become so as young adults, as they encounter these developmental tasks [63]. Non-adherence may reflect a desire that everything associated with the illness and transplant now be over, so they can return to the life they would have had if they had been healthy.

Factors associated with medication non-adherence in pediatric patients

Much has been written about the factors that are associated with immunosuppressive medication non-adherence [24,34,64]. Many factors have been identified (Table 120.1). It is important to realize, however, that the research methodologies used to identify the factors in question vary greatly between studies. Thus it is challenging to establish the validity or comparative predicative power of these factors. As a general rule, clinicians (as opposed to researchers in the field of medication adherence) use these factors as a rough guide to uncover non-adherence and address/relieve barriers to adherence that might be modified. Table 120.1 contains a list of risk factors associated with medication non-adherence. Many of the factors that appear in pediatric/adolescent patients overlap with those observed in adults. The factors that appear with the greatest consistency in the literature are discussed further on.

The WHO identified five distinct categories of risk factors for medication non-adherence [1]. These include socioeconomic factors, patient related factors, condition related factors, treatment related factors, and factors related to the healthcare system and team. A number of these factors fall into more than one category.

Socioeconomic factors

Into this category fall such issues as the cost burden of medication [65], low socioeconomic status [65–67], African American ethnicity [68], family instability, poor social support from parents [30,66,69], and single parent homes [66,67]. Other factors are detailed in Table 120.1.

In general, adolescents living in stable, supportive environments show better adherence with medical treatment compared to those growing up in an atmosphere of family conflict with lack of family cohesion [24,67,69–74]. It is also important to recognize that a patient's social support network may change over time. The medical team needs to continually evaluate the social support network as well as the patient him/herself. Caregiver "burn-out" can set the stage for worsening medication adherence [75,76].

Patient-related factors

These include those behavioral factors that would cause an adolescent to forgo medication administration. Some of these are shown in Table 120.1. Greenstein and Siegal [27] established a useful classification of some patient related factors. They identified at least three non-adherence patterns: accidental non-adherence which implies forgetfulness [30]; the invulnerable pattern [30,65], which may be common in adolescents; and the decisive non-adherence pattern, which can involve risk-taking behavior [24,77–79]. In adults, it appears that kidney transplant recipients are more likely to evidence non-adherence due to forgetfulness than to intentional behavior [80].

Other patient-related characteristics appear to be related to the experience of the transplant as a traumatic event or events, with resulting symptoms of PTSD [81]. For these transplant recipients, daily medication can serve as a traumatic reminder of all of their negative experiences. Avoidance of the medication provides some respite from the memories of hospitalization, illness, absence from friends, and blood tests. It can help them to feel "normal", a wish often cited in studies of adolescent transplant recipients [82]. Intervening with the post-traumatic stress may be useful in improving non-adherence in these situations [67]. Interestingly, parents can also experience PTSD [50] in response to their anxiety about their child's wellbeing [24,66]. The stress of the illness and necessary treatment can also result in clinically significant anxiety and depression [66,71,78], particularly if the recipient was depressed before transplantation. Recipients may have low self-esteem [65,71], which can be associated with non-adherence, particularly if the treatment is leading to an altered body image. On the other hand, the ability

Table 120.1. Factors that associate with medication non-adherence (Data from Wolff et al. [64], Dobells et al. [24,34], Butler et al. [123], Denhaerynck et al. [3] and Bunzel and Laedrach-Hofmann [211])

- Socioeconomic factors
  - Pediatric
    - Poverty or poor socioeconomic status
    - Race/cultural background (often a surrogate for low socioeconomic status)
    - Medication costs / inadequate healthcare coverage
    - Family dynamics:
    - **I.** Family instability / poor family cohesion
    - **II.** Single parent family
    - **III.** Lack of parental supervision / social support
    - **IV.** Poor intrafamily communication
    - **V.** Parental anxiety, overprotection, or PTSD
    - Social isolation
  - Adult
    - Younger age
    - Race / cultural background (often a surrogate for low socioeconomic status)
    - Lower educational background
    - Marital problems/divorce
    - Lack of social support
- Patient related factors
  - Pediatric
    - Poor Knowledge of:
    - **I.** Names and doses/ timing of medications
    - **II.** Functions of medications
    - **III.** Inappropriate health beliefs
    - Low self-esteem:
    - **I.** Poor Body Image
    - **II.** Not liking to carry medications with them
    - Forgetfulness:
    - **I.** Busy life style
    - Developmental delay
    - Age:
    - **I.** At transplant
    - **II.** At the time the patient is currently being followed
    - Psychological:
    - **I.** Previous non-adherence [222]
    - **II.** Depression / anxiety
    - **III.** PTSD
    - **IV.** Anger
    - **V.** School dropout
    - **VI.** History of child abuse
    - **VII.** Denial
    - **VIII.** Substance abuse
    - **IX.** Poor coping mechanisms
      - **a.** Feeling overwhelmed by transplant issues
    - Social:
    - **I.** Poor social skills
    - **II.** Problems with social adjustment
    - **III.** Deficient social support
    - **IV.** Reluctance to admit to friends that patient has a transplant
    - Stages of psychological development:
    - **I.** Risk taking behavior
    - **II.** Progression towards independence
      - **a.** Difficulty with resolving dependence on parents versus need for autonomy
  - Adult
    - Poor knowledge about their own healthcare
    - Health beliefs diverge from those of the medical team
    - **I.** External locus of control
    - **II.** Perceived lack of autonomy
    - Forgetfulness:
    - **I.** Poor organizational skills
    - **II.** Interference with life style/ work
    - Pretransplant non-adherence
    - Lack of motivation:
    - **I.** Low self-efficacy
    - **II.** Difficulties with self-care
    - **III.** Substance abuse

(*Continued*)

Table 120.1. (*Continued*)

Disease related conditions
Pediatric
Time:
I. Duration of illness
II. Longer time post-transplant
Feeling of good health:
I. lower perception of vulnerability
Never having been on dialysis
Adult
Depression
Longer time since transplant
Feeling of good health
Physical limitations secondary to infection or rejection
Treatment related factors
Pediatric
Cosmetic side effects
Complexity of medication regimen:
I. Total number of medications/pills
II. Higher number of doses during the day (i.e., thrice daily vs. twice daily)
Other attributes of medications:
I. Taste
II. Size of pills and difficulty swallowing pills
Adult
Concern about adverse effects of medications
Use of non-prescribed drugs
Increasing dosage frequency
Increased number of medications
Evening dosing
Healthcare system and team related factors
Pediatric
Communication between parents and healthcare team
Selective attribution by healthcare team:
I. Healthcare workers consider the non-adherent patient "bad"
II. Healthcare team unaware of the attitudes they may have which can affect the desire of the patient/parent to adhere to regimen
Adult
Lack of insurance
Inability to pay for car
Poor patient-provider relationship
Transition from pediatric to adult oriented care

to have a great deal of hope is associated with improved adherence, in both pediatric and adult patients [83,84].

It is important for pediatric transplant recipients to gradually take control of their own healthcare. However, a decline in adherence has been noted as pediatric transplant recipients assume responsibility for taking their medication, and the role of parents in administering medications is reduced [37,85,86]. Similarly, adherence declines during the transition of transplant recipients from a pediatric healthcare system to an adult healthcare system [87,88].

An individual who believes that health outcomes are controlled by chance rather than by their own actions (external locus of control) are more likely to forgo medications [89]. On the other hand, it has been clearly shown that adolescents who know the name of their medications, and the purpose of those medications, are far more likely to be adherent [90].

Disease condition-related factors

Non-adherence is more likely when the transplant has been functioning for one or more years [91]. This is generally a point when physicians feel that they do not need to see the transplant recipient as frequently. Unfortunately, this reduced interaction with the medical team is associated with decreased adherence by adolescents [92]. While non-adherence can be demonstrated early after transplant, as time passes the urgency of taking medications decreases, and adherence with medications also decreases [93–95]. Ironically, the feeling of good health that the adolescent perceives as a result of a successful transplant helps to encourage, rather than discourage the occurrences of medication non-adherence. Since there are no immediate adverse side effects when a dose of medication is missed, it is easy for the adolescent to assume that there will be no consequences for missing medications.

Treatment related factors

Treatment related factors include the characteristics of the medications administered and the complexity of the medical regimen. In pediatrics, bad tasting medications [86], medications that are difficult to swallow, or medications that cause adverse side effects [85] may be associated with non-adherence. The complexity of the medication regimen is also highly associated with non-adherence after transplantation [96]. This includes both the frequency of dosing and the number of pills that have to be taken.

Healthcare system and team related factors

The approach of the healthcare team is also an important factor in non-adherence. Wolff et al. [64] stress that the team needs to avoid selectively attributing all of the problems leading to non-adherence solely to the patient [34]. The messages sent by the healthcare team must be clear and unambiguous. As an example of one problematic type of interaction [34], a study found that a counterproductive message was sent by scheduling tests or follow-ups at a time which interfered with medication administration [97]. Some evidence

Table 120.2. Barriers to adherence [102]

Barrier Type	Examples	Parent reported barriers/Number/%	Adolescent reported barriers/Number/%
Total number of barriers		76	73
Forgot or distracted	"Not paying attention to how much is left"; "ran out"; "completely forgot"; "doing something else"	13/17.1	21/28.8
Poor planning and scheduling problems	"Keeping 24 hour pill rotation is difficult"; "On weekends, sleeping in"	52/68.4	42/57.5
Physical barriers or medication issues	"Too tired"; "Nauseous in the morning";	4/5.3	7/9.6
Voluntary resistance or attempts to be normal	"When I see my friends don't have to take it, I don't want to take it"; "Teenage lifestyle"; "Just not doing it"	7/9.2	3/4.1

supporting the role of the team is the finding that non-adherence rates appear to differ between transplant centers [34,98]. How the healthcare team relates to recipients and parents plays a key role in determining the presence and severity of medication non-adherence.

Healthcare system factors such as insurance to cover the cost of medications obviously have some interaction with socioeconomic factors. However, there are other examples of healthcare system factors leading to non-adherence. These include the mandatory transition of care from a pediatric to an adult facility at a specific age, and the loss of insurance coverage for a "child" as she/he turns 21 years old (or at whatever age is deemed the "transition" age) [99,100]. There is usually a system of mandatory transition, whether or not the patient is appropriately prepared for this. Since medication non-adherence increases when either a planned or unplanned transition occurs [53,87,88], it is in the patient's and healthcare system's best interest to provide an organized transition program that recognizes the risk for increased non-adherence at this critical juncture. This program must include financial counseling [100].

Barriers to adherence

The factors associated with non-adherence discussed above are those which have been noted in studies examining correlations of specific demographic, treatment and systems variables with a specific measure of adherence. "Another way of understanding what causes non-adherence is to ask transplant recipients and their parents what they see as barriers to adherence". One of the most frequently used measures of perceived barriers to adherence was developed by Simons et al. [85]. The authors queried 80 adolescent transplant recipients and their parents using standardized open-ended questions to identify important categorical dimensions of barriers to adherence, and described them in four categories [101].

The overall number of perceived barriers was significantly greater in the transplant recipients who were classified by the Medical Adherence Measure (MAM) [86,101] as non-adherent. Moreover, patients in this study who experienced a rejection episode reported a greater number of overall barriers. Table 120.2 shows that the two major barrier types described in this study were forgetfulness/distraction and poor planning and scheduling [101]. Non-adherence was also found to be more likely when adolescents, as opposed to parents, were responsible for administering the medication, and when taking morning rather than evening doses (ostensibly because they were late for school). These results are consistent with other reports that describe significant barriers to include cognitive barriers [102,103,104], problematic characteristics of the medication [103,105], and voluntary resistance to medication taking [104].

Simons and Blount have formalized the testing for barriers to medication adherence with two validated questionnaires based on this work. The Parent Medication Barriers Score (PMBS) and the Adolescent Medication Barriers Score (AMBS) [101]. The PMBS consists of 16 items with a Cronbach's alpha of .87 indicating strong internal consistency. There are four factor-analytically derived subscales: "Disease Frustration/Adolescent Issues" with seven items ($\alpha = .84$), "Regimen Adaptation/Cognitive" with five items ($\alpha = .82$), "Ingestion Issues" with three items ($\alpha = .69$), and "Parent Reminder" with one item. The AMBS consists of 17 items with a Cronbach's alpha of .86 indicating strong internal consistency. There are three factor-analytically derived subscales: "Disease Frustration/Adolescent Issues" with eight items ($\alpha = .84$), "Ingestion Issues" with five items ($\alpha = .70$), and "Regimen Adaptation/Cognitive" with four items ($\alpha = .76$). Each item is rated on a five point Likert scale ranging from "strongly disagree" to "strongly agree".

In an important follow-up to the perceived barriers research discussed above, Simons et al. in 2010 [106] found that these perceived barriers did not change over time. More importantly, the adolescent-perceived barriers of "disease frustration/adolescent issues" and parent-perceived barriers of "regimen adaptation/cognitive issues" were associated with poorer adherence to medication taking at follow-up. Medical complications and mortality were significantly associated with both parent and adolescent-perceived "ingestion issues" barriers.

Others have also studied the presence of barriers to adherence and the prevalence of medication non-adherence in pediatric transplant recipients. Gerson et al. [107] found that elevated levels of parental stress, dysfunctional parent–child interactions, and child behavior problems were associated with poorer medication adherence based on electronic monitoring of adherence. They also found evidence to support the relationship between subjective dissatisfaction with appearance and poorer medication adherence.

Tielen et al. proposed an alternative to identifying adolescent patients at risk for non-adherent behavior by investigating their attitudes about their post-transplant lifestyle [108]. They utilized a robust hybrid technique, which combines qualitative and quantitative measurements. This technique allows for the systematic study of subjectivity, beliefs, feelings, and opinion [109]. This type of Q methodology has been used in adolescents to study their health lifestyle attitudes [110]. Four distinct health lifestyle attitudes among young adult transplant recipients were identified: (a) concerned and controlled, (b) appearance orientated, (c) opinionated and independent, and (d) easy going and pliable [108]. This

self-categorization of these attitude types appeared to be of use in predicting non-adherence. While attitudes a, b and c were positively associated with adherence, it was suggested that attitude types b and c called for close medical professional monitoring. Bullington et al. [111] also used Q-methodology and found that three factors — medication issues (taste, side of pills, frequency of dosing and scheduling), "troubled" adolescent (poor home life, overwhelming medical situation, depression) and deliberate non-adherence (attention seeker, infallible attitude) helped to identify those at risk for non-adherence as well as informing management approaches. Pai reported the efficacy of the Allocation of Treatment Responsibility (ATR) scale, a brief measure of the distribution of treatment tasks across the family members of a child with a kidney transplant. In its initial report, this standardized and validated instrument measured the modifiable family processes, allowing for the development of targeted interventions [54].

The cost of immunosuppressive medications is a barrier to non-adherence that is common to both pediatric and adult transplant recipients. In the US, lack of continuous insurance coverage for outpatient immunosuppressive medications is a distinct barrier to successful medical management. In 2010, a joint project involving the American Society of Transplantation (AST), the United Network for Organ Sharing (UNOS) and the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) launched a descriptive study of transplant programs to establish the scope and magnitude of the problem [112]. Over 70% of all programs reported that at least 20% of their patients encountered difficulties in their ability to pay for immunosuppressive medications. Over 43% of all programs reported that at least 10% of their patients were not taking their medications because of cost issues. This issue is particularly acute in adults, since the main source of funding for adult recipients is Medicare, and Medicare only covers immunosuppressive medications for three years after transplantation. This problem of medication cost may be less acute in pediatric transplant recipients, because of a patchwork of aid programs in many states. Since the coverage of immunosuppressive medications is cost-effective, it has been argued that indefinite extension of Medicare benefits should be granted [113,114].

Consequences of medication non-adherence

The consequences of medication non-adherence are quite serious. In pediatric renal transplant recipients, the overwhelming data suggests that medication non-adherence is likely the major contributor of poor late allograft outcome [5,6]. The majority of studies establish the association between medication non-adherence and disastrous clinical outcomes including rejection and graft loss [6,32,115]. A recent literature review found that 14% of renal grafts were lost because of immunosuppression non-adherence [24]. In other pediatric solid organ transplant recipients, almost 16% of pediatric liver transplant recipients and 35% of heart recipients lost their grafts due to medication non-adherence [24]. Again, there was a preponderance of graft loss in adolescents [5]. In studies focused solely on adolescents, non-adherence accounted for almost 32% of allograft losses; in other studies examining a mixed pediatric/adolescent population, the rate was 14.1%. Immunosuppression adherence appears to be an important predictor of outcome in pediatric renal transplantation [115].

Studies have reinforced the message that medication non-adherence takes a huge toll in transplantation, both in clinical outcomes and economic burdens. Two studies have used large databases and calculated the "medication position ratio", a metric that is defined as the number of days that medication is supplied over a one-year period. This metric utilizes pharmacy records to compare the number of doses supplied to the number of doses that should be taken if adherence were perfect [116]. Pinsky et al. found that patients aged 19–24 years old had the lowest level of non-adherence by this metric [117]. Somewhat surprisingly, Chisholm-Burns et al., using the same metric, found that adolescents were more adherent than younger patients [115]. Both studies confirmed the poor clinical outcomes and the vast economic consequences that accompany medication non-adherence. In the model constructed by Chisholm-Burns, a 10% improvement in the medication position ratio would lead to an 8 % reduction in graft failure among children [115].

Late acute rejections often appear to be the result of medication non-adherence [4]. In adolescents, non-adherence was responsible for 23.2% of late rejection episodes, which are highly predictive of chronic graft failure [24]. Thirty-three percent of late acute rejections in pediatric liver transplant recipients [118–120], and over 70% of late rejections in pediatric heart recipients [121] are associated with medication non-adherence. Prospective studies in pediatric liver [79] and kidney transplants [122] have borne out these findings. Similar findings are present in studies of adult recipients [3,123]. Pediatric renal allograft recipients with outstanding adherence appear to have significantly better long-term outcomes than do adults [115]. In adult recipients, immunosuppressive medication non-adherence is significantly associated with progressive worsening of renal function [14] and late acute rejection [124]. The worsening of renal function over time occurs even in the absence of overt acute rejection [125].

Another consequence of non-adherence has recently come to light. In kidney transplantation, anti-HLA antibodies directed against the antigens of the donor, so called donor specific antibodies (DSA), have a strong relationship to antibody mediated rejection [126,127] and poor graft outcome [128]. Antibody mediated rejection, along with interstitial fibrosis, tubular atrophy and cell mediated rejection, in turn are prominently associated with medication non-adherence [125,128]. Thus, it seems likely that de novo DSA development might be a good indicator of medication non-adherence [129]. This has been suggested in our work in pediatric renal transplant recipients [130], and other recently published work [128,131].

Measuring non-adherence

There is no agreed upon definition of how much non-adherence is necessary for adverse clinical outcomes. The assessment of the damage done by medication non-adherence is confounded by the difficulty in defining and documenting clinically meaningful non-adherence. There also is also no currently agreed-upon measurement to precisely determine the outcomes of non-adherence. Transplant professionals need to discover non-adherence in "real time" which would thus permit intervention before the graft is irretrievably damaged [9].

Shemesh and Fine established some characteristics that would provide a practical and useful measure of adherence [132]. These recommendations include measures that: (1) would be easily integrated into clinical practice; (2) pose no additional burden on patients; (3) are directly measuring the ingestion of medication; (4) rely on as simple a procedure as possible; (5) are correlated with

an adverse outcome, such as rejection; (6) have the discriminatory power to raise a valid concern about a patient's behavior; and (7) provide evidence in real time (as well as post hoc) so that an intervention can be undertaken.

There are two broad categories of non-adherence detection methods: Direct and indirect [133].

Direct methods

These include directly observed therapy (DOT), measurement of concentrations of a drug or its metabolite in blood or urine, or detection of a biologic or electronic marker added to the drug formulation. As a general rule, direct measures of medication adherence are cumbersome, expensive, burdensome to the healthcare team, and possibly susceptible to manipulation by a resistant patient [133]. Without doubt, DOT is the most accurate method of assuring adherence. Often the parents can be the observers for a pediatric patient, but as children become adolescents, there may be less willingness to submit to DOT. Besides its general impracticality, DOT is susceptible to children "cheeking" the medication and then discarding the pills. Pediatric patients can become so adept at this behavior that they avoid medications even under direct observation in the hospital.

The use of drug levels of immunosuppressive medications has become standard practice. Calcineurin inhibitor (CNI) drug levels are routinely performed at clinic visits, but accurate adherence assessment using a single level is challenging [133]. It is not advisable to use a single aberrant level to make a clinical judgment. This is particularly true when one is assessing 12 hour trough levels. Patients may mistime their taking of medications, and the resulting level maybe abnormally high or low. Perhaps more importantly, non-adherent patients may try to disguise their non-adherence by taking a large dose on the evening before their clinic visit and/or blood level determination. All of this activity has been termed "white coat compliance" [134].

Thus, it is more logical to measure the fluctuation of medication levels over time to assess adherence. This has been tested in multiple pediatric liver transplant centers [67,132,135–137]. Specifically, these centers determined the standard deviation of a series of tacrolimus levels over time, and found that a standard deviation (SD) above a given threshold was significantly associated with late rejection [132,137]. This approach correlated well with results of electronic monitoring (see further on) [138]. Pollack-BarZiv et al. extended the SD approach to children with other solid organ transplants, and found similar results with regard to late rejection [139]:

> We utilized this standard deviation (SD) technique to examine its use in 46 renal transplant recipients. We found that the median SD was 5.3 in patients with rejection and 3.5 in patients not experiencing rejection (P = NS). We then used the coefficient of variation (CV% = SD/mean multiplied by 100) as a marker for variability in tacrolimus levels [122]. In the 46 adolescent recipients, the median tacrolimus CV% was significantly higher in patients with rejection (53.4%) than those without rejection (30%) ($P = 0.005$). There was no overlap of discriminatory values. Importantly, we were not able to find any similar relationship when studying mycophenolic acid levels, and so this technique appears for now to be restricted to tacrolimus [122]. Follow-up studies solely in adolescents validated this approach and established that a CV% $\geq$ 31% had a significant association with late rejection [140].

Perhaps the most direct, albeit the most invasive and impractical method for diagnosing clinically significant non-adherence is the renal biopsy. Protocol biopsies performed at standardized times can reveal "subclinical" rejections [141,142] and, as noted above, this may be the first evidence of medication non-adherence. While the usefulness of protocol biopsies in kidney transplantation is outside the scope of this discussion [143], the presence of biopsy proven acute rejection (BPAR) is the *sine qua non* for measuring allograft damage and thus a direct mode of identifying clinically significant non-adherence with immunosuppressant medications [26,144]. The use of protocol biopsies is also standard of care in many heart transplantation programs [145].

A new technology holds promise as a direct measure of adherence [146]. Ingestible event markers (IEMs) are tiny, digestible sensors made from food ingredients, which are activated by stomach fluids after swallowing. The IEMs are manufactured at "wafer scale" on silicon and are therefore extremely economical to produce, costing a few cents per sensor in large quantities. Once activated, the IEM creates an ultra-low-power, private, digital signal detected by a microelectronic recorder configured as a small bandage style skin patch. The patch is easily placed over the stomach. The detector date- and time-stamps, decodes, and records information. This information can then be uploaded to a patient's cell phone. From there, the information is further uploaded to a "Cloud" system, which is then downloadable to investigators. This technology is currently in use in clinical trials, and has been approved by regulators in the European Union and the FDA. As of this writing, the information about this technique is only available in abstract form [146]. Clinical trials in transplantation have been in progress and the first publications are awaited eagerly.

Indirect methods

These assessments of medication adherence are generally recommended for use as sets of measures to better identify ("triangulate") the presence of non-adherence [31,147,148]. Currently, the approach of using a multidimensional "toolbox" may not be fully practical or evidence-based [149], but it is fair to say that there is a consensus in the literature that this is an effective way to study and monitor medication non-adherence [31,150,151].

Patient (and parent) self-report scales

These are perhaps the easiest and simplest measures of medication non-adherence [152]. Their advantages include: (1) simplicity, (2) low cost, (3) ease of administration, (4) usefulness in clinical situations, (5) patients who are self-reporting are likely to be truthful, and (6) self-report can give insights into social, situational and behavioral patterns that are leading to non-adherence [31,153–157]. Disadvantages include: (1) self-report overestimates adherence, (2) inaccuracies due to recall bias, social and medical desirability ("telling the doctors what they want to hear"), (3) wording of questions can be confusing, (4) timeframe of adherence recollection can affect accuracy, and, (5) requires a non-judgmental approach [153,154,156–158]. The inherent difficulty with self-report, overall, is that the patient or parents may not represent their experience accurately [152]. In comparing methods, self-report tends to underestimate the actual incidence of non-adherence, as assessed by other measures [151].

There are many adherence self-report questionnaires in the literature, and no single measure that is universally regarded as the

most useful. As might be expected, there is much more literature that deals with adults in this area. An exhaustive meta-analysis identified three self-report instruments that achieved appropriate reliability, validity and responsiveness in adults and could be recommended for clinical transplant practice [31]. These tests included the Basel Assessment of Adherence to Immunosuppressive Medication Scale (BAASIS) [159] [31,160,161], The Brief Antiretroviral Adherence Index [162–164], and the Medication Adherence Self-Report Inventory (MASRI) [165,166]. These latter two indices are validated for AIDS, and would need to be validated for transplantation as well. These instruments were considered best for transplantation clinical care because [31]:

1 These instruments take into account both the taking and regularity of medication intake.
2 They are simple to use and easy to score, making it appropriate for busy clinical settings.
3 All instruments have been validated and have shown good psychometric properties.

The BAASIS appears to be particularly appropriate for use in pediatric transplant recipients because it was designed for transplantation. This questionnaire can be finished in approximately five minutes, rendering it extremely practical. Interestingly, this instrument has also been used successfully in a pediatric renal transplant trial [167].

Reliable instruments specifically for self-report in pediatric transplantation have been slower to develop. The MAM, mentioned above, assesses adherence over a wide range of health behaviors and barriers [168]. It has been reported to be particularly useful since it focuses on the timing of medication administration as well as the medication-taking itself [34].The Basic Medical Questionnaire (BMQ) also assesses self-efficacy, making it useful in the post-transplant clinical setting [169,170]. It asks directly who is responsible for medication administration (the patient vs. the parent/guardian vs. a shared responsibility). This questionnaire thus yields information about the administration (or lack thereof) of medications and the possible reasons for immunosuppressive medication non-adherence.

Pill counts

Despite their apparent simplicity, pill counts are notoriously unreliable as true measurements of adherence [152]. It is easy to discard medications and return empty medication bottles, falsely suggesting good immunosuppressive adherence [171]. When measured against electronic monitoring devices, pill counts have been shown to underestimate non-adherence [172]. In certain low resource areas, pill counts and pharmacy refill records (see further on), have been used with HIV treatment, but it has been shown that these measures must be supplemented with direct measurements of adherence to be effective [173].

Prescription refill rates

These can be powerful tools in adherence research when a large database is available [115,117]. It can also be useful in individual patients [174], particularly if there is a closed pharmacy system and/or the use of mail ordering of prescriptions and refills [175]. On a local level, one can use refill rates in as many as four different pharmacies [176]. However, in an environment of multiple managed care organizations, the logistics may be challenging. This could change with more extensive use of electronic medical record systems that communicate with one another. A larger concern lies with the defiant adolescent, since the absence of a pill does not indicate the ingestion of that pill.

Electronic monitoring

Electronic monitoring systems have been touted as the "gold standard" for measuring medication non-adherence, and are recognized as the best of the indirect methods to detect non-adherence [97,122,146]. A continuous microprocessor, usually attached to the cap of a medication container, records each container opening as a presumptive dose and documents the time and frequency of the medication event by date and time stamping [28]. Recorded data can then be retrieved and an assessment of adherence made on the assumption that these medication events correspond to drug ingestions and that absent openings correspond to missed medications [28,94,152]. While a number of electronic monitoring systems are currently in use, the one most commonly cited in the pediatric non-adherence literature in the Medication Event Monitoring System (MEMS, Aardex Ltd). MEMS utilize an on-line transfer of the dosing history at each clinic visit to a secured server. The data is processed according to several predefined and validated algorithms. The Web portal displays reports (e.g. calendar plots, chronology plot) with adherence information. At the end of the study a report is generated that a study statistician can analyze.

Electronic monitoring has been used in studies with renal transplant recipients [28,94,152,177]. These data have successfully identified early non-adherent patterns, which carried through to the late post-transplant period [94]. This method is thought to provide the most accurate way to detect non-adherence [123,177,178] in that, when used correctly, the dynamics of medication taking are clearly recorded. This modality has been used successfully in pediatric patients to measure adherence [107]. Unfortunately, this methodology is expensive and difficult to implement in clinical practice (see further on). Its greatest use has been in clinical trials examining possible interventions for medication non-adherence to implement in clinical practice.

A recent study meticulously examined several factors that could jeopardize the validity of electronic monitoring studies in adult transplant recipients [179]. The first factor is the requirement that the equipment functions properly. Early studies in kidney transplant recipients did not permit an assessment of the exact number of non-functional caps [98]. In the study of Denhaerynck et al., the system was functionally reliable, with a failure rate of $\leq$0.5% [179].

The second factor in electronic monitoring reliability is the assumption that each time the patient unscrews the EM-bottle cap he/she also ingests the prescribed dose, and does so immediately. This may not be the case however. More or less can be removed, and pills ingested then, later or never, thus underestimating non-adherence [178]. It is also possible for patients to correctly ingest the medication from a source other than the MEMS bottle, or from a supply of pills previously removed from the MEMS bottle (perhaps because of impracticality or embarrassment), resulting in overestimation of non-adherence [98,180,181]. While this can be ameliorated to some degree by asking the patient to keep a diary of possible discrepancies [4,181] patients who are non-adherent, and particularly adolescents, are likely to keep poor records [182] or deliberately obfuscate the process. Denhaerynck et al. evaluated this approach with the electronic monitoring system and found that with adults who are accurately keeping a diary, accurate identification of adherence occurred in over 96% of the correctly dosed days [179].

The third factor to consider in assessing MEMS reliability is the "Hawthorne" effect [183,184]. This is the tendency for a patient's behavior to change in response to the awareness that he/she is being studied. The observed assessment cannot be assumed to reflect behavior when the patient is not being studied. Medication adherence may be enhanced because of study participation [181]. However, it is also possible that medication adherence is hampered because the patient who uses a daily pillbox is prevented from doing so by the constraint of the MEMS bottle [185]. Previous investigations of the impact of MEMS on adherence by Denhaerynck and others have been inconclusive [179,186].

The last concern about the validity of electronic monitoring regards selection bias. The use of MEMS requires commitment, and because of that, only motivated patients with increased adherence would join or persevere in a MEMS study. Thus, an accurate sampling of the population would be impossible [182,185]. Denhaerynck et al. could not confirm or deny the presence of such selection bias [179].

Overall, it is appropriate to conclude that the MEMS system is a potentially powerful tool, yet several factors can impact the devices' utility [185] and validity. It is therefore important to recognize the limitations of the "gold standard" for adherence measurement [187]. MEMS caps are generally inappropriate for younger patients who are receiving liquid medication. In the study by Shellmer and Zelikovsky [187], 41% of patients reported that it was onerous to transfer their medication to the designated pill bottle, 27% felt that the pill bottles were a burden to carry, 22% thought it changed their routine, and 10% worried it would cause them to miss their medications [185,187]. This led 51% of patients approached to refuse to participate in the MEMS study. Nevertheless, only one of 27 recipients who were using the MEMS technology stated that it could increase the possibility of medication non-adherence. One study experienced difficulty with MEMS as a measure of adherence, since 40% of adolescents simply did not return the caps with the memory chips [84]. Strategies for achieving greater acceptance of MEMS are described by Shellmer and Zelikovsky [187].

A number of studies investigating non-adherence have used multiple measures to refine their accuracy [147,148,151]. The combination of self-reported non-adherence/or at least one clinician reporting non-adherence with assessment for sub therapeutic blood levels had a sensitivity of 72% and a specificity of 43% [151]. It will be important in future prospective studies to utilize and validate direct and indirect measurements such as DSA, the IEM, anti-HLA antibodies and renal biopsy, alone and in concert, to determine the most accurate combination of measures.

Interventions to prevent or improve non-adherence

There are a very large number of descriptions in the medical, psychological, behavioral and nursing literature describing interventions to avert or improve medication adherence in chronically ill populations (both pediatric and adult). Numerous types of interventions in transplant populations have been proposed. As a general rule, these interventions are tailored and targeted to address the factors that are associated with non-adherence and the barriers that are identified as impairing medication adherence. Interventions include, but are certainly not limited to: educational approaches [53,69,188,189]; behavioral approaches [39,190] including contracting [191]; removal of financial barriers to the purchase of immunosuppressive medications [192]; and multiple studies utilizing electronic and digital technology [187,193–196].

Disappointingly, there is only a weak evidence base for identifying successful interventions to prevent or correct immunosuppressive medication non-adherence in transplant recipients [34,197,198]. In adult transplant recipients, a few medication non-adherence studies with a methodologically sound and randomized controlled design have been published [24,198,199]. This having been said, there are a number of interventions available which have been used to address non-adherence with other types of medications or treatments. But even here, the rigorous evidence base is often lacking.

The lack of an evidence-based approach in transplantation is illustrated by considering the KDIGO (Kidney Disease Improving Global Outcomes) Guidelines for Care of Transplant Recipients [200]. The expert panel could not even grade the quality of evidence for their recommendations for the management of medication non-adherence [201]. Many of the interventions described in the KDIGO Guidelines or elsewhere represent "common sense", based on the recognition of the factors that are associated with non-adherence as opposed to an evidence base [202].

When evaluating interventions for success in medication non-adherence, there are two basic types of outcome measures. The focus can be on evaluation of the true adherence behavior to the medical team's directives. However, if the concern is primarily with clinically significant non-adherence, biological outcomes will be the most useful measure [203]. This is a common procedure in pediatric HIV research [204,205] where adherence can be inferred by improving CD4+ T cell counts or decreasing viral loads. The success of kidney transplantation adherence interventions could be evaluated using frequency of late rejection episodes, allograft survival, or biopsy results.

As a guiding first principle, it should be clear that there are different patterns of medication non-adherence, from occasional mistiming of medications, to severe timing infractions, through occasional missed doses, to drug holidays/frequent severe timing infractions, all the way to outright refusal to take any doses [28,206]. Therefore, it should be clear that with numerous types of non-adherent activity, many behavioral "predictors", and multiple barriers to adherence, a "one size fits all" approach is impractical and doomed to failure. Interventions must also be tailored for the developmental stage of the recipient [207,208]. The lack of immediate consequences for a missed dose and the individual variations in immune responsiveness contribute to a tendency of adolescents to question the instructions of their parents and the healthcare team, as the teen strives to be an independent decision-maker [209]. There is a strong tendency for adolescents to focus on the "here and now" [206]. They have difficulty in abstract thinking about the long-term. Specifically, there is no immediate pain or suffering that the adolescent experiences when an immunosuppressive medication is missed. And since immune responsiveness differs from individual [208] to individual, there is also no current biological test that can give reliable immediate feedback. In kidney transplantation, the medical team still relies on serum creatinine levels, which are both insensitive and nonspecific. The lack of reliable immediate feedback hampers the effort to support immediate detection of immunosuppressive medication adherence and prompt intervention.

Even within adolescence, interventions must be constructed that take into account the specific developmental stage of a given patient [205]. Regardless of chronological age, different adolescents may function differently along the developmental spectrum. Adolescents are striving to become independent decision makers, but they often develop negative behaviors in an attempt to become

decision makers independent from their caregivers/parents [209]. Further problems may develop because different members of the healthcare team may differ in their assessment of an adolescent's competence to be a constructive and motivated autonomous decision maker [209,210]. It is therefore incumbent on the healthcare team to carefully craft the non-adherence intervention — it should have a grounded base in theory and specifically address all of these challenges. With these caveats in mind, we will describe a series of classifications of interventions that have been discussed in the literature, and their practicability in clinical practice.

Pretransplant evaluation and behavior modification

It would appear intuitive that pretransplant medication non-adherence, as well as other behavioral and psychosocial issues, might predict post-transplant non-adherence [211]. Surprisingly, there is a paucity of data on this subject [212]. There appear to be conflicting views on the subject [212]. A report examining the predictive value of previous non-adherence was limited by its retrospective nature and reliance on weak criteria to define pretransplant non-adherence [213]. On the other hand, in theoretical models designed to explain health behavior, past behavior can be a powerful tool to predict future behavior such as medication non-adherence [212,214]. Pretransplant evaluations are the first clinical opportunities to examine possibilities of medication non-adherence. Even if pretransplant behavior is predictive, it is not entirely clear that pretransplant clinical interventions will significantly modify post-transplant non-adherent behavior [215–219].

On the other hand, a recent prospective study by Dobbels et al. [220] in adults suggested that pretransplant medication adherence, poor social support for medication taking, low scores on the personality trait "conscientiousness", and higher education levels predicted post-transplant non-adherence and poor graft outcome. The finding of *higher* education level as a predictor of non-adherence came as something of a surprise, since other studies suggested that *lower* educational levels were associated with non-adherence [221]. Most notable was the finding that pretransplant non-adherence was a strong predictor of late acute rejection episodes [220].

The KDIGO guidelines on kidney transplantation [200] recommend preventative interventions for non-adherence, including the provision of "education, prevention and treatment measures to minimize non-adherence to the taking of immunosuppression medications, and to increasingly screen those patients at increased risk for non-adherence" [215]. However, the specific ways that these general pretransplant interventions might be implemented are not detailed. The KDOQI commentary on the KDIGO Guidelines for pretransplant interventions comments on the need to address factors suggestive of post-transplant non-adherence. However, they point out that KDIGO offers little guidance or evidence except to state that it is important to involve multiple disciplines in the provision of appropriate interventions [216]. It has been proposed that the pretransplant evaluation for adult kidney transplantation should consider non-adherence to the dialysis program and medication taking, and should delay transplantation until suitable adherence is achieved [14]. However, non-adherence in one area does not guarantee non-adherence in another. For example, studies in liver transplantation have found that substance abuse (viewed as a non-adherent activity) in the pretransplant period did not necessarily eventuate in medication non-adherence [217,218].

The Transplant Program at the University of Minnesota has reported their experience with a protocol whose results may inform the construction of pretransplant assessments and interventions. The protocol describes the steps that must be considered for a second renal transplant for patients who have failed a first transplant because of non-adherence. This protocol was first described in 1995, and updated in 2009 [218,219]. While these reports do not describe a clinical trial, they utilized a historical control group and represent the only large published clinical experience. The 114 patients who lost their first renal allograft to medication non-adherence, documented by self-report, underwent a complete re-evaluation, which included an educational class and a visit with the full transplant team. The specific evaluation components were: (1) an individualized discussion with the candidate and the transplant coordinator, nephrologist and surgeon, dealing with the reasons for the prior non-adherence and how to prevent subsequent non-adherence; (2) an evaluation by the transplant social worker and neuropsychologist to identify additional factors that could lead to non-adherence; and (3) a point by point discussion with the candidate laying out the conditions that must be met before transplantation is offered [219]. Major criteria that had to be fully met in the Minnesota protocol included: (i) full adherence for at least six months to the entire dialysis, medication/laboratory and other testing, and clinic visits; (ii) completion of all recommendations by the social worker and neuropsychologist; (iii) the amelioration of those factors that were identified as contributing to the prior non-adherence; and (iv) in cases where a living donor is planned, full discussion of the entire protocol with the prospective donor. A final consultation was scheduled to assure the medical team that the candidate fully understood and planned to implement the requirements and terms for transplant. This entire pretransplant intervention is not unlike that practiced at many transplant centers.

Seventy-five of the 114 (66%) patients initiated the pretransplant screening and intervention protocol. Of these 75, 48 were able to satisfactorily complete the evaluation/intervention protocol, and 37 of the 48 had received kidney transplants at the time of this report. The authors found no significant differences between these patients and the historical control group with regard to patient survival rates, death-censored graft survival, or chronic rejection-free survival, although there was a suggestion of a trend towards differences in the latter categories. There was a significant increase in acute rejection episodes in the patients who had manifested non-adherence with their first allograft. However, there was no increase in the incidence of late acute rejection, a hallmark of medication non-adherence. This appears to be contrary to other reports [220]. Unfortunately, there appeared to be some important durability in the non-adherent behavior, notwithstanding the pretransplant interventions. In the group of previously non-adherent patients, 14% lost their retransplant to non-adherence, while only 2% of the control retransplants lost their grafts to non-adherence [219]. Moreover, 57% of the originally non-adherent retransplant recipients exhibited non-adherent behavior.

This study raises some important questions about the extent to which pretransplant interventions can be effective. On the one hand, it is disappointing that non-adherent behavior persisted in those patients with prior non-adherence after retransplant [222]. On the other hand, we are not given sufficient information from the Minnesota study (e.g., the presence of anti-HLA DSA) and the study did not really have enough power, nor was it sufficiently controlled, to fully answer the question of whether their pretransplant interventions were effective. Indeed, the clinical outcomes were acceptable, if somewhat less than optimal.

Taken together, what conclusions can be drawn about pretransplant interventions to prevent non-adherence? It seems reasonable to conclude that a necessary part of the pretransplant evaluation is the investigation of candidate's adherence status. Every pretransplant candidate should be considered at risk for non-adherence [222]. Prior to transplant, the patient's adherence should be repeatedly assessed, ideally by individuals who are skilled in identifying non-adherence and making use of available time, such as while the patient is on dialysis. Interviewers should explore the underlying reasons for a patient's problematic behavior. The pretransplant team (particularly the social worker, psychologist and transplant coordinator) should implement tailored interventions to target any underlying issues that can be identified, using the factors outlined previously [222] (see Table 120.1).

In the pediatric/adolescent candidate, pretransplant interventions that seem to be appropriate (notwithstanding the absence of a strict evidence based evaluation) should include:

- Educational intervention methods to instruct adolescent and caregiver(s) about post-transplant medical regimen and importance of consistent, and long-term adherence.
- Interventions to remediate skill deficits (e.g. organizational strategies, public transportation use, thermometer reading, and lab value interpretations).
- Treatment of identified emotional and/or behavior problems.
- Interventions to improve provider/patient relationship and communication.
- Interventions to increase/optimize social/emotional support for adolescent.

Pretransplant educational interventions should also follow the following guidelines:

- Information should be given by several different educators.
- Specifically address issues of medication knowledge, side-effects, and timing.
- Emphasize reconciling health beliefs between patients/parents and health providers.
- Approach the patient in an understanding manner.

We use an approach that acknowledges that adherence is sometimes difficult ("I know you must find it difficult to remember to take your medications when you are out with friends or are in school"), and work with him/her to acknowledge the barriers, so that they can be addressed.

Siegal and Greenstein have identified three patterns of medication non-adherence [223] that have briefly been described above. The following recommendations about the type of intervention are tailored to address these specific patterns or circumstances:

Accidental

These individuals tend to have strong beliefs that the immunosuppressive medications are effective and understand that the medication administration should not be missed or delayed. They tend to believe that the mode of action of the immunosuppressive agent in question is limited to 12 hours. These patients need interventions that work to remind the patient to take the medication in question. Pillboxes for each day that are filled once a week can be helpful, as can cueing techniques. They also require counseling on integration of their medication with their lifestyle.

Invulnerables

These patients tend to be younger, less well educated and have had their kidney transplants for a shorter period of time than the other groups. These patients have a high tendency not to believe in the efficacy of the medications or the need to time their medication administration accurately. Educational interventions need to address the long-term effects of medication non-adherence.

Decisive non-adherers

These patients tend, on average, to be more highly educated or, if adults, have white-collar jobs. They are accustomed to making independent decisions and understand the need for the immunosuppressive medications, but believe that the effect of the medication continues for >24 hours and further believe that an occasional late or missed dose does not have great import. Interventions with these individuals need to take into account their independent decision making habits.

Psychological distress

A number of patients may not fall into any of these categories, but instead may suffer from psychological problems such as depression about their disease or PTSD [67]. These issues must be identified and addressed before transplant if possible. It is possible that caregivers, such as close family members, may suffer similar disorders and require care as well [50].

Peritransplant and post-transplant interventions

As with pretransplant interventions, every transplant recipient should be assumed to be at risk for medication non-adherence [92,222]. Thus, it is important to utilize every post-transplant clinic visit to reinforce adherent behavior, both with medication administration, and with other health activities, clinic visits, and healthy lifestyle choices. The medical team must continually educate, as well as to introduce other measures to maximize adherence because results are more pronounced in the near term after a discreet intervention [39]. As time goes on, the results of a discrete intervention diminish with time. This is certainly in keeping with findings that interventions, particularly psychological treatment effects, tend to weaken over time [224]. Some overall guidelines for preventative interventions are listed below.

1. Interventions involving the medical team's communication with the patient/family:
   - Adopt an "Interactional Model", not a "we/they" approach; *Listen* to the patient/family.
   - Assume a non-judgmental approach.
   - Avoid selective attribution (the "fault is the patient's") [64].
   - Stress a "team" approach — parents are part of a team to help "coach" (remind), but not to control; healthcare professionals are part of team.
   - Have different team members develop "personal chemistry" with specific patients. These connections should be fostered during the interactions between medical staff and patients, especially adolescents
2. Interventions after transplantation attempting to forestall non-adherence:
   - Continual education with every visit.
   - Written instructions that are modified as time goes on.
   - *Recognize and address* patient and parent psychological and social problems — depression, anxiety, insurance changes, school counseling.
   - Essentials for discussion:
     i. medications have an effect only for 12–24 hours
     ii. delay or postponing medication will not have immediate consequences, but will in the long run. Damage is not immediately noticeable, but it is slowly cumulative.

The descriptions of interventional studies in the literature are often incomplete [225–227]. In a recent review by De Bleser et al. [198], 12 studies were identified that dealt with research on interventions for non-adherence in the transplant recipient. The majority of these studies merited only a weak or moderate ranking [198]. We will review those transplant-specific interventions below. Only peer-reviewed publications will be outlined. Interventions were classified as either: (1) educational/ cognitive: conveying information; (2) counseling/behavioral: the changing of behavior to empower patients to participate in their care and develop new skill sets of self-care; (3) psychological/affective: strategies dealing with feelings, emotions or social relationships; and (4) mixed interventions which utilize a combinations of these [188,197].

Educational/cognitive interventions

In the non-adherence literature dealing with pediatric patients taking medication for chronic diseases (but not transplantation), a recent meta-analysis found that educational interventions were an important component of every adherence enhancing intervention [228]. A study of 21 pediatric transplant recipients, 17 of whom were adolescents, was not as positive [72]. Twenty-one patients and/or parents were counseled at every clinic visit, which averaged about every two months. Written reinforcement of the counseling was provided, as were medication calendars, schedules and pamphlets. The authors concluded that the medical education program improved patients and parents knowledge of their medications, but did not increase compliance significantly. However, since this study contained a small sample size, and utilized a methodologically flawed measure of medication adherence, this report should not be taken as a blanket indictment of education as a tool to improve adherence.

Annunziato et al. [53] evaluated an educational intervention targeting the transition from parent-provided care to self-care. Twenty-two pediatric liver transplant recipients were enrolled for a two session educational study. Ten were enrolled because of a perceived difficulty in transitioning care from caregiver to patient, while 11 patients were enrolled sequentially without any predetermined entrance criteria. As judged by improvements of the standard deviation scores for tacrolimus levels, the educational interventions significantly improved adherence in the patients who were perceived to have had difficulty in transitioning from parental-care to self-care. However, adherence was not significantly improved in the group who entered the study without any perceived difficulty in the transition process. While the study sample was small, and there was no control group, the report did suggest that a targeted educational intervention aimed towards patients and families who were having difficulty in transferring responsibility to adolescents from parents has potential merit. In another study, verbal prompts by the care giver and verification that medication was taken were both related to higher adherence rates [229]. Klein et al. [188] examined educational strategies building on previous studies that suggested that clinical pharmacy services could positively impact medication compliance in renal transplantation [224], as well as other areas of medicine [230]. In a prospective, randomized controlled trial, the authors studied the effect of a 12 month pharmaceutical care program addressing medication adherence in 20 liver transplant recipients, compared to 21 control patients. Patients in the intervention groups received educational counseling about the immunosuppressive medications one week before the transplant and every one to three months after transplantation. Non-adherence was measured by electronic monitoring (MEMS), "immunosuppressive medication levels", pill counts, a Morisky questionnaire [231] and self-reports. The intervention group showed statistically significant improvements in adherence in virtually all measures, particularly in the electronic monitoring group. The number of patients was small, and there were patient dropouts because of the cumbersomeness of the MEMS. In addition, the authors could not correct for a Hawthorne effect. However, when taken in concert with a previous study [224], these findings strongly suggest that pharmacists can play a valuable role in an educational adherence intervention.

By contrast, Dean et al. found that in children and adolescents, educational interventions alone are insufficient to promote or sustain optimal adherence [232]. This was confirmed by the analysis of Kahana et al. [39]. Another, meta-analysis of adherence in chronic disease concluded that educational programs alone did not in themselves improve adherence or positively affect outcomes [233]. It is appropriate to conclude that educational interventions are necessary components for success, and can be effective when targeted, but are not sufficient to prevent medication non-adherence [234–236].

Counseling/behavioral interventions

Hardstaff et al. [190] studied the impact of a strictly behavioral/ counseling intervention with 75 kidney transplant recipients who were >1 year out from surgery. All patients used the MEMS system. The patients were randomized to either receive feedback about their MEMS results after their first clinic visit, or receive no feedback. Neither group received any further feedback for the rest of the 12-month trial. The one session of feedback resulted in no improvement in medication adherence. It may be that the intervention was too brief, or not targeted. A number of other negative studies dictate that more research is necessary [231,236–238]. However, the pediatric HIV literature strongly suggests that a behavioral component may successfully enhance outcomes [39,237]. It would appear from the literature that continued assessment and feedback to the patient has the highest likelihood of success as a behavioral intervention [233], and such strategies should be strongly considered in mixed interventions. In the adult chronic disease literature, there are successful interventions using operant conditioning with financial reinforcement principles [238]. In other words, patients are paid for being adherent. A similar concept was attempted in substance abusing adolescents, where prizes were awarded for desirable behaviors. This proved effective [239]. It is reasonable to suggest that such positive reinforcement could be a part of a successful adolescent adherence intervention, so long as the appropriate reinforcement moieties are chosen. It has been demonstrated that for the chronically ill adolescent, the personal significance of the illness and the treatment, and the degree of individual motivation, markedly affect adherence [240].

Psychological/affective interventions

There have not been any significant intervention studies with pediatric transplant recipients using only psychological/affective interventions [196], although a pilot study suggested that a targeted intervention for PSTD was successful in improving adherence in pediatric liver transplant recipients [65].

Mixed interventions

In examining interventions in chronic disease adherence management, multicomponent and behavioral interventions have produced particularly marked effects on adherence behaviors [39,241].

Most combined interventions included educational and behavioral interventions, with a small number using social support strategies with educational or behavioral elements [233]. It is thus reasonable to expect some success with mixed interventions in transplantation. The review by De Blesser et al. [198] identified five studies that adopted a mixed intervention approach combining educational/cognitive, counseling/behavioral and affective/psychological approaches [198].

De Geest et al. [150] conducted the highest quality study of these five. They identified low self- efficacy [242] and depression [243] as targets for a randomized controlled trial in adults undergoing kidney transplantation who had been identified as non-adherent. Patients were randomized to an "enhanced usual care group" and an intervention group. Electronic monitoring using MEMS tracked adherence for the three-month intervention/control period and for six months of follow-up. The authors used a structured interviewing technique [4] to evaluate the MEMS validity and reliability. A comprehensive home visit was made for each of the patients (and family member, when available) to assess the specific barriers to adherence that might be targeted. The "intervention nurse" discussed and inaugurated a series of interventions including behavioral elements to enhance self-efficacy (e.g. motivational interviewing [244]), other behavioral interventions to remind the patient to take the medications, tailored education modules to reinforce the patient's knowledge about adherence, and helping the patient organize social support to aid in medication taking. Eighteen non-adherent patients were selected to participate in this pilot. Six were included in the intervention group and 12 in a comparison group. Medication adherence improved in both groups, and it appeared to improve more in the intervention group, although the effect did not reach statistical significance. The randomized controlled trial was very underpowered. In addition, the multiple elements of the intervention were very time and labor intensive. The authors suggested that although their model was impractical in the usual clinical setting, an ongoing set of psychosocial and behavioral elements could be used in an ongoing continuity of care model or a chronic disease-management model [245,246]. This is an approach that is used in many pediatric transplant clinics, where the patient and family are seen in a multidisciplinary fashion so that not only medical, but psychosocial and behavioral approaches can be utilized.

The first mixed interventional study with pediatric renal transplant recipients [70,247] used combined educational and behavioral approaches, and involved the entire family, as is appropriate in a pediatric intervention. In addition to educational materials, the intervention involved parents giving weekly awards for adherent behavior. Utilizing a multi-parameter measurement system, recipients in the experimental group were more knowledgeable about transplantation. Moreover, adherence with azathioprine and prednisone improved by approximately 60%, while the control group experienced only a 33% improvement.

Shemesh et al. [248] identified non-adherent pediatric liver transplant recipients and used an approach featuring increasing the frequency of clinic visits and providing a targeted educational program to the patient and family about the importance of adherence. They followed the standard deviation of tacrolimus levels in conjunction with the increased visits. After the intervention, the number of patients with high alanine aminotransferase levels decreased significantly from eight before the intervention to four afterwards. Other outcomes, including the number of rejection episodes and adherence to tacrolimus, also improved, but did not achieve statistical significance [248]. Since this type of intervention is feasible for clinical practice [192] it will be important to test it with a randomized and more fully powered trial, perhaps adding in a more formalized behavioral module (e.g. reviewing adherence measurement by electronic monitoring).

Another small study utilized a mixed interventional approach with 12 patients [236]. Clinical pharmacists employed monthly educational counseling and medication reconciliation, direct feedback by telephone, and behavioral motivational counseling. Adherence, as measured by pharmacy refills and immunosuppressive blood levels, was statistically significantly better in the patients receiving the clinical pharmacists' interventions than in 12 controls. The study was small in size and the assessments of adherence utilized measures that were methodologically weak. Nevertheless, this mixed intervention supports the concept that multiple interventions that are targeted to the specific patient have great merit. A four month educational support program using web-based electronic communication with the healthcare team resulted in improved medication adherence for those who were most actively involved, but was not statistically significant for the overall group [194].

It should be acknowledged that most of these reports have enough important weaknesses to mandate a good deal of circumspection about the evidence based foundation of interventions for non-adherence. Nonetheless, it would appear that multidimensional interventions involving not only education, but behavior modification, encouragement of self-care, the development of stable social support and appropriate therapy for psychological issues such as depression could play an important role in constructing successful programs to prevent or improve medication non-adherence.

Other interventions for improving medication non-adherence

Simplifying the drug regimen

Simplified drug regimens are associated with improved medication adherence in patients with chronic illnesses [134,233,249] with a large effect on adherence [250–253]. Eisen et al. demonstrated that adherence improves incrementally as the medication dose frequency decreases [254]. This effect has also been demonstrated in adult renal transplant recipients [98]. Since the drug regimen for transplant recipients is quite often complex, simplification has an obvious advantage. As an example, recent studies using a new once daily sustained release formulation of tacrolimus [255] have found a positive effect on medication adherence [248,256] although the method of measuring adherence was not robust. This approach is not without problems [257]. The pharmacokinetics of the single drug in question (in this case tacrolimus) may not be equivalent to twice daily dosing, necessitating dosage changes [258,259]. In addition, if the patient is non-adherent and misses his/her once-daily dose, there may be increased clinical repercussions [257]. Nevertheless, with appropriate monitoring of adherence, a simplification of the immunosuppressive medication appears rational, although definitive data on the specifics of the simplification require validation in appropriately conducted studies.

Avoidance of medications with noxious side effects

The unacceptable side effects of certain immunosuppressive medications can lead to medication non-adherence, particularly in adolescents. A prime example of this is the use of corticosteroids in post-transplant immunosuppression. The noxious side effects of steroids on body image [260] and growth [261,262] (among other

side effects) are important reasons why patients are non-adherent with these medications [263]. The use of steroid-free and steroid-sparing protocols have been shown to be successful [19,264,265]. By minimizing or totally avoiding corticosteroids, it is reasonable to assume that at least one important barrier to adherence can be overcome.

Additional possible medication modifications

Clinical tolerance

By definition, the state of immune tolerance refers to the ability to maintain a well functioning allograft and a competent immune system to third party invaders with no additional immunosuppression [266]. While this may not modify other risk-taking behaviors characteristic of the adolescent transplant recipient, the state of tolerance would represent an answer to medication non-adherence [267–269]. Unfortunately, it is not possible to reliably produce tolerance in the human clinical setting, and this is particularly true in the pediatric setting [270]. Spontaneous or operational tolerance is occasionally observed when an organ survives unscathed in the face of withdrawal of immunosuppression, either under medical supervision or as a result of non-adherence. If biomarkers can be identified that identify the state of operational tolerance, some transplant recipients could theoretically be withdrawn from immunosuppressive medications [271]. This could be of benefit to some adolescents, and might be particularly common in liver transplant recipients [271]. In this regard, it is interesting to note that in pediatric patients, recipients of combined liver-kidney transplants have improved renal allograft survival compared to those receiving only kidney transplants [272].

Long acting parenteral immunosuppressive agents

The use of safe, long-acting immunosuppressive medications has appeal in the context of medication non-adherence, in that the administration of such a medication is simple and can be directly observed [133]. This strategy prompted us to examine the use of Figolimod (FTY 720), which depresses peripheral lymphocyte count for up to one week [273].There is even greater theoretical appeal for such a medication to be administered parenterally by medical personnel. In pediatric renal transplantation, daclizumab, a humanized monoclonal anti-CD25 antibody has been used successfully for over six months with excellent results [265]. In non-infectious ocular inflammatory disease, daclizumab has been used successfully for over three years [274]. Prolonged, subcutaneously administered daclizumab is currently being evaluated for use in relapsing-remitting multiple sclerosis [275], but is not currently being evaluated for use in renal transplantation.

One strategy that has attracted considerable interest is the use of belatacept. For a T cell to become fully activated, signals must be transduced through the T cell receptor and through a costimulatory molecule or molecules. Interruption of this costimulation renders the T lymphocyte anergic. There are a number of dyads (a molecule on the antigen presenting cells ligating with an antigen on the T lymphocyte), and the specifics of these are discussed in detail elsewhere in this book. One of the first reported and most prominent of these costimulatory pathways is the CD 28/B7 (i.e., CD80 and CD86) ligation. The engagement of CD28 on the T cell by B7 on the surface of antigen presenting cells, in conjunction with the signaling of the T cell receptor by the MHC antigens results in marked T cell activation and proliferation. CTLA-4, another T cell surface receptor, binds 100 times more avidly to the B7 antigens, thus blocking the CD28 costimulatory signal. Belatacept is a fusion protein containing CTLA-4. This causes strong binding to B7 and blockade of the CD28 signal [276]. Of importance for this discussion, belatacept can be given parenterally monthly, with resulting excellent and probable safe immunosuppression. This agent has been studied in phase III trials, with durations of administration of over three to five years [277,278]. Formal clinical trials have not yet begun in pediatrics as of this writing. One can be cautiously optimistic that if adolescent patients are getting at least one effective immunosuppressive agent reliably, this may result in some amelioration of the impact of medication non-adherence [279]. Two notes of caution must be struck. Belatacept is recommended only for use in EBV seropositive patients, to protect against the generation of PTLD [280]; thus belatacept may not be appropriate for every adolescent. Additionally, the successful administration of belatacept may not be accompanied by good adherence with the other oral immunosuppressive agents.

Addressing underlying psychological problems

Adult patients with chronic illness [281,282] and specifically end stage renal disease, commonly manifest depressive symptoms. In one study, adults beginning chronic hemodialysis underwent psychometric analysis, and 44% had scores which indicated significant depression [283]. The psychological distress appears to persist, although to a somewhat decreased extent, after kidney transplantation [284]. The same is true with pediatric patients. Children with chronic illnesses are over twice as likely to develop psychological and behavioral problems when compared to healthy children [285]. Children undergoing dialysis and transplantation have classically demonstrated depression, school problems and emotional distress [279,286,287]. Later studies using more sophisticated instruments have confirmed these observations [77]. Illness-related uncertainty appears to play an important part in this [84,288] while hope appears to moderate depressive symptoms [84].

There appears to be a strong linkage between emotional problems such as depression/anxiety and medication non-adherence [289,290]. This occurs in a significant number of chronically ill patients, including recipients of renal and liver transplants [291–295]. Similarly, in adolescents with chronic illness, there is an association between poor adherence and emotional problems [83,296–298]. Penkower et al. [77] studied 22 adolescent transplant recipients, and found a significant association of non-adherence with anger, but not with depression or anxiety. Others have suggested that there is an association between compromised emotional functioning and non-adherence in pediatric transplant recipients [72,299]. It has been strongly suggested that illness-related-uncertainty can mediate depression and this in turn mediates medication non-adherence [84]. On the other hand, the presence of hope, by mitigating depression, appears to be associated with immunosuppressive medication adherence [84]. Interestingly, it appears that the development of anxiety after transplantation may not foreshadow increased levels of medication non-adherence, but in fact may be associated with more stable adherence patterns [300]. Finally, the development of PTSD, as detailed earlier in this chapter, is associated with medical adherence difficulties.

Summary

It is not overstating the issue to suggest that medication non-adherence represents one of the most important unmet needs in solid organ transplantation. The problems associated with medication non-adherence are under recognized, both in pediatrics and

adults. The research in this field is plagued by difficulties in uniformity of definitions, detection techniques, agreement on relevant barriers and precipitating factors, and proven interventions. Long-term transplant outcomes, particularly in kidney transplantation, have not changed dramatically over time, although short-term improvements have been made. It is quite likely that some or most of the long-term barriers to improved graft outcome can be realized with a more thoughtful and concerted effort to improve immunosuppressive medication adherence.

CHAPTER 121

Management of the Organ Transplant Recipient in the Transition from Pediatric to Adult Care

Sandra Amaral[1] and Lorraine E. Bell[2]

[1] University of Pennsylvania, The Children's Hospital of Philadelphia, Philadelphia, PA, USA
[2] McGill University Health Centre, Montreal Children's Hospital, Montreal, QC, Canada

Introduction

In the 1960s and 1970s, pediatric transplantation was in its infancy. Pediatric transplant rates were low and mortality high [1]. The number of recipients reaching adulthood was small and the consequences of their move to adult care received little attention. Since the 1980s, with remarkable medical, pharmacological and surgical progress in pediatric transplantation, ten-year recipient survival rates for some organs approach 95% [1,2]. Both the absolute number of pediatric transplants and the proportion of children transplanted in infancy and early childhood has increased and an ever-expanding number of pediatric recipients are emerging into adulthood. Pediatric providers are challenged to help them transition from being children with chronic illness to young adults with complex medical issues, equipped with the knowledge and skills to effectively function in an adult healthcare system. This chapter will discuss facilitators and barriers to successful transition and review recommendations for best practices to enhance the quality of care for transitioning patients. Additional discussion of adherence issues germane to this topic can be found in Chapter 120.

Background

It is vital to consider transition and transfer as two separate entities. The former is a process and the latter an event. Transition is best defined as "the purposeful, planned movement of adolescents and young adults with chronic physical and medical conditions from child-centered to adult-centered healthcare systems." [3] This definition incorporates the broad range of psychosocial, biological, and developmental changes which occur during adolescence. The provision of transitional care is a process which occurs over a prolonged period of time with transfer being a discrete point along the continuum of care. Importantly, transition does not end at the time of transfer. The concept of transitioning youth is not specific to pediatric organ transplantation. Indeed, many of the current practice recommendations and guidelines for optimizing adolescent and young adult care are drawn from studies of patients with a wide range of chronic illnesses [3,4].

Addressing the transition needs of adolescent and young adult transplant recipients is crucial not only to their graft function but also their survival. Several large studies have observed higher rates of graft failure during the time frame and the age range of transfer to adult care. Using a Canadian registry, Samuel et al. examined whether increased graft loss occurred during the peri-transfer adaptation phase [5]. They considered the "adaptation period" to be the time encompassing 6 months before and 2.5 years after the first recorded adult visit. Compared with the period immediately prior, the adjusted hazard ratio (HR) for graft loss within the adaptation period was 2.24 (95% Confidence Interval (CI): 1.19–4.20). When they narrowed the adaptation period to six months before and six months after transfer, the adjusted HR for graft failure was even higher at 5.42 (95% CI: 2.83–10.39). Similarly, a US Government report by the General Accountability Office examined rates of kidney transplant failure among different age groups, pediatric vs. "transitional" vs. adult [6]. The study classified "transitional" transplant recipients as those who were transplanted as children and turned 18 years of age during the seven year follow-up period. By five years post-transplant, the percentage of transitional recipients who experienced a transplant failure (33%) was double the percentage of pediatric recipients (16%) and slightly higher than adult recipients (28%). It is assumed that this transitional group would have transferred medical care during the follow-up period. In contrast, a single centre Canadian study of 115 kidney transplant recipients found no increase in graft failure following transfer and a study from the Netherlands showed no increase in acute rejection rate among patients transferred to adult care at a mean age of 18 years [7,8]. Thus, transfer does not inevitably lead to rejection or graft loss. Further research is needed to clarify which patient and healthcare system factors may protect from vs. predict allograft dysfunction or loss surrounding the time of transfer.

Age has been suggested as an independent risk factor for increased risk of allograft loss during the transition of adolescents and young adults. Smith and colleagues reported a higher risk of graft loss, late acute rejection and incomplete rejection reversals among US adolescent renal transplant recipients aged 13–17 years compared with younger transplant recipients in the North American Pediatric Renal Transplant Collaborative (NAPRTCS) [9]. Using a larger database, the United States Renal Data System (USRDS), Foster et al. found that age-standardized graft failure rate was 12.9 per 100 person-years among patients who transferred at less than 21 years of age compared with 8.7 per 100 person years among those who transferred $\geq$21 years of age [10]. In Canada,

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Kiberd compared graft survival rates between pediatric patients <18 years who were transplanted in a pediatric hospital, with young adults transplanted in an adult hospital, in two different age ranges: 18–24 years and 25–35 years [11]. Those in the 25–35 year age range had significantly better graft survival compared with the pediatric and younger adult (18–24) groups (HR 0.45; 95% CI: 0.25–0.82). However, graft survival rates were similar between the pediatric patients and the young adults aged 18–24, regardless of transfer of care. In a recent and very important USRDS study, Foster et al. examined both age at transplant and current age as risk factors for allograft loss [12]. Among first kidney transplant recipients younger than 40 years of age, older adolescent and young adults ages 17–24 years had the highest risk of graft failure, compared with the younger and older age groups, irrespective of age at transplant and time since transplant.

The normal developmental processes of adolescence and emerging adulthood likely contribute to the increased graft loss observed during this period (Table 121.1) [13–17]. The "emotional" brain and "executive" brain have different developmental trajectories, with executive functions being slowest to mature [18]. Elegant neuroimaging studies have shown that full brain maturation is not achieved until young adults are in their mid-to-late twenties [19–22]. Risk-taking normally peaks in young adulthood; this can be seen in both sophisticated neuropsychological experiments and in morbidity-mortality statistics [18,23]. Young adults (age 18–25 years) have the highest rate of accidental death, substance abuse and sexual risk taking [23]. This peak risk taking age coincides with the time most youth transfer to adult care. It is often a period when other stressful events may occur, such as leaving home, moving to another city for work or education, and intense emotional or romantic relationships. The confluence of all these factors, in a young person with a chronic illness, may play a role in medication non-adherence and missed medical appointments.

Regardless of whether age or transfer matter more, the need to prevent allograft loss in a transitioning young adult transplant recipient is critical not only for the individual patient but also for society. Every potentially preventable organ loss that occurs due to problematic transfer or transition adds to a higher demand for organs in a world of limited supply. In addition, there is substantial economic burden when a patient loses an allograft and returns to dialysis treatment. A patient on dialysis is generally less able to work than one with a transplant and the healthcare costs of dialysis are substantially higher than those of transplant [6].

Although non-adherence is believed to contribute to allograft loss during the transition period, adherence is the focus of a separate chapter in this book; the current chapter will concentrate on more systematic issues related to the provision of transitional care.

Recommendations and guidelines for the provision of care to the transitioning adolescent and emerging adult transplant recipient

There have been numerous reviews providing recommendations for the provision of transitional care but there are few data to support specific evidence-based guidelines [17,24–29]. Bell et al. reported transitional care recommendations for solid organ transplant recipients from an international collaborative effort of multiple transplant societies [17]. This report reflected expert opinions from a wide variety of pediatric and adult transplant physicians and nurses, psychologists, social workers, and administrators. Webb et al. later conducted a similar conference in the UK but also included patients and parents [30]. In general, diverse expert groups have suggested several major themes and critical transition components (Table 121.2) which are in concert with the basic principles and fundamental steps of transitional care provision promoted by the Society

Table 121.1. Developmental stages of adolescence and young adulthood and corresponding clinical approach suggestions

	Early adolescence (ages ~ 10–13 years)	Mid adolescence (ages ~ 14–16 years)	Late adolescence (ages ~ 17–21 years and beyond)
Cognitive, affective and moral	• Concrete thinking • Beginning of abstract thought in some • Cannot grasp long-term outcome of decisions • Heightened emotional arousability • Sensation seeking • Reward oriented	• Increased abstract thinking • Concrete thinking in stressful situations • May begin to perceive future consequences of actions but not utilize in decision making • Heightened vulnerability to risk taking • May have difficulty regulating affect and behaviour	• Complex abstract thinking (some) • More future oriented: can act on long term plans, delay gratification, set limits • Greater emotional stability • Idealism but sometimes absolutism, with intolerance of opposing views
Self-concept/Identity formation	• Fantasy and present-oriented • Self conscious about appearance	• Increased introspection • May have intense feelings of inner turmoil • Concern with attractiveness	• Progression of personal identity • More stable body image; attractiveness may remain important
Family and peers	• Beginning of emotional separation from parents • Need for privacy • Beginning of strong peer identification and affiliation	• Further emotional separation from parents and family • Struggles and conflicts over autonomy • Strong peer identification and involvement	• Separation from family emotionally and physically • Peer group/peer values diminish in importance • Formation of stable relationships
Relationship to society	• Adaptation to middle /early secondary school years	• Assessment of skills and opportunities • Early vocational plans • Realistic role models critically important	• Career decisions central • Progress of vocational capability and financial independence
Suggested subjects to explore and discuss at clinic visits	• Introduce concept of private confidential visits to parents and patient • Simple directed interactive questions to patient • Straightforward interactive counselling	• Enquire about friends, free time activities, home life, school • Ask in non-threatening, non-judgmental manner about any experimentation with drugs, alcohol or sexual activity or any trouble with law • Discuss healthy living	• Discuss healthy living habits and personal interventions for improving overall wellness • Identify unhealthy living habits and their consequences • Discuss personal, educational and vocational goals • Build upon questions from early age ranges (to left)

Table 121.2. Critical components for the provision of transitional care to adolescents and young adult transplant recipients

1	Start discussion of transition early in adolescence.
2	Transitional care must be flexible, individualized and developmentally appropriate. Care must address common health and lifestyle concerns of adolescents.
3	Care must be directed at enhancing patient autonomy, increasing a patient's sense of personal responsibility and facilitating self-reliance in concert with a patient's potential for independence.
4	There must be a designated healthcare professional who takes responsibility for the transition process. Each patient and family should have a transitional care coordinator and advocate.
5	There should be a detailed written transition plan that is developed and updated with each young person and his/her family.
6	There must be a concise, portable medical summary accessible to both the patient and the receiving healthcare provider.
7	There must be attention given to supporting continuous health coverage for the transplant recipient during transition and transfer.
8	There must be communication between the pediatric and adult health care providers preceding, during and subsequent to transfer of care.
9	Transfers should not occur in times of crisis and should be agreed upon jointly by the family, patient and pediatric and adult providers.
10	Guardianship and legal competency issues should be clarified before the age of majority.

for Adolescent Medicine [3]. Many of these recommendations are supported by small qualitative studies from diverse transition stakeholders' perspectives. Herein we will discuss each of these critical components. It is crucial to keep in mind that "the optimal goal of transition is to provide healthcare that is uninterrupted, coordinated, developmentally appropriate, psychosocially sound, and comprehensive" [3].

Start early

Most consensus guidelines and recommendations suggest that preparation for transition begin early in adolescence, generally between the ages of 12 and 14 years [31–33]; some advise earlier, in order to foster progressive independence both socially and medically [17,25,34]. There is no one age, time or method that is known to be best for introducing the concept of transition. Early introduction may mean simply acknowledging that one day the patient will be of adult age and will need to transfer. It may be a relief for parents to realize that the physician expects their child to reach adulthood, despite their illness, and that they need to plan for his/her future. Early introduction of the concept of transition can help parents establish age and developmentally appropriate tasks and responsibilities for their child with a chronic illness and reinforce the need for regular school attendance and social activities. Table 121.3 illustrates how parents and their child can share healthcare tasks and gradually shift the major locus of responsibility from parent to child [17,35,36]. These are key elements in helping a child gradually develop self-responsibility and autonomy.

During medical visits the pediatric nurse and physician should spend part of the interview directly communicating with the child, encouraging him/her to answer some of the medical history questions and to understand the treatment plan. This can help the patient feel a member of the team and reinforce his/her active role in the therapeutic process.

In addition, even in early adolescence, pediatric providers should consider interviewing patients independently for part of the visit. Private one-on-one time during healthcare visits plays a significant role in the quality of care perceived by youth, and is recommended as a component of quality healthcare for adolescents by the American Academy of Pediatrics [37]. In early adolescence this independent interview may be very concrete, with the provider asking, "What is your favorite subject at school? What do you like to do for fun?" The content is not crucial but the relationship and trust that begin to build between the provider and patient can be. This private interview (no caregiver present) provides a chance for the patient to hone communication skills vital to adult health self-management and affords opportunities for the patient to communicate confidential information, which might otherwise remain unrevealed. Patients have reported that being seen independently is an important component of preparing them to transfer [38,39]. Some centers place posters in the waiting room which explain confidentiality rights and may serve as a reminder to patients and families that the primary relationship lays between the healthcare provider and the patient, not parent. It is important for the healthcare provider to know and understand the state, provincial and/or federal laws that govern confidentiality and consent issues for minors, as these vary by jurisdiction.

Flexible, individualized and developmentally appropriate care

Organ transplant recipients may have neurocognitive and maturational delays and sometimes these are not readily apparent [40–43]. Thus transition of care strategies require flexibility. It is important to develop a transition plan in the context of the patient's neurocognitive function. This may necessitate involvement of a psychologist to formally assess the patient's potential for healthcare self-management and independence and to avoid the pitfalls of unrealistic expectations, either set too high or too low. The aims of transitional care include helping patients with goal setting, self-advocacy, healthcare self-management, and problem solving. The expectations of the patient, family and healthcare team must be in concert with the ability and potential of the patient.

Provision of developmentally appropriate care also refers to adolescent-centered care. Providers need to address common health and lifestyle concerns of adolescents and young adults, such as reproductive health, negative health behaviors (drinking, smoking, unprotected sex), as well as positive health behaviors (healthy diet, exercise), and mood disorder screening. In the US, it is estimated that over 13% of high school adolescents have seriously considered suicide and 47% have had sexual intercourse, of whom 12.9% did not use birth control [44]. Violence is also prevalent amongst US high school adolescents, with 32.8% reporting having been in a physical fight and 8% reporting sexual abuse [44]. A broad psychosocial interview, including sexual history, is equally important for both sexes. Recent studies suggest that the sexual and reproductive health needs of male adolescents may often go unrecognized [45]. A common psychosocial interview mnemonic for adolescents is HEEAADSSS (Home, Education and Employment, Eating, Activities, Affect, Drugs, Sexuality, Suicide and Depression, Safety) [13]. Although transplant subspecialists may feel that these adolescent themes are best deferred to the general pediatric provider, adolescents generally have very low primary care usage rates [46,47]. Thus, adolescent transplant recipients may not have an established primary care provider with whom they have built trust and rapport. In addition, they may benefit from discussing their psychosocial concerns in the context of their transplant and medical regimen and have special areas in need of more attention, such as optimal vaccination, health related travel risks, sexuality, and genetic counseling around reproduction.

Another component of comprehensive, individualized care is a vocational and educational assessment, guidance and support.

Table 121.3. Suggested approach to development of child and adolescent's leadership /self management skills

Stage/age	Child capabilities/actions forming basis for leadership skills	Parent(s)' leadership actions supporting child's increasing capabilities
Toddler (1–3 yr) Parent as "CEO"	• Cooperates with routine treatment with limited acting out • Understands firm limits of parents • Helps hold equipment and supplies (e.g. oral medication dispensers, enteral feeding supplies)	• Rituals for treatment: child knows what to expect and can learn by repetition • Identify possible treatment roles to share with child • Emphasize hygiene in prevention of infection (e.g. hand-washing, teeth cleaning, safe handling of pets)
Pre-school (4–5 yr) Child begins to learn basic self care	• Participates further in self-care (e.g. helping gather medications or treatment supplies) • Medical play: such as nurse or doctor kits, doll that undergoes similar treatments to patient (e.g. venipuncture, peritoneal dialysis, feeding tube, etc) • Begins to identify body parts important to his/her health condition • Learns name of health condition (e.g. heart, kidney, liver transplant, etc) • Learns simple terms for transplant related problems and medication side-effects (e.g. for feeling unwell, nausea, painful urination, skin lesions)	• Explain in simple concrete terms what will happen at clinic/hospital visits • Set fair and appropriate limits (e.g. taking medication on time, teeth brushing, dietary and fluid requirements, infection prevention strategies) • Allow choices (where appropriate); such as which medicine to swallow first • Model acceptance of management routines and limits • Reassure child he/she is not to blame or being punished when treatment causes discomfort (e.g. injections, blood drawing)
Early school age (6–9 yr) Child provides some self care	• Recognizes one or two major internal body cues of a problem (e.g. fever, abdominal pain, graft pain, dysuria, swelling) • Participates actively in concrete care and monitoring of condition (e.g. oral hygiene, fluid intake, recording medications on personal medication record) • Increases concrete level of understanding of the health condition, cause of original organ failure, requirements of treatment	• Negotiate with child "rules" for working together to get all treatment done (e.g. taking medication on time in parent's presence) • Encourage healthy living (regular exercise, healthy food choices) • Support normative activities (sports, other organized activities) to encourage fitness, teamwork, and sense of achievement • Discuss and model approach to telling teachers, friends, and coaches about health condition, and the amount of detail to share
Early Adolescence (10–13 years) Parent becomes "Manager" vs. "CEO" Adolescent performs greater self care and some self management	• Increases understanding of the transplant condition and its affect on daily life • Learns signs/symptoms of transplant organ rejection • Begins to communicate directly with health care provider, initially in parents' presence • Independently completes some medical self management tasks (e.g. alarm watch for medication, agenda with appointments and tests, learn medication names, doses and times, and allergies) • Prepares medication dose boxes, with parental supervision • Learns how to respond to peer pressure and yet still take care of self	• Provide tools so child can self-manage (e.g. notebook and/or agenda for record keeping of treatments, medication taken) • Observe process closely, to offer immediate corrective feedback • Remain present and involved in care, decision making, and monitoring • Be there for new symptoms, changes in treatment and emergencies • Ensure child has told important others (e.g. friends, teachers, coaches) of his/her transplant and what assistance they could provide if needed • Further encouragement of healthy living and normative activities as above
Mid adolescence (14–16 years) Parent becomes "Supervisor" Adolescent becomes main "Manager" of daily routine care	• Achieves more abstract knowledge of treatment requirements, complication prevention and transplant organ rejection • Develops strategies to complete routine management tasks, such as taking medication on time (alarm watch, cues linked to daily routine) • Learns medications' roles, side effects, consequences of taking irregularly • Participates in appointment making • Effectively asks for assistance in complex situations • Reads more about transplantation and his/her underlying condition	• Negotiate and renegotiate who does what • Discuss new issues (e.g. sex, drugs, alcohol), related peer group activities/pressures and any effects on transplant condition • Begin to discuss vocational and educational goals and insurance issues • Encourage community involvement (e.g. club, volunteer work, extra-curricular activity groups) • Consider adolescent's participation in limited part-time or summer employment
Late adolescence Parent becomes "Consultant" and resource person to adolescent	• Achieves sense of self as capable manager of the transplant condition • Integrates realities of his/her transplant care with risk taking of peers • Can appreciate the benefits of transplant despite constraints of management • Continue to develop more independent health and community support network with transition to adult based services • Make commitment to lifetime of treatment	• Develop flexible way of communicating with the adolescent to remain informed but not interfering • Remain present for support and problem solving • Provide encouragement and guidance as the youth transitions from paediatric to adult care services • Encourage vocational, college or university training and/or integration into the work force

Education is an important determinant of health and is linked to health related behaviors, self-determination and empowerment, employment, socioeconomic status, and health insurance [48,49]. Optimizing the education potential of pediatric transplant recipients can contribute to their long-term health and well being and their adaptation in adult life. A social worker is a vital team member to help address these issues in a multi-disciplinary transition service.

At times, patients may bring peers or significant others to clinic appointments. These are rich opportunities to assess and engage the patient's support system. Including peers in the conceptualization of the patient's support system is important. Patients have also expressed the desire to have a "buddy" with similar experiences to help transition [50]. In the UK, youth workers who serve as peers and role models have been incorporated into a transition clinic model [51]. Possibilities for peer support include encouraging adolescent and young adult transplant recipients to engage with each other on the days of their clinic visits and facilitating regularly scheduled social events for them to interact outside of the medical setting [51].

Enhance patient autonomy

Young adult transplant recipients often express a preference to be treated as adults prior to transfer [33,38]. It is essential for the healthcare provider to collaborate with the patient and family to identify specific tasks for which the patient assumes increasing responsibility. For example, the patient may listen to the parent call the pharmacy for refills; then do it him/herself with parent

supervising; then do it independently. Making a healthcare appointment is another learned skill. The patient can listen to the parent make the appointment by phone or in person after a clinic visit. The patient can do it together with the parent several times and then independently thereafter. An analogy is when a teenager learns how to drive. A parent or guardian may walk the teen through it, show them were the brakes and accelerator are, how to turn the key, how to accelerate, etc. The parent then has the teen drive with the parent in the car, providing feedback. Finally, after practice, the teen is comfortable enough to obtain a driver's license and drive independently. Although there is no driver's license equivalent to healthcare self-management, the steps involved in learning to drive parallel many of those in learning to be an independent health advocate. These task-based accomplishments take time, practice and supervision, and the parent or guardian should be an active partner in the process. Suggestions for progressive enhancement of autonomy are found in Tables 121.1 and 121.3.

Designated healthcare professional

Guidelines suggest that there should be a transition "champion" to lead transitional care efforts [17,31]. Generally, this responsibility would fall to a physician in either the adult or pediatric center, but ideally both. There is also a need for a transition advocate or coordinator for each patient, usually someone in direct service, such as a transplant coordinator, nurse, social worker or case manager. In some centers, he/she may be a youth worker [51]. This person is the primary contact for assessing the patient's transition progress and helps the patient navigate the healthcare system during transfer. Ideal site resources include the transplant physician(s), and surgeon(s), designated transplant nurse(s), nurse coordinator, social worker, psychologist and designated transfer liaison; in the adult centers these may also include a reproductive specialist and urologist [17,51]. Additionally, it is highly recommended that the patient have an identified primary care provider who will provide continuity of general care.

Written transition plan

It is important for the provider, patient and family to work together to construct a patient-specific written transition plan. A center may start with a general plan for all patients and tailor the plan based on patient and family feedback and the patient's developmental stage and potential for independence. A written plan encourages expectations and goals to be clearly set and systematically assessed. It should be regularly reviewed and updated based on patient progress and challenges. Some programs conduct a formal transition evaluation yearly. The interval needed may depend on the patient and the program's resources, but at a minimum it should be annually.

Portable medical summary

The pediatric healthcare provider should formulate a concise but comprehensive medical summary for both the patient and the accepting healthcare provider to facilitate the transmission of knowledge when the patient transfers and in the case of emergencies. At a minimum, it should include the primary diagnosis, date of transplant, major transplant events (e.g. biopsies, rejection, medication changes, infections, etc.), an updated medication list, drug allergies and intolerances, psychosocial status, healthcare insurance status, the most recent laboratory studies and comprehensive contact information for health providers to reach the patient and/or caregiver. An excellent example of a patient-oriented portable medical summary is "MyHealth Passport" from the Hospital for Sick Children in Toronto, Canada [52]. It is readily accessible on the internet, includes a transplant-specific model and can be completed by the patient with assistance from a healthcare provider. The data entered are transformed into a printable, wallet-sized medical summary. The electronic health record can also be tailored to produce a concise medical summary. A portable, concise summary may come in many forms and include pictures, audio, video or storage on USB drives. The use of information technology to enhance the transfer of health information among medical providers and across various healthcare settings has been promoted by the American Academy of Pediatrics, as a means to improve the quality of care for transitioning patients [53].

Healthcare insurance coverage

Transfer to adult care should take place with due consideration of the adolescent/young adult's financial factors. If a patient is at imminent risk of losing health insurance, delay of transfer should be considered. Young adults have the lowest rates of health insurance compared with any other age group [54]. Between 2000 and 2010, the percentage of American adults 18–64 years of age with private health insurance coverage decreased while the numbers of uninsured increased [54]. There are widespread advocacy efforts in the US to extend immunosuppressive coverage for kidney transplant recipients, in order to avoid graft loss due to insurance gaps. It is estimated that extension of immunosuppressive coverage would actually produce significant cost savings [55]. While absence of insurance is a major concern, no less important is underinsurance. Many insured adolescents suffer adverse health consequences due to inadequate coverage for needed services, including preventive, reproductive and behavioral health [47,56,57]. Regardless of the national healthcare system in place, it is crucial to ensure that transitioning young adults can access and afford to continue receiving necessary medications and treatments that promote graft and patient survival throughout the transfer period and beyond.

Communication between adult and pediatric providers

In some transplant centers, pediatric and adult providers participate jointly in seeing patients, either alternating visits or seeing patients concurrently. In other centers, transition efforts are focused in the pediatric or adult center respectively. The model of transitional care implemented depends greatly on the available resources and structure of the healthcare system. None is currently known to be superior to another. Regardless of the model of care, it is essential for pediatric and adult providers to communicate with each other to ensure optimal continuity of care for the patient. Patients have expressed frustration with insufficient communication between pediatric and adult medical providers [33]. Communication should ideally take place before, during and after transfer, and should occur through multiple modalities, such as written communication as well as phone calls or live meetings. The communication should also focus on provision of a concise but comprehensive summary of the pertinent medical and psychosocial issues.

It may be very helpful for a pediatric healthcare team member to do a site visit of the adult transplant center during a typical clinic day so that transitioning patients can be told more accurately what to expect. This may include the content of the physician and nurse interaction, duration of appointment, how blood testing is arranged, what the waiting room looks like, how long the wait usually is,

where to park, etc. Many patients express lack of understanding of the differences between the pediatric and adult healthcare centers [50]. Some centers provide tours of the adult facility prior to the first formal adult visit and this is generally very well received by patients [38,50].

Another important communication aspect is the sharing of information on treatment protocols. It is important for both the adult and pediatric transplant professionals to be familiar with each others' approaches. Ideally any modifications in immunosuppression regimens should occur prior to transfer and allow for a period of drug level stability before the patient changes sites. Medication revisions occurring early after transfer can lead to confusion, dosing mix-ups and sometimes lack of trust.

Avoid transfer in crisis

Ideally, the timing of transfer should be anticipated and agreed upon by the patient, family and providers [17,30,50]. There is no ideal age to transfer although many healthcare systems mandate specific age cut-offs. However, if a patient is in an unstable or evolving medical situation at the required transfer age (for example experiencing a serious complication like rejection or post-transplant malignancy), every effort should be made to postpone transfer until a reasonable period of stability has been achieved. Transferring a patient during an evolving treatment plan, or when the patient's condition is deteriorating, may undermine the patient and family's confidence in the new treating team. Similarly transfer should be avoided during a psychosocial crisis. In some cases, unexpected events may necessitate an urgent or unplanned transfer; for example, some pediatric centers may oblige transfer for female pregnancy whereas others have an adolescent medicine service that can assist in following the patient jointly with a high risk obstetrical center, before and after delivery. When urgent transfer is required, the best approach is to secure good communication between the pediatric and adult providers, and have a transfer plan that is transparent to the pediatric and adult teams, and to the patient and family. This will help avoid the problem of "bounce-backs". It is important to reinforce to the family that care will be taken over by the adult team if that is the plan. In such cases, the patient should be discouraged from ricocheting back and forth, as this can create problems of discontinuity of care and increase the risk of inadvertent negative health outcomes.

Guardianship, consent and confidentiality issues

Prior to transfer and before the age of majority, a provider should discuss the patient's legal rights with the patient and his/her family, as well as any age related changes in confidentiality and informed consent. In some jurisdictions, minors can provide consent before the age of 18 for defined procedures or conditions. It is important for the healthcare provider to be aware of state, provincial and/or federal laws that govern age-related confidentiality and consent issues, as these vary considerably by jurisdiction [58–62]. Some patients may feel overwhelmed by the responsibility of self-consent and some parents may feel left out or that their sense of control is abruptly severed. Anticipatory counseling is important to help prevent confusion, anxiety, and resentment.

Guardianship issues are particularly important when cognitive limitations exist; in transition planning it is crucial to consider the developmental stage and capacity for independence of the individual patient. A neurocognitive evaluation may be necessary. This is discussed further on in this chapter.

The developmentally challenged patient

Patients with cognitive delays often face healthcare disparities and increased health risks beyond those of the healthy adolescent with a transplant [63–65]. Challenges related to their transition planning and preparation include heightened anxiety about transfer, adaptability to changes in routine, capacity for independent living, sexuality, vocational issues, modes of communication, decision making and consent, guardianship and substitute decision making.

A key component in the transfer document of these patients is a summary of their potential for self-management and medical decision-making [64]. Intellectual capacity and ability to perform activities of daily living are not synonymous entities. Although an IQ less than 70 is traditionally considered cognitively delayed, IQ testing comprises only part of the assessment for independent function and test results can be misleading, particularly when comorbidities such as learning disabilities or depression exist. Labeling a teen's ability by education level, developmental age or IQ may not reflect his/her ability to perform self-care or follow directions. Assessment of adaptive behaviors such as daily living activities, communication and social skills is essential. A clinically practical method is to ask a parent or caregiver to describe a typical day for their teen, inquiring specifically about what he/she does for self-care, how he/she communicates, and how he/she solves problems [64]. Clinical observation alone may be deceptive and potentially either overestimate or underrate their abilities. Teens may behave differently in the clinical setting and limited time may restrict the range of adaptive behaviors observed. Furthermore, unless one probes deeply, it may be difficult to appreciate that a young person doesn't fully comprehend the questions posed or instructions given.

Issues of consent for different types of procedures and treatments and whether substitute decision making is needed can be complex and relate in part to the type of procedure (e.g. starting intravenous antibiotics versus complicated elective surgery), level of understanding needed to comprehend benefits and risks, and medical or surgical urgency. It is best to evaluate and plan for these contingencies well in advance of the patient's age of majority. It is also very important to relay to the adult provider how best to communicate with the developmentally challenged young person. One must assess his/her ability to both speak and understand, and tailor the approach to that level. There is a need for the dialogue to be calm and clear. Generally one should include caregivers in the interview but also offer time to the patient to be interviewed alone.

Vocational and educational issues can be of great concern for cognitively challenged youth and options may be more limited. Yet work can provide structure, stability and insurance coverage. In early adolescence, the transition team should inquire about how the patient is being prepared for a vocation. A social worker can serve as an excellent liaison with the educational system to ensure a modified educational plan is put in place early [66]. It can be helpful to have the patient meet another cognitively disabled individual who is employed. Additionally, forming social networks may be challenging for the patient, but there may be community organizations that can help the patient learn social skills and engage in social networks in a safe, supervised way.

As with other adolescent patients, it is very important to provide developmentally appropriate sex education for these patients. One cannot assume that a cognitively challenged patient will not engage in risky behaviors or not be sexually active; similarly it should not be supposed that sexual activity is non-consensual. Another factor to consider is living arrangements. Parents may suppose that the patient will live with them or with another caregiver forever and

may not fully appreciate the patient's ability or desire for independent living.

Because cognitively delayed adolescents usually do well with structured routines, their adherence may be better than in those with normal intellect. However they may be less able to adapt to changes in routine, such as figuring out how to take medications when not at home or how to deal with missed doses due to illness. Specific organizational skills can be addressed with the patient during the transition process as well as after transfer, and contingency supports put in place.

It is valuable to give cognitively challenged patients opportunities to take more responsibility in their care and allow them to develop as much autonomy as they are able to have. A longer transition period may be needed and more done to engage community support. A proper assessment of cognitive delay is also important to help families access potential social and financial resources. These are all issues that need to be considered throughout the transition process.

Barriers to smooth transition and assessment of transition readiness

There are many potential barriers to young adults experiencing smooth transition. To overcome barriers, one must first identify and understand them. It is helpful to consider three potential barrier sources: providers/healthcare systems, parents/caregivers, and patients themselves.

Healthcare provider and healthcare system-related barriers

Pediatric providers have often developed long-term relationships with patients and their families and may experience difficulty relinquishing their care. This may result in patients being retained in the pediatric healthcare system longer than necessary. It also may result in pediatric providers fostering feelings of dependency by their patients and families. Pediatric providers may unintentionally communicate distrust to patients about the adult healthcare environment. Improving communication between adult and pediatric providers may help overcome pediatric providers' hesitation to transfer ownership of their patients.

Currently no formal "transition of care" competencies exist for adult or pediatric providers and both may feel inadequately trained to handle issues that usually fall more into the other's realm. Adult providers have expressed a need for better training in congenital and childhood-onset conditions as well as concerns about adolescent and young adult patients' psychosocial issues and maturity [67]. Pediatric providers may help by providing insight into special inherited conditions, congenital urologic anomalies and other syndromes that need careful follow-up or consideration of other organ involvement. Conversely, adult providers may impart useful information about their practices of anticipatory guidance, with more attention to reproductive healthcare, cancer prevention and screening, cardiovascular disease and other later-onset complications of transplantation.

By improving communication between the adult and pediatric providers opportunities will be gained to learn from each other. Rather than operating in silos, pediatric and adult providers can mutually benefit through engaging in discussions of transitioning patients, whether informally or in scheduled case conferences. Shared review of patient cases could help mitigate several barriers to smooth transition. For example, adult social workers could be engaged early to prevent impediments to access of care, such as gaps in insurance or transportation obstacles. For patients with significant cognitive delays, shared discussion may help set realistic expectations by the adult healthcare team in terms of the extent to which the patient can be independently engaged in his/her healthcare self-management.

Improved training for healthcare professionals who look after adolescents with chronic diseases is greatly needed. In the UK, the National Health Service (NHS) sponsors an adolescent health programme of e-learning modules for healthcare professionals, to support the delivery of quality care to adolescents and young adults [68]. These modules cover a wide range of adolescent health issues that are non-disease specific, including issues of consent and confidentiality. They also provide feedback to participants and are eligible for continuing education credit. This innovative program may serve as a model for creating metrics for quality in adolescent healthcare delivery.

Healthcare system barriers are a key area to address and include insufficient healthcare provider time and resources and often an inefficient healthcare system. Young adult patients may need longer visits to ensure comprehensive care but providers may feel time constraints [67]. Obtaining an appointment in an adult hospital setting may be challenging for the transitioning patient, with longer delays due to higher volumes of patients. In addition, there is often less ancillary support to capture missed appointments or laboratory tests. Each of the above factors may contribute to loss to follow-up for young adult patients not yet comfortable managing independently in the new medical environment. In addition, incompatibility or lack of electronic medical record keeping systems can impair transfer of medical information, even when pediatric and adult care facilities are within the same healthcare system. A fixed inflexible age of transfer, with no room for adaptability for health crises or special needs, can also be a major deterrent to success.

Historically in the US, timing of transfer and the timing of public insurance termination for transplant immunosuppressant medication have often coincided, leaving young patients vulnerable to insurance gaps. Recent healthcare reform measures may mitigate this particular barrier but further study needs to be undertaken.

Parent/caregiver barriers to smooth transition

Parents of transplant recipients may experience difficulty relinquishing control of healthcare responsibility to their adolescent and feel hurt and angry if excluded from healthcare consultations at the adult center, particularly if they have been very involved in each pediatric visit. In the literature, there is no definite consensus about whether parents should be excluded from the consultation in the adult center [30,31].

Parents of liver transplant recipients have reported recognition of the importance of transitional care but poor knowledge of the process [69]. Pediatric providers need to encourage parents to gradually promote their child's independence and self-responsibility from an early age (Table 121.3). This includes supervised participation in healthcare routines at age appropriate levels with gradual increase in responsibility and skills. In early to mid-adolescence, this may include the parents giving the patient increasing responsibility to call in prescriptions, starting with those that are non-essential medications. A parent can then move on to another specific task, such as making appointments for healthcare visits. At the same time, the child needs to be encouraged to participate in other normal age related activities and tasks, so that an age-appropriate sense of self-reliance can develop. If parents are hesitant

to share health responsibilities with their teen, it can be helpful to make parallel comparisons between healthcare expectations and other age-appropriate life expectations, such as doing homework independently and learning to drive. As adolescents learn new tasks, parents should remain available to monitor and support them. Parental modeling of positive health behaviors is also important to emphasize.

Patient barriers to smooth transition

Many patient-related barriers to the transition process result from the normal developmental phases of adolescence and emerging adulthood, or the consequences of having a complex chronic illness from an early age. In addition, transfer to adult care usually occurs during emerging adulthood, the age range of 18 to 25 years, when risk behaviors peak [70].

The period of adolescence/emerging adulthood is one of exploration, identity formation, boundary testing, risk-taking, intense emotion, and creativity [70]. The imagination, energy and idealism of youth have led to important advances in many domains. However, the burden of a chronic illness can play havoc with this potentially carefree time of life. This is compounded by the difficulty adolescents have in perceiving future consequences of present actions, making it hard for them to understand the relevance of current limitations for future health [71,72]. Attempts by adolescent/emerging adult transplant recipients to emulate the more casual lifestyles of their peers may lead to treatment non-adherence, and in turn graft failure. Adherence is believed to be the major factor in the high graft loss rate during adolescence and emerging adulthood, and during transition to adult care [5,12,73].

The experience of chronic illness as a child can lead to cognitive, emotional and social challenges, which pose potentially important barriers to successful transition to adult care [63–76]. A recent study by Berney-Martinet and colleagues used semi-structured psychiatric diagnostic interviews and questionnaires (Youth Self Report) to examine the psychological and psychiatric profiles of 40 adolescent renal transplant recipients (mean age 15.2 years) and 40 healthy adolescent controls, matched for age, gender, socioeconomic status and ethnic background. The parents of the patients were also interviewed and the parents of both groups filled out questionnaires (Child Behaviour Checklist). School delays or educational problems were striking. Sixty percent of transplant recipients had repeated at least one school grade (vs. 12.5% controls, $P < 0.001$). The prevalence of learning difficulties was 30% (controls 7.5%, P 0.03) and was associated with younger age at renal disease diagnosis, hemodialysis treatments, and lower socioeconomic group. Almost all those with learning difficulties were in a special class at the time of the study, for behavioral problems and/or disability (27.5% vs. 2.5% in controls, P 0.005). Psychiatric co-morbidity was high, with 65% of recipients meeting DSM-IV criteria for a lifetime psychiatric disorder and 50% having two or more concurrent psychiatric diagnoses. Included were depression (35%), attention deficit hyperactivity disorder (ADHD)(23%) and phobias (20%). The transplant adolescents were also significantly more withdrawn and socially isolated than their age matched peers. Another report, a systematic review of qualitative studies involving more than 300 adolescent transplant recipients, revealed that they had lowered self-esteem, and perceived negative reactions from their peers, a loss of belonging, and uncertainty about their life expectancy [77]. Both these studies illustrate the importance of pro-active assessment of pediatric transplant recipients' psychological health.

Education is an important social determinant of health and of success in later life [48,49,78]. As a group, pediatric organ transplant recipients have more challenges with school achievement than their peers and a higher unemployment rate in adulthood [70,79]. Although many of them wish to set long-term academic and vocational goals, extensive school absenteeism may cause some to fall behind and be overwhelmed with the struggle to achieve satisfactory grades [77]. Repeated or extended school absences not only lead to missed opportunities to master core skills, but can also make young people lose confidence in returning to school and less at ease socially, as they experience the challenge of rebuilding friendships that may be perceived to, or actually, have "moved on" [70]. Pediatric health professionals need to be vigilant, routinely screening transplant recipients for educational and social difficulties, and guide their parents to obtain appropriate supportive/interventional resources. Possible means to optimize the educational and vocational potential of transplant recipients include educational intervention programs, school-reintegration programs for those who have had prolonged absences, and greater coordination between hospital and school settings [80]. A well-timed intervention is key because students who show low levels of school engagement at the beginning of adolescence are more likely to drop out [81]. Wolf–Branigin et al. developed an innovative program to help integrate youth with disabilities into adulthood. It encompassed after-school activities, job "boot camp", summertime employment preparation, self advocacy skill development, a six-week "Summer Institute" of work experience and classroom activities, monthly workshops, parenting support classes, a youth leadership forum, and an intensive individualized education program focusing on high school completion [82]. Participants ranged in age from 12–20 years, with the mean age 14.8 years. Physical health, school functioning, and total functioning improved during the two year program, as measured by the Pediatric Quality of Life Inventory 4.0. The Career Maturity Inventory—Attitude Scale (CMI-AS) was used to assess employment readiness and showed a mean improvement over two years only for those in the youngest-age/grade cohort, suggesting a need for intervention early in adolescence.

Additional barriers to transition may result from adolescents' lack of engagement and lack of knowledge in the process of transition. Findings are mixed on how adolescents and young adults view the importance of transitional care. Anthony and colleagues conducted a qualitative study examining the perceptions and beliefs of 14 adolescent heart transplant recipients (mean age 15.7 years, range 11.7–17.8) [83]. They found the adolescents to be disinterested and apathetic toward the transition process, in striking contrast to the fear and anxiety of their parents. None of the teens were interested in becoming more involved or autonomous in their care. The authors speculated that caregiver overprotectiveness might have encouraged the adolescents to disengage from the transition process. Fredericks et al. studied the transition perspectives of adolescent/emerging adult liver transplant recipients using a comprehensive questionnaire [69]. The cohort consisted of 31 liver recipients between the ages of 12–17 years, and 15 between 18–21 years, as well as the parents of the younger group. These investigators found a low level of prior thought about transition, a very low level of knowledge about the process, and only moderate interest in learning about it. When dividing the patients by age group, those over 16 years had more interest in learning about transition. These two studies corroborate recommendations to begin discussing transition at an early age and to sensitize parents to the importance of promoting their child's involvement in his/her care, with supervised

progressive self-responsibility [17,25,31–34]. Some have expressed concern over the extent of responsibility adolescents should have for their medications. Simons et al. examined barriers to medication adherence in adolescent kidney transplant recipients. It appeared that non-adherence was more likely when the adolescents were responsible for taking their medications, rather than their parents; they did not report how the transition of medication responsibility from parent to adolescent occurred [84]. Studies have also shown that abrupt transitions of healthcare responsibility from parent to adolescent may cause distress to both. Nonadherence correlates with lower family cohesion and parental feelings of distress, and family conflict can negatively affect mental health outcomes of adolescent transplant recipients [85–87]. Healthcare practitioners need to be sensitive to these risks and provide counsel and support to patients and their families throughout the transition of healthcare responsibility.

In summary, patient level barriers to successful transition include the normal neurocognitive developmental processes that occur during adolescence and emerging adulthood, adherence issues, learning difficulties, missed educational opportunities, reduced social and work experience, psychiatric co-morbidities and lack of integrated patient preparation. Timely, proactive and multilevel interdisciplinary processes are needed to enhance integration of adolescent transplant recipients into adult care and to optimize their quality of life in adulthood.

Transition readiness

A major challenge in achieving successful transition is identifying the right time for transfer. Some centers have a specific chronological age by which transfer must occur. However patients of similar age may be very different developmentally, with some ready to transfer much earlier than others. The transition process includes not only the transfer of care but also transition of healthcare responsibility from parent to patient. Many consensus recommendations and guidelines advise that transfer should occur when the patient, caregivers and the pediatric and adult healthcare teams agree that the patient is ready [17,31]. Yet, how can providers best assess a patient's transition readiness? To truly understand what is required to optimize a young person's engagement in the adult healthcare system, standardized tools and metrics to assess transition readiness need to be developed and investigated. This is a burgeoning area of interest with several recently developed tools showing promise for clinical and research use. When assessing transition readiness tools for organ transplant recipients, there are four primary principles to apply:

1 Assessments should include multiple perspectives, including input from both the patient and the family. Several studies suggest discordance between patient and parent reporting [69,88,89]. In general, patients tend to report more healthcare independence than their caregivers do [69].
2 Assessments of transition readiness should be theoretically informed, reliable and valid. Achieving transition readiness requires progressive behavior changes on the parts of the patient, caregiver and provider. Using behavioral theories and models to inform the design of assessment tools can lead to better understanding of the successes or failures of behavioral interventions [90].
3 Assessments should be repeated on an ongoing basis throughout the transition process. The ideal transition readiness measure is sensitive to change and can be applied longitudinally.

Table 121.4. Transition milestones

1	Understand and be able to describe etiology of organ failure.
2	Be aware of long and short-term complications of transplant for overall health.
3	Understand impact of illness on sexuality and reproductive health.
4	Have sense of responsibility for own healthcare. This includes calling in refills, having medication knowledge, preparing pill box, adhering to medical regimen and managing healthcare appointments.
5	Demonstrate capacity to provide most self-care.
6	Express readiness to move into adulthood.
7	Own medical information in the form of a concise summary.
8	Be a knowledgeable health consumer. Be able to relay personal medical history. Understand health insurance coverage. Know how to seek emergent aid. Know how to communicate health concerns to providers independently.

4 Assessments should include proficiency in self-care, healthcare decision-making and self-advocacy, in addition to disease-related skills and knowledge [91]. Milestones for transition readiness have been suggested in various literature reviews and consensus statements [17,92] (Table 121.4)

The goal of a planned coordinated transition from pediatric to adult healthcare is to "optimize health and facilitate each person's achievement of his or her maximum potential." [93] Sawicki et al. developed the Transition Readiness Assessment Questionnaire (TRAQ) to identify areas in which emerging adults with special healthcare needs require additional preparation to achieve healthcare self-management [94]. It is based on the "Stages of Change" model which requires evaluation of a person's stage of readiness to adopt specific behaviors. TRAQ is a 33 item patient-completed questionnaire which measures skills needed to successfully transition in health, education, work, and daily life. It is reported on an ordinal scale and focuses on two domains, self-management and self-advocacy. The self-management questions include items about managing medication, medical appointments and health insurance. The self-advocacy questions include items about communicating with health providers as well as self-advocacy in education and employment. This questionnaire does not include caregiver or provider perspectives. It was validated in patients ages 16–26 years with a diverse range of special healthcare needs. It has not yet been tested as a longitudinal measure with predictive validity.

Another disease-generic questionnaire, the Developmentally Based Skills Checklist, was used to assess healthcare self-management skills in liver transplant recipients. It consists of 22 questions about understanding one's medical condition, communicating with providers, managing medications and appointments, and living a healthy lifestyle. Patients respond "Never, Sometimes or Always" to each specific behavior [95]. In liver transplant recipients, it identified significant baseline deficits in areas such as making appointments and understanding insurance. However, it is not known if it relates well to transition readiness or medical or behavioral outcomes and was not used as a longitudinal measure. Like TRAQ, it is a patient-focused measure with no parallel caregiver assessment.

Pai et al. created the Allocation of Treatment Responsibility (ATR) scale, to assess healthcare responsibility of adolescent and emerging adult transplant recipients and their caregivers [89]. This 18 item measure incorporates three subscales: oral medication, clinic attendance and laboratory attendance. It is completed separately by the patient and caregiver, and assesses who is primarily responsible for treatment-related tasks in the home. It was validated in 39 pediatric renal transplant recipients, ages 7–18 years, and their

caregivers. Discrepancy between patient and caregiver reports of total patient responsibility was associated with greater nonadherence. The ATR may have potential as a metric of healthcare self-management but has not yet been shown to reflect transition readiness.

Fredericks et al. has developed a transition readiness assessment tool for pediatric liver transplant patients 11–20 years of age [96]. It consists of 38 items and four healthcare provider administrated questions. Responses are either Likert scale (questions) self-report or direct demonstration of skills. There are four domains: self-management, medication knowledge, demonstrated skills and psychosocial adjustment. There is a separate 36 item survey for caregivers. The authors compared transition readiness scores with age, medication adherence, clinic attendance and liver function in 71 patients. There were no significant associations between transition readiness with adherence, clinic attendance or health outcomes. Older patients reported higher self-management skills but notably their perception did not equate with better ability to demonstrate those skills, such as being able to describe one's medication regimen. Moreover, greater healthcare self-management by the adolescent or emerging adult was associated with increased non-adherence, suggesting that decreased parental involvement may be associated with more medication indiscretion by the patient. This finding was also supported in a study of pediatric kidney transplant recipients who were more likely to be non-adherent when they had primary responsibility for administering their medications [84]. These data emphasize the need for providers to help patients and parents transition healthcare responsibility in a step-wise, systematic way, rather than having a parent relinquish total responsibility abruptly or, conversely, maintain total control as an adolescent matures.

In another study of kidney transplant recipients aged 15–21 years, Gilleland et al. tested the Readiness for Transition Questionnaire (RTQ), a 22 item tool which separately surveys patients and caregivers about (1) the patient's responsibility in healthcare self-management behaviors and (2) overall parental involvement in these behaviors [88]. In addition, patients and caregivers separately report on the patient's readiness (1) to assume full responsibility in healthcare and (2) to transfer to adult care. Patient and parent reports of overall transition readiness correlated positively with their reports of patient responsibility but inversely with reports of parental involvement. Thus, the patients most ready to transition had increased healthcare responsibility and decreased parental involvement. These patients also reported more medication knowledge, greater likelihood to call in their own refills and a better relationship with their parents. Reported increased transition readiness was linked with fewer medication barriers, but surprisingly was not associated with medication adherence. The RTQ is robust in that it considers multiple perspectives, is theory-based and valid, and considers medical skills and knowledge as well as personal health advocacy. This measure, however, like the others mentioned above, has not yet been tested longitudinally.

Thus, although the above peer reviewed published measures of transition readiness and healthcare responsibility are currently in use, none is perfect. They have not yet been tested longitudinally nor shown to be sensitive to change. Additionally, they are either self- and/or caregiver reports but do not include healthcare providers. Healthcare providers' input is also integral in the transition process and their objective assessments need to be interwoven with patient and parent reports. There are also several additional web-based tools that the reader may wish to refer to but none has been rigorously assessed for reliability, validity and ongoing predictive value [97–99].

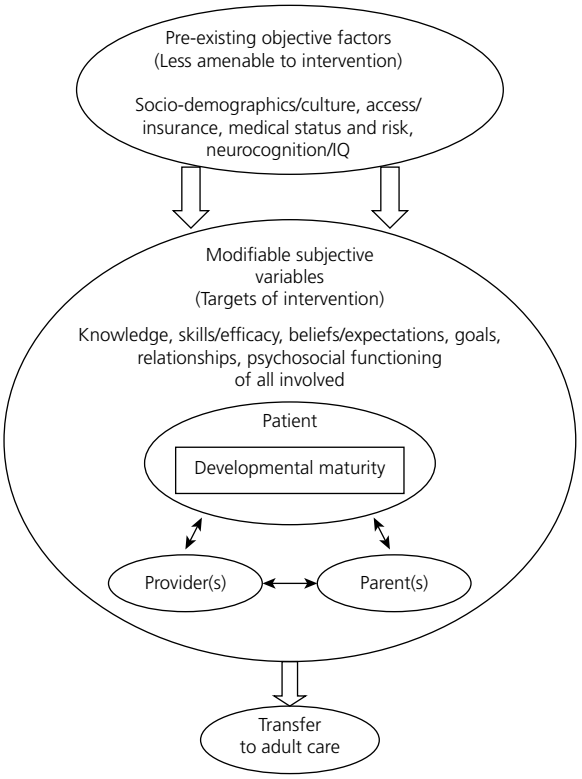

Figure 121.1. Social-ecological model of adolescents and young adults readiness for transition.
Reproduced from [91] Schwartz *et al.* with permission from Wiley.

A theoretical model proposed to operationalize assessment of transition readiness is the Social-ecological Model of Adolescents and young adult Readiness for Transition (SMART) shown in Figure 121.1 [91]. This model incorporates the complex interactions of patients, family and providers within the context of the patient's socio-demographic status and health experience. One component considers factors that may not be readily amenable to intervention, such as age, race, ethnicity and family structure, as well as potential transition barriers, such as impaired healthcare access and neurocognitive impairment. Another component focuses on the patient's developmental maturity, health knowledge, healthcare management skills, transition beliefs, goals, relationships and psychosocial functioning. This model is being tested in cancer survivorship but could also provide a comprehensive foundation for the development of future transition readiness assessment tools for transplant recipients. It adds to current measures by providing a comprehensive theoretical model which considers the partnership between providers, patient and family, within the context of the healthcare system and the patient's personal life outside the medical setting. This model shows promise to inform, build and test future transition readiness tools and interventions.

While establishing metrics of transition readiness remains challenging, much progress has been made in the last decade and current research efforts will continue to advance the science of transition.

Transition outcomes and research needs

The overarching goal of adolescent transition to adult care, originally published in 2002 and reiterated in numerous journal articles since, is to "maximize lifelong functioning and potential through high-quality, developmentally appropriate uninterrupted healthcare services that are patient-centered, flexible, coordinated, responsive, and comprehensive" [100]. In this section, we will discuss transition outcomes and research needs in the context of the above objectives.

Two published large database studies have clearly shown that the adolescent/emerging adult age group of transplant recipients is a very high risk demographic for graft loss and that the time period surrounding the event of transfer to adult care, especially the first-year, is associated with a remarkably high risk of graft failure [5,12]. These two reports provide important evidence of the need to be particularly vigilant in care of recipients who are in the 17 to 24 year age range and to improve the process of transition and transfer. They are important studies, as previous evidence for transition being a risky time was largely based on small single center series.

How should one proceed to improve the process of transition and evaluate the effects of interventions? A priority and a challenge are to define reliable measures of outcomes, what to measure and how to measure it. To assess the transition goal of "maximizing lifelong functioning and potential" we need to look at a wide range of elements, including graft function, graft and patient survival, overall physical and mental health, and psychosocial elements. However graft and patient survival may not be adequate for the purposes of many transition studies. Clearly defined rigorous endpoints that are sensitive (e.g. biomarkers of graft function such as in the areas of metabolomics, proteomics, and genomics, rather than graft loss) but also specific, with clear delineation of normal and abnormal ranges are needed. We need to discern changes in graft function early, before significant damage occurs. A confounding factor in assessing for changes in graft function following transition is that, for most organ transplants, there is a normal slow decline in function over time. Normal function may also have small day-to-day variations, so measures in current use may not be sufficiently sensitive and specific.

Evaluation of health and medication insurance adequacy and continuity of coverage throughout the transition period and into early adulthood are critical elements to assess for "uninterrupted care" and may be considered as good outcomes measures. However, assessment of "uninterrupted healthcare services" requires accurate databases of transitioning patients and their relevant transplant data both pre and post-transfer to adult care. A major limitation of current national databases is that they do not define the point of transfer to adult care, making it very difficult to evaluate large-scale effects of transition and transfer. Elements important to study include whether transitioning patients maintain their follow-up after transfer, have defined accessible healthcare providers for both transplant and primary care and attend clinic and laboratory appointments as expected. Hospitalizations and emergency room visits can also be examined but practice variation and policies of hospitalization and emergency room use may differ between pediatric and adult centers, making it difficult for a patient to serve as his/her own control.

Health related quality of life (HRQOL) is central to maximizing a patient's potential, and is an essential element to assess in transitioning patients. In evaluating patients prior to transfer it is important to keep in mind that parent/caregiver and patient reports may differ, and that it is the patient's evaluation that will be followed over time [87,101]. Factors that contribute to HRQOL, such as healthy nutrition, physical exercise and conditioning, and social integration can be actively incorporated into transition programs and evaluated. Attention is also needed to optimize the potential for education, a major determinant of health, and the preparation for satisfying employment, important in long-term quality of life. Thus, educational and vocational training outcomes are critical to study. Currently there is a paucity of HRQOL measures that can be applied and interpreted longitudinally as patients mature from childhood to adulthood. One unique tool to measure HRQOL over time across conditions and age ranges is The National Institutes of Health' Patient Reported Outcomes Measurement Information System (PROMIS), a reliable, valid, precise and responsive assessment tool that measures patient-reported health status [102]. This tool is not disease-specific however.

Once outcomes are defined, exposures must also be considered. An important component of outcomes assessment for success or failure of transition must include treatment-specific factors that contribute to optimal graft function and patient survival, such as medication adherence (discussed separately in this text) and treatment sequelae (e.g. malignancy, diabetes, hyperlipidemia, altered immunity).

When considering various study designs, both qualitative and quantitative studies are valuable, but study designs and objectives must be clear and reproducible. Qualitative research is important to assess elements such as, "developmentally appropriate, flexible and responsive" care. Patient experiences can be more richly described and deeply analyzed with carefully conducted qualitative studies and these works can help define questions to subsequently evaluate in a more widespread quantitative manner. In addition, patient experiences can inform quality assurance at a program level [17].

Transition research must be collaborative. On an institutional level, research efforts should be multi-disciplinary to incorporate the various biopsychosocial aspects of transition. While single center studies are important to inform the feasibility and design of various approaches, multi-center collaborations are necessary to ensure sufficient power and generalizability. To date, there are few publications on outcomes of transition processes and most are descriptive small cohort analyses, often single-center, sometimes with historical controls [7,51,103]. Although the results are encouraging, studies with historical controls generally cannot account for subtle but significant adjustments in treatment protocols, changes in healthcare personnel or variations in disease characteristics, particularly with the small patient numbers in pediatric transplantation.

Transition research should ideally be longitudinal. One challenge to longitudinal data collection is securing patient consent to permit long-term follow-up [17]. It has been suggested that national registries collect more granular data to better assess long-term patient outcomes [104].

Beyond patient outcomes, future transitional research efforts should examine the education and training of healthcare professionals around transitional care to promote service delivery that is comprehensive and systematic. In the UK, it has been proposed to establish a set of performance standards for operating a transition service so that performance may be assessed [30]. In 1993, Blum et al. reported that "while we can define the concept and goals of transition, there is simply too much that is not known about the

process" [3]. At that time, Blum cited lack of knowledge regarding which care models are most effective and for whom, and whether, health outcomes change as a result of formal transition programs. These deficits in knowledge still exist 20 years later. If the provision of transitional care is systematic and theoretically informed, it will be easier to understand clinical interventions and interpret observed results. Systematic quality assurance and improvement studies as well as cost-effectiveness analyses are crucial to inform and support research approaches.

Summary

- Transition is a dynamic process with many stakeholders. Care must be planned, accessible, coordinated and continuous as well as psychologically/developmentally appropriate. Think about transitional care for patients starting from the age of 10–12 years and possibly even earlier.
- Consider various sources of barriers to smooth transition, including the patient, caregiver, provider and healthcare system. Once barriers are identified, work with patients and families to develop targeted approaches to promote successful transition.
- To evaluate "high-quality, developmentally appropriate uninterrupted healthcare services that are patient-centered, flexible, coordinated, responsive, and comprehensiveness," there are a multitude of factors to study, some easier than others. A major domain is preparing patients and families for transition and transfer. We need clearly defined tools for patient preparation, longitudinal assessment of progress and metrics to measure readiness for transfer. It is important to use behavioral theory in intervention design and the most effective efforts to make change may result from collaborations between clinicians, psychologists, social workers, educators, and behavior theorists.

Conclusion

The goal of transition programs for adolescent and emering adult transplant recipients is to improve long-term health outcomes, including graft survival and psychosocial elements, such as gainful employment and health related quality of life. The need to prevent allograft loss in transitioning transplant recipients is critical not only for the individual patient but also for society. Every potentially preventable organ loss that occurs due to problematic transfer or transition adds to the burgeoning demand for limited organs. Although multi-disciplinary care may appear to require substantial resources, the potential benefits are great.

Smooth transition need not remain an elusive concept when providers, patients and families are engaged in the process of healthcare self-management early, and on an ongoing basis. Important components of advancing improvements in transition are education and training of healthcare professionals, to promote systematic and effective service delivery. Research is essential to evaluate efficacy of interventions and future research efforts must be multidisciplinary, comprehensive and longitudinal.

SECTION 9

Transplant Administration

CHAPTER 122

Transplant Coordination

Dianne LaPointe Rudow
Recanati/Miller Transplantation Institute, Department of Health Evidence and Policy, Mount Sinai Medical Center, New York, NY, USA

Introduction

The successful management of a transplant patient is due in part to the multidisciplinary team approach to their care before, during and after their transplant. Transplant Coordinators are essential members of multidisciplinary transplant teams and their role in all phases of transplant care has become established in essentially all robust transplant centers. Transplant coordinators have numerous roles, but in general help patients navigate the complexities of transplant care, and assist physicians in ensuring that the required monitoring and care is delivered. This chapter will focus attention on the evolution of transplant coordinators as invaluable members of a transplant team, detail their numerous roles and responsibilities, and summarize the current training models employed for their certification. Additional details regarding the roles of coordinators can be found in Chapters 124 and 125, discussing inpatient and outpatient service structures respectively.

History and the evolution of the role of the transplant coordinator

Currently a nursing role, transplant coordination was developed out of necessity in the early days of transplantation to "coordinate" any aspect of the donation and transplant process. Early coordinators were from many disciplines including nursing, surgical technicians, and laboratory personnel. They were involved in organ recovery, preservation and post-operative management of the transplant patient.

The role has evolved to an advanced nursing role with a defined scope of practice, competencies, and a certification process. Additionally it is divided into two types of coordinators; procurement coordinators managing the organ donation process, and clinical transplant coordinators caring for the transplant patient. The clinical transplant coordinator role has further specialized into organ specific roles as well as pre and post-transplantation. Emerging is the utilization of the advanced practice nurse functioning as a transplant coordinator and a transplant coordinator role specifically for the care of the live organ donor.

The inception of the role of the transplant coordinator

As the early physician pioneers of transplantation worked on the surgical and immunological ways of making solid organ transplantation possible, in the background were people performing many of the tasks to support the efforts of the physician. This was the role of the transplant coordinator. These tasks included helping with recovery, preservation, and implantation of the donated graft, to selecting and evaluating patients and assisting in developing ways to allocate the organs available. Essentially, it was any non-physician role that needed to be done to assist in making the miracle of transplant happen. "The term, "Transplant Coordinator" was likely coined by transplant surgeons who looked for people who could, and would, need to multi-task, would be asked to provide skills from several disciplines, and to coordinate what was then a work in progress" [1].

The first transplant coordinators in the US. worked in the early 1960s, in Europe in the mid 1970s and in Asia in the 1980s [1]. Initially as a "jack of all trades", Transplant Coordination has evolved into a profession and has become very specialized over time, with more than one type of coordinator involved in the success of transplantation. Early procurement coordinators started with the consent process working with families to understand the concept of organ donation and assisting surgeons in the surgical retrieval of organs, preservation and pumping organs, and transporting them to the destination safely. The first clinical coordinators, often dialysis nurses, transitioned from the procurement role to maintain waiting lists, assisted patients getting evaluated for transplant, and managing post-operative issues such as complications and immunosuppression management, while surgeons were in the operating room. In fact, the utilization of a transplant coordinator to work with physicians and surgeons is likely one of the first instances where a multidisciplinary team was critical to the success of the surgery.

In 1979 the North American Transplant Coordinators Organization (NATCO) was formed as a national society where those in the role could work together to establish the transplant coordinator as a profession, define a scope of practice, identify educational needs of future transplant coordinators. This early group of transplant coordinators also needed to collaborate to address the many allocation, legal, medical, social, financial and religious issues which had arisen as the success of transplant has improved.

Before the inception of the United Network for Organ Sharing (UNOS), and The Organ Procurement and Transplant Network (OPTN), early allocation of kidneys was accomplished by the Southeastern Procurement Foundation (SEOPF), but many don't realize that it was the transplant coordinators through the

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

NATCO that manage a "24 hour alert system" to allocate extra-renal organs [1]. Initially as an answering machine and eventually a computer system that allocated organs 24 hours seven days a week. It is with the persistence, drive and passion for the success of transplant that these early pioneers helped to define the scope and practice of our current transplant coordinator.

Transplant certification

As the field of transplant grew and more people chose transplant coordination as a profession it was determined that a national certification process was needed to enforce standards for those who care for donors and recipients. A task force of various transplant professionals who assumed the role of the transplant coordinator was created to perform a job analysis, look at certification of other allied health groups, and consult other professions involved in organ donation and transplant. In 1988 The American Board for Transplant Certification (ABTC), an independent, non-profit organization, was founded [2]. Initially offering procurement and clinical transplant certification, currently the ABTC is the certifying agency offering four transplant certifications: Certified Procurement Coordinator (CPTC), Certified Clinical Transplant Coordinator (CCTC), Certified Clinical Transplant Nurse (CCTN) and the Certified Transplant Preservationist (CTP). These are voluntary accredited examinations in the field of organ transplantation. Its goals are to:

- Establish educational and competency standards for the transplant professional.
- Define transplant coordination, nursing and organ preservation as a profession.
- Credential transplant professionals.
- Maintain a list of credentialed practitioners.
- Promote continued professional growth of practitioners through education and recertification [2].

Currently, transplant coordinators must work in the field for at least one year prior to sitting for the exam and maintain currency through continuing education credits. In 2010, there were over 2100 certified transplant coordinators in the US [3].

Procurement coordinators

Today's procurement coordinator functions in many capacities and may assume one or all of the following roles depending on the organ procurement agency's organizational structure [4]:

- Facilitates hospital development and professional education.
- Evaluates organ and tissue donors.
- Approachs families about organ donation and obtain informed consent.
- Obtains extensive medical and social history by interviewing the family and available resources.
- Ensures that all medical and legal requirements are met prior to organ donation and recovery.
- Assists with organ donor management to maintain optimal organ function.
- Ensures allocation is efficient, timely and proceeds according to UNOS policy.
- Assists the surgical team with organ recovery and tissue preservation.
- Maintains donor records.
- Communicates and supports the donor family.
- Communicates with collaborates with and supports the donor hospital staff.

Clinical transplant coordinators

Just as the role of the procurement coordinator has changed over time, the clinical transplant coordinator has evolved as well. The reason for this is multifaceted. First, patients are more complex, many sicker and older with more co-morbidities, there are more regulatory requirements for programs to comply with, there are more transplants being performed, medication regimens are more elaborate and programs have become organ specific. Additionally both UNOS/OPTN and Centers for Medicare Conditions of Participation (COP) have requirements for the types of professionals who can be clinical transplant coordinators and roles they must perform.

The OPTN describes the clinical transplant coordinator as a member of the transplant team who will be responsible for coordinating clinical aspects of candidate's care. This includes working with patients and their families to be listed, and followed, through transplantation. The transplant coordinator must be a registered nurse or other licensed clinician who performs or oversees other healthcare personnel [5].

The Medicare COP require a clinical transplant coordinator to ensure continuity of care of patients and live donors during the pretransplant, transplant, and discharge phases of organ transplantation and live donation [6]. This includes addressing elements identified in the assessment and care plan, educating patients, live donors and families about treatment options, post-operative care and therapies, monitoring medical, surgical and psychosocial status and providing feedback to other team members. Kidney transplant coordinators must document communication with dialysis facilities. Additionally, all coordinators must be a registered nurse or clinician, licensed in the state in which they practice, and have experience and knowledge of donation and transplantation [6].

Furthermore, the COP requires adequate training of nursing staff and clinical transplant coordinators that should include; thorough orientation program, documented review of policy and procedures, structured continuing education, and evaluation of the coordinators training needs [6].

Neither regulatory body dictates if the same personnel or different personnel perform the various roles pre, peri and post-operatively. Individual transplant programs implement the roles differently. Some have a pre and post-transplant models, others have the same transplant coordinator care for a patient throughout the entire process. Additionally some programs utilize registered nurses only while others have a mix of other healthcare professionals working together to incorporate the various roles. Examples of care models are shown in Table 122.1, and core competencies for clinical transplant coordinators are found in Table 122.2.

Pretransplant

Evaluation

The transplant referral and evaluation process is the initial step to treat end organ failure by determining suitable candidates for a successful transplant. A clinical transplant coordinator must understand the purpose of and help coordinate the transplant evaluation [7]. This includes the medical, psychosocial, laboratory, radiological, nutritional and financial evaluation. They must

Table 122.1. Transplant coordinator care models utilized at transplant programs

Staffing
- Registered Nurse(RN) only Transplant Coordinators
- Advanced Practice Nurses(APN) and/or Physician Assistants hired to perform traditional role of Transplant Coordinator with no autonomy
- Combined APN/RN model
- APN only model

Care models
- Separate pretransplant and post-transplant coordinators with on call responsibilities
- Continuity of care model: same coordinator pre and post-transplant
- On Call teams
- Single organ teams and multi organ teams
- Adult and pediatric combined or separate

Table 122.2. Competencies for the clinical transplant coordinator (CTC)

Pretransplant

Transplant referral and evaluation
- CTC must understand the purpose of and help coordinate the transplant evaluation
- CTC must follow UNOS/OPTN regulations for listing of the candidate

The waiting period
- CTC must have knowledge and ability to monitor and coordinate care of the patients awaiting transplant
- CTC must be knowledgeable of CMS and UNOS/OPTN requirements
- CTC must maintain complete documentation of the pretransplant phase and education

Perioperative period
- CTC has the knowledge and ability to facilitate the transplant process when an organ is available for the intended candidate
- CTC must adhere to current UNOS/OPTN allocation policies

Post-transplant

Inpatient period
- CTC is knowledgeable of post-transplant management including medications, complications, interventions
- CTC is involved in discharge planning
- CTC collaborates effectively with the multidisciplinary team

Outpatient period
- CTC is knowledgeable and is able to coordinate the care of the outpatient recipient
- CTC facilitates a recipient's ability to achieve optimal physical, social and emotional health

Professional practice
- CTC is proficient in and continues to advance his/her knowledge of transplant
- CTC is responsible for sound judgment and administration of quality care to donors, recipients and families

Adapted from the NATCO Core Competencies for the Clinical Transplant Coordinator [7].

collaborate with the multidisciplinary team to determine blood type and immunological data for compatibility, serological data to assess for the presence of infectious disease, screen for evidence of cancer and identify co-morbidities that may increase the risk of or preclude transplantation as an option for the candidate [5–7].

The psychosocial, psychiatric and financial status of the candidate must be assessed and the clinical transplant coordinator must work with the team to determine the educational level, cultural background, ability to comply and evidence of adequate support for a successful transplant. Additionally they must collaborate with referring physicians, consultants, and the transplant team regarding the candidacy of the patients.

Table 122.3. Critical components of education and informed consent

- Transplant evaluation process
- Options for transplant:
  - living donation
  - standard criteria deceased donation
  - expanded criteria deceased donation
- Alternatives to transplant
- Organ allocation
- OPTN regulations
- Waiting for a transplant
- Requirements for re-evaluation when needed
- Need for support throughout the process
- Option to multiple list for transplant
- Transplant process
- Risks and benefits to transplant
- CDC high risk factors
- Risk of recurrent disease
- Center specific patient and graft survival and compare it to national survival rates
- Financial aspects of transplantation
- Postoperative course:
  - monitoring of vital signs
  - diet and activity
  - medication, purpose, dosing and side effects
  - need for biopsy and laboratory tests
  - health maintenance and adherence to treatment regimen
- How to communicate with the transplant team
- Need for and frequency of follow-up
- Method for accessing psychosocial services and local medical care
- How to identify complications:
  - rejection
  - infection

Data from UNOS/OPTN Policy, CMS conditions of participation and NATCO Core competencies [5–7].

The clinical transplant coordinator must understand and comply with all UNOS/OPTN and CMS regulations for listing of the candidate [5,6]. Lastly, and most importantly, the clinical transplant coordinator must educate the patient, family and support team about all aspects of transplantation and document in the medical record. Critical elements of the education for transplant patients are shown in Table 122.3.

The waiting period

A clinical transplant coordinator designated to waitlist management is a crucial role especially in large abdominal transplant programs, due to the length of time it takes for an organ to become available and the demand to keep evaluation tests current, thus ensuring that candidates are ready for transplant when an organ is allocated. Depending on the age, disease and organ needed, re-evaluation testing varies in type and frequency. The clinical transplant coordinator must understand policies and procedures related to wait list management and be familiar with the national recommendations for retesting to ensure ongoing candidacy. They must have the knowledge and ability to monitor and coordinate care of the patients awaiting transplant, maintain relationships with patients and collaborate extensively with local physicians and dialysis centers [7]. The entire pretransplant medical record must be maintained complete with documentation of the testing performed during the pretransplant phase, education and informed consent process, and any correspondence between patient and referring team required for regulatory compliance.

Perioperative period

The clinical transplant coordinator works closely with the Organ Procurement Agency (OPO) surgical team and patient when an

organ is offered. They must have the knowledge and ability to facilitate the transplant process when an organ is available for the intended candidate [7]. This includes, but not limited to, understanding what makes an organ suitable for transplant; communication with the OPO and transplant team about organ suitability, logistics, and policy; compliance with organ allocation policy; education and support of the candidate about the process and specifics of the particular organ allocated (Table 122.3). Various other roles including coordinating transportation, obtaining crossmatch results, list management, verifying vital data between the donor and recipient, arranging for presurgical procedures such as dialysis and documentation of the process may also be performed by the clinical transplant coordinator. It is imperative that the coordinator comprehends and adheres to current UNOS/OPTN allocation policies during the perioperative period.

Post-transplant

Inpatient period

At the time of transplant, a patient and their support system may be overwhelmed with the enormity of receiving a new life saving organ. Whether the recovery is smooth or complications arise, the clinical transplant coordinator is integral to working with the multidisciplinary team to care for the patient in this transition period. The clinical transplant coordinator must be knowledgeable of post-transplant management including medications, complications, and interventions [5–7]. Communication is essential between the team and the referring physician, consultants and payers. A coordinator can be a facilitator of this communication. Additionally, the coordinator must be involved with discharge planning to anticipate any medical psychosocial and financial needs prior to leaving the hospital. Education is of utmost importance and it must be culturally and education level appropriate (Table 122.3).

Patients need to learn the medications needed post-transplant, this includes their purpose and dosing as well as side effects. They need to be able to identify signs of rejection and infection. They need education about diet; exercise, restrictions and how to comply with post-transplant protocols. This can be overwhelming and therefore knowing the transplant coordinator is accessible and available to assist with questions after discharge is key [7]. Lastly, the coordinator needs to communicate verbally and in writing to any medical team that will be involved in the post-transplant care to ensure optimal care.

Outpatient period

A clinical transplant coordinator caring for a transplant recipient after discharge must be knowledgeable and able to coordinate the care after organ transplantation. These patients are very complex and are at risk for complications, medication interactions and side effects. The transplant coordinator must monitor a patient, often in person and by telephone, and be competent to determine needs and risk factors for complications. They must provide ongoing education and reinforcement of education to ensure comprehension. Additionally, they must assess for any evidence of non-adherence that may affect graft function. This monitoring may include review of lab values that determine organ function, assessment of therapeutic range for medications and identification of complications. It is often the coordinator that reviews these labs and makes adjustments in medications according to agreed upon post-transplant protocols. They must collaborate with the physicians and surgeons on the team to make appropriate changes in regimens. They are also involved in coordinating follow-up and consultant appointments and work with other disciplines to facilitate a recipient's ability to achieve optimal physical, social and emotional health [7].

Professional practice

A clinical transplant coordinator's role is an essential role in transplant and as the field changes so to must the coordinator. They must be proficient in and continue to advance his/her knowledge of transplantation. One way to do this is to become certified in transplant coordination and attend continuing educational seminars to remain current. Additionally one must review professional literature in transplant journals and incorporate this into the care of the patients. Often a coordinator is asked to participate in, or facilitate transplant related research, and publish finding as appropriate.

To ensure ongoing quality care, experienced transplant coordinators must mentor new staff to assist in the development of new professionals. Adherence to regulations, allocation policy, professional conduct and sound judgment is essential for the administration of quality care to donors, recipients and families.

Live donor coordinator

As the regulatory requirements for transplant programs have increased, so has the requirements surrounding the care of the live organ donor. Transplant programs that perform live donation must have a separate team independent of the recipient to care for the live donor. Each donor must be assigned an independent donor advocate and a Live Donor Transplant Coordinator is involved in the multidisciplinary process to coordinate the care pre and post-transplant donation [6,8].

The live donor coordinator roles are similar to that of the clinical transplant coordinator caring for transplant patients, however, as the field of live donation has evolved, the needs of live organ donors has become very specialized making it a new subspecialty of transplant [9]. Coordinators caring for live donors need a unique set of competencies to delivery quality care. These are shown in Table 122.4. It is important that a live donor coordinator maintains an understanding and working knowledge of transplantation and related policies and procedures because potential donors need to understand the recipient process, risks and chance of surviva,l and rely on a knowledgeable donor team to prepare them for donation. They must identify appropriate living donor candidates upon referral and coordinate the evaluation process of the living donor. It is of utmost importance that donor safety remains a priority and those with contraindications are excluded early in the process [10]. This coordinator must have the sophistication and experience to

Table 122.4. Role of the live donor transplant coordinator

- Maintains an understanding and working knowledge of transplantation and related policies and procedures
- Demonstrates knowledge of OPTN/UNOS policies and listing requirements
- Identifies appropriate living donor candidate upon referral
- Coordinates evaluation process of the living donor
- Education of patients, families and the public about live donation, process, risks, benefits and need for follow-up
- Assesses donor motivation, ability to comprehend risk and desire to proceed with donation
- Assists in determination of donor suitability
- Collaboration with the multidisciplinary team involved in donor care and the live donor advocate
- Provide direct patient care, support and education post donation both in the perioperative period and through long term follow-up.
- Provides Living Donor Advocacy before and after donation and in the setting of choosing not to donate

assess a donor's motivation, ability to comprehend risk and desire to proceed with donation. Often the coordinator will be involved in the education of patients, families and the public about live donation; process, risks, benefits and need for follow-up. They collaborate with the multidisciplinary team involved in donor care and the live donor advocate to determine donor suitability. If unsuitable or if a donor decides not to proceed with donation, the coordinator ensures donors are comfortable with the outcomes and provides support as needed. They provide direct patient care, support and education post-transplant donation both in the perioperative period and through long-term follow-up. Ultimately a live donor coordinator provides care and advocacy before and after donation and in the setting of choosing not to donate.

Role of the coordinator in education

Likely the most important role a clinical transplant coordinator holds is that of educator [11]. Although much more common place than years past, transplantation remains a specialty that has a limited number of clinicians competent to care for this complicated patient populations. Regardless of which organ specialty they work in or which aspect of the care they deliver, a transplant coordinator must educate their patients and families about transplantation. The specific topics have been discussed previously (see Table 122.3). Additionally it is often necessary to educate other nurses, consultants, referring physicians, residents, medical students, and fellows rotating through a transplant service. Outside the medical team a clinical transplant coordinator may need to educate payers, regulatory agencies, financial coordinators, pharmacies, and the public about the nuances of transplantation in order to advocate for their patients. Therefore it is important for them to understand all aspects of transplantation.

Role of the advanced practice nurse as coordinator

The traditional role of the clinical transplant coordinator is an advanced role with significant autonomy required. For this reason more transplant programs are utilizing the advanced practice nurses (APN) in the care of transplant patients, either in combination with the traditional transplant coordinator or in its place. The reasons include:

- APN are educated about physical assessment, diagnostic testing and trained to independently manage complex disease processes.
- APN are licensed to practice autonomously.
- APN have prescriptive authority in most states.
- APN have the ability to bill for services thru Medicare, Medicaid and many private payers.
- Transplant centers are overburdened with the volume of patients requiring healthcare and there is shortage of house staff and physicians entering the field of transplant to care for them, APN fill this void.

An APN in transplantation has been described as a healthcare provider with an advanced level of education in their profession who directs care for patients who are potential/actual organ donors (living or deceased), transplant candidates or transplant recipients. APNs are medical providers who are not physicians, but who are licensed to diagnose and treat patients in collaboration with a physician, extending the availability of health care [12].

Roles performed by the APN as transplant coordinator include pretransplant education and evaluation, waitlist management, collaboration with referring physicians, assisting the surgical team in the operating room, inpatient management of pre and post-transplant patients, outpatient post-transplant management of immunosuppression and complications, long term management or the transplant recipient, care of the live organ donor, care of the pediatric transplant recipient, management of outreach clinics, psychological management pre and post-transplantation, and professional development and leadership [9,12–17].

APNs complement existing staffing models. Care models utilizing the APN vary but the ability to reimburse for care is a financial incentive [18]. They can relieve an overburdened medical team and provide quality care and education to the patients. Figure 122.1 shows an example of how ANP can be incorporated into the current

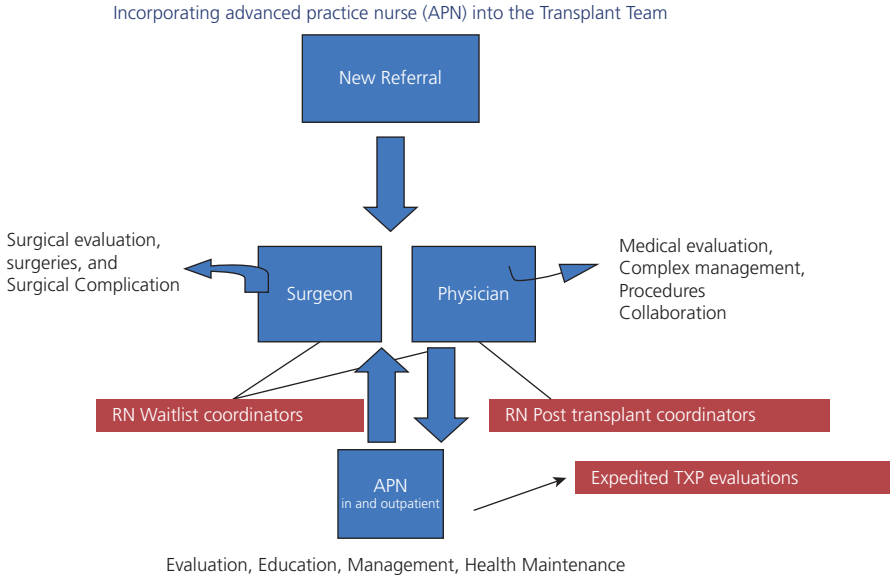

Figure 122.1. Care model utilizing an advanced practice nurse.

transplant team. They can work in combination with or in place of pre and post-transplant coordinators to care for patients in collaboration with the physicians and surgeons. Broad cost analysis and data on successful utilization is needed to understand the true benefit to programs and the transplant patients.

Summary

Regardless of which aspect of organ donation or transplant the transplant coordinator works, it is a critical role whose key components are to support, clinically manage, educate, and work collaboratively with the other members of the transplant team to achieve successful outcomes. Traditionally a generalist coordinator role who was a registered nurse, current transplant coordinators have many specialties and includes advanced practice nurses. As healthcare reform continues to change transplantation, so too will the role of the coordinator need to evolve to meet the demand of our patients.

Introduction

The success of organ transplantation is arguably as dependent on the proper use of an expanding array of pharmacological agents as on any other factor. Indeed, management of immunosuppressive drugs, anti-infective agents, and an often daunting list of medications required to address recipient co-morbid conditions occupies a substantial amount of a transplant teams' efforts, and often involves navigation of significant drug interactions and incompatibilities. As such, pharmacists have become integral members of most transplant teams, and accordingly, the expectations of transplant pharmacists have become increasingly defined and codified. This chapter will describe the role of a transplant pharmacist as part of a broader multidisciplinary transplant service, provide the reader with a general understanding of the training necessary to become a transplant pharmacist, and the manner in which they can improve patient outcomes and care. Specifics of the pharmacology of transplantation are covered in Chapters 98–102.

Evolution of transplant pharmacy

Pharmacists have been part of the multidisciplinary transplant care team for almost a half a century. The first publication detailing the pharmacists' role on the transplant team was published by John Mitchell from The Ohio State University in 1976 [1]. Mitchell describes the pharmacists' role in the 1970s as one that is very similar to how many pharmacists practice today. In 2007, Dr. Gilbert Burkart published reflections on the past 30 years of transplant pharmacy [2]. In this paper much credit is given to Dr. Thomas Starzl at the University of Pittsburgh and Dr. John Najarian at the University of Minnesota for being the first surgeons to include pharmacy faculty members as part of the transplant team recognizing their pharmacotherapy expertise. Burckart and colleagues Venkataramanan and Ptachcinski facilitated therapeutic drug monitoring of cyclosporine into clinical practice, and published detailed cyclosporine pharmacokinetics in 1986 [3]. Since the mid-eighties, pharmacists have continued to make significant contributions to the transplant literature with publications on the pharmacokinetics and pharmacogenomics of immunosuppressive therapy in addition to numerous publications focusing on clinical outcomes in transplantation [4–10]. The direct impact of the transplant pharmacist on patient outcomes has been demonstrated in publications showing improved medication compliance and blood pressure management with transplant pharmacy services [11–13].

The pharmacist's membership within the transplant team has transitioned from a novelty to an expectation for today's transplant clinicians. Most notably, the first publication outlining role of the pharmacist as part of the multidisciplinary transplant team was published in the *American Journal of Transplantation* in 2011 [14]. This paper outlines the various roles the pharmacist can have in the inpatient, ambulatory and research setting and describes the necessary training required to be competent in these roles.

In addition to contributions to the literature, transplant pharmacists have become increasingly recognized by various professional pharmacy and medical societies. The membership within these professional societies has grown exponentially over the past five years. Since its inception in 1994, the American College of Clinical Pharmacy (ACCP) Immunology and Transplantation Practice and Research Network has grown from 75 members to over 330 members, most notable is the increase in membership from 2004 to 2011 where the group grew from 170 to 332 members [15]. The majority of this growth has been related to the increased need for transplant pharmacists subsequent to the requirements set forth by Centers for Medicare and Medicaid Services (CMS), which will be discussed in length later in the chapter.

The ACCP and the American Society for Health System Pharmacists (ASHP) now identify transplant pharmacy as a discipline worthy of recognition commensurate with the highly specialized patient population served. The ASHP now has specific accreditation standards for postgraduate year two (PGY2) transplant residency programs and has begun to accredit transplant pharmacy residency programs across the country [16]. This is an important step in the evolution of transplant pharmacy training, as it ensures that pharmacy residents are meeting specific standards and receiving high quality training. The number of PGY2 transplant residency programs has also increased dramatically in the past ten years growing from less than six programs to nearly twenty in 2012, with the majority now being ASHP accredited programs. This will allow the profession to continue to grow, and maintain high standards of excellence for pharmacy services provided to all transplant donors and recipients.

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

In October 2008, the board of directors within the American Society of Transplantation (AST) incorporated transplant pharmacists into the community of practice (CoP) model. This CoP was initiated in 2009, and as of November 2011 had over 160 members, including a chair, chair-elect, past-chair and four members at large. This formalized development of a specific practice group within the AST was followed by the appointment of a transplant pharmacist onto the Editorial Board of the *American Journal of Transplatation*, the latest step in recognizing pharmacists as vital to the overall success of transplantation and significant contributors to the ongoing research into optimizing drug therapy in this high risk patient population.

Governing body support for transplant pharmacy

In 1984, the US Congress under the National Organ Transplant Act (NOTA) established the unified transplant network known as The Organ Procurement and Transplantation Network (OPTN). The act called for the network to be operated by a private, non-profit organization under federal contract. The OPTN has two primary goals: (1) Increase the effectiveness and efficiency of organ sharing and equity in the national system of organ allocation, and (2) Increase the supply of donated organs available for transplantation. The OPTN is a unique public-private partnership that links all of the professionals involved in the donation and transplantation system. The OPTN is administered by the United Network for Organ Sharing (UNOS) under contract with the Health Resources and Services Administration of the US Department of Health and Human Services [17].

A set of bylaws developed by UNOS specifies the exact criteria that each transplant program must follow in order to be compliant with the standards. These bylaws were amended in 2004 to recognize and identify the roles and responsibilities of the pharmacist as an essential member of the transplant team. Specifically, these bylaws mandate that "all transplant programs should identify one or more pharmacists who will be responsible for providing pharmaceutical care to solid organ transplant recipients" [18]. The transplant pharmacist should be the designated member of the team who plays a key role as the drug information expert on the team and is responsible for compliance to institutional protocols, screening and anticipating drug interactions, patient and caregiver education, along with responsibilities outlined in later sections of this chapter [18].The CMS currently provides accreditation for transplant programs allowing them to receive payment for services rendered. CMS performs formal site visits at all CMS approved transplant centers every three to four years to ensure the transplant centers are meeting the established conditions of participation. On March 30, 2007, CMS published the *Medicare Requirements for approval and Re-Approval of Transplant Centers to Perform Organ Transplants*. This document outlines the specific requirements set forth by CMS for accreditation. With regards to the role of the pharmacist on the transplant team, the document states "a transplant center must identify a multidisciplinary transplant team (composed of individuals from medicine, nursing, nutrition, social services, transplant coordination, and pharmacology) and describe the responsibilities of each member of the team". The document does not specifically state that the pharmacist must be the team member with the pharmacology knowledge. However, in an open comment session CMS did refer to the UNOS bylaws for details on the specific role of the pharmacist on the transplant team [19]. An updated version of the interpretive guidelines was published in June of 2008 [20]. Important updates outlined in this document include the need for all members of the multidisciplinary team to document all activities in the medical record as well as the need for the multidisciplinary team to be involved with the care of both the donor and recipient throughout all distinct phases of the donation and transplantation process. These phases include the pretransplant phase before listing, the perioperative period, the immediate post-transplant hospital admission and the discharge process.

In addition to the updated interpretive guidelines, CMS also published a set of documents in September 2008 to assist centers in planning for surveys [21]. This document specifies that during the CMS visit the inpatient pharmacy will be toured and the designated transplant pharmacists will be interviewed. This document provides examples of the typical questions that will be asked of the pharmacist. The pharmacist personnel files are also reviewed to evaluate the pharmacist's transplant specific training, current competency and continuing education related to transplant.

Education and training of the transplant pharmacist

Transplant pharmacists have various levels of training and education. A recent survey of the ACCP transplantation and immunology Practice and Research Networks (PRN) reveals that the majority of practicing transplant pharmacists have advanced training beyond their PharmD degree. Sixty six percent completed at least a postgraduate year 1 (PGY1) residency and an additional 45% completed advanced training in transplantation through a transplant residency and/or a fellowship. Even though the majority of transplant pharmacists are pursuing advanced training, the minimum qualifications for the transplant pharmacist vary from center to center. Thirty-seven percent of survey responders indicated that their employers required a minimum of a PharmD degree. Another 35% required at least a PGY1 residency; 29% required at least five years of transplant experience or a postgraduate year 2 (PGY2) residency in transplant; and 26% required a PGY2 in transplant.

Historically, a four year Bachelor of Science degree was required to become a registered pharmacist. However, in the 1990s the degree was converted from a bachelor's to a doctorate degree. Currently most schools of pharmacy subscribe to a four year (three year accelerated year-round) doctor of pharmacy program following completion of prerequisites or a four year bachelor of Science in Pharmacy, followed by a two year doctor of pharmacy program. The final year of the doctoral degree program consists of a series of clinical rotations focused on patient care. After obtaining the PharmD, all individuals must pass a mandatory national (competency) and state (law) exam along with completing a specified number of internship hours prior to receiving licensure to practice pharmacy as a registered pharmacist.

Transplant pharmacists practicing prior to the advent of formal postgraduate training

Many of the current mentors in the transplant pharmacy field entered practice without formal residency training in solid organ transplant. These pharmacists are responsible, along with their non-accredited trainees, for developing the principles and current educational standards of new transplant pharmacists and their accredited residency programs.

Postgraduate residency training

The complexity of transplantation and limited exposure to transplant during didactic PharmD course work has led to the need for formalized postgraduate clinical training. The first stage of postgraduate training is often completion of a PGY1 pharmacy residency program. This residency should be accredited by ASHP. Completion of a PGY1 residency allows one to rotate through various clinical patient care settings such as internal medicine, surgery, intensive care, specialties such as transplant, infectious disease, cardiology, ambulatory care and others. In addition to the clinical rotations, PGY1 residents are exposed to administrative practices, teaching activities and some gain experience in conducting clinical research through their training. This introduction serves as a foundation for developing skills and competence in providing pharmaceutical care in multiple practice settings.

Following the PGY1 residency, transplant pharmacists should complete a PGY2 specialty residency in transplantation. The majority of these PGY2 training programs are accredited by ASHP. The required educational outcomes, goals, and objectives for PGY2 pharmacy residencies in solid organ transplant are designed to transition PGY1 residency graduates from generalist practice to specialized practice focused on the care of solid organ transplant recipients and, in some instances, living organ donors. The graduates are equipped to participate on interdisciplinary teams assuming the responsibility of medication related aspects of patient care including education and research in both the inpatient and outpatient settings.

Transplant fellowship training

Although fewer in number, some transplant pharmacists, have undergone specialized fellowship training. The numbers of programs suited for this type of training are limited. These programs are typically two years in length and are usually completed following a PGY1 or PGY2 residency. Unlike a PGY2 transplant specialty residency, where the emphasis is patient care, the emphasis during a transplant fellowship is basic and/or clinical research in the field of transplantation. The goal of a fellowship is to train the pharmacist to become an independent researcher in the field of transplantation.

Additional formal education

Master of Science in clinical research (MCR) programs have surfaced around the country with the intent of providing clinicians from multiple disciplines the skills and education necessary to enter into clinical research as successful independent and collaborative investigators. These programs augment the research potential of the novice transplant pharmacist specifically in the areas of research design, epidemiology and biostatistics. Additionally, some transplant pharmacists engage in other types of additional formal education, including Master of Science in public health (MPH) or business administration (MBA). The options are limitless and are often pursued based on the individual transplant pharmacist's practice setting and professional goals.

Description of roles and responsibilities on the patient care team

Inpatient transplant pharmacists roles and responsibilities

Clinical transplant pharmacists combine the principles of several sub-specialties to be effective members of the multidisciplinary inpatient transplant patient care team (also see Chapter 124). This includes optimization of pharmacotherapy across the phases of care from the intensive care unit to the time of discharge for adult and pediatric transplant recipients and living donors. Knowledge of drug delivery systems, pharmacoeconomics, drug information and drug literature evaluation, statistics, immunology, pharmacokinetics, pharmacology, pharmacogenomics, pathophysiology, pharmacotherapy, pharmacovigilance, regulatory standards, and medication safety are a necessity. Transplant pharmacists have substantial expertise in the management of novel and traditional immunosuppression and incorporate this with other subspecialties such as infectious diseases, cardiology, hepatology, nephrology, pulmonology, endocrinology, hematology, pediatrics, and critical care in order to manage patients with multiple co-morbid conditions.

While serving on the inpatient clinical team, the transplant pharmacist has a number of responsibilities during the peri and post-transplant period. These include continual assessment of the appropriateness of drug therapy prescribing practices as well as outcomes of therapy through active monitoring of safety and effectiveness parameters. Daily activities include therapeutic drug monitoring, pharmacokinetic and pharmacodynamic surveillance, drug (drug and food) interaction management, and optimization of drug administration, delivery and costs. In addition, the transplant pharmacist assumes the role of facilitating admission and discharge medication reconciliation in collaboration with the nurse coordinator, midlevel practitioner, social worker and other members of the patient care team.

The transplant pharmacist is also typically involved in development of transplant medication use protocols, ensuring adherence to the protocols during the transplantation process, and then proactively measuring the protocol related outcomes, collecting data that can be used to make informed modifications to the protocols over time. The data collection involved with evaluating the effectiveness of the protocols also often goes hand-in-hand with research efforts of the transplant center, with the transplant pharmacist taking an important lead in quality improvement. The results often prove meaningful to peer institutions and have contributed to the growing literature describing methods for optimizing patient outcomes [22].

These protocols typically require agreement among the transplant physician provider and approval from drug use oversight committees within the healthcare organization, for example, the Pharmacy and Therapeutics Committee. In this role, the transplant pharmacists ensure the protocols are consistent with institutional guidelines and when necessary secure the required approval from oversight committees. These protocols may be implemented and enforced in conjunction with collaborative practice agreements.

Collaborative practice agreements between physicians and pharmacists exist in which one or more pharmacists and one or more physicians enter into a medication therapy agreement that may occur in any setting in which a pharmacist-patient relationship can be established [23]. A collaborative practice agreement provides the pharmacist authority to manage medication therapy within a scope of practice. In the transplant setting, such an agreement authorizes the pharmacist to deliver patient care services, including but not limited to the following, according to the individual needs of the patient:

- Establish provider-patient relationships with patients outside of the practice of medication dispensing.
- Perform assessments and interviews to obtain complete medication, medical, social, and other pertinent patient information.

- Evaluate and monitor medication therapy through obtaining and assessing objective and subjective markers of effectiveness and/or tolerability.
- Initiate, modify and discontinue medication therapy.
- Order laboratory tests.
- Administer medications, including injectable agents, for example, vaccines.
- Educate patients and/or caregivers on medications, medical conditions, relevant non-medication interventions, and health promotion factors
- Document and communicate the encounter within the patient's health record.

Another major emphasis of transplant pharmacy practice is patient and caregiver education. A significant portion of the education patients and family members receive regarding medication occurs in the post-transplant period during the initial hospitalization. The pharmacist provides or coordinates much of this education and assesses the ability of the patient and family to independently manage the medications upon discharge. As a result the transplant pharmacist, in conjunction with the rest of the multidisciplinary patient care team, plays a vital role in coordinating drug therapy as they follow the patient throughout their continuum of care.

In addition to educating patients and caregivers about the appropriate administration of post-transplant medications, there is an increasing need for pharmacists to focus education on risks and side effects of immunosuppressive therapy. The heightened awareness of such risks arises from new Food and Drug Administration (FDA) regulations regarding risk evaluation and mitigation strategies (REMs). In March 2008 the FDA was granted authority to require drug manufacturers to submit proposed REMs as part of the drug approval process if it is determined that REMs are necessary to ensure a drug's benefits outweigh its risks [24]. The required components of REMs vary based on the severity of perceived risk. REMs may require any or all of the following:

- a medication guide and/or patient package insert;
- a communication plan;
- or elements to assure safe use (ETASU).

REMs programs are required to undergo regular assessment by the manufacturer and the FDA. These assessments take place at least 18 months, 3 years and 7 years post-REMs approval. Transplant providers must stay on top of the ever changing REMs requirements to ensure patients are properly educated about the risks of their medication therapy. The mTOR inhibitor everolimus was the first immunosuppressive agent approved by the FDA with a REMs program in place. The original REMs program included both a communication plan and a medication guide; the medication guide was removed from the REMs a year and a half after its approval. The REMs for sirolimus (medication guide) was added 10 years after it was approved by the FDA only to be removed 6 months later [25]. Belatacept is a first in class biologic immunosuppressive agent approved by the FDA in June 2011. Belatacept was approved with a REMs program that requires use of a medication guide and a communication plan. Typically medication guides are required to be dispensed by retail pharmacies with the initial prescription fill and all subsequent refills. Belatacept is unique in that it is the first intravenous maintenance immunosuppressive agent. Given its route of administration and the fact that the first dose of belatacept is given in the perioperative phase of transplantation, there has been some debate as to when it is necessary to provide the patient with a medication guide. In November 2011, the FDA published guidance surrounding the provision of medication guides to inpatients [26]. This document states that a medication guide should be provided:

1. any time a patient or caregiver requests the medication guide;
2. if the drug is subject to an elements to assure safe use (ETASU) REMs that includes specific requirements for providing and reviewing a medication guide;
3. the first time a drug is dispensed to a healthcare professional for administration to a patient in a clinic or infusion center;
4. the first time a drug is dispensed to a healthcare professional for administration to a patient in a clinic or infusion center after a medication guide is materially changed; and
5. any time a drug is dispensed directly to a patient or caregiver in an outpatient setting.

Gabardi and colleagues published a detailed review in 2011, of the REMs system, and its implications in transplantation. These reviews should be consulted for a more detailed overview of REMs in transplantation [27,28].

Transplant pharmacists develop tools and individualize strategies and systems to improve drug adherence. Some of these range from educational techniques to use of reminder tools to help ensure adherence with complicated medication regimens. Examples include: development of educational material such as written, video or other visual aids; provision and instruction on the use of pill boxes or other storage devices; electronic methods such as automatic text message or email reminders; implementation of web-based medication lists and organization programs; and self-medications programs where the patient manages their new medication while in the hospital, building confidence and demonstrating skill at assuming responsibility for their medication management while still under the direct supervision of the transplant team.

In addition to educating patients and family members the transplant pharmacist is also responsible for education of other transplant care providers and other pharmacists within the medical center who may manage aspects of pharmacotherapy for the transplant recipient. The transplant pharmacist in the inpatient setting also communicates and documents all of the activities described above in the medical record to ensure practitioners at all levels of the care team understand the plan of care for transplant pharmacotherapy. Furthermore, it is essential for the transplant pharmacist to articulate key issues regarding changes in medications and therapy plans with both the patient and their family or caregivers. Hereby, pharmacists make a vital contribution in creating a smooth and safe transition of care [14].

Integration of the transplant pharmacist into the ambulatory care setting

Implementation of transplant pharmacy services into the ambulatory clinics has been a recent addition to the variety of services impacting patient outcomes. Transplant pharmacists provide a broad spectrum of clinical and operational services complementing the numerous responsibilities handled by the outpatient transplant services (see Chapter 125). Several studies have evaluated the impact of the transplant pharmacist in the ambulatory setting. Chisholm and colleagues evaluated the cost savings associated with implementing a clinical pharmacist lead patient assistance program in a kidney transplant clinic [29]. A total of 61 patients were enrolled which lead to $124 793 in cost avoidance in the first year of the program secondary to acquisition of immunosuppressants through industry sponsored patient assistance programs. The cost incurred for the pharmacist's time was estimated at $16 650. The impact of clinical pharmacy services on transplant outcomes and

adherence was also evaluated in a subsequent study lead by Chisholm and colleagues in 2008 [30]. This group investigated two groups of kidney transplant recipients. The intervention group (n = 12) were provided intense clinical pharmacy services aimed at compliance, adherence, medication education and access to medications while the control group (n = 12) received standard care. Results indicated that the intervention group had a higher mean adherence rate (96.1% ± 4.7%) versus the control group (81.6% ± 11.5%, $P < 0.001$). In those patients who eventually became nonadherent improved adherence lasted longer in the intervention group versus the control group (mean 11 months vs. 9 months in the control group, $P < 0.05$) [30].

The return on investment from the transplant service lines for implementation of dedicated pharmacist's services include improved patient and allograft outcomes, along with increased reimbursement for specific therapies (e.g. basiliximab, antithymocyte globulin, intravenous immune globulin) by facilitating the appropriate coding and billing procedures. Additionally, transplant pharmacists are well positioned in the clinic to identify patients at high risk for non-compliance secondary to financial issues. Pharmacists are able to refer these individuals to patient assistance programs or modifying their regimens to maximize cost effectiveness.

Several centers have also implemented ambulatory care transplant pharmacy services to increase their outpatient pharmacy revenue and improve patient outcomes through developing additional disease state management services (e.g. pharmacist run collaborative diabetes, anticoagulation, hypertension, or hepatitis C) allowing for quick, concise referrals yielding immediate results or utilizing that pharmacist to provide the pathway for patients to return to the outpatient pharmacy to fill their prescriptions beyond their immunosuppressants [31]. Several ambulatory transplant pharmacist models exist which can aid in improving the continuity of patient care from the inpatient to the outpatient stay. Specifically, when the inpatient and outpatient pharmacists rotate between the services, a dedicated ambulatory pharmacist can provide inpatient discharge counseling for patients they are going to see in clinic. Additionally, utilization of an electronic note system accessible by all providers can facilitate communication of patient issues, such as the need for patient assistance, adherence barriers, or variables which may contribute to infections or rejection.

More recently, from a regulatory standpoint, the transplant pharmacist is required by Centers for Medicare and Medicaid Services (CMS) to evaluate patients proceeding through the pretransplant work up. This is an additional opportunity for the team to utilize the ambulatory transplant pharmacist to reconcile medications prior to transplant, identify any barriers to post-transplant medication compliance and provide recommendations for perioperative medication selection if necessary.

The impact of a comprehensive inpatient and ambulatory pharmaceutical care program on post-transplant medication compliance was published in 2009 [32]. This study was a prospective, randomized controlled trial, designed to evaluate the impact of a 12 month pharmaceutical care program on post-transplant compliance in 50 liver transplant recipients. Methods used to assess compliance in this study include medication event monitoring systems (MEMs) caps, immunosuppressant concentrations, pill counts, self-reports and the Morisky questionnaire. In addition to routine clinical care, patients randomized to the intervention group received pharmaceutical care services provided by a dedicated hospital pharmacist. The pharmacist began meeting with patients approximately one week prior to discharge, at this meeting they discussed dosing instructions, possible side effects, monitoring and discharge instructions. This review occurred three to four times prior to discharge. Additionally, on discharge, these patients were given written information about their medications, a discharge plan and diary for documenting vital signs and labs. During the first year, post-transplant patients met with the pharmacist on a quarterly basis to review medication changes, labs and drug related problems. Results indicated that patients randomized to receive pharmaceutical care had a higher dosing compliance rate ([# of days with correct number of bottle openings/# of monitored days] × 100) measured by electronic compliance monitoring compared to controls (90.2% ± 6.2% vs. 80.8% ± 12.4%, $P = 0.015$). Compliance as measured by pill counts showed large intra and interpatient variability, especially in the control group. However, the median compliance rate was still found to be significantly higher in the patients who received pharmaceutical care compared to the controls. Target serum immunosuppressant levels were achieved in a significantly higher proportion of patients receiving pharmaceutical care compared to controls (78% vs. 51%, $P < 0.001$) [32].

Despite the need for pharmacy services in both the inpatient and ambulatory care setting, the results of a recent survey indicate that 43% of transplant pharmacists focus their time on the inpatient setting. Thirty six percent are able to split their time between inpatient and outpatient and another 3% split their time between inpatient, outpatient, research and transplant administration. The majority of effort is focused on kidney (79%) liver (63%) and pancreas (61%) transplant recipients. A growing number of pharmacists are also providing care to heart (34%) and lung (29%) transplant recipients. As composite tissue allograft programs are becoming more prevalent 5% of pharmacists responding to the survey state that they are incorporated as part of this multidisciplinary team.

Determining the ideal patient to pharmacist ratio remains a challenge. The survey captured both the number of pharmacists per site and the annual transplant rate, which allowed quantitation of the current pharmacist to patient ratios at responding centers (Figure 123.1). Transplant centers performing over 200 transplants

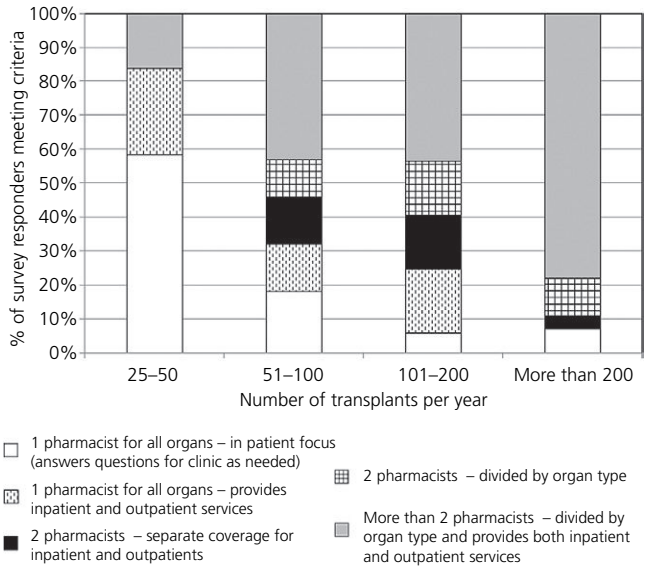

Figure 123.1. Transplant pharmacist coverage by transplant volume.

a year are most likely (78%) to employ more than two pharmacists who cover all organs and provide coverage to both the inpatient and ambulatory setting.

The role of the pharmacist in clinical research

Understanding the pharmacist potential for expertise as a clinical scientist

Clinical and translational research is not a singular activity but rather a continuum of efforts. By virtue of its interdisciplinary nature, pharmacy aligns extraordinarily well with this continuum [33]. Specifically in transplantation, many transplant pharmacists serves as a liaison between the inpatient and ambulatory care team [14]. The advanced perspective of the transplant pharmacist positions them well to develop, facilitate and analyze transplant related outcomes through clinical and translational research.

A unique set of challenges exists for pharmacists within immunosuppressive pharmaceutical research. They are increasingly required to understand drug development processes, best clinical practices, federal regulations and guidelines, and clinical research protocol development, implementation, and monitoring. In addition, extensive training and experience in writing protocols, including background, rationale, and methods sections, are required as part of any clinical research protocol. Pharmacists have a strong technical background in areas such as dosage form technology, medicinal chemistry, pharmacology, and therapeutics that are critical to the drug development and commercialization process and are thus effective investigators for clinical research related to immunosuppressive drug therapy. In the areas of discovery and translational research, pharmacists with specific training can provide input into preclinical studies that assess new technologies and methods applicable to pharmacogenomics and design approaches to develop clinically useful biomarkers. They may also oversee and plan clinical development strategies; design studies; write research protocols; oversee study implementation; analyze data, author reports, and publications; and review the scientific content of informational materials. Individuals with specialized training in pharmacokinetics and drug metabolism are typically required to design and analyze data obtained from a variety of transplant studies. Focus on the safety and efficacy components of phases II and III studies that support regulatory approval, or oversight of phase IV post-marketing research that addresses critical questions regarding novel immunosuppressant combinations and optimal treatment strategies are all areas of research in which transplant pharmacists are involved [34].

Rarely in transplantation is a large study powered appropriately to evaluate the use of all agents in the various transplant organ types or regimen combinations. With such a rapid transition from research to practice, the pharmacist is uniquely educated to combine their knowledge of therapeutics with the clinical knowledge of transplantation to critically evaluate such therapies with focus to efficacy and toxicity. While this should never replace well controlled clinical trials, this practice is inevitable in transplantation. The pharmacist is uniquely positioned to critically evaluate the smaller pilot experiences and cautiously transition these to practice while never loosing site of our responsibility to "first do no harm".

With the introduction of comparative effectiveness research, a new research endpoint has developed focused on overall healthcare cost containment. While the cost effectiveness of many drug therapies are debated, drug therapy costs are seen as one of the "easiest" ways to contain healthcare costs. Pharmacists have a unique understanding of the overall impact of drug costs which may provide an influential perspective away from drug costs alone to overall healthcare cost management. This is especially important in transplantation due to the costs associated with lifelong immunosuppressive therapy.

Pharmacist's role in the continuum of clinical research

Success in the arena of research typically requires productive collaborations with physician or multidisciplinary investigator teams. The collaboration amongst a multidisciplinary team is well established within transplantation, however recently the role of the pharmacist within this team has strengthened. The role of the pharmacist may take a variety of forms primarily related to the knowledge base and strengths of the individual combined with the institutional needs. Likewise, the pharmacist roles and responsibilities on the research may be varied.

As a clinical researcher, pharmacists have been involved in all phases of clinical trials, Phase I–IV. The pharmacist's delineation of responsibilities within the various studies can include principal investigator, co-investigator, sub investigator, coordinator, investigational pharmacist, research coordinator, research assistant, etc. The pharmacist serving as principal investigator, is the individual who is responsible and ultimately accountable for design, conduct, reporting, and monitoring of a study.

Pharmacists participating as co- or sub investigators work in concert with physicians to carry out the regulatory and reporting requirements needed to maintain compliance with these increasingly complex studies. As co-investigators pharmacists have the ability to use their own unique knowledge of immunosuppression to consent and enroll patients in these trials, then follow their progress throughout the post-transplant course. Pharmacists participate on daily rounds and in clinic, to aid clinicians and study investigators with trial procedures, as well as, provide expertise with drug therapy management.

Interface between transplantation and the investigational pharmacy

The principal investigator is responsible for the plan to control the investigational product. For example, how it will be stored, controlled, and dispensed so that only qualified investigators and the participants may use the investigational drug. Many times this responsibility is delegated to an investigational drug pharmacist. Investigational pharmacy services can be very complex for studies in solid organ transplant due to the fact that most transplants are not scheduled procedures thus requiring around the clock services with most transplant studies require long term study drug administration to assess long term outcomes. A dedicated investigational pharmacy service with experience in solid organ transplant can facilitate the conduct of the study on many levels. For many transplant studies, randomization and/or administration of the investigational product must occur prior to or during the transplant procedure. Assuring this service and delivery of the investigational product in a timely manner so as not to delay the transplant procedure is of vital importance. This requires close collaboration and communication with the investigational pharmacist and the clinical research team. Facilitating the dispensing of chronic medications over a long-term period of time in a timely manner that meets regulatory compliance standards for investigational products is challenging. This must be done in the context of the already complex post-transplant pharmacotherapy regimen. Understand-

Table 123.1. Stages of coordination with investigational pharmacy

Phase	Stages
I Planning	Time in which the investigator/designee is aware of a potential study which administers an investigational drug. During this phase activities may include defining individual drug services (IDS) scope of work, identifying desired IDS services, constructing an accurate budget for IDS services, establishing a timeline for subsequent study phases, meeting with study monitors for site evaluation visits, etc. At this point, the study protocol may or may not be finalized. If the intent of the investigator is to manage the storage, inventory control, and distribution of any substance used as part of a study, the investigator or designee must submit appropriate documentation of this process for review. This plan is in the context of other institutional regulations for substance storage and distribution
II Start up	Time in which the investigator/designee deems there is a high likelihood the study will be initiated. During this phase activities may include, IRB submission, contract review, notice of grant award, etc.
III Open enrollment	Time when IRB, contract and institutional approvals are complete. Study drug is available on site and ready to dispense
IV Close enrollment	Time when enrollment is completed, but patients remain in follow-up
V Study closure	Time after last patient, last visit when all study documents are finalized and corrected

ing the complexity of the individual study and the coordination of investigational drug services (IDS) can be maximized by effective communication. Effective communication at each study phase is optimal. Table 123.1 outlines the phases of communication necessary to ensure optimal results.

With the extensive use of off label medication, one of the basic challenges in transplantation is determination if your study includes an investigational drug. To determine if your study meets the definition of an investigational drug you may ask, "Is the drug used in human research study for the primary intent of accumulating scientific knowledge?" If yes, your study could be considered using an investigational drug. Whether or not investigational drug services may be necessary can be facilitated by the diagram in Figure 123.2. The decision tree includes the basic questions, however, implementation must be tailored to specific institutional requirements. Use of investigational drug services does not necessarily require dispensing by a pharmacy.

Pharmacists as directors of clinical research

Several pharmacists have become Directors of clinical research programs. In this role, the pharmacist combines administrative and clinical knowledge to facilitate the overall conduct of transplant clinical research within a given institution. While many universities tend to provide infrastructure for National Institutes of Health (NIH) sponsored research, many do not provide the necessary infrastructure for an active clinical research program. Independent of the study's scientific component, successful clinical research programs require expertise from additional areas such as regulatory, laboratory, clinical skills, financial, administrative, and collaboration between several institutional departments, such as anesthesia, surgery, nephrology, pathology, etc.. Strength in these areas is equally important as the scientific expertise to facilitate overall success in the clinical research area. In today's economic environment, industry needs centers which will enroll many patients quickly and provide quality data. Likewise, universities can no longer financially support clinical research teams who are not financially viable. This is not possible without a focus on not only science and patient care, but on business and finance also.

Financial justification for clinical pharmacy services

Integration of clinical pharmacy services

It is well established that clinical pharmacists are an integral part of a hospital and health system's patient care team. Hospital and health systems with outpatient pharmacies and clinical pharmacist involvement are able to take the patient's care one step further, following the continuum of care directly to the outpatient prescription setting at time of discharge, as well as post-discharge. In addition to enhancing quality of care, an outpatient pharmacy with the ability to bill Medicare Part B (health insurance)and specialty pharmacy services allows additional revenue for hospitals and health systems currently looking for avenues to reduce cost and maximize revenue. By capturing this outpatient revenue and referring patients to a robust internal pharmacy program, expense of pharmacist resources can be offset, allowing for a win-win for all parties involved. With support from transplant and hospital leadership, and an educated pharmacy staff willing to embrace the opportunities available through a transplant specialty pharmacy service line, significant revenue can be realized. When institutions develop a transplant specialty pharmacy service line and are able to maintain patients within their own system they have the opportunity to utilize this revenue as further financial justification for their clinical pharmacy services.

Another potential opportunity for transplant pharmacists to financially justify their positions is to bill for their services. Although there are a limited number of transplant pharmacists that are currently pursuing this route, Maldonado and colleagues demonstrated that pharmacists in one year (208 pharmacist visits) were responsible for increasing the outpatient reimbursement by nearly $10 000 or roughly $100/visit. This increase in reimbursement along with other factors was utilized to substantiate the case for clinical pharmacy services [35]. In the current healthcare environment any opportunity to offset/justify resources must be evaluated. New technology, electronic health records, electronic prescribing, and medication therapy management will continue to allow pharmacists to expand their roles, and ensure that medication needs of patients are appropriately addressed during all stages of inpatient and outpatient care.

Establishment of mail order transplant pharmacy services — impact of 340B drug pricing program

The 340B Drug Pricing Program was established in response to the passage of Section 340B of US Public Law 102–585, the Veterans Health Care Act of 1992. Section 340B of this law limits the cost of drugs to certain grantees of federal agencies and other entities identified in the statute. This program is administered by the Office of Pharmacy Affairs (OPA) of Health Resources and Services Administration (HRSA), under the federal US Department of Health and Human Services (HHS).

The federal 340B Drug Pricing Program provides access to reduced price prescription drugs to over 16 869 (as of September 30, 2011) healthcare facilities certified by the HHS as "covered

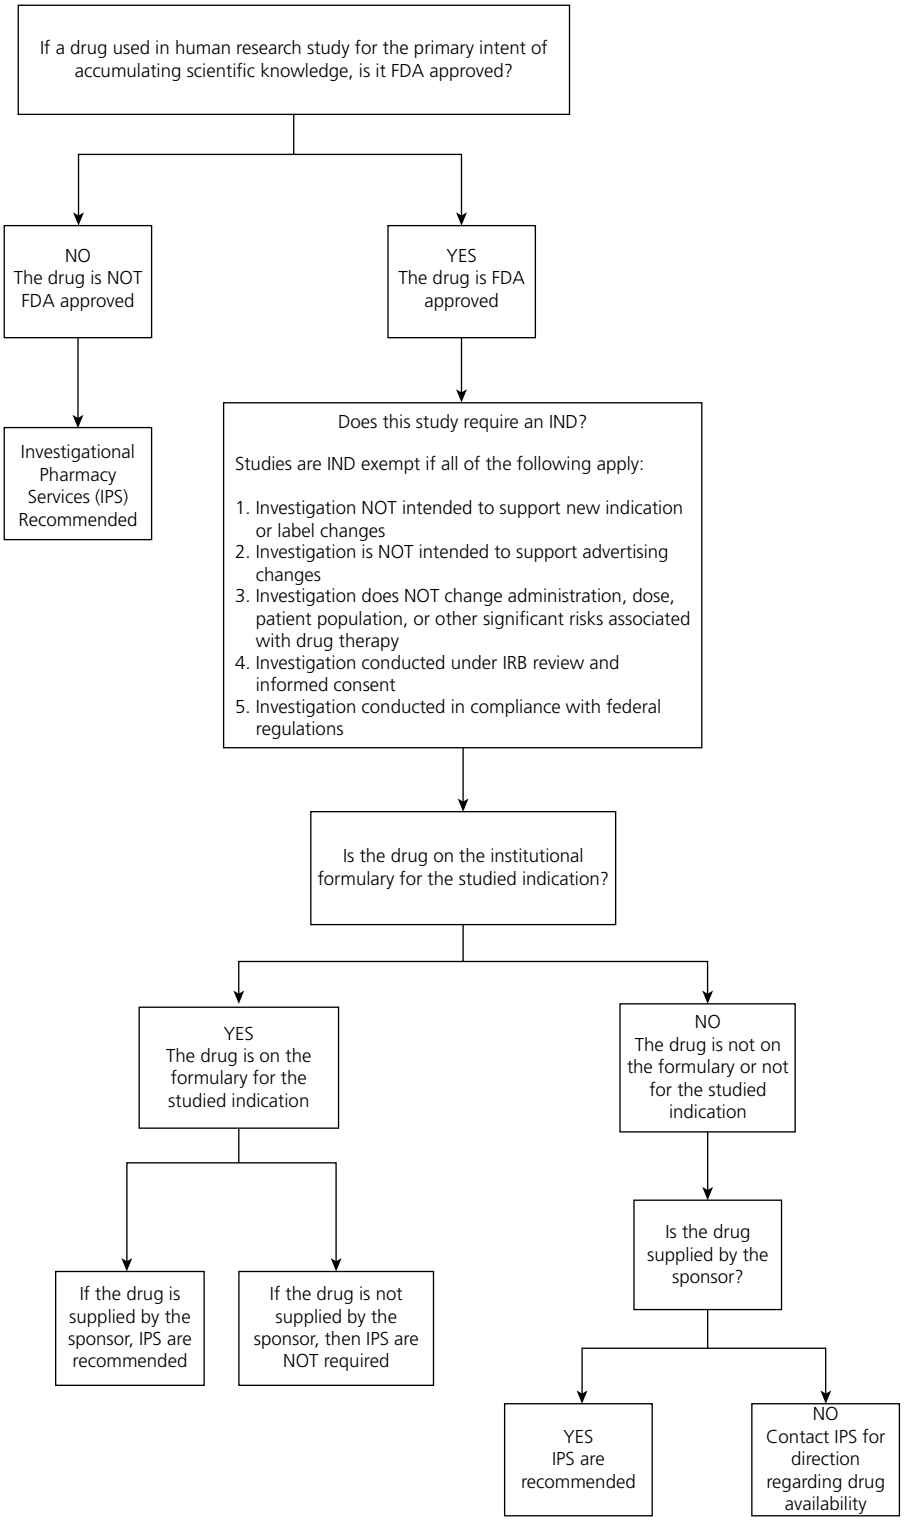

Figure 123.2. Evaluation of the need for investigational pharmacy services.

entities". These clinics, hospitals, and centers in turn serve more than ten million patients in all 50 states, in addition to commonwealths and territories.

Maximizing participation in 340B pricing under the federal Public Health Act allows for increased savings and expanded access to prescription drugs for states and clinics. This represents a significant opportunity for transplant programs to capture revenue as the 340B price is 19% below the average Medicaid "best price" net or rebates, 39% below the average insurance reimbursement, and 51% less than average wholesale price (AWP). Strategies to maximize savings are to target the most costly aspects of pharmacy programs, or most costly patient populations and/or disease states, such as

mental health, transplant, hemophilia, HIV/AIDS, and other categories of patients with expensive and chronic disease states. Transplant institutions that pursue setting up an outpatient pharmacy system and maintain their patients in their system have the opportunity to recognize significant financial gains again financially justifying a transplant pharmacist salary.

Specialty pharmacy establishment

The high cost of medications and the complexity of pharmacy billing and reimbursement have discouraged many independent and small retail pharmacies from participating in the Medicare Part B and "specialty" market, and have allowed the business to be taken over by larger, more "sophisticated" retail giants and mail order pharmacies. Over the last 30 years, "specialty" pharmacy has grown from a notion to an industry approaching $100 billion annually, and has become a major force in healthcare quality and innovation [36].

Specialty pharmacies offer services for providers and insurers by streamlining the delivery process and regulating the challenges in healthcare delivery. Many specialty pharmacies focus on pharmaceutical and biologic products with high acquisition cost, that are difficult to manage from both a patient care and reimbursement standpoint. Patient's prescription drug benefit plans often require that patients obtain these specialty medications from a mail order pharmacy participating with the insurer's specialty drug network. Medical supervision and/or instruction is often required for certain injectable medications, and many medications considered "durable medical equipment". As a result, many medications may be covered by *either* pharmacy or medical benefits, thus making care even more complex for providers, patients, and pharmacy staff.

As medications for high cost therapies may be covered under pharmacy and/or major medical benefits, it is important to understand how to identify and properly bill for these medications. Medications that cross over to medical coverage include, but are not limited to injectable and infusion therapies, and therapies that require complex care such as: cancer, HIV/AIDS, organ transplantation, hepatitis C, and rheumatoid arthritis.Facilities and pharmacies with existing transplant and oncology patient populations have the potential to develop work flow plans and processes around these patients to allow for a seamless encounter for patients, along with personalized medication management. The creation of a robust mail order pharmacy to retain patients outside the pharmacies immediate area, and to allow patients to remain in the system for maintenance medications and long term medication needs, adds substantial profit to a hospital/facilities bottom line thus again offering an opportunity to offset the expense associated with a transplant pharmacist and other much needed resources.

Impact of medicare coverage

Thousands of individuals receive a Medicare covered kidney transplant every year through the Medicare End Stage Renal Disease (ESRD) program. Kidney failure, or ESRD, is the only disease specific Medicare benefit, providing coverage of dialysis, transplantation, and immunosuppressive medications, among other services. Individuals with ESRD automatically qualify for Medicare if they or their spouse or parent have paid into Social Security for at least ten years.

Medicare established an immunosuppressive drug benefit to allow for coverage of costly immunosuppressive medications post-transplant that has continually expanded since the establishment of coverage in 1993. The Benefits Improvement and Protection Act of 2000 eliminated the previous 36 month limitation for Medicare aged and disabled transplant recipients who were Medicare eligible at the time of their transplant. Currently, if a patients eligibility is based solely on ESRD status, coverage will end 36 months post-transplant. However, if a kidney transplant recipient had Medicare ESRD status at the time of their transplant and their 36 month time limit expired, if they later attained Medicare coverage based on age or disability status, Medicare coverage of their immunosuppressive medications would resume. Legislation to remove the 36 month coverage limitation for immunosuppressive medication has repeatedly been introduced to Congress. Passage of this legislation to law is both fiscally and medically responsible.

For outpatient prescription drugs, Medicare has two distinct programs with a maze of complex policies. Drugs that are billed by pharmacy suppliers and administered through durable medical equipment are covered by Medicare Part B, as are some oral medications billed by pharmacy suppliers and self-administered by the patient, such as immunosuppressive medications and some oral anti-cancer medications. For Medicare Part B medication coverage in a physician's office, the medication must be furnished "incident to" a physician service. This typically means the medication is physician prescribed and dispensed or physician prescribed and administered during the course of an office visit. Medicare Part B drug coverage is usually limited to drugs or biologicals administered by injection and infusion, unless the injection is generally self-administered. Medicare uses a combination of local and national coverage determinations, and in absence of a CMS national coverage determination, local coverage determinations are made by individual Medicare carriers.

Medicare Part B defines several take home medications as "durable medical equipment". Those items include: nebulizer solutions, immunosuppressive medication, diabetic supplies, and certain oral anti-cancer medications [37–39].

Medicare cost report and organ acquisition discussion

The largest primary payer of organ transplantation in the US today is Medicare. Transplant programs must account for all allowable direct and indirect expenses to the appropriate Medicare acquisition cost center in order to receive appropriate reimbursement from Medicare, and in a market of continually dwindling reimbursement, capturing all Medicare allowable expenses is critical for success.

Medicare reimburses hospitals that are certified transplant centers for certain costs associated with the acquisition of organs for transplant to Medicare beneficiaries. Medicare requires that claimed costs be reasonable, properly allocated, and supported. Medicare allows as organ acquisition costs all costs associated with the organ donor and recipient before admission to a hospital for the transplant operation (i.e. pretransplant services) and hospital inpatient costs associated with the donor. At the end of each year each hospital files a cost report which is reconciled by Medicare to insure that all costs are allowable as defined in Medicare regulations and policy.

Medicare requires that transplant hospitals allocate only the portion of costs that relate to time spent on allowable organ acquisition activities as organ acquisition costs on the Medicare cost report. Institutions are required to use a reasonable basis to allocate costs to appropriate cost centers for pretransplant, post-transplant, and non-transplant related activities. For every

Table 123.2. Transplant pharmacist activities

Fundamental activities

1 The pharmacist's time is dedicated to transplant patients, with few commitments to other patient populations/services.
2 The pharmacist has dedicated hours for the clinic and inpatient transplant service.
3 The pharmacist regularly makes rounds as a member of the multidisciplinary transplant team to provide pharmacotherapeutic management for all transplant patients.
4 The pharmacist coordinates the development and implementation of drug therapy protocols and/or transplant pathways to maximize benefits of drug therapy.
5 The pharmacist prospectively evaluates all drug therapy for appropriate indications, dosage, drug interactions, and drug allergies; monitors the patient's pharmacotherapeutic regimen for effectiveness and adverse drug events; and intervenes as needed.
6 The pharmacist ensures adequate reconciliation of the medication record between the hospital and clinic at the transplant center.
7 In conjunction with the clinical dietician, the pharmacist recommends modifications to the nutritional regimen.
8 The pharmacist identifies adverse drug events and assists in their management and prevention, and develops process improvements to reduce drug errors and preventable adverse drug events.
9 The pharmacist uses the medical record as one means to communicate with other health care professionals and to document specific pharmacotherapeutic recommendations.
10 The pharmacist provides pharmacokinetic monitoring of immunosuppressive medications and other medication when such monitoring is necessary.
11 The pharmacist provides drug information to the transplant team.
12 The pharmacist participates in training pharmacy students, residents, and fellows through experiential transplant rotations, where applicable.
13 The pharmacist maintains transplant protocols and appropriate references.
14 The pharmacist provides medication therapy-related education to transplant team members.
15 The pharmacist participates in reporting adverse drug events to institutional quality assurance committees and to the FDA's MedWatch program.
16 The pharmacist provides updates and education to the transplant team surrounding the REMs requirements of immunosuppressive therapy.
17 The pharmacist provides and documents medication use education to all transplant recipients, certifies that patients are capable of managing their medications and reconciles home medications with post-transplant drug list.
18 The pharmacist reviews patient drug history to determine which medications should be continued after transplantation:
  (a) The pharmacist clarifies previously effective dosages, dosage regimens and provides recommendations for dosage adjustments as needed following transplant
  (b) The pharmacist assures that any drug-drug interaction is managed appropriately.
  (c) For all suspected drug-related hospital admissions, the pharmacist assesses the patient drug history for causality and documents in the medical record any findings that will impact the patient's management.
19 The pharmacist ensures the patient has access to all required transplant medications prior to discharge from the hospital.
20 The pharmacist documents clinical activities that include, but are not limited to, disease state management, general pharmacotherapeutic monitoring, pharmacokinetic monitoring, adverse drug events, education and other patient care activities.
21 The pharmacist acts as a liaison between pharmacy, nursing, and the medical staff to educate health professionals regarding drug-related procedures, policies, guidelines and pathways.
22 The pharmacist contributes to the hospital newsletters and drug monographs on issues related to transplant medication utilization.
23 The pharmacist implements and maintains departmental policies and procedures related to the safe effective use of transplant medications.
24 The pharmacist collaborates with nursing, medical staff, and hospital administration to prepare the transplant program for The Joint Commission (TJC), Centers for Medicare and Medicaid Services (CMS), and United Organ Sharing Network (UNOS) surveys and responds to any identified deficiencies.
25 The pharmacist provides consultation to hospital committees, such as Pharmacy and Therapeutics, when transplant pharmacotherapy issues are reviewed.
26 The pharmacist identifies how drug costs may be minimized through appropriate use of transplant medications and through implementation of cost-containment measures.
27 The pharmacist will ensure safe utilization of generic narrow therapeutic index medications.
28 The pharmacist participates in quality assurance programs to enhance pharmaceutical care.
29 The pharmacist is involved in non-patient care activities including multidisciplinary medical review committees and educational in-services.

Desirable activities

1 The pharmacist regularly meets with patients in the transplant clinic to provide follow-up education and ensure proper adherence to prescribed medication regimen.
2 The pharmacist maintains knowledge of current primary literature pertinent to transplant pharmacotherapy.
3 The pharmacist provides didactic lectures to health professional students in transplant pharmacology and therapeutics, where applicable.
4 The pharmacist uses a documentation program that attaches both a clinical significance and an economic value to clinical interventions.
5 The pharmacist is actively involved in transplant pharmacotherapy research by assisting in the screening and enrollment of patients by serving as a study coordinator or contact person, where applicable.
6 The pharmacist participates in research design and data analysis, where applicable.
7 The pharmacist contributes to the medical literature, for example, case reports, letters to the editor, and therapeutic, pharmacokinetic, and pharmacoeconomic reports.
8 The pharmacist promotes awareness in the community about the importance of organ donation.

Optimal Activities

1 The pharmacist assists physicians in discussions with patients and/or family members to help make informed decisions regarding treatment options.
2 The pharmacist provides formal accredited educational sessions, such as grand rounds, for medical staff, students, and residents.
3 The pharmacist develops residencies and/or fellowships in transplant pharmacy practice.
4 The pharmacist identifies and educates lay groups and medical personnel in the community about the role of pharmacists as part of the multidisciplinary transplantation team.
5 The pharmacist independently investigates or collaborates with other transplant practitioners to evaluate the impact of guidelines and/or protocols used in transplantation for drug administration and management of disease states associated with end-organ disease.
6 The pharmacist uses pharmacoeconomic analysis to prospectively evaluate existing or new pharmacy services and the place of new medications in transplant pharmacotherapy.
7 The pharmacist is proactive in designing, prioritizing and promoting new pharmacy programs and services for transplant patients.
8 The pharmacist seeks funds for conducting research.
9 The pharmacist reports results of clinical research and pharmacoeconomic analysis to the pharmacy and medical community at regional and national meetings.
10 The pharmacist publishes in peer-reviewed pharmacy and medical literature as a result of any of the following activities:
  (a) Clinical research or other original research that quantitatively or quantitatively evaluates drug therapy and the provision of pharmacy services.
  (b) Investigator-initiated grants and contracts.
  (c) Pharmacoeconomic and outcomes research.

transplant center the capture of pretransplant related cost associated with personnel salaries is vital. All transplant centers are very familiar with utilizing tools, such as time studies, to capture the amount of time that transplant coordinators, social workers, financial coordinators and administrative staff spend working in the pretransplant phase. These pretransplant salary costs are Medicare allowable and should be captured for partial reimbursement via the cost report. As both Medicare and UNOS now require the participation of a transplant pharmacist in the pretransplant phase, it is vital that transplant centers include pharmacists in these time studies. As centers document and appropriately capture pharmacist pretransplant time for inclusion on the cost report a substantial portion of a pharmacist's salary can be offset. The amount of offset will vary by each institutions Medicare organ percentage and the amount of pretransplant pharmacist involvement [40–42].

Summary

Recognition of the role of the transplant pharmacist by governing bodies such as CMS and UNOS has transitioned the role of the transplant pharmacist from a novelty to a necessary member of the multidisciplinary transplant team. The value of the transplant pharmacist as a member of the inpatient, ambulatory, research and transplant administration team is becoming evident. The various transplant pharmacist activities performed in the inpatient, ambulatory and research setting are outlined in Table 123.2. *Fundamental activities* are defined as expected activities to ensure safe and effective pharmaceutical care and access to medications for the transplant recipient. Fundamental activities should not be considered the minimum standards of activity of a transplant pharmacist. *Desired activities* include fundamental activities in conjunction with enhanced transplant related pharmacotherapy responsibilities and transplant related research. *Optimal activities* include fundamental activities and desired activities and incorporate the roles and responsibilities of the transplant pharmacist as the leader of transplant related pharmacotherapy research and education. They also incorporate the highest levels of expertise to optimize patient and allograft outcomes. Transplant pharmacists should strive to become the drug therapy expert on their perspective team and optimize pharmacotherapy at their practice site in addition to their numerous other responsibilities. The list of activities is not all inclusive and is constantly evolving with the practice of pharmacy and medicine.

Introduction

Care of the solid organ transplant candidate or recipient requires specialized skills and high level competencies in the staff on transplant units. The complexity of care required of this patient population is best guided through multidisciplinary planning on daily rounds. Surgeons, physicians, nurses, transplant coordinators, nurse practitioners, pharmacists, social workers, dietitians and clergy comprise the multidisciplinary team members collaborating and planning individualized care of each transplant recipient or living donor. The bedside nurse implements the plan of care, evaluates outcomes, communicates results to transplant team members and educates patients and families. The role of a nurse practitioner on an inpatient unit has evolved over time and varies among transplant programs. It is becoming more common for units to have three or more nurse practitioners functioning in the role of a hospitalist on transplant units and in the Intensive Care Units [1]. Some nurse practitioners take calls for the transplant unit.

Pre transplant candidates for heart or liver transplantation are often cared for in an intensive care unit or a specialized progressive care unit as they await a suitable organ for transplantation. Over the last ten years there has been a sharp rise in the use of mechanical circulatory support devices such as a left ventricular assist device or total artificial heart as a bridge to heart transplantation. These devices require highly specialized and competent staff to ensure safe, efficient care for patients. Many transplant centers have designated, specialized units for care of the post transplant recipient due to the complexity of care required of this population. Most units are further specialized with either thoracic or abdominal transplant recipients. Immediately following surgery, liver, lung or heart recipients are taken to their specialized intensive care unit (ICU) for care. Many hospitals care for kidney recipients and living kidney donors in progressive care units rather than in an ICU environment. However, some surgeons prefer all kidney recipients are recovered in an ICU for at least the first 24 hours. This chapter addresses structure, management and staffing issues as they relate to the inpatient care of candidates and recipients on thoracic and abdominal transplant units. Outpatient clinic management and the roles of transplant nurse coordinators are specifically covered in Chapters 122 and 125, respectively.

The physical environment and resources — infection control

It is a fortunate few who experience the luxury of creating a physical environment from scratch for our transplant units. Most of us inherit the space in which we practice and we make accommodations for our unique population. Private rooms for every patient top the list of our transplant wishes. When only a semi-private room configuration is available, decisions to maximize infection control are essential for patient placement. For the patient who has just received a solid organ transplant, and is newly immunosuppressed, the private room scenario seems obvious. The same private room can be just as important to a pretransplant patient, as any infection may make that patient temporarily unable to receive an organ, effectively lengthening the time on a waitlist. This consideration applies to the ICU as well as the progressive or general care unit. On a unit where there are multiple semi-private rooms, decisions often need to be made to block one bed in a double room in order to create the private room scenario. Support from hospital administration for this practice can present a challenge when overall facility census is high. Discussions and planning for this potential situation should be held prior to the actual event. The hospital epidemiology experts are helpful in such discussions.

Another serious consideration for infection control on any transplant unit is the quality of the airflow. High efficiency particulate airflow (HEPA) should be readily available, if not a constant state of the unit ventilation system. The merits of true positive pressure ventilation (ppv), implying a sealed room with an extremely high air exchange rate per hour, have long been debated but have never been proven scientifically [2]. An outbreak of aspergillosis on a transplant unit can be deadly. It is then that a discussion of the merits of ppv are most often heard. Prevention is the best intervention. Frequent rounding to assess potential breakdown in the physical environment is the key to avoiding problems. For example, dialysis on a transplant unit is a common occurrence as not all patients are able to travel to a central dialysis area. The dialysis procedure requires water, and a lot of it. Secure machine connections to a source of water and a place to drain that water after the treatment are required. Poor connections can lead to constantly moist areas, a condition which leads to mold and mold begets aspergillosis. Less common than dialysis, but also a source of moisture buildup, is a window that chronically leaks in a hard rain. The

wise manager of a transplant unit develops an ever vigilant posture and promotes the same vigilance in the bedside nurse and support staff, including environmental services and plant operations workers.

The human resource — staffing

While the thoracic transplant/mechanical support device unit are comprised of a multidisciplinary team of cardiology physicians, cardiothoracic surgeons, nurse practitioners, advanced practice nurses, registered nurses (RNs), care partners, a dietician, physical therapists, occupational therapists, pharmacists, social workers, care coordinators (utilization review/discharge planner), the unit's budget is largely comprised of nursing personnel. The nursing budget is comprised of clinical nurses, care partners, unit secretaries, clinical coordinator, clinical nurse specialist and nurse manager. The nurse manager prepares the unit's budget with input from all staff on the unit, and advocates for the necessary resources to provide safe and competent care to complex cardiothoracic surgery patients.

To prepare an operational budget for an inpatient unit, a nurse manager must be familiar with the financial structure and goals of the organization. There must be a strong understanding of the organization's priorities, so that the unit's plan is aligned with the organization's strategic direction. A budget is the plan for a year that allows the organization to prepare activities and control costs within its means. Nurses and nurse managers are key to cost control, and more importantly, they are instrumental in maintaining patient safety and ensuring positive quality patient outcomes.

The level of training and knowledge of nurse managers varies among various types of organizations. The Chief Nurse Executive holds ultimate accountability for nursing's budget development and expense management. Front line managers must have skills to plan the budget, control costs, and make effective decisions regarding resource allocation [3]. The budget identifies the unit's level of service and workload that determine personnel and non personnel resources required [4]. Nursing's personnel budget is a large portion of the healthcare organization's labor expense. A strong plan for allocating resources and the leader's ability to manage those resources are key to operating a successful inpatient transplant unit.

Nurse staffing is traditionally measured in one of two ways, hours (of care) per patient day, or nurse to patient ratio. The staffing plan for inpatient transplant units is established by the organization utilizing hours per patient day (HPPD). This measure, HPPD, was developed by the American Nursing Association for the National Database of Nursing Quality Indicators (NDNQI) [5]. Nursing HPPD refers to the number of nursing care hours needed relative to the nursing workload. The HPPD values are determined from hospital direct care hours and unit census data, individualized per unit based on historical census data. Census data is determined each night at midnight. Nursing workload varies based on the type of unit. The nursing workload is greater in an ICU than an acute care unit. Acute care units may be intermediate or progressive care or medical-surgical telemetry units. As nursing workload increases, the nurse to patient ratio must decrease. Each year, the staffing budget is determined based on historical average daily census (patient days). Patient days are projected for the year, based on historical census data.

Staffing a nursing unit for transplants is an important concept to understand, so that managers can advocate for sufficient resources to care for complex patients. Hours per patient day and staffing resources have been studied in recent years to assess the relationship between staffing numbers and patient/hospital outcomes [6,7]. Results of those studies have shown mixed results regarding the relationship between staffing and patient outcomes. Studies have shown a correlation between nursing care hours and patient outcomes [6–8]. Increasing nurse staffing resources is costly to organizations, as nursing budget is already a large portion of the hospital's budget. However, a reduction in adverse events and improvement of nurse sensitive indicators can be shown to be cost beneficial to the organization. HPPD accounts for volume. Increased levels of nursing staff have been shown to improve outcomes and studies continue to evaluate the validity and reliability of this measure of workload [6–8].

Once the unit's budget has been established, it is the responsibility of the nurse leader/manager to effectively manage those resources. Careful consideration must be given to the patient acuity and the skill mix of staff working on the unit. At the authors organization, a staffing grid guideline is developed based on HPPD and a nurse to patient ratio established for the unit to provide front line staff a guideline of how many RN's should be working, based on current total unit census.

The Labor Management Institute, a consulting, education and research firm provides services in the areas of workforce management and operations. They conduct and annual survey of 360 hospitals from 45 states regarding hours per patient day and nurse to patient ratio. According to the Labor Management Institute 2009 Annual Survey of hours, intermediate care units (stepdown) HPPD and total hours per patient day, averaged between 9.6–11.1 (total HPPD). Direct hours per patient day averaged between 9.3–10.8. Nurse to patient ratio for RN's is 1:3.6–1:3.8 for teaching hospitals [9].

Once equipped with a well designed plan for staffing resources, it is the leader's challenge to allocate the nursing resources to provide safe and expert care to complex heart surgery patients. A grid can be developed as a guideline for determining the number of staff members needed based on current patient census. This tool can be helpful in maintaining expenses within framework. As census fluctuates, staff can be reallocated to areas of need within the organization.

The thoracic transplant unit

On the thoracic transplant/mechanical circulatory support device (MCSD) unit, competency is determined in three phases: at hire, during orientation, and on a continual basis. At the time of hire, RN competency is assessed through verifying licensure, registration, certification, behavioral interviewing, and previous experience. The initial competency phase focuses on the skills and abilities necessary to care for the patients during the first year of employment [10].

During the orientation competency period, RN staff on the thoracic transplant/MCSD unit are introduced to a variety of experiences to prepare them for independently caring for both transplant and MCSD patients. This initial orientation period is usually 12 weeks and includes didactic classroom content, hands on orientation to a variety of MCSDs, as well as observational experiences. The RN is assigned to a primary and associate preceptor who guides them through care of patients on our unit. They are immediately assigned to take care of MCSD patients, including left ventricular assist device patients (LVAD) and total artificial heart (TAH) patients, under the supervision of their preceptor. The didactic

portion of their orientation is usually provided at the end of their orientation. Providing hands on review and training with their preceptor in advance of the classroom content allows for the orientee to better understand the classroom content. Prior to the end of orientation, the orientee completes a hands on competency assessment including emergency measures to change batteries, respond to alarms and in some cases switch out drivers (total artificial heart and freedom driver-portable TAH-t (Table 124.1) [11]. Staff on this unit review and complete a transplant competency test on an annual basis as well as MCSD competency testing.

The didactic content includes indications for left ventricular assist devices, components of the devices, postoperative management of the patients, alarm management, and pump malfunction, drive line care (care of the exit wound), battery changes and charging, complications, and equipment management. A competency checklist is completed for each device used in the environment. New staff observes and performs wound care to the exit drive line care under the observation of their preceptors. Meticulous, sterile technique must be used, and a immobilizer device should be placed on the drive line to minimize the movement of the lines at the exit site.

Other concepts important in the care of the transplant/MCSD patients include care of the postoperative heart surgery patients. Once transferred out of the ICU, nursing priorities include medication management, preventing pulmonary complications, progressive mobilization of patients, wound care, pain management, and addressing psychosocial aspects of caring for patients with MCSD.

For small programs, it is challenging to maintain competency when these procedures are low volume. Nursing leaders may consider limiting the number of staff oriented to care for the MCSD and transplant patients, in order to maintain competency. For other programs, where implantation of mechanical circulatory support devices and thoracic transplants are routine, all nursing staff should be trained and validated annually for competencies. Ongoing competency assessment should include new procedures, technologies, policies or initiatives or changes in initiatives, procedures, policies. High risk responsibilities that could cause harm, death or legal action should also be included in the ongoing competency assessments [10]. A variety of competency verification methods should be utilized in order to assess different aspects of the job skills including technical, critical thinking and interpersonal. A variety of methods can be used to demonstrate competencies including post tests, exemplars, observation of skills, case studies, peer reviews, mock events [10]. Review of case studies is an excellent way to incorporate critical thinking skills and to apply knowledge to specific patient scenarios. Actual patient events are described. The employee reflects on the event and answer questions as to appropriate interventions.

The abdominal transplant unit

An abdominal transplant unit provides care for the patient population who receive kidney, kidney-pancreas, pancreas alone, liver, intestines and/or multivisceral organs. Frequently, they suffer from multiple system complexities with disease processes that are seldom limited to one organ. In some cases, patients are receiving a combination of two or more of these organs. Resources required to sustain a successful abdominal transplant inpatient unit include both an appropriate physical environment and a patient care staff with knowledge, skill, and professional behavior.

The inpatient unit may be as small as ten or as large as 80 beds. If the unit is small, it may provide care for only the immediate postoperative, sometimes known as freshly transplanted, patients. A larger unit provides care for patients all along the transplant continuum from the evaluation phase, the waiting period, perioperative period and for any post-transplant admissions as well. In a unit such as the latter, many patients may be admitted and discharged several times throughout the course of their chronic, acute, and recovery phases. These repeated visits over time can create a very personal environment for the patients and the care givers, in particular the nursing and adjunct therapy staff. This is one component of transplant care that staff find rewarding.

An additional cadre of patients for the abdominal transplant unit may be the living donors of kidneys or sections of a liver. We are aware of programs that routinely place related and unrelated, known and confidential, donors on the same unit as the recipients. A related or a non-related donor, whose identity is known to the recipient, would not generally be placed in a bed in the same room or an immediately contiguous room. Physical separation allows for privacy but also is intended to protect each patient from the stress of worry over the other. On the unit within which we practice, the separation of a donor from a recipient, when the two know each other, is often the impetus for one or the other to take that first walk down the hall to visit. These walks often provide moments of joy and humor for the patients and gratification for the staff.

In the case of a confidential donation, also known as a Good Samaritan or altruistic donor, it is possible to place the donor on the same unit as the recipient; however, extra care must be taken to ensure that the identity of the two patients is protected. The size and design of the physical space of the unit and the number of staff dictates how that confidentiality is accomplished. For example, it would be unwise to have one RN caring for both the donor and the recipient. In some programs, either all donors or just the confidential donors are placed on separate post surgical units with the specific intent to maintain confidentiality.

Staffing the abdominal unit

Similar to the thoracic transplant area, the abdominal transplant team consists of nephrologists, transplant surgeons, pharmacists with a transplant specialty, transplant coordinators, nurse practitioners, RNs, a dietitian and social worker, unlicensed assistive and clerical staff. The support services of physical and occupational therapy are also involved in the daily planning of care. The responsibility for staffing the unit falls to the unit manager and includes only the direct care RNs and unlicensed assistants.

The mechanics of staffing numbers, as presented previously, are at the core of the staffing model for any hospital inpatient unit. The number of full time equivalents (FTEs), spread among licensed and unlicensed assistive positions, is established annually and forms the structure within which a unit manager must work. The day to day, shift to shift, story of staffing is much more fluid, and particularly so on an abdominal transplant unit due to variations in census and variations in acuity, which are the norm.

Transplant surgery is an uncertain event to a great degree. If the program performs living kidney and/or living liver donation, the surgeries are scheduled with bed and staffing need being planned in advance. However, the availability of organs from deceased donors cannot be predicted. The size of the center's waiting list, the medical demographics of those that are waiting (ABO type, severity of illness etc.), the size and quality of the donor pool, and the number of transplant centers within a geographic area all have an impact on the number and frequency of the organ transplant event and thus the patient census on a transplant unit. Staffing must be accomplished not only with baseline numbers but also a plan to flex up or down with changes in census and acuity.

A 20 bed unit with three newly transplanted liver recipients transferred from the ICU, five newly transplanted kidneys on vasoactive drips, and ten patients at varying stages of procedural intervention must be staffed at a higher nurse patient ratio than a 20 bed unit with ten empty beds and no recent transplants in the other ten beds. This kind of variation in staffing need has the potential to force reassignment, usually referred to as "floating" staff to other units when they are not needed on the "home" unit or forcing them to use paid time off. Neither of these options is palatable for the bedside care giver and leads to dissatisfaction, turnover, and staff vacancies. All of these outcomes can ultimately lead to the unintended consequence of poor patient outcomes [12].

One strategy to maintain a full and stable census on such a unit is to identify non-transplant service patients that fit well on the unit without compromising infection control or staff competency. The unit we are most familiar with has been able to safely accept overflow from neurology and cardiology areas, as well as some individual surgical specialties, for example parathyroidectomies. Key to this strategy is the ability to screen all patients quickly for signs of infection prior to accepting them for admission to the transplant unit. Placing these patients on the transplant unit has a mutual benefit to the organization's throughput needs and can stabilize the fluctuations in census and staffing for the abdominal transplant unit.

Staff training, education, competencies, and certification

The nursing staff chosen to work on the abdominal transplant unit range from novice to experienced nurses. Basic competency is determined at hire based on licensure, behavioral interviews, certifications and core nursing skills. Through an extensive orientation, approximately 12–14 weeks of both didactic and hands-on work, increased competency is developed. Each RN orientee is assigned to a primary and a secondary preceptor. The preceptors have all successfully completed a course that trains them in general preceptor skills. It is the primary job of the preceptors to guide and coach the orientee through the entire training period. On our particular unit this process is overseen by the unit Nurse Clinician who is an advanced practice RN.

On the abdominal transplant unit, initial competencies are looked at from the perspective of clinical knowledge and practice. Those specific core competencies to be mastered before a nurse finishes orientation on the abdominal transplant unit include:

- Administering immunosuppressive medications, intravenous (IV) and oral.
- Monitoring lab values for therapeutic levels.
- Monitoring patient response to these medications and quickly identifying adverse reactions.
- Recognizing signs and symptoms of rejection or infection.
- Administering and titrating vasoactive IV medications to achieve tight blood pressure control.
- Monitoring of fluid balance with early recognition of need to adjust fluid intake, ability to accurately replace fluid as needed by use of an established protocol.
- Monitoring for signs and symptoms of bleeding, at surgical sites, in drains, or in hemodynamic stability.
- Monitor central venous pressure (CVP); ability to interpret readings and identify cause of changes.

Table 124.2. Competencies for transplant staff nurses (Data from [13])

Category	Competency	Activity to demonstrate competency
Assessment	Systematically and comprehensively collects, prioritizes, and documents data on a given patient, including past and current history Assesses and documents all aspects of family and care giver support systems (tasks, stressors, etc.) Assesses adherence to therapeutic recommendations in the past and present.	Identifies impact of history on current condition Identifies impact of systems on patient and potential outcomes Identifies risk factors for future adherence. Identifies educational needs of patient, family, etc.
Nursing sensitive diagnosis	Makes nursing diagnosis based on the assessment. Refines and revises diagnoses continually, based on new data Documents and discusses the diagnoses with the patient, family, other caregivers, and members of the multidisciplinary team.	Differentiates variations between normal and abnormal for the transplant population
Outcomes identification	Identifies expected outcomes that are patient oriented and developmentally appropriate, evidence-based, attainable, and realistic Modifies outcomes based on ongoing evaluation	Ensures the expected outcomes are mutually acceptable to the patient and caregivers. Documents outcomes in measureable goals
Planning	Develops an individualized plan of care, aligned demographically with the patient, utilizing strategies and alternatives, to meet the expected outcomes Defines the plan to reflect current regulations and standards of transplant nursing practice	Collaborates with patient, care givers, and team in development of plan and setting priorities Considers the economic impact of the plan on the patient. Documents the plan, using standardized terminology and technology
Implementation	Implements the identified plan in a safe and timely manner Uses evidence-based interventions specific to the diagnoses Coordinates delivery of care Employs strategies to promote health and a safe environment	Collaborates with the interdisciplinary team to implement Documents implementation and any modifications or changes Documents coordination clearly Creates an environment in which learning can take place and provides health teaching
Evaluation	Conducts systematic, ongoing, criterion-based evaluation of the outcomes	Evaluates the effectiveness of the planned strategies
Quality of practice	Systematically enhances the quality and effectiveness of nursing practice Participates in nursing practice QI activities	Evaluates the practice environment in relation to existing evidence, identifying opportunities for new research Considers access, safety, cost, satisfaction, and effectiveness
Education	Attains knowledge and competency that reflects current nursing practice and standard. Obtains professional certification	Utilizes self-reflection and inquiry to identify personal learning needs.
Professional practice evaluation	Evaluates own nursing practice in relation to professional practice standards and guidelines, current regulatory environment	Obtains feedback from peers, patients, and colleagues. Takes action to achieve goals identified in evaluation process
Collegiality	Contributes to the professional development of peers and colleagues	Shares knowledge and skill with peers and colleagues, including feedback Mentors others
Ethics	Integrates ethical principles in all aspects of practice Contributes to the resolution of ethical issues by participating on interprofessional teams, ethics committees, etc.	Maintains patient and donor confidentiality Informs patients of the risks, benefits, alternatives, and potential outcomes of healthcare regimens
Research	Integrates research findings into practice	Uses the best available evidence in practice; actively participates in research activities
Resource utilization	Considers factors related to safety, efficacy, cost, and impact on practice in the planning and delivery of services	Assists the patient and family to become informed consumers about options, costs, risks, and benefits of care
Leadership	Provides leadership in nursing practice and in the nursing profession Shows respect for the inherent dignity and value of other people	Engages in teamwork as a team player and a team builder Willingly accepts mistakes by self and others and uses them as opportunities for learning

- Monitoring, interpreting, and completing a 12 lead electrocardiogram (EKG).
- Recognizing electrolyte levels which require heart monitoring.
- Caring for central lines, including peripherally inserted central line catheters (PICC) lines and dialysis catheters.
- Monitoring signs of metabolic disorders, such as diabetes.

There are broader and more comprehensive competencies which are demonstrated on an all encompassing behavioral level. Those competencies have been identified by the International Transplant Nurses Society and are summarized in fifteen domains [13]. Table 124.2 outlines those domains and summarizes some of the observable practices within the domains.

Certification

Certification is a process which validates the qualifications and knowledge of an individual nurse in a specifically defined area of practice [14]. The organization which grants the certification is non-governmental and the award is based on a set of predetermined standards [15]. Licensure for a nurse is based on minimum professional requirements. Certification denotes a recognized higher standard of knowledge and practice. While requirements vary according to the particular nursing specialty, all certifications include elements of practice, a known body of required knowledge, and a testing blueprint [16].

For the nurse working in a transplant area, there are many options for certification:

- Progressive Care Certified Nurse (PCCN)
- Critical Care Registered Nurse (CCRN)
- Certified Clinical Transplant Nurse (CCTN)
- Certified Clinical Transplant Coordinator (CCTC).

Why would a transplant nurse want to be certified? The American Board of Nursing Specialties (ABNS) published a white paper on nursing certification in 2006 which stated that certification is perceived by nurses and by the public as influencing accountability,

professional accomplishment and growth, and specialized knowledge [17]. The paper noted that nurses felt greater personal accomplishment, professional challenge and professional credibility.

Why would a nurse manager, nurse leader, promote and encourage specialty transplant certification on the inpatient unit? There is strong evidence that specialty nursing certification has a positive impact on a unit, on the organization as a whole, on the profession of nursing, and locally on nursing satisfaction and retention [16].

Discharge planning

Preparing patients for discharge begins on admission and requires considerable individualized planning. Fragmented care in the discharge planning process can result in rehospitalization [17]. Multidisciplinary planning for a patient's discharge requires communication to ensure the highest quality of preparations for patients to be successful at home. Transitioning patients from a controlled hospital setting to home provides opportunities for adverse events and errors with medication and self care [18]. According to the Institute of Medicine report, "To Err is Human", the majority of medical errors are a result of systemic problems [19]. Because discharge planning is a systemic process, errors are likely to occur. With the multidisciplinary approach, planning for a patient's discharge must be well documented to maintain continuity of care and communication among staff. Multidisciplinary rounds must demonstrate that each member of the team has signed the plan of care to indicate coordination of care. A discharge that is well planned and coordinated among the disciplines serves as a platform to prevent errors.

Structured, individualized discharge plans have been shown to decrease length of stay and readmission rates [20]. Some centers have a discharge pathway that is used by multidisciplinary team members [21]. Each discipline signs off on sections assigned to teach in preparation for each patient's discharge. Others also use a discharge pathway and document their education in the patient's chart. During multidisciplinary rounds a patient's progress is discussed to determine readiness or obstacles to discharge.

Patient and family education is one of the most important roles of transplant coordinators, nurse practitioners and staff nurses in preparing patients for discharge. Patient education actually begins in the pretransplant phase and continues throughout the admission, discharge and in the ambulatory care follow-up processes. Probably the most complex process for patients and families to grasp is the medications required post-transplantation. Educating patients and asking them to demonstrate self-medication is challenging within a busy hospital environment. Medications provide many opportunities for errors as patients begin the self-medication process. The frequency and changes in dosages, sometimes on a daily basis, adds to the complexity. As medications and dosages are individualized, it is not unusual to change immunosuppressive agents, thus adding to the confusion. Even though patients have learned about the many medications they will be required to take after transplantation, the reality sets in as they prepare for discharge.

Many transplant programs use an on line discharge planning program for medications called MedActionPlan [22]. This program can be accessed by patients once they are home and by providers during the patient's hospitalization and in the ambulatory care setting. It is an excellent resource for clinicians and educational tool for patients. Medications can be updated daily and printed out in a format that can be carried in a wallet or on a clipboard. Pictures of most medications are available to guide patients through the complex process of learning each new medication. Access is also available for iphones and Android devices with reminders being sent to patients by email or text messaging [22].

Case managers and social workers often help with the discharge planning process and transition to the home care environment by educating patients and families about community resources. The transition to ambulatory care can be frightening to some, especially those being discharged with a mechanical circulatory support device. While patients and families may have individualized education prior to discharge, once they are home there are questions and concerns that need answering. All transplant and device programs have an on call system where patients and family members can call to ask questions and seek guidance. An important part of the discharge planning process is providing patients with the number to call where a physician or nurse is available 24/7 to respond to concerns. Written protocols and guidelines are available to nursing staff on call to respond to patient questions with physician back up for more complex cases. This on call system helps patients transition from inpatient to ambulatory care. On call staff members must also maintain competencies that are assessed annually for each organ system and for mechanical circulatory support devices.

Quality assessment and performance improvement

Until 2007, most transplant programs reviewed their outcomes internally. Few had quality improvement programs. Today, transplant programs must demonstrate to surveyors and insurers that they are monitoring their outcomes and sharing their data with hospital Quality Assurance and Performance Improvement (QAPI) programs. The regulatory environment has led to many transplant programs developing a role for a Quality Improvement Coordinator with larger programs actually having a Transplant QAPI Department. Centers of Medicare and Medicaid (CMS) has provided the transplant community with guidelines and a surveyor's worksheet for reviewing quality programs. During the initial CMS surveys between 2007 and 2010 surveyors evaluated programs for their adherence to program policies and procedures. On the second survey of transplant centers, the focus is clearly on QAPI. Programs are being asked to provide minutes from quality team meetings, from QAPI meetings and to demonstrate the relationship to a hospital's quality program. As surveyors review a center's quality program they are requesting evidence of process improvement projects underway or completed in addition to reviewing adverse events experienced in the program.

Establishing performance measures that reflect the transplant process, pretransplant through postoperative follow-up, is key for each program. While programs utilize reports from the Scientific Registry for Transplant Recipients, this data represents cohorts that provide outcomes for up to five previous years to determine three year outcomes [23]. To stay abreast of a program's current outcomes, real time data must be maintained in key areas such as death on the waitlist, graft loss, patient death. While most QAPI programs for transplant are followed by the ambulatory care clinics, a clear relationship to the inpatient units that care for transplant recipients and candidates is needed. Staff nurses, intensivists and operating room (OR) staff should be members of QAPI teams. Results of quarterly QAPI reports should be presented to staff on each unit as well as to the (OR) staff.

Communication is a key component to capturing important data for QAPI programs. Adverse event reporting requires communication with the OR, inpatient units and ambulatory care clinics. Having members from each organ system that cares for transplant candidates and recipients on QAPI teams assists with ensuring data is complete. Transplant programs must maintain an adverse events monitoring system. Each unit should maintain an adverse events log. Morbidity and mortality meetings should include a review of adverse events. Committee meeting minutes are maintained for each QAPI meeting. Agenda items are developed based on unit events as well as following up on plans and problems identified in the previous meetings.

Process improvement projects are developed based on needs of each program. Patient satisfaction scores, patient safety issues or an increase in graft losses are projects that may be selected by transplant programs to improve. Projects should also align with hospital goals each year. For instance, patient safety is a major focus for hospitals at this time. Staff members are invited to participate in projects to improve practice in their areas. Working together on projects such as this allows staff an opportunity to take a leadership role on the transplant team. Co-chairs are selected and provide updates at staff meetings and at organ specific quality team meetings.

Regulatory issues

The CMS established Conditions of Participation (COP) for organ transplant programs on March 30, 2007, and with an effective date of June 28, 2007 [24]. With the advent of the new CMS Transplant COP, a new regulatory process for transplant programs was set in motion that would define further the future of transplantation. A transplant program is defined by CMS as a component within a transplant hospital that provides transplantation of a particular type of organ. All organ transplant programs must be located in a hospital that has a Medicare provider agreement. In addition to meeting the transplant COP the transplant program must also comply with the hospital's Medicare COP specified in 42 CFR 482.1 through 482.57 which is a separate document from the Transplant COP [25].

Transplant programs that were previously Medicare-approved prior to June 28, 2007 were required to apply for continued participation to CMS by December 26, 2007 [24]. Some of the key points with the COP included notification to CMS of significant changes to a transplant program, evaluation of compliance with Medicare's requirements, and the process for requesting consideration of mitigating factors in CMS' determination of Medicare approval of organ transplant centers [24].

In notification to CMS of significant changes to a transplant program, centers are required to provide notice within seven days of any changes that could affect its compliance with Medicare's requirements 42 CFR 482.74. This includes changes in key staff members such as the primary surgeon or primary physician of a specific program, change in the transplant administrator, a significant decrease in the volume or outcomes of a program, termination of an agreement between the hospital and the Organ Procurement Organization, and inactivation of the transplant program [24].

With implementation of transplant center COP program outcomes are monitored by regulatory agencies through data submitted by each program and analyzed by the Scientific Registry for Transplant Recipients (SRTR) [23]. Data is submitted through forms submitted electronically to the Organ Procurement and Transplantation Network (OPTN) for each candidate and recipient. Data submission is monitored to ensure 95% of a center's data is submitted no later than 90 days after its due date (COP 482.8). Failing to submit data in a timely manner may result in a deficiency accessed by the surveyors [23].

Candidates are registered with the OPTN and listed for a new organ through the computerized system. Once transplanted, follow-up forms are submitted regularly through the first year, then annually for the life of the recipient. Graft and patient outcomes are analyzed by the Scientific Registry of Transplant Recipient's (SRTR) based on forms submitted to the OPTN. These outcomes are publicly reported every six months and provide 30 day, one year and three year outcomes for both graft and patient survival. CMS, insurers and the OPTN all monitor these outcomes. Centers falling below expected outcomes are subject to a Systems Improvement Agreement (SIA) issued by CMS. This document requires a transplant program to improve their practice during a one year probation period. If the program does not improve, it may lose Medicare and Medicaid coverage for transplantation.

The process for requesting consideration of mitigating factors in CMS determination of Medicare approval of organ transplant centers describes three general areas that will be evaluated to determine whether or not a program can be approved based on the following mitigating factors: (1) the extent to which outcome measures are met or exceeded; (2) the availability of Medicare-approved transplant centers in the area; and (3) extenuating circumstances that may have a temporary effect on meeting the COP [23].

In reviewing outcome measure failure, CMS evaluates the extent and nature of the outcome measure failure and to what extent has the risk-adjusted performance departed from the standard. Important trends are reviewed for improvement, status quo or worsening along with the length of time the center has been below standard. One of the key factors measured by CMS is the risk-adjustment anomalies. CMS evaluates the evidence to determine the extent that performance has been adversely affected by transplant risks not captured in the SRTR risk-adjustment methodology. Experimental protocols would also be included in the review. Other factors included are the evidence of access to care and unusual access to care issues, patient population, organ type and factors beyond the control of the hospital, natural disasters and other factors.

Transplant programs function in both the inpatient and ambulatory care settings of a hospital. Unannounced surveys by CMS occur every three years, but CMS may survey a program earlier if patient and graft outcomes consistently decline in a program. Surveyors use tracer methodology to evaluate compliance with documentation and to determine if practitioners are following their program policies and protocols. This process involved both inpatient and ambulatory care documentation. During the survey, daily inpatient census of patients admitted to the hospital are provided to site surveyors. They may interview patients about their care during this time. Surveyors also request the names of all patients with ambulatory care visits during the site survey. Records from this population are also reviewed and patients in the clinics may be interviewed about their care [26].

The OPTN also performs site surveys, however, they provide transplant programs with the dates of their planned visit to a program and also give the center a list of patient charts they plan to audit during their one to three day survey [27]. In 2011, the OPTN began surveying living donor programs separately from the deceased donor transplants surveys. Thus, a transplant program that performs living and deceased donor kidney transplants

could have three surveys in one year: A CMS site visit as well as two separate OPTN site surveys. While the regulatory aspects of transplantation have created a more standardized structure for transplant programs, the staffing requirements have increased to oversee the data management, quality and compliance issues. Inpatient and ambulatory care settings are working more closely together to ensure safe, quality programs recognizing that volume and outcomes are being monitored and are tied to payment.

In addition to the CMS regulations and OPTN policies, the Joint Commission conducts surveys for disease specific certifications such as the Ventricular Assist Device (VAD) programs associated with heart transplant programs in the US [28]. Mechanical circulatory support devices such as the various VADs have become a large component of most heart transplant programs as either a bridge to heart transplantation or as destination therapy [29]. Surveys are conducted every two years by The Joint Commission to maintain a certification that verifies a program has met safety and quality standards established by The Joint Commission [28]. Nurses responsible for the care of patients on mechanical circulatory support devices in the intensive care and progressive care units are interviewed by surveyors to evaluate their knowledge of patient care and to discuss their orientation to the devices. A review of staff competencies is often requested along with documentation of continuing education of staff.

Joint Commission surveyors conduct tracers on patients with mechanical circulatory support devices from the emergency room to ambulatory care settings. Once discharged, patients are followed in the ambulatory care clinics by pretransplant staff including cardiologists, surgeons, RNs and nurse practitioners. Nurses and staff in ambulatory care settings are also interviewed by Joint Commission surveyors and reviewed for their updated competencies. Surveyors request documentation of nurses' orientation and continuing education about device therapy to ensure they are current with their knowledge and expertise in the care of this population.

Several heart transplant programs also implant the total artificial heart (TAH). Nursing staff in the intensive care and progressive care units who care for this patient population are interviewed by The Joint Commission surveyors on their knowledge, expertise and competencies in the care of TAH patients. In 2011 the portable TAH, an investigational device, allowed patients to be discharged on the TAH.

Disease Specific Certification for VADs requires that programs develop quality indicators to follow while patients are implanted with devices. The QAPI program must include at least four performance measures that address both outcomes and process. At this time the performance measures are not prescribed by The Joint Commission and can be identified by each program based on clinical practice guidelines. Once data from all certified programs has been analyzed, The Joint Commission plans to standardize performance measures. Data is submitted to the Joint Commission on a quarterly basis. All certified VAD programs are required to participate in a national database registry called INTERMACS. Data is collected and submitted to INTERMACS on both inpatients and ambulatory care patients as long as they remain on a VAD. Outcome reports from this database are published annually [29].

Summary

Transplantation is a highly regulated area of healthcare due to its high costs and high risks. Transplant programs have become more standardized and focused on quality outcomes within this regulatory environment. Many transplant programs have expanded staff to include a quality and compliance experts and additional data coordinators to monitor real time outcomes. The frequency of regulatory surveys by CMS, the OPTN and The Joint Commission has resulted in additional staffing requirements to be ever ready for those unannounced surveys. In large transplant programs, candidates and recipients are often cared for in specialty units allowing the entire staff of nurses to become familiar with the complexities and competent with the skills needed to care for these patients and their families. In smaller transplant programs, patients may be integrated with non-transplant patients. In such cases a specialized core group of nurses provide care for transplant candidates and recipients. Competency testing for nursing staff may be semiannual or annual. Certification is highly recommended for staff nurses as well as transplant coordinators to further ensure they maintain current knowledge in their specialty area. The multidisciplinary team approach is very effective in caring for this complex patient population with the different perspectives from each team member culminating in the comprehensive care these patients require and deserve.

CHAPTER 125

Transplant Clinic Management

Elizabeth A. Kallenborn,[1] Chris Shay-Downer,[2] Kathy Schwab,[3] and Shelley Zomak[1]

[3] Mayo Clinic, Rochester, MN, USA

Introduction

The field of transplantation has evolved far beyond the fabled 13th century operating room of Saints Cosmos and Damien to sophisticated multi-program transplant centers. Surgical skills and medical advancements aside, over time it has become clear that additional clinical resources are needed to provide long-term care to a population of increasingly complex patients. Outpatient transplant clinics staffed with clinical experts have been developed to provide comprehensive, cost-efficient care to transplant candidates, recipients and living donors. Major challenges facing transplant programs today include high acuity candidates facing increasingly long waiting times, an aging transplant recipient population confronted with many chronic disease issues, and shortened pre and post-transplant lengths of stay.

Little information is found in the literature regarding the development or evolution of the early outpatient transplant clinics, but the value of organized delivery of care is commonly discussed. Organized delivery of care yields improved clinical quality of care and control of chronic disease, improved patient satisfaction, and a reduction of hospitalizations, emergency visits, and prescription drug expenses [1]. Pioneering transplant efforts have been largely that of a "team", typically consisting of surgeons, physicians and transplant coordinators. Much is written about the early days of transplant coordination from the surgeons' perspective, but few publications focus on the role of early transplant clinics [2]. Therefore, the aim of this chapter is to describe current outpatient transplant clinic management operational strategies. This overview is applicable to all phases of transplantation: evaluation, candidate/wait-list management, and recipient/living donor long term care management.

In the US, transplantation is highly regulated by the federal government. The operational strategies discussed in this chapter are often based on these regulations, which will be introduced to the extent that they impact clinic management. More detailed treatment of governmental oversight can be found in Chapter 128. Detailed treatment of inpatient unit design and management is found in Chapter 124.

Role of regulatory agencies

Organ Procurement and Transplantation Network/ United Network of Organ Sharing (OPTN/UNOS)

Until the 1980s, relatively few medical centers performed transplants, and organ allocation was managed locally. With the improvement of transplant outcomes, increased number of existing transplant programs, and as more patients became transplant candidates, the federal government recognized the need for a centralized, national organ distribution system assuring all patients an equal chance to receive donor organs. With the enactment of the 1984 National Organ Transplant Act (NOTA), a national Organ Procurement and Transplantation Network (OPTN) was mandated to build a system for the equitable allocation of donated organs and to increase the supply of available donated organs for transplant that is operated by a private, non-profit organization under federal contract. The United Network of Organ Sharing (UNOS) currently holds the OPTN operational contract. UNOS' mission is to advance organ availability and transplantation by uniting and supporting transplant communities for the benefit of patients through education, technology, and policy development [3]. At the same time, a national Scientific Registry for Transplant Recipients (SRTR) was designed to compile and analyze data on all transplants performed for identification of potential improvements to enhance the lives of transplant patients [4].

The OPTN Final Rule was implemented March 16, 2000 and resulted in a substantially different regulatory environment throughout the US for solid organ transplantation. The Final Rule established a regulatory framework for operation of the OPTN. Several factors impact organ transplantation, of which the most profound is the national shortage of donor organs. As a result of this shortage a need developed to mandate transparency in assessment of transplant programs to enhance the supply, allocation, and management of donor organs. The Organ Procurement Transplant Network (OPTN) is a private, not-for-profit entity with expertise in organ procurement and transplantation whose role is to maintain an equitable system for organ allocation, maintain a wait-list of potential recipients, match potential recipients with organ donors

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

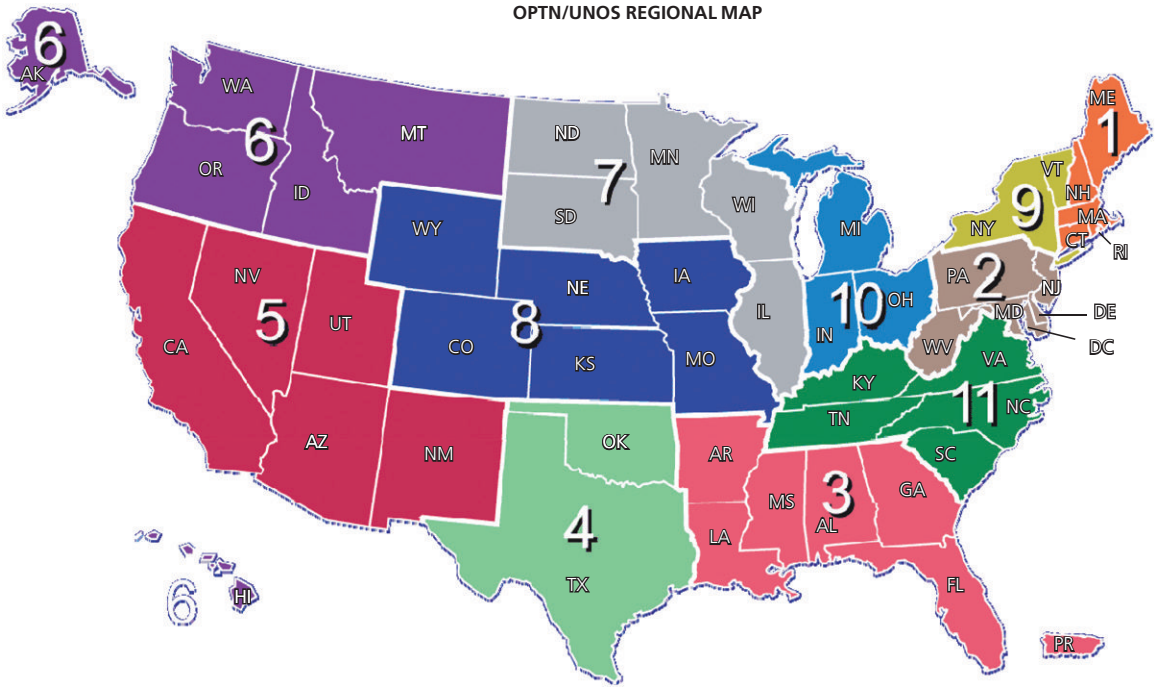

Figure 125.1. UNOS regional service areas map. Reproduced from [6] UNOS Regions Map. http://optn.transplant.hrsa.gov/ (accessed 1 December 2011).

according to established criteria, and list and remove transplant patients. The OPTN also collects, analyzes, and publishes data on pre and post-transplant events to advance the fields of organ transplantation, organ procurement, organ preservation, and immunogenetics. These data is managed through an online database system called UNet. UNet contains data regarding every donation and transplant event since October 1, 1987. The OPTN has established policies and bylaws to administer the bureaucratic aspects of policy development, allocation of donated organs, and collection of transplant data throughout the US. The OPTN is composed of 22 national committees, 23 Regional and National Review Boards, and a board of directors to develop policies. OPTN/UNOS has defined the country into 11 Regional Service Areas; each region is subdivided into Organ Procurement Organization (OPO) Donor Service Areas (DSA) to support fair and equitable allocation of donor organs [5] (Figure 125.1).

The OPTN conducts ongoing and periodic surveys and evaluations of each OPO and transplant hospital for compliance with the OPTN Final Rule and policies. For compliance monitoring, the OPTN uses defined processes and protocols, applications for program membership and key personnel, specific required notification elements, and onsite and desk performance audits, all developed by the OPTN Contractor in accordance with the federal contract. The OPTN makes every effort to bring members into compliance through the development of corrective plans, use of sanctions including prompt corrective action as necessary and confidential peer review through the Membership Professional and Standards Committee (MPSC). This process encourages participation in quality improvement using the following disciplinary sanctions: Letter of warning (confidential peer review), Probation (public notice), and Declaration of "Member Not in Good Standing" (public notice) [7,8].

Centers for Medicare and Medicaid Services (CMS)

Conditions of Participation (CoPs) for organ transplant programs were established in 2007. The Final Rule set forth expectations for safe, high quality transplant services delivered by Medicare-participating facilities. Areas of regulation include compliance with federal, state, and local laws, and laws related to patient care plans, patients' rights, utilization rates, service requirements, and reasonable and necessary national coverage decisions.

In 2004 the Office of the Inspector General (OIG), in what appears to be the initial steps to the current CoPs, recommended that CMS should develop criteria for recipient volumes and survival rates, develop guidelines and procedures to deal with transplant programs that do not meet the volume and survival rates criteria, and oversee improved data collection related to volume and survival of transplant recipients.

Over time, other program quality and service specific issues, as well as complaints, demonstrated that self-reporting of significant changes was not adequate to ensure high quality and safe transplant services. In addition explicate criteria for de-certification had not been identified or established by the OIG. As a result, The Final Rule and subsequently CoPs established requirements for the initial approval and re-approval of Medicare approved hospitals that provide transplantation services for adult and pediatric patient and living donation services.

The Department of Health and Human Services (HHS), with CMS as the responsible federal agency, launched the transplant program approval and re-approval application process in March 2007. The CMS survey certification process assesses a transplant program's initial and ongoing compliance with the CoPs. Transplant hospitals are expected to provide notification to CMS of any significant changes to the transplant program which includes key staff changes, changes in clinical experience and outcomes,

termination of Organ Procurement Organization (OPO) agreement, and/or inactivation of a transplant program. After self-reporting, transplant centers must apply for "consideration of mitigating factors" when they knowingly do not meet one of the CoPs [9].

Other agencies

The HHS Advisory Committee on Organ Transplantation (ACOT) was established as an advisory committee acting through the Health Resources and Services Administration (HRSA) in regards to organ donation, procurement, allocation, and transplantation issues as directed by the Secretary of Health. The mission of this committee is to review significant proposed OPTN policies when submitted to the Secretary for approval on a variety of transplant related topics.

Donation and Transplantation Community of Practice, under the direction of HRSA, established the Organ Donation Breakthrough Collaborative in 2003 with the goal to end transplant waitlist deaths by increasing the number of deceased organ donors, increasing number of organs available per donor, and creating best practice guidelines. These collaborative efforts have continued and broadened to include all aspects of donation and transplantation. In 2007 the HRSA Transplant Center Growth and Management Collaborative Best Practice Final Report was issued. This report presents best practice observations from selected high-performing transplant centers that have achieved high organ transplantation rates and efficiency in recovered organ use, while maintaining expected or higher than expected patient and graft survival outcomes [10].

Design/layout of outpatient transplant clinics

Goals and purpose

Outpatient clinics can range from a simple medical office providing primary care, to highly specialized, complex facilities that are essentially hospitals without inpatient beds. Goals of outpatient transplant clinics are incorporated into each individual center's mission statements, but usually are broad in scope and maintain a shared vision and commitment of optimization of wellness and wellbeing of candidates, recipients, living donors, and their families. The clinics' purposes are to provide evaluations of transplant candidates and living donors, optimize medical management of transplant candidates and recipients, including prescribing, monitoring and adjustment of immunosuppression; diagnosis and management of acute and long term complications of transplant, and living donor follow-up. To ensure optimal patient care and continuity of care, transplant teams need to have a collaborative approach.

Operations

Transplant clinic operations and designs can vary. Most are based on the needs, volumes, and patient population of the transplant center in which they exist. All exist as part of the larger medical center of which they are affiliated, with the commonality of integrating continuity of patient care from inpatient to outpatient setting, therefore becoming the patient's primary center of transplant-related care delivery.

To meet expanding patient needs and enhance access to transplant related services, off-site satellite clinics are also being utilized to facilitate patient care. Satellite clinics have emerged as part of integrated healthcare systems that accommodate large academic centers, community centers, and rural centers for ease of patient care delivery. This is an opportunity to utilize diagnostic and surgicenters off-site but still within the larger healthcare system for pre and post-transplant follow-up care. These clinics reduce the travel and financial burden for patients and may ultimately enhance their adherence to the prescribed transplant plan of care. Satellite clinics may also help increase referral bases for transplant centers and ultimately expand the program. These clinics are staffed with designated personnel in laboratories, radiology, and procedure areas; however, the multidisciplinary teams have the ability to travel within the system to see transplant patients at these facilities as well as the transplant center [11].

Governance and regulation of outpatient transplant clinics can either fall under hospital-based clinic management or ambulatory care clinic management. Operational regulations and reimbursement schedules vary according to type of clinical management and state accreditation structures. Briefly, hospital-based clinics function as Physicians' offices providing services specific to the population of patients served; however, they operate under the hospital's licensure and are accountable to the same federal and regulatory bodies as the hospital, that is, The Joint Commission on the Accreditation of Healthcare Organizations (JCAHO). Attention must be paid as to how the various types of clinics are surveyed by local, state, and federal regulatory agencies and national accreditation bodies relative to their respective requirements.

Design

Specific to transplant clinic operations, a dedicated transplant structured clinic is optimal. The concept behind a transplant structured clinic is the ability of specially trained transplant personnel to provide comprehensive transplant-specific services within a space designed solely for the care of transplant candidates, recipients, and living donors. The function of this type of clinic ranges from the coordination of an extensive candidate or living donor evaluation to long term follow-up of transplant recipients and living donors.

Hospital and transplant administration, along with physician leaders, provide the building blocks to any clinic development, design, and management. Structural logistics and limitations must be considered in the physical design of clinic space. Varying size and types of services offered are common attributes of all outpatient transplant clinics. Transplant patients are coming to the medical center for complex services and by nature this patient population may be accompanied by multiple family members plus medical equipment such as oxygen tanks, walkers, or wheelchairs. In order to enhance the functionality of the work environment, the clinic design team should ideally include administration, medical architecture personnel, and transplant team personnel who are providing services within the given space. Patient and family input must be soliaccessed as well. General themes to be considered in structuring an outpatient clinic include:

- ability to offer services in a cost efficient manner
- flexibility and expandability to meet the current and future needs of the program
- environmental quality and safety
- visibility and accessibility to include American's with Disabilities Act regulations
- therapeutic, nonthreatening environment for patients
- sustainability
- Health Insurance Portability and Accountability Act of Privacy and Security (HIPAA) compliance [12].

Ideally, facilities management would adequately support the needs of the transplant program without operational limitations.

Clinically, an adequate number of clinic rooms for consultation and evaluations would be available in addition to dedicated workspace for the medical team to review records and complete documentation. The number of clinic rooms required is dependent on the size of the program and annual clinic volumes. Dedicated transplant specialty laboratories, staffed with personnel who are familiar with the extensive transplant-specific blood tests ordered, should also be available within or near the clinic space. Amenities such as: registration areas for patient check in and discharge; private consultation rooms; patient education facilities for individual or group teaching; a patient library; and spacious waiting rooms, all need to be considered in the physical design and layout of the transplant clinic. Despite physical limitations of any clinic design, the primary efforts of the transplant team should be on excellent customer service delivery with the long-term goal of measurable, sustained quality patient outcomes.

Clinic scheduling models

Models

There are various types of clinic scheduling models available that can be the basis for the transplant clinic to develop as their standard. No matter which model is incorporated as the foundation for the clinic structure, the ability to offer any needed transplant service in a patient and family centered approach with sustained quality outcomes is the common goal of all transplant programs. Basically there are two types of patient service delivery models — physician driven or clinic/service line driven approaches. Traditional physician driven clinics are scheduled per provider with designated clinic times. In a clinic/service line driven clinic model, patients are generally scheduled with common arrival times according to organ type, and transplant status (pre/wait-list/post/living donor), without a direct provider specified.

Regardless of which clinic model is adopted, clinic staffing patterns can vary greatly. One staffing pattern is to have fully dedicated clinic staff. This type of staffing would include support staff, phlebotomists, medical assistants, and transplant clinic nurses functioning under the direction of a dedicated clinic nurse manager and office manager with the sole purpose of treating patients presenting to clinic. An alternative staffing pattern is one in which the clinic space is staffed by service lines, including the transplant coordinators and support staff. Regardless of the staffing pattern selected, efficient quality patient care must be maintained as well as regulatory compliance and ongoing patient satisfaction monitoring.

Types of clinic visits: Pretransplant and post-transplant

Pretransplant clinic visits

Typically, the first encounter the potential candidate or living donor will have with the transplant center is at the time of evaluation for transplantation or donation. The goal of a transplant candidate evaluation is to determine the medical need for organ transplantation for patients in end-stage organ failure when traditional medical options have been exhausted. Potential transplant candidates will be referred to the transplant center at various stages of end-stage organ failure. Prior to the actual transplant evaluation, medical records are reviewed by members of the multidisciplinary team to determine the appropriate level of evaluation to be scheduled. Once the patient is medically approved and financial authorization is in place, a formal transplant evaluation is scheduled. During the course of the initial transplant evaluation, the cause of end-stage disease, and the indications and contraindications for transplant will be determined. Further work-up and management of co-existing medical conditions may be required in order to complete the evaluation. A dedicated transplant clinic affords the ability to coordinate a comprehensive testing schedule. Typically, each candidate's evaluation will be tailored to their medical needs, as well as program and organ specific directives. A dedicated transplant clinic and personnel provides a venue for the comprehensive multidisciplinary assessment of potential transplant candidates. Members of the clinical transplant team must partner with the referring physician to keep him/her abreast of the patient's progress throughout the evaluation. This begins at the point of referral and becomes the foundation of life-long mutual patient care team collaborations (Figure 125.2).

From the patient's perspective, the clinic appointment starts before the actual visit. A welcome packet of information is sent to the patient outlining the upcoming visit. This packet typically includes driving directions, information on local housing, medical center directions, patient evaluation schedule, specific test preparation instructions if any, organ-specific education materials, regulatory documents (e.g. UNOS materials, Informed Consent), and other center specific items. A confirmation of the candidate's upcoming evaluation should be communicated to the referring physician also. Items for schedulers to be mindful of include obtaining alternative telephone numbers for patients and lodging location during the evaluation for those patients who are traveling. Schedulers should also confirm appointments 24–48 hours in advance. Due to the complexity of transplant candidates' medical conditions, frequent hospitalizations are not uncommon but contribute to a higher rate of "no-shows" or missed appointments. This also contributes to lengthened time between referral and transplantation, which ultimately may affect overall patient outcomes.

From a transplant team perspective, the number of clinic appointments scheduled on any given day is dictated by the number of clinic rooms available, provider availability, and length of given appointment type. Coordination of testing and consultations among ancillary departments is crucial to the flow and success of the visit.

Prior to the patient's arrival, accessibility of parking and navigation through the system must be facilitated. Amenities such as a designated patient drop-off area or valet parking with handicapped accessibility provide a caring first impression to an anxious, overwhelmed population. Wheelchairs and/or scooters should be readily available for patients use upon arrival, in addition to hospital concierge and transport specialists. Hospital signage must be up to date and easy to follow.

Upon arrival at the transplant clinic, check-in and registration will take place. Due to the extent of the transplant evaluation, it is expected that these patients will be in the clinic for a prolonged period, perhaps over several days. The actual length of the evaluation is variable and dependent upon each transplant center's organ-specific selection criteria requirements and the patient's overall health status. The clinic team will guide the patient through the evaluation process. This would encompass services such as phlebotomy, medical assessment, medication reconciliation, consultations, patient education, and additional testing specific to the transplant candidate's medical status and history. The staff member who completes the outlined tasks may vary per facility: medical assistants (MA), registered nurses (RN), transplant coordinators (TC), advanced practice nurses (APN), physician assistants (PA),

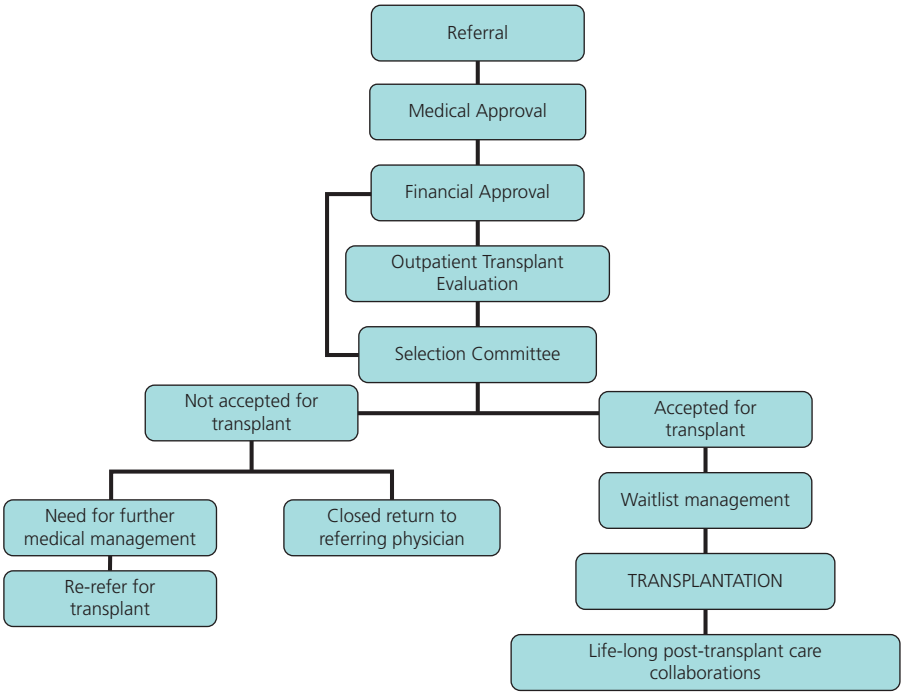

Figure 125.2. Transplant process chart.

or transplant physicians. At the end of each visit, reinforcement of the upcoming prescheduled evaluation should be reviewed with the patient and family.

Any additional needs are also addressed upon checkout prior to the patient's departure from the clinic. Ideally at the end of the evaluation a "wrap up" visit after all consultations and testing have been completed should be conducted. Preliminary test results and patient concerns and questions should be addressed at this time. Once a patient has completed the evaluation and has been waitlisted, return visits to clinic will be determined by listing status and individual needs.

The transplant evaluation process must adhere to both UNOS and CMS regulations. The CMS CoPs identify the transplant professionals who are required to participate in candidate and living donor evaluations. Included in the multidisciplinary team are: medicine (transplant surgeon and transplant physician), nursing, social service, clinical transplant coordinator, nutrition, and pharmacology. Specific to evaluation of living donors is the Independent Living Donor Advocate evaluation. Additional members of the multidisciplinary transplant team potentially include: administrative support staff, schedulers, medical records staff, UNOS data coordinators, transplant financial coordinators, and research staff. Each of these identified team members possess a unique skill set and expertise required to comprehensively provide life-long care to transplant patients across the transplant continuum. CMS regulations require that institutions develop individual policies that specify the multidisciplinary evaluation team members, as well as their qualifications, credentials, and roles within their transplant center [13].

Medicine (transplant surgeon or physician)

Transplant physicians and surgeons are responsible for directly overseeing transplant surgical and medical services. A designated surgeon must be available immediately when an organ is offered for transplantation. The primary physicians and surgeons must be approved by the OPTN [13].

Nursing

Nurses provide care to transplant patients at all points along the transplant continuum. From referring physician offices, to outpatient transplant clinics, intra-operatively, intensive care units, general nursing units, rehabilitation units, long term care facilities, skilled nursing facilities, home care nurses, research teams, nursing educators, and nursing administrators are all various types of nurses involved in the care of transplant patients. Levels of nursing education range from licensed practical/vocational (LPN/LVN), registered (RN), or advanced practice nurses (APN). Specialty certification in transplantation is available to transplant nurses with one year of transplant specific nursing experience [13,14].

Social services

Social services are an inherently important part of the transplant team, providing continuity of care to the patient throughout the entire process. Their focus is to convey to the patient that they are not experiencing the transplant process alone, but as members of the team. Transplant social workers provide support, education and counseling to help reduce the stress of undergoing a transplant. Performing evaluation assessments is mandated by CMS CoPs with the goal to ensure that the patient and team have all information necessary to achieve a potentially successful outcome for both the patient and the program. Topics addressed in a social services evaluation include:

- risk and benefits of transplantation acknowledged
- adherence assessment
- mental health history, including substance and alcohol use/abuse
- assessment of available coping abilities
- assessment of financial capabilities, resources

- assessment of adequate social, transportation, lodging support [13].

Clinical transplant coordinator

Transplant coordinators (TCs) must be registered nurses or clinicians licensed in the state of practice that possess knowledge and experience in transplantation issues. TCs ensure continuity of care and coordinate the clinical care of candidates/recipients/donors throughout all phases of transplantation/donation and also act as a liaison with all members of the multidisciplinary team involved in the patient's care [14,15]. Transplant coordination has evolved into a critical component of essentially all transplant teams and is covered in depth in Chapter 122.

Nutrition

Nutritional assessments and diet counseling must be available at the transplant center by qualified dietitians for all transplant patients, candidates and living donors, in the evaluation phase. Education is provided to the patient specific to their individual needs. Medical nutritional therapy is provided when indicated. Nutritional services are also available to recipients and donors post-operatively to discuss nutritional concerns and issues (i.e weight gain, weight loss, electrolyte imbalances, dietary restrictions due to medications). Individual transplant center's policies must outline the utilization of nutritional services including nutritional assessment, diet counseling, or nutritional interventions [15].

Pharmacology

Transplant pharmacists help to manage the everyday care of the transplant patient. They assess and suggest plans of care based upon the individual not just specific to the transplanted organ. They provide valuable insight into immunosuppression management and rejection therapies. Throughout the transplant continuum, transplant pharmacists monitor medications prescribed specifically looking for interactions and therapeutic drug levels. Consideration must be given to over the counter medications and supplements the patient may use as well. Transplant pharmacists are often members of transplant research teams [15,16]. The role of the transplant pharmacists is discussed in detail in Chapter 123.

Living donor advocate

Transplant centers that perform living donor transplants must identify an independent living donor advocate to ensure protection of prospective living donor's rights. This individual should function independently from the transplant team [15].

UNOS data coordinators

Some large, multi-program transplant centers have UNOS data coordinators on the multidisciplinary team. UNOS data coordinators are individuals that manage UNOS/UNet related data entry. Completion of Transplant Candidate Registration (TCR), Transplant Recipient Registration (TRR), Transplant Recipient Follow-up Forms (TRF), activations, in-activations, listing status recertifications, and removals are examples of tasks UNOS data coordinators perform. These coordinators are also important members of quality improvement (QAPI) committees and are participants in quality control auditing.

Transplant financial coordinators

One of the first members of the transplant team a new patient meets is the Transplant Financial Coordinator (TFC). This person functions as a counselor to the patient as well as an insurance liaison/coordinator for the provider. After an in-depth review and verification of insurance benefits, a consultation appointment is scheduled with the patient during the evaluation to review all eligible insurance coverage benefits and limitations. The TFC explains what the financial impact for the high cost transplant related services could potentially be, and guidance is given to those who need additional assistance due to coverage and benefit limitations. The TFC also acts as a liaison for the medical and administrative departments, alerting the team to limits or restrictions of coverage and when authorizations for services are required [17].

Post-transplant clinic visits

Post-transplant visits tend to be shorter, but equally important in promoting successful long-term patient outcomes. The goals of this type of visit include optimal management of immunosuppression, monitoring and diagnosis of both acute and chronic complications associated with transplantation, as well as overall health promotion. These visits may or may not include lab draws, but would include patient assessment, medication reconciliation, consultation, education, and transplant specific testing as needed. Of note, one can expect the initial post-transplant visit to be more in-depth and longer due to the level of re-education involved for the patient and the family by both the nurse and the physician.

Transplant clinics alone are not able to provide all services transplant patients require. Coordination of services must be available within the medical center system. Integration of care with other members of the multidisciplinary transplant team including but not limited to pathology, radiology, infectious disease, nephrology, hepatology, cardiology, pulmonary, anesthesia, endocrine, pharmacology, psychiatry, and palliative care is essential to the long term care of the transplant recipient. Standing protocols or pathways may be developed by the transplant team, in conjunction with the identified specialties, to facilitate implementation of patient care.

A dedicated transplant outpatient procedure unit is also critical to the care of this complex patient population. This type of unit provides an intermediate level of organ specific pre and post-transplant services and treatments, and other invasive procedures unique to the transplant population requiring more intensive medical management than the outpatient clinic can provide. Included would be delivery of interventions and treatments that do not require hospitalization but do require patient oversight to assure patient safety. Typical nurse to patient staffing ratios are one nurse to three or four transplant patients. Services that an outpatient procedure unit can offer include daily monitoring post hospital discharge, phlebotomy, biopsies, blood product administration, medication administration, invasive radiology testing, and plasmapheresis. Associated cost-saving benefits of this type of service include promotion of early discharges, prevention of readmissions, and delivery of an intermediate level of care that cannot be provided in the home.

At some point in time, the care of transplant recipients may be transitioned to a healthcare provider outside the transplant team for long-term healthcare services such as a primary care physicians (PCPs) or other non-transplant related specialists. Coordination of care between the transplant team and other members of the multidisciplinary team must be built on open communication and collaboration to deliver the appropriate services to this complex patient population. Long-term transplant follow-up must be coordinated through the transplant office to ensure compliance with regulatory reporting requirements.

Staffing

CMS CoPs have stipulated which multidisciplinary team members must participate in a transplant patient's care. The CoPs clearly state that each patient must be under the care of a multidisciplinary team. This team is to be coordinated by a transplant physician who must be involved in all aspects of patient care throughout transplant and discharge phases, including evaluation and routine follow-up care [13]. However, how individual transplant centers integrate these roles varies greatly among programs. Center- specific policies regarding the multidisciplinary team must address the composition of the team members, roles, qualifications, and supporting documentation. The complex, chronic nature of the transplant candidate, recipient, or living donor coupled with the need for specialized medical management further compounds the staffing dilemma. Additional limiting factors include the number of examination rooms available, number of providers and levels of support staff available, and annual volumes of the clinic population served.

Two models of general staffing practice in existence include the "Medical Model" and the "Nursing Model." In the "Medical Model" the traditional provider (physician, PA), medical assistants (MA), and support staff run the clinic. This type of provider-run clinic has lower operating costs but consequently offers a limited scope of services. In the "Nursing Model" led clinic, this environment increases utilization of nurses with the provider (physician, PA) in addition to the MAs and support staff. This type of nurse led clinic supports the acuity of a specialty care outpatient environment by enhancing the scope of available patient services and education, and enhancing quality patient outcomes [18].

In response to staffing dilemmas, in 2003 UNOS developed the Transplant Administrators Staffing Survey through UNet to help determine optimal staffing levels given the size and characteristics of the transplant program. This survey identifies roles of members of the multidisciplinary transplant team. The Transplant Administrators Committee Staffing Survey examines the size and scope of each transplant program. It also identifies the type of personnel working at the center, as well as how many perform in each role. An interactive report permits a transplant center to compare staffing levels to other transplant centers of similar size on a confidential basis. Again, this tool is to be used as a staffing guide as there currently are no measurable, agreed upon metrics for transplant clinic staffing. Data reported on this survey is only available to transplant centers that have participated in the survey [19].

Competencies

Transplant professionals provide highly specialized care to candidates, recipients, families, and living donors. As technological, surgical, and pharmacological advances continue, transplant professionals must continually update their knowledge base and demonstrate expertise in their field to care for an increasingly complex patient population. All healthcare providers are held to some level of competence. "Competencies" is an all-inclusive term used to capture broad elements of performance. Competencies include assessment of behaviors, skills, technical knowledge, and proficiencies at a healthcare system, department specific, and regulatory level. Annual healthcare system competency training can be facilitated electronically for global competencies to ease completion and assure consistency in the delivery and completion of organizational core competencies. Departmental specific competencies and regulatory competencies are conducted in addition and individualized to the discipline and the healthcare provider delivering the care. Transplant coordinators would be expected to participate in clinical competencies unique to the patient population they are providing care for, as well as regulatory specific transplant related competencies. UNOS data coordinators or other support staff would be expected to participate in competencies associated with clerical and administrative tasks. This could include UNet and regulatory specific transplant related tasks.

In 2009 The International Transplant Nurses Society (ITNS) in collaboration with the American Nurses Association (ANA) developed the *Transplant Nursing Scope and Standards of Practice*. The function of these standards of practice and professional performance provide specific measurable elements that can be used by nursing professionals to measure professional performance [20]. Transplant centers can refer to this document when establishing transplant specific annual competency assessments within their department.

Electronic medical record

Over the past 20 years there has been a growing impetus for electronic medical records (EMRs). With stricter federal government oversight and the ongoing healthcare reform, most centers are seeing integration of EMRs into practice. EMRs are longitudinal electronic records of patient health information generated by one or more encounters in any care delivery setting. EMRs provide immediate access by authorized providers to patient records that enhances quality, safety, and efficiency of patient care [21].

Key capabilities of EMR according to the American Health Information Management Association (AHIMA) are the ability to capture data at point of care in real time, integrate data from multiple internal and external sources, and to support clinical decision making. Core components/capabilities of any EMR include health information and data storage, efficient results management, order entry management, clinical decision support, communication and connectivity enhancing continuity of care among all providers, patient support and access to their protected health records, and direct interface with regulatory reporting [22].

There are many commercial EMRs available to healthcare systems. EMRs have the ability to generate a complete patient record, as well as supporting other care related activities directly or indirectly via interface. This would include such activities as evidence-based decision support, quality management, and outcomes reporting. Providers need to choose the system that best fits the program's needs. Transplant specific applications are available as well to support daily operations, research data collection, and regulatory reporting integration.

Patient education/informed consent

Education of transplant patients has been recognized as a contributing factor in the success of transplantation. Comprehensive patient and family education begins at the time of transplant referral and is ongoing. Transplantation is overwhelming and requires an open and trusting relationship between the patient and transplant team to ensure success. Transplantation involves major lifestyle changes and the transplant center becomes the primary source of education for patients and their families. All members of the multidisciplinary team are involved in the education process, which

begins as soon as a patient is informed of the need for a transplant. Ongoing education throughout the transplant process is necessary to enable patients and their families to make informed decisions about their care and successfully manage their health.

Informed consent

The CMS CoPs provide the foundation for all transplant education programs. The CoPs clearly outline patient and living donor rights, including the process for obtaining Informed Consent and documentation of patient education. Topics to be included in the Informed Consent include the evaluation process, surgical procedure, alternative treatments, medical or psychosocial risks, outcome results, donor risk factors, right of refusal, and limitations of not having transplant performed at a Medicare approved transplant center. During the evaluation phase laboratory and diagnostic tests results, selection criteria, psychosocial issues identified that may impact transplantation, financial concerns, and necessity of strict adherence to a medical regime post-transplant are discussed in detail. The surgical procedure discussions must occur on multiple occasions prior to the transplant. Detailed discussions of the surgical procedure, anesthesia risks, risks associated with use of blood products, post-transplant recovery, and associated risks and benefits of the surgery must be discussed and any limitations imposed by the patient must be documented in the EMR. Options for alternative treatments will vary per organ type and patient's overall medical condition and must be presented to potential candidates prior to listing. Medical risks discussions need to include postoperative complications specific to wound infections, pneumonia, blood clots, rejection, need for retransplant, need for lifelong immunosuppression, multi-organ failure, and death. Psychosocial risk discussions need to include topics related to depression, post-traumatic stress disorder (PTSD), and anxiety. CMS CoPs require national and transplant center-specific outcomes from most recent SRTR reports be made available to all potential candidates. This is to include the transplant center's observed and expected one-year patient and graft survival, national one-year patient and graft survival, and notification of all Medicare outcome requirements not being met by the transplant center. Updated outcome reporting must be made available to all candidates in the evaluation and wait-list phases every six months upon release. Discussions of organ donor risk factors that could affect the success of graft function need to include medical/social history, age, condition of the organ, risk of HIV, hepatitis B virus, hepatitis C virus, or cancer. Candidates need to be informed of their right to refuse transplant at any time during the process [23].

Informed consent for living donation must include all of the above and also specifically address the possibility that future health problems related to the donation may not be covered by the donor's health insurance, the possibility that the donor's ability to obtain health, disability, or life insurance may be permanently affected, and discussion outlining the donor's right to opt out of donation at any time during the donation process [23].

During a CMS survey, auditors will ask to see copies of all educational materials provided to patients by the transplant center as part of the outlined Informed Consent process, as well as supporting documentation in the patient's medical record that educational materials were provided to the patient and family. Transplant centers must develop organ-specific informed consents and policies pertaining to who is responsible for discussing the Informed Consent process with the patient, who is responsible for obtaining informed consent, and methods and documentation of patient education per CMS guidelines [23] (Figure 125.3)

Multiple listing

During the initial evaluation potential transplant candidates must be informed of the options for "multiple listing". According to current OPTN/UNOS policy 3.2 Organ Distribution: UNOS Patient Waiting List for 2011, patients may be listed as transplant candidates at multiple centers. Multiple listing is a way of increasing chances of receiving an organ offer. Patients must be made aware of this option as well as some of the associated responsibilities and costs. Transplant center documentation that the patient has been notified of multiple-center listing option is required per OPTN policy and subject to audit [24].

Ongoing education

As stated, education of a transplant patient is a continuous process and must occur on many levels. For most patients and families, transplantation is a highly stressful and life-changing process. Patient and family education focuses on the maintenance of optimal health while undergoing transplant evaluation and waiting for an organ, as well as maintenance of a healthy organ post-transplant. Each encounter with a patient should be viewed as a teaching opportunity. Clear, concise, consistent education at every patient encounter ensures understanding of current treatment plan of care and the patient's responsibilities. All patients learn differently. Stress and emotional status, physical status, learning styles, willingness/readiness to learn, in addition to any identified barriers to learning, all must be incorporated into individualized education plans. Because all learners learn differently, a multisensory approach should be taken. Written materials should be provided at a reading level and in layman's terms so that those with a basic education will comprehend them. Among educators this is agreed upon to be a sixth grade educational level. Materials also need to be available in foreign languages or interpreters must be available to translate. Visual aids such as pictures and posters to reinforce the written materials should be incorporated into teaching plans. Computer based educational tools should be provided for group or individual viewing. Structured group education sessions can be built into candidate evaluations and postoperatively prior to discharge from the hospital. Individual education reinforcement occurs during clinic visits and during any form of communication with the patient. Accessibility to the transplant center via phone must be offered 24 hours a day, seven days a week. This service must be offered to answer patient questions regarding treatment plan and associated complications.

Education of the transplant candidate initiates the life-long transplant learning process. The content presented to candidates varies based on transplanted organ involved and among transplant centers. Patients must learn to manage their health by adhering to treatment plans, following dietary guidelines, taking their medication correctly, and knowing when to call the center for help. These can be major lifestyle changes for patients, and they look to the transplant center as a primary source of education. It is important to begin patient education at the point of referral. This includes organ specific education on the process of transplantation and life after transplant. Key information must be reviewed as necessary to promote patient and family retention. Providing clear, consistent, and continuous education during every patient interaction ensures

patients and their families understand their roles and responsibilities [25] (Table 125.1).

Outcome measures reporting

The field of transplantation, including living donation, is highly regulated by OPTN/UNOS, HRSA and CMS. CMS CoPs clearly identify outcome reporting requirements. Transplant outcome measurements include reporting across the full transplant continuum, beginning at activation on the transplant list through graft failure or patient death.

OPTN/UNOS data submissions from the transplant centers directly create the SRTR program specific reports. Program specific reports are available for the entire transplant community including patients and families, payers, transplant centers, and the federal government. These program specific reports include many features of the transplant program such as:

- wait-list activity — additions and reasons for removal
- characteristics of wait-listed patients
- transplant and mortality rates for wait-listed patients
- waiting times
- number of transplants performed
- characteristics of recipients, donors and transplant procedures
- graft and patient survival rates compared with expected rates reported at one month, one year, and three year outcomes for a 2.5 year cohort of patients.

These reports are published every six months in January and July with revised data about each transplant program in the US. The outcomes are adjusted to reflect the specific center's donors, recipients, and practices. Risk adjustment permits individual centers to compare their reported outcomes to the national outcomes for similar patient among transplant programs across the country. Adjusting for recipient and donor characteristics ensure that transplant centers are not penalized for accepting hard to treat patients and aggressively using expanded donors. Transplant centers need to aggressively and proactively learn to manage their data for accuracy, identify the risks for failure, and develop best practices for quality outcomes. Accurate and on-time submissions of "transplant candidate registrations", "transplant recipient registrations", and "transplant recipient follow-up" forms is essential for individual programs to independently monitor their outcomes as well as demonstrate compliance with regulatory reporting submission requirements [28]. All of the data is important to monitor the success of programs and development of best practices, however; the three year graft and patient survival data is most reflective of the ongoing outpatient management.

Patient satisfaction measures

A fairly new approach to measuring the level of quality care provided to patients is to request feedback from the patient themselves regarding their experience [29]. Developing strong patient relationships with high levels of satisfaction is a challenging, but realistic goal. A culture of mutual patient and provider trust, commitment and understanding of individual patient's needs promote quality patient care. Administration needs to address the following when discussing patient satisfaction; what is the utility in measuring patient satisfaction; how is it best measured for a specific patient population; and what to ultimately do with the results? Clinicians, medical centers, and payers all have a vested interest in measuring patient satisfaction for practical, professional, and ethical reasons. Measuring patient satisfaction is not clear cut, but rather a qualitative measure of a patient's perception of their healthcare experience.

There are numerous fee-for-service organizations available to monitor patient satisfaction. One of the most popular is Press Ganey Associates, Inc. Press Ganey Associates, Inc. has been in the business of helping providers improve the delivery of healthcare for more than 25 years. Press Ganey Associates' Inc. philosophy is that patients have a valuable perspective to offer regarding the quality of care they received and work to ensure that patients were heard by healthcare organizations looking at ways to evaluate and improve quality of care. With the use of specialized tools, services, consulting, and data analysis, Press Ganey Associates, Inc. provides information to healthcare providers on how well they are performing and ways to improve their performance [30].

In 2010 Press Ganey Associates, Inc. in conjunction with UNOS Transplant Administrators Committee (TAC) developed a specialized inpatient and outpatient transplant survey. Items specific to the outpatient transplant survey include generalized background questions addressing phase of transplantation, organ transplanted, and waiting time in clinic. Non-transplant specific issues associated with registration and the transplant facility are addressed. Transplant specific care and education items addressed include medications, diet, wound care, blood work, when to call the transplant

team, how to contact the transplant team, associated costs, and patient ratings of the multidisciplinary team members. Transplant centers can use these results to develop performance improvement initiatives directed at enhancing patient satisfaction [31] (Figure 125.4).

Financial considerations for transplant

Transplant is considered an elective life-saving procedure, sometimes the only treatment remaining to patients with end-stage organ disease. Transplant institutions need to maintain fiscal strength in a competitive market. Monitoring of the program's financial strength, reimbursements, performance, outcomes, and volumes assist in negotiating contracts and maintaining overall fiscal strength of the transplant center. Transplant centers need to competitively offer services efficiently and effectively to remain profitable. Due to the complexities and chronic nature of transplantation, the associated costs for services can be astronomical and life-long. Financial limitations can be imposed on the patient's level of benefits and coverage for transplant services. Prior to initiating any transplant service a thorough evaluation of the patient's benefits must be determined by specialized transplant financial coordinators.

There are four basic types of coverage for most patients: Medicaid/Medical Assistance (MA), Medicare (MC), commercial payers, and private/self-pay. CMS includes MA/MC plans and is the largest single payer in the US. Most commercial payers follow CMS regulations regarding reimbursement. Transplant centers must develop policies clearly outlining acceptable levels of coverage and reimbursement for transplant related services. The following is a brief overview of the common insurances seen in transplantation. There are patient assistance foundations for pharmacological assistance, as well as foundations that assist patients with fundraising and charitable care options.

Medicaid fee-for-service

Most states require the MA recipients to receive medical care within their home state when available. All providers of care, including the hospital and each individual physician who treats a patient, must be assigned (enrolled) with the state in order to be reimbursed. State funds are limited; this impacts the amount available to pay for transplant associated medical care costs. Depending on the MA reimbursement schedule, providers may experience a net loss in revenue. Transplant financial coordinators must be diligent when reviewing what transplant services are and are not covered by the state as well as the packaged coverage a patient may have. The MA fee-for-service programs are strictly regulated and not open for the negotiation of additional benefits.

Managed medicaid organizations

Managed Medicaid Organizations (MMO) products are similar to MA products. MMO's may not require providers to be enrolled with the state for reimbursement but the recipients are managed by primary care physicians (PCPs) who must coordinate all care. This creates the challenge of obtaining authorizations for referrals and post-transplant services not ordered by the PCP. If a patient is referred out of network and/or out of state, the transplant provider may negotiate an acceptable reimbursement rate for services with the MMO.

Traditional medicare

Traditional Medicare (MC) can be considered universal as there are no assigned networks or states and reimbursement rates are geographically determined. Almost all providers are enrolled with MC and no referrals are required. Patients may be MC eligible through age, disability, or end-stage renal disease (ESRD). However, an individual must be qualified to receive MC benefits. Qualification is based on work history; therefore, the TFC must review this with the individual.

Medicare components

There are four components to MC: Parts A, B, C, and D. Individuals who qualify for MA are automatically enrolled in MC Part A at no cost. MC Part A covers inpatient hospital care; however, a deductible and co-insurance applies as determined by the length of stay. An individual must elect and pay a monthly premium for MC Part B, which covers 80% of the outpatient hospital and professional charges. In addition to MC Parts A/B, the individual should be counseled to purchase MC Part D, which covers prescription medications. A co-payment applies to most prescriptions.

As noted above MC does not offer full coverage, exposing individuals to potential financial hardships. MC recipients should be advised to purchase a "medicare supplement". And it is just that, it supplements the MC payment to the extent an individual would be considered fully covered eliminating the liability of the deductibles and co-insurances.

Managed medicare/medicare advantage

Many companies offer a Managed Medicare/Medicare Advantage (MC Part C) product in the form of health maintenance organizations (HMOs) or preferred provider organizations (PPOs) but individuals must be enrolled in both MC Part A and MC Part B. The disadvantage to MC Part C is that there are assigned networks and an individual cannot choose where to seek care. Much like MMO's, referrals are needed. In some cases the MC C company will work with the providers to negotiate an agreeable reimbursement which also includes waiving the member's higher out of pocket liability [33].

Commercial insurance

Individuals can obtain commercial insurance either through an employer group or through individual purchase. In either case not all plans are the same, even if the coverage is through the same company. When individual insurance is purchased, the amount of member deductible and/or co-insurance responsibility is determined by the amount of premium paid. A higher premium means a lower out-of-pocket member responsibility; likewise a lower premium means a higher out-of-pocket member responsibility. Coverage through an employer group in most cases offers the best coverage.

Whether the insurance is obtained on an individual or group basis, patients must be aware of the differences in coverage and must be very careful and understand the level of coverage they select. When considering commercial insurance, there are choices of indemnity plans, preferred provider organization (PPO) plans, and a health maintenance organization (HMO) plans. An insurance company can offer any or all of these plans, so again it cannot be assumed that the coverage is the same for all members of the same company. Indemnity plans are the least restrictive plans offered commercially. PPO plans have both in-network and out-of-network benefits. If the member uses an in-network provider the amount of financial liability incurred would be less.

In some cases an insurance company and provider may consider an agreement on behalf of an individual often called a Single Case

CLIENT LOGO

OUTPATIENT SERVICES TRANSPLANT SURVEY

We thank you in advance for completing this questionnaire. When you have finished, please mail it in the enclosed envelope.

BACKGROUND QUESTIONS

1. Have you had your transplant surgery yet?..... ○ Yes ○ No
2. How many **minutes** did you wait after your scheduled appointment time before you were called to the test or treatment area? ..... ☐☐☐ minutes
3. How many **minutes** did you wait in the test or treatment area before your test or treatment began?..... ☐☐☐ minutes
4. On what day was your most recent visit?
   ○ Monday ○ Thursday ○ Saturday
   ○ Tuesday ○ Friday ○ Sunday
   ○ Wednesday
5. At what time of day was your most recent visit?
   ○ 6:00 am - 8:00 am ○ 2:01 pm - 4:00 pm
   ○ 8:01 am - 10:00 am ○ 4:01 pm - 6:00 pm
   ○ 10:01 am - Noon ○ 6:01 pm - 8:00 pm
   ○ 12:01 pm - 2:00 pm ○ 8:01 pm - 10:00 pm

INSTRUCTIONS: Please rate the outpatient transplant service you received from our facility. Select the response that best describes your experience. If a question does not apply to you, please skip to the next question. Space is provided for you to comment on good or bad things that may have happened to you.

Please use black or blue ink to fill in the circle completely. Example: ●

REGISTRATION

	very poor 1	poor 2	fair 3	good 4	very good 5
1. Helpfulness of the person at the registration desk	○	○	○	○	○
2. Ease of the registration process	○	○	○	○	○
3. Waiting time in registration	○	○	○	○	○
4. If you spoke with the Transplant Center by phone, helpfulness of the person you spoke with	○	○	○	○	○
5. Degree to which you were informed about delays	○	○	○	○	○

Comments (describe good or bad experience): _____

FACILITY

	very poor 1	poor 2	fair 3	good 4	very good 5
1. Comfort of the waiting area	○	○	○	○	○
2. Ease of finding your way around	○	○	○	○	○
3. Cleanliness of the facility	○	○	○	○	○

Comments (describe good or bad experience): _____

YOUR TEST OR TREATMENT

	very poor 1	poor 2	fair 3	good 4	very good 5
1. Friendliness/courtesy of the staff who provided your test or treatment	○	○	○	○	○
2. Explanations from the staff about what would happen during your test or treatment	○	○	○	○	○
3. How well the risks of your tests or treatments were explained to you	○	○	○	○	○
4. How well your options for alternative treatments were explained to you	○	○	○	○	○
5. How well your right to refuse tests or treatments was explained to you	○	○	○	○	○
6. Your perception of the skill of the staff who provided your test or treatment	○	○	○	○	○
7. Staff's concern for your comfort	○	○	○	○	○
8. Staff's concern for your questions and worries	○	○	○	○	○

Comments (describe good or bad experience): _____

TRANSPLANT CARE & EDUCATION

	very poor 1	poor 2	fair 3	good 4	very good 5
ANSWER ONLY IF THE QUESTION APPLIES TO YOU.					
1. How well the education you received about the following prepared you to feel more comfortable caring for yourself at home:					
a. Medications	O	O	O	O	O
b. Diet	O	O	O	O	O
c. Incision care	O	O	O	O	O
d. Blood work	O	O	O	O	O
e. When to contact the transplant team	O	O	O	O	O
f. How to contact the transplant team	O	O	O	O	O
g. Costs associated with your Transplant care (e.g. housing, transportation, medication)	O	O	O	O	O
2. How well the transplant team worked together to meet your needs	O	O	O	O	O

Comments (describe good or bad experience): _____

PERSONAL ISSUES

	very poor 1	poor 2	fair 3	good 4	very good 5
1. Our concern for your privacy	O	O	O	O	O
2. Our sensitivity to your needs	O	O	O	O	O
3. Quality of staff's response to concerns/complaints made during your visit	O	O	O	O	O
4. Extent to which staff wore identification badges	O	O	O	O	O
5. Extent to which staff introduced themselves to you	O	O	O	O	O
6. Upon entering your room, extent to which staff sanitized their hands	O	O	O	O	O
7. Degree to which you were able to participate in decisions about your care	O	O	O	O	O
8. Degree to which your family/significant other were able to participate in decisions about your care	O	O	O	O	O

Comments (describe good or bad experience): _____

OVERALL ASSESSMENT

	very poor 1	poor 2	fair 3	good 4	very good 5
1. How well clinic staff worked together to provide care during this visit	O	O	O	O	O
2. Overall rating of the care you received during this visit	O	O	O	O	O
3. Likelihood of your recommending this facility to others	O	O	O	O	O

Comments (describe good or bad experience): _____

RATING

Using any number from 0 to 10, where 0 is the worst experience possible and 10 is the best experience possible, what number would you use to rate the transplant outpatient clinic?

Worst possible **Best possible**

0	1	2	3	4	5	6	7	8	9	10
O	O	O	O	O	O	O	O	O	O	O

Patient's Name: *(optional)* _____

Agreement (SCA). This type of agreement is used when it is necessary to seek treatment from an out-of- network provider. The SCA provides for a specified reimbursement; therefore, balances above the agreed upon rate and the actual charges are waived in the same way as if the care was provided in network.

HMO plans are the most restrictive of the choices because the member is limited to seeing only in-network providers, consequently this type of plans have the lowest premium and member liability. If a member must use an out-of- network provider, the company must give authorization and negotiate a SCA.

Self-pay/private-pay individuals

The uninsured patients are the most challenging. TFCs should consider if the patient would be eligible for public assistance programs, or low cost insurance coverage plans if available. There are also numerous funded assistance programs available for qualifying transplant patients. Eligibility rules vary according to individual programs as well as amount of available assistance. Patients without insurance should be strongly encouraged to contact assistance programs. Transplant programs must have financial policies pertaining to the eligibility for transplant services specifically for the uninsured population of patients.

Foreign national patients

UNOS policy 6.0 Transplantation of Non-Resident Aliens permit foreign national patients to seek transplant services in the US. Current UNOS policy 6.0 from 2005 permits individual transplant programs to transplant 5% of their overall volumes to foreign national patients annually [34]. Individual transplant centers must develop policies pertaining to the management of foreign national patients. A dedicated international department within the health system facilitates the logistics of arranging services, including the cultural needs, for this unique population throughout the transplant continuum. These services may include prearrival assistance and ongoing assistance with obtaining VISAs and other required travel documents for patients and accompanying family members; lodging arrangements while undergoing evaluation, waiting time on the transplant list, and post-transplant care; 24 hours a day, seven days a week availability of interpreters to assist patients throughout the transplant process; coordination of outpatient clinic visits with the multidisciplinary transplant team; inpatient admissions/hospital stays; transitioning patients to home country when medically discharged; and assistance with facilitating longitudinal care monitoring in the patient's home country. By offering personalized services to this group of patients and reducing the barriers of navigating a healthcare system in a foreign country can help eliminate some of the obstacles encountered during the transplant process.

Some challenges unique to this population of transplant patients include patient and family expectations regarding the transplantation process and further patient and family expectations regarding limitations of care. This can be particular difficult when the expectation does not equal the services offered to the patient's satisfaction due to lack of understanding of organ allocation systems and extended waiting times. Reluctance of patients to return home when medically discharged and coordination of care upon discharge to home can be particularly challenging, especially if transplant services are limited in the patient's home country. Based on available funding and sponsorship of transplantation, the ability to return to the transplanting center for follow-up care may also be limited. Negotiations must be clear from the point of acceptance to the transplant program of the extent of covered services and agreed upon costs to the patient and sponsor, excluding complications. All aspects of patient transplant education and the Informed Consent process must be provided in the patient's native language prior to listing.

Hospitality houses

Transplantation can draw patients from around the world to transplant centers. The financial costs of accommodations associated with transplantation can be devastating to patients and their families. As a result of this void, hospitality houses emerged nationwide. "The National Association of Hospital Hospitality Houses, Inc. (NAHHH) is a nationwide professional association of nearly 200 unique, non-profit organizations that provide lodging and support services to patients, families and their loved ones who are receiving medical treatment far from their home communities." [35]. These houses can be small, accommodating just a few people, to facilities that can hold almost 200 residents. At any given house in the US approximately 20–25% of current residents are transplant related patients. Current US facilities can vary as to whether the facility is for children or for adults; and then again whether or not the patient can stay at the location or if it is just for family while the patient is hospitalized. Since the first house opened in Philadelphia in 1981 hospitality houses have grown as a direct result of compassion, determination, and generosity into so much more than just a place for patients and families to sleep in.

These houses are strictly residential facilities and part of the hospitality industry and as such they follow hotel regulations/standards, provide no direct medical care, and are not held to hospital regulations. They have become an integral part of healthcare delivery for patients away from home. Just as if the patient returned to their home following discharge from the hospital post-transplant or waiting for transplant, they would need to call 911 for any medical emergencies. Home health staff visit these facilities to provide needed support in home treatment, durable medical equipment, and assistive devices are permitted. Infection control standards, generally from the hospital, are implemented in the homes and become a learning tool for the patient and their family before returning to their home. They receive hands on training on how to safely clean and live with others as they prepare for the transition to their homes.

These houses provide a community setting for the constantly evolving return to "normality" for the patients and their families. At any given time, the house's current residents become a support group for each other as they learn to navigate the medical system together on the same journey to wellness. Facilities like these are able to provide a holistic approach to the day- in and day-out activities while decreasing financial and emotional strain on the families. The reduced cost of housing and, if needed, financial support from 501(c)(3) fundraisers may be available to supplement what a family can afford. These homes are a fee-for-service which covers approximately 65% of the expenses with the remaining revenue coming from donations and fundraising.

Typically activity within the house picks up in the evenings following visiting hours. Families gather in common areas to share food and more so to talk about their day and learn what to anticipate from others who have been going through a similar experience for a longer period of time. Some facilities utilize volunteers to help provide experiences throughout the month (activities or meals) while attempting to maintain as normal a lifestyle as

possible. Hospitality houses are continuously evolving to meet the guests' needs, as well as developing life long bonds of spirit and strength.

Summary

As the field of transplantation continues to evolve, so does the clinical management of the transplant candidate, recipient, and living donor. More care by an extended multidisciplinary team is being provided in outpatient transplant clinics. Every transplant center functions differently but must be held accountable to the same federal rules and regulations, which provide the basis for policy development. Transplant centers must have a vision and mission statement that guides their practice while demonstrating regulatory compliance, transparency, and producing measurable quality patient outcomes. The topics included in this chapter are not meant to be all-inclusive but to serve as a reference guide to be incorporated into the development of an outpatient clinical practice.

CHAPTER 126

Transplant Center Management and Leadership

A Case for Structured Intrapreneurship

Luke Preczewski,[1] Gwen McNatt,[2] and Michael Abecassis[1]

[1] Northwestern University, Feinberg School of Medicine, Chicago, IL, USA

[2] Northwestern Memorial Hospital, Chicago, IL, USA

Introduction

An entrepreneur is an individual who translates innovation into economic goods using financial and business acumen. Such an initiative may require forming a new organization, or alternatively, the revitalization of an existing organization in response to an opportunity. Although the term has traditionally referred to business initiatives, it has taken on broader applications; social, political, and more recently, knowledge entrepreneurships have emerged. The study of entrepreneurship reaches back to Richard Cantillon and Adam Smith in the late 17th and 18th centuries, but a resurgence of interest in the dynamics of business and economics in the past few decades has refocused our attention on the significance of entrepreneurs. Entrepreneurship is a process by which a new idea or invention is converted into a successful, and typically profitable, innovation. Innovations, in this context, are more likely to represent incremental improvements, rather than quantum discoveries. Entrepreneurs may bear risk, putting their financial security or careers on the line in the name of an idea, demonstrating initiative in the face of uncertainty.

The role for innovation and entrepreneurship in transplantation stems from the fact that no other viable alternatives to end-stage organ failure, particularly kidney failure, existed. The first successful kidney transplant was performed at a time when dialysis was so primitive as to be considered ineffective. Perhaps because surgical solutions to the technical challenges of transplantation preceded effective immunosuppression by several decades, surgeons are considered to be the original innovators in transplantation, while immunologists and scientists were concomitantly defining the very essence of transplantation immunology. It took the entrepreneurial spirit and perseverance of surgical pioneers to incrementally convince primarily academic institutions (medical schools and partnering hospitals) to become laboratories for these unprecedented experiments. Surgeons took personal risk by putting their careers on the line in the name of an idea, and institutions aligned themselves with the surgeons by putting both reputational and financial security at risk. As it became clearer that transplantation was a viable therapeutic option for end-stage organ failure, more institutions joined the ranks of those with existing transplant programs, demonstrating a commitment to the transplant initiative in the face of decreasing uncertainty. As transplantation evolved, the entrepreneurial spirit that marked its birth and growth remained an essential aspect of the transplant culture, allowing transplant centers to continue to be focal points of innovation within medical centers, converting new ideas into therapeutic approaches. The past three decades in particular have witnessed a transition of transplant procedures from experimental and investigative exercises to proven therapeutic interventions.

As transplant programs have evolved, so has the complexity of the administrative structures necessary to support them. At their onset, transplant teams typically consisted of one or two surgeons, collaborative physicians, and one or two nurse coordinators assigned to a low- to mid-level hospital administrator, with varying levels of oversight from the hospital's leadership. During this entrepreneurial phase, vibrant enthusiasm was palpable, primarily from those intimately involved in direct patient care, and passion was fueled by a clear and compelling vision, usually communicated by the surgical leader. Attitudes from others in the medical center were generally supportive, but might have ranged from indifference to benevolent curiosity. In this early phase, the team usually enjoyed strong support from the Chairman of the Department of Surgery (who, in all likelihood, recruited the lead surgeon), and varying levels of enthusiasm and support from the Chairman of the Department of Medicine. As transplant centers have evolved further as the transplant experiment has become successful, administrative structures have also evolved to accommodate the needs of the programs. This has occurred in parallel with a need for further investment of resources and personnel, commanding a higher level of attention from hospital administrators. In a typical scenario, the surgical team continues to drive the agenda, recruiting more collaborative physicians, forfeiting some of the pre and post-transplant care to their respective specialties, while the non-physician components of the team also expand to meet the needs of the growing number of patients evaluated, listed and transplanted. Again, the surgical team leads these efforts, but incrementally forfeits administrative and leadership functions to hospital administrators, relinquishing some decision points regarding both operational and budgetary issues. Although the growth in the physician component of the program may require some structural and organizational

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

changes in both departmental (medical school) and practice plan hierarchies, such as creation of a transplant surgery division within a Department of Surgery, growth in the non-physician components is likely to be associated with more significant changes in hospital administrative and management structures, with inherent and requisite sets of rules and operational procedures.

Together, these changes in organizational structure will inevitably introduce an element of corporate culture and discipline, particularly as the transplant program gets increasing attention from institutional leaders. Though genuinely interested in the success of the program, they also have their own respective agendas, as they are often responsible for the broader issues of budgets and compliance. As the program grows, its main oversight will shift incrementally from the medical school and physician practice to that of the hospital, which assumes the mandated responsibility for the program's regulatory compliance. As a direct consequence, the program, coincident with its growth, needs to fit into a more corporate organizational structure, abounding in administrative silos, each with its own set of processes and rules. An unintended consequence of this evolutionary development is a transition from the entrepreneurial spirit responsible for the success of the program, to a more corporate discipline, replete with confining hurdles and constrictive boundaries that inevitably curb the freedom to innovate. Therefore, institutional demands for adherence to well-defined organizational charts and reporting lines, manuals of policies and procedures, compliance with both institutional and regulatory requirements, and discipline directed at fiscal responsibility may ultimately stifle the energy and passion required for continued innovation. As the center of gravity of the program transitions from the entrepreneurial spirit to the corporate culture, the physicians are unavoidably held to the same corporate norms and standards as their non-physician colleagues. The institutional uniform becomes the business suit instead of scrubs and a white coat. In fully integrated healthcare delivery systems, a common set of rules governs all components of the program, which nearly always lean more towards the corporate. In less integrated systems, both medical schools and practice plans must also abide by, and be responsive to, an increasingly regulatory environment, such that the academic leadership is likely to welcome administrative filters imposed by the hospital leadership. Thus, it is inevitable that as programs grow and mature, they are, in a sense "victimized" by their own success, sacrificing their nimbleness and limiting their ability to be responsive to some of the more novel approaches to the challenges of transplantation.

The administrative structures dictated by the corporate culture are essential for achieving high reliability, improving efficiency, meeting financial goals, and maintaining full regulatory compliance, but at the same time their inherently process-oriented and risk-averse culture can cast a shadow on entrepreneurship and innovation. Thus the challenge for transplant leaders consists of maintaining the "esprit-de-corps" and innovative energy that first galvanized the team, while realizing the benefits associated with a corporate culture and structure. The successful transplant enterprise will adapt to the requirements of the corporate culture, while remaining at the margins of discovery, leveraging the strengths and benefits of both, to assure a highly reliable, efficient, and compliant center that remains an engine of innovation. In this chapter, we will discuss further the evolution of transplant centers, outline the critical elements of leading and administering established transplant service lines, and explore mechanisms proven in other areas that transplant leaders can use to establish and defend this essential middle ground.

Evolution of culture in transplant centers

The early days of transplantation were a clear example of the "tough-guy macho culture", marked by risk taking and rapid feedback and reward [1]. In the Deal and Kennedy model, organizational culture was defined by two axes: tolerance for risk, and immediacy of feedback. Starzl expounds on the two ends of the spectrum as he highlights the polemic clash of "surgeons-against-the-bureaucrats" in *The Puzzle People* [2]. As transplantation has evolved from the investigational realm to become a widely accepted therapy, transplant centers find themselves transitioning toward less risk-taking and less immediate feedback and reward. This "process culture", as defined by the Deal and Kennedy framework is marked by bureaucracy, safety and corporate culture. The affinity of large healthcare organizations toward self-protection is sensible, given both financial and reputational liabilities. The lure of innovation is foreshadowed by the realities of corporate responsibility and accountability. As a result, institutional bureaucracy, and policies and procedures designed to contain risk and increase predictability will trump any entrepreneurial desire to assume risk, especially when high profile fiascoes are even remotely possible.

This tendency for hospitals in particular to avoid risk has been magnified by the recent focus on transplant center regulations and public policy. The National Organ Transplantation Act (NOTA) first regulated the allocation of deceased-donor organs as a public good at the federal level [3] and established both Organ Procurement and Transplantation Network (OPTN) and Scientific Registry of Transplant Recipients (SRTR) contracts, giving Health Resources and Services Administration (HRSA) regulatory oversight of transplantation. Included in the provisions of NOTA was a requirement for public disclosure of center-specific patient outcomes [4]. In addition, the End-stage Renal Disease (ESRD) entitlement gave the Centers for Medicare and Medicaid Services (CMS) additional authority in regulating transplant centers by withholding reimbursement [5]. In the early part of the 21st century, a number of high-profile sentinel events attracted much government bureaucrat and politician attention. These events included the death of a living liver donor at a center in New York [6], a blood-type incompatible heart transplant in North Carolina that led to the death of a pediatric patient [7], and a series of articles by Charles Ornstein of the Los Angeles *Times* detailing problems at several California transplant centers. Ornstein highlighted the failure of United Network for Organ Sharing (UNOS) and CMS to detect and address those problems [8]. These events led to an Office of the Inspector General (OIG) investigation and Congressional hearings, which found CMS lacking in their oversight responsibilities. The result was the creation and publication of Medicare Conditions of Participation specific to transplant [9]. These regulations created prescriptive requirements mandating transplant hospitals to create transplant-specific policies and procedures and meet certain volume and outcome requirements. CMS implemented triennial compliance audits of transplant centers to enforce these requirements. In response, transplant centers have raised the issue of regulatory compliance to the highest levels of leadership within hospital structures. In similar fashion, HRSA has escalated its oversight by means of the OPTN contractor. The scope and authority of the OPTN was significantly enhanced with revision of NOTA in 2000 and the codification of that revision in the Final Rule in 2005. The OPTN contractor has policy or is proposing policy to create oversight over a wide scope of transplant operations; including, but not limited to, patient education, staff qualifications, the evaluation and selection of living donors and the prevention of disease transmission. The

OPTN exercises this regulatory oversight by both monitoring performance and outcomes and on-site surveys of policy adherence. A perennial cycle of external surveys and compliance audits complicates daily transplant clinical operations.

The threat to innovation by regulations has grown exponentially in the past decade. Both HRSA and CMS share the laudable goal of improving outcomes for transplant patients and living donors [4,10], but the rigid enforcement of the policies and regulations combined with the potential of overreaching interpretations by the bureaucrats and surveyors tasked with enforcing them may lead to the kind of mindless compliance that actually decreases transplant programs' reliability and resilience, stifles innovation and creativity, and drains resources away from clinical activities. Several centers volunteered, or were forced to, withdraw from Medicare participation and reimbursement due to either low volume or poor outcomes [8,11] in the first round of CMS surveys, and other transplant centers report changing practice to avoid similar fates [12]. More oppressive than any hospital corporate structure, over-regulation threatens the overall vitality of transplantation. The challenge to transplant leadership at both the program and national level will be to advocate with government leaders and bureaucrats to keep regulators in their proper role: promoting good self-governance as objective external reviewers [10] and providing peer review guidance [4]; not dictating practice or creating unsustainable administrative burdens. Hospital administrators have become increasingly aware of the need for compliance with these regulations, particularly outcomes requirements. Therefore, the evolution of transplant centers to corporate structures and the rapid deployment of federal regulations with potentially punitive actions have created the perfect storm with respect to risk averseness. As a result, transplant programs have witnessed significant convergence between the stated goals of bureaucratic institutional structures and those of regulatory oversight.

There is great merit to the implementation of evidence-based best practices, and the standardization of processes and improvement of outcome measures espoused by both corporate structures and regulations, as it is well established that standardized processes are a key element in increasing reliability and decreasing the risk of error. The implementation of the principles of high reliability [13] has become topically important in the initiative to improve quality in health care impelled by the Institutes of Medicine's landmark reports in 1999 and 2001 [14]. These principles include, not only structured processes and roles, but a "preoccupation with failure", defined as a constant vigilance for sources of error and accident, and the operational sensitivity to successfully manage the unexpected. The highly reliable organizational (HRO) culture dictates that established therapies be delivered safely and consistently, with efforts to reduce the risk and consequences of individual human failures. These principles, developed to prevent clinical errors, can also be successful in mitigating financial and legal risk. HRO principles have been shown to help manage the evolution of proven procedures into highly reliable service lines, and they require administrative oversight by professionals familiar with the business principles that make large organizations reliable, efficient, and adaptable, as well as with the many complexities and nuances of transplant practice, business operations, and compliance. As a result, this culture is becoming more common in, and being embraced by, transplant centers. Therefore, the widespread risk-taking, typically exhibited by those faced with few, if any, viable treatment alternatives for their desperate patients previously accepted in the earlier days of transplantation, are no longer tolerated. The culture of "never events" dominates in deliberations about healthcare delivery, and may lead to a clash of cultures between the more innovative entrepreneurial spirit of the transplant leader, and the more risk-averse corporate administrative leadership. Although everyone desires the avoidance of risk, most transplant clinicians would agree that the only way to never have significant complications is to never perform transplants. Whether the specific issue is live donor death, donor transmission of communicable conditions, or a novel approach to immune tolerance, implementation of best practices and processes cannot possibly guarantee a complete avoidance of potentially disastrous complications. And if there is little room for mitigating circumstances to be taken into consideration in addressing complications, the resulting risk-aversion may not allow the potential complication related to such a complex set of procedures. Therefore, throughout the application of HRO principles, it is essential that the center not allow itself to blindly adopt a risk-averse culture. Rather, center leadership needs to be vigilant in setting expectations and mitigating potential risks, and then embrace the opportunity to learn from both failure and success. Preoccupation with failure should not be misapplied to stifle entrepreneurship. It should instead empower innovation by adding rigor to the exploration of new approaches to care. All involved should fully understand and accept the risks of innovation, should work to mitigate them to the greatest extent possible, and should support these efforts, despite some inevitable setbacks. To this end, stringent informed consent processes must be deployed.

Intrapreneurship — balancing the entrepreneurial spirit with the corporate culture

The challenge for transplant leaders is to successfully leverage the strengths of corporate cultures, while preserving the entrepreneurial spirit. Service lines of care must be made as safe, reliable, and efficient as possible. These lines benefit from standardization, reproducibility, and transparency. At the same time, development of new ideas and creation of new programs will require the culture of entrepreneurship that has made transplantation an engine of innovation. In *Great By Choice*, Collins and Hansen propose that the most successful companies (10Xers) combine creativity and discipline: "The great task, rarely achieved, is to blend creative intensity with relentless discipline so as to amplify the creativity rather than destroy it. When you marry operating excellence with innovation, you multiply the value of your creativity" [15]. Many businesses have tackled the problem of maintaining an entrepreneurial spirit within a corporate culture, dubbed "intrapreneurship", and these models may be instructive for transplant centers. The terms intrapreneur and intrapreneurship, first described in the late 1970's by Gifford and Pinchot [16], were popularized in 1982 by Macrae [17]. The terms were first used in the popular media in 1985 by *TIME* magazine in an article entitled "Here come the Intrapreneurs" [18], and in the same year, in a quote by Steve Jobs, then Apple's Chairman, in *Newsweek*. In that article, Jobs was quoted: "The Macintosh team was what is commonly known as intrapreneurship, only a few years before the term was coined — a group of people going, in essence, back to the garage, but in a large company" [19]. In 1992, the American Heritage Dictionary acknowledged the word intrapreneur [20]. Intrapreneurs are encouraged to behave as entrepreneurs within the context of the resources, capabilities and security of a larger organization, and this allows for the dynamic and energetic nature of entrepreneurship,

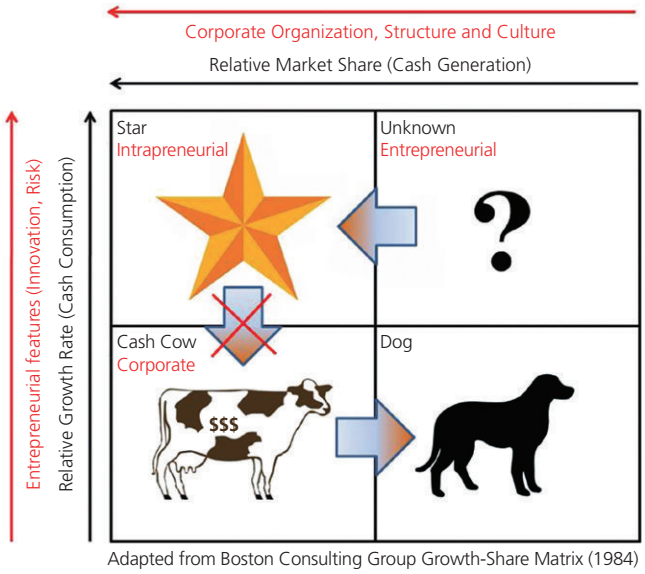

Figure 126.1. Adaptation of Boston Consulting Group (BCG) growth-share matrix to transplant cultures. To build transplant programs that last, it is essential to develop highly reliable corporate organizations to preserve market share during product growth, and to use the strengths of entrepreneurial culture to assure differentiating innovation and continued growth — as well as introduction of new product lines with the potential to become stars themselves — to avoid becoming cash cows destined for commoditization. Simultaneously maximizing both strong corporate organization and aggressive innovation is the hallmark of intrapreneurship.

while providing protection against the risks and accountability normally associated with entrepreneurial failure [21]. Thus, intrapreneurship combines the ability of individuals to transform an idea into a profitable finished product through assertive risk-taking and innovation, with the protection and backing of a large corporation allowing for the application of corporate management practice within "mini-firms".

Contemporaneous with the development of the intrapreneurship concept, the Boston Consulting Group (BCG) developed the Growth-Share Matrix (Figure 126.1) to evaluate product lines within organizations being targeted for investment or acquisition. The authors used the matrix to suggest that as market share increased, so did cash generation, and that as growth rate increased, so did cash consumption. This matrix illustrated a natural business cycle, in which a new idea (represented by a question mark) consumed significant resources without generating much revenue. These "question marks" represent risky targets, but if they progressed successfully to high market share by establishing competitive success, they become "stars", continuing to require investment, but also generating the revenues and margins to offset the investment. As the product is recognized to be profitable, investment in further innovation of the product decreases and the product becomes a "cash cow", continuing to generate revenue while requiring little cost. Although this may intuitively appear to be the best product position from a financial standpoint, as the innovation that differentiated these products from competitors and commanded a premium from consumers and producing healthy margins fades, such product lines inevitably become commodities. Competitors duplicate and successfully compete, and the product lines quickly become dogs, competing for small market share in a saturated market now based more on who can produce the product most cheaply. We propose that the corporate culture is a positive force along the same axis as market share, allowing increased volume reliably and efficiently. On the other hand, entrepreneurial culture is a positive force along the growth axis, allowing the product line to continue to evolve and expand. Therefore in this analogy, much like every attempt should be made to maintain a product line in the "star" category (and avoiding its natural tendency towards a cash cow) by continuing to differentiate the product through investment in innovation, every effort should similarly be made to keep the entrepreneurial and innovative spirits alive and well, while leveraging the benefits of the corporate organization. This push to this particular quadrant of the 2 × 2 grid can occur in one of two ways as illustrated in Figure 126.1. Obviously, question marks can become stars (that is, after all, the natural cycle), or alternatively the transition to cash cows can be avoided by reinvesting in innovation and by allowing the entrepreneurial spirit to remain in the context of the corporate structure. Both represent examples of intrapreneurship.

Intrapreneurship can be implemented in two models. In the first, it is deployed as part of a broad culture change. An example of this is 3M, which allowed its engineers to uniformly spend up to 15% of their time on their own projects [22]. This initiative led to the development of innovations such as Post-It notes. Similar environments produced the Sony PlayStation and the JAVA programming language. The second model consists of establishing a small entrepreneurial group within the larger corporate culture. This group is empowered to adopt a culture of innovation, is freed from many constraints of the larger corporate culture, but is still able to leverage its resources and capabilities. The classic example of this model is the Skunk Works™ at Lockheed Martin, which was formed to rapidly design new aircraft. Led by a young engineer named Kelly Johnson, the group was tasked with developing an entirely new aircraft design in the midst of World War II. They did so in 143 days. Lockheed Martin attributed this to allowing Johnson the autonomy to truly create a different culture. "What allowed Kelly to operate the Skunk Works so effectively and efficiently was his unconventional organizational approach. He broke the rules, challenging the current bureaucratic system that stifled innovation and hindered progress" [23]. It is this model of intrapreneurship, in essence allowing the team the ability to function as an entrepreneurial group within a corporate environment, that we propose as the most relevant to transplantation.

Govindarajan and Trimble studied this specific intrapreneurial model by chronicling initiatives in diverse organizations (e.g. New York Times Company, Corning, Hasbro, Cisco, Kodak, Johnson & Johnson, Thomson Corporation) to assemble best practices for what they called "managing strategic experiments", defined as high-risk, potentially high-return innovation requiring unique managerial approaches. They identified three key strategies:

1. "forgetting" — breaking from the core business, even in areas that are critical to the core business' success;
2. "borrowing" — leveraging the experiences and assets of the core business, giving intrapreneurial initiatives a marked upper hand over independent entrepreneurial competitors; and
3. "learning" — required to fill in those things that cannot be borrowed [24].

We believe that these three strategies are relevant to adopting an intrapreneurial culture in transplant centers. These same authors also described errors made in implementing this model across industries that we believe should serve as important cautionary

notes for transplant leaders wishing to adopt this model. They observed that core businesses often projected their way of doing things, from organizational structure to process management, onto the new ventures. This led to a lack of adaptability, as the new initiatives needed greater freedom to change and required reacting more nimbly to new information. The same business standards that made the large organizations successful and efficient stifled the new ventures. At the same time, many new ventures failed to adequately leverage the advantages of being part of large, established organizations. They cited as an example the New York Times Digital group that had worked so hard to make itself independent of the original organization, that it failed to leverage the content and advertiser base that should have been available to it, and even fought with the print side of the business. And as a failure of learning, the authors examined Hasbro Interactive, whose leaders became so focused on growth and vision that they lost the introspection to identify and learn from their own mistakes. The leaders tracked the wrong metric and set unrealistic targets, which ultimately led to their demise [24].

Leaders of transplant centers will be most successful if they heed the experiences of these initiatives. Successful centers will balance forgetting, borrowing, and learning to leverage the best of both worlds. On one hand, they will leverage the assets, experience, data, planning, human resources, process improvement, etc., available to them as one small piece of a large, successful healthcare organization. On the other, they will maintain the spirit of innovation and entrepreneurship, the capacity for rapid change, and the willingness to take risks that made their programs successful during their development and growth phase.

Transplant center management: structuring intrapreneurship

Most of us have heard someone say: "You've seen one transplant center, and you've seen one transplant center". This statement intimates that the organizational structures that govern transplant programs vary significantly among institutions. And there are two main reasons for this. First, the academic medical centers that typically house transplant programs, themselves, vary greatly in structure. In fact, there are even a small number of transplant programs that do not reside in academic institutions. Within academic institutions, there are a number of models that encompass the hospital, the medical school and the physicians [25]. Second, even within two almost identical academic medical centers, transplant programs may have developed differently over time, and therefore their structure may vary widely. For instance, some may be heavily anchored within a departmental structure, typically a department of surgery, whereas others may have evolved into centers or institutes [26]. And even between centers or institutes, there may be significant variation as to the functions that are governed by these structures. The purpose of this section of the manuscript is not to list every combination and permutation possible, nor is it to recommend one structure over another, but instead we propose to espouse the tenets of Intrapreneurship, as they apply to transplantation, while exploring potential structural frameworks.

Medical directors and administrators must work together to lead and manage the complex and diverse components of a transplant program, while they individually resist both internal and external pressures to operate at either end of the Deal and Kennedy spectrum. HRO expert Karl Wieck (1987) described this as "requisite variety" and recommended embracing complexity, and resisting the corporate tendency to oversimplify and centralize [27]. Different functions within a transplant center require specialized skills and knowledge (Table 126.1). Early on in the evolution of transplant programs, the surgical team is primarily focused on the clinical delivery of transplant services, and management skills and process are not as essential as is clinical excellence. As the programs grow, and as the regulatory and financial considerations become more significant, administrative and management issues take on increased importance and relevance, and transplant leaders must defend against the corporate tendency towards centralization of functions and must become champions for transplant-specific interests and resources, especially preserving the freedom to innovate.

The transition to a more formally structured HRO described previously is essential as the complexity of operations increases, particularly in the setting of a highly regulated healthcare specialty. However, the program's physicians often struggle with the resulting attachment of formal processes and layers of approval attached to decision-making, growth, and change. Although hospitals tend to have well-defined organizational charts, with certain areas

Table 126.1. Administrative functions in a transplant center

Function	Specialized knowledge required?	Comments
Financial		
Accounts payable	Yes	Cost report compliance
Revenue: Billing	Yes	Managed care transplant phases/Medicare secondary payments
Revenue: Collections	No	Low volume/high dollar
Revenue: Pricing	Yes	Managed care contracts, Standard organ acquisition charge (SAC)
Cost report preparation	Yes	
Budget preparation and management	Yes	Acquisition cost centers
Contracting	Yes	Managed care transplant phases
Analysis	Yes	Cost report reimbursement, SAC
Patient counseling	Yes	Managed care, ESRD Medicare, required by OPTN/UNOS
Marketing/outreach	Yes	Specialized product knowledge
Human Resources		
Benefit and payroll administration	No	
Compensation structure	Yes	On call compensation, compensation for outreach/ marketing activities
Recruitment (non-physician)	No	Need targeted advertising
Staff (physician and non-physician) management	Yes	Clinical knowledge valuable; CMS, OPTN knowledge essential
Non-physician staff: Nursing, social work, mid-level providers, dietary, non-licensed professionals	Yes	Specialized knowledge and training for most professionals required by CMS, OPTN
Quality Assurance / Performance Improvement/Regulatory Compliance	Yes	Knowledge of CMS, OPTN regulations and reporting requirements essential
Data Management/IT	Yes	Use of transplant-specific database/EMR
Overall Program Administration	Yes	Management of the requisite complexity of the entire program regardless of where each function is housed

reporting to specific Vice Presidents who are focused respectively on operations, finances, human resources, regulatory compliance, etc., physicians are typically embedded in academic departments and in practice plans that may not be structured to deal with the complexities of transplantation, particularly its interdisciplinary nature. Therefore, as transplant programs grow, it is not uncommon for their administrative center of gravity to shift towards the better organized structure and to adopt its inherent organizational behavior and culture. Hospitals provide excellent homes for this organization, and are well-equipped to support large, complex service lines including transplantation. In contrast, the physician infrastructure tends to be less rigid and more nimble. Unfortunately, academic departments and physician groups are typically not in a position to offer much in terms of resources. Transplant physician practices often require support from their hospitals since a significant amount of work done on behalf of the program is not billable through the standard relative value units (RVU) mechanisms, and is therefore not recognized when medical schools and practice plans calculate physician productivity. It is difficult enough for the physician employers to justify the salary support of their physicians and surgeons. Departments of medicine in particular, are often in need of support for their transplant physicians. The result is that the hospital initiates a transfer of services agreement that is compliant with Stark and other anti-kickback laws on a contractual basis. The inevitable consequence is that some control of the physicians shifts to the hospital. The hospital, fulfilling its responsibilities to both regulators and its governance, will need to exercise some form of oversight on physician activities that relate to the program. In highly integrated healthcare delivery systems, especially those where physicians are employed by the hospital, these circumstances work against the entrepreneurial origins of transplantation. For instance, it may be difficult for the hospital to quantify and incentivize academic efforts such as innovative research. Research is often underfunded by extramural granting agencies, especially for surgeons and other specialists, whose market-based salaries exceed the federal cap for inclusion on National Institutes of Health (NIH) and other federal granting agencies, threatening the financial viability of an academic transplant physician practice. Defined compensation plans that reward clinical activities over and above research activities create an incentive for transplant surgeons to fill any time not occupied by their clinical transplant responsibilities with well-remunerated general surgery operative cases, and a disincentive to participate in research and teaching activities. Regardless of the structure that underpins the delivery of care, as transplant programs grow in volumes and revenues, they risk taking on a corporate culture that tends to favor clinical productivity and cost control over innovation and research. This structure adheres closely to the norms of a clinical enterprise, allocating resources much as it allocates overhead, using the simplest formula that works across the entire clinical enterprise. And because of the complexities and subtleties of transplantation, one of the first unintended consequences is loss of the innovative spirit that bred the success of the program in the first place. In addition, transplant surgeons are often assigned administrative roles within the transplant centers, which cause them to inevitably adopt the corporate culture. Given that these surgeons/administrators are often part of the senior leadership of the institution, they often need to buy into the culture despite the fact that they fundamentally disagree with the restrictions imposed on truly innovative initiatives.

Physicians and surgeons, and their trainees, typically reside in departments within a medical school. A historical perspective of the evolution of Centers and Institutes, as well as the strong rationale for their development, is provided in a comprehensive paper by Braunwald [28]. In this paper, the authors also espouse the value of matrix organizations. But in their conclusions, they remind us that the administrative details of an organization, particularly in academic healthcare is only a means to an end, specifically that of carrying out the tripartite mission of education, research and patient care. Nonetheless, the author stressed the importance of galvanizing different specialties around common themes, and in the context of transplant centers, this theme or mission is to meet the needs of transplant patients. In a separate study, Mallon warns the reader about the risks of centers and institutes and suggests that although it is important to capitalize on the strengths of centers and institute, it is also essential to reward leaders who embrace a collaborative point of view while developing a culture that frowns on empire building. His main argument is that departments must maintain their place in academic institutions [29]. These arguments notwithstanding, it is clear that multi-specialty initiatives, which transplantation embodies, require organizational and administrative structures to transcend the traditional silos of the departmental structure of an academic environment. Braunwald accessed the evolution of cardiac centers around cardiac surgery. There are numerous parallels between this example and transplantation. Certainly, transplantation is significantly more diverse in its participant providers than cardiovascular disease. It is important that any structure that is created is used to facilitate the advancement of transplantation and that it does not become a bureaucratic hurdle driven by individual desires for independence and empire building. Enunciating the objectives (Table 126.2) of a center can serve as a set of guiding principles that will prevent the degeneration of the original intent. A list of such guiding principles for transplant centers should include the following:

1 foster interdependence among interdisciplinary members to fulfill the tripartite mission;
2 enhance, facilitate and remove disincentives to interdisciplinary collaboration;
3 overcome potentially restrictive organizational structures allowing for effective access to the necessary resources to support progress;
4 align interdepartmental objectives around transplantation;
5 provide a fiscal structure that supports the academic mission of the transplant program; and
6 foster pride of enterprise and a sense of shared responsibility and destiny among the various specialties engaged in transplantation.

In addition, transplant centers should *not*:

1 duplicate existing competencies otherwise available at the institution;
2 compete unfairly for available resources with other centers; and
3 strive to make departments obsolete.

If these principles are followed, centers and institutes should be viewed as positive developments by departments, rather than threatening competitors for power and resources. To this end, it should be clear from the onset that the stakeholders of the center or institute include department chairs, such as the departments of surgery and medicine. Finally, there should be an understanding that if the original objectives can be met without the need of the structure, it will be "sunset" in short order, or alternatively, that whatever functions the center or institute provides can be repatriated to departments if it makes more sense. One of the clear benefits of a center or institute that operates under these principles is the

Table 126.2. Two distinct but complementary sets of Guiding Principles for achieving Intrapreneurship in a highly reliable transplant center

Guiding Principles for a Transplant Center's Academic Mission	Guiding Principles for a Transplant Center's Clinical Mission
• Foster interdependence among interdisciplinary members (to fulfill the tripartite mission). • Enhance, facilitate, and remove any disincentives to interdisciplinary collaboration. • Overcome potentially restrictive organizational structures to allow effective access to the necessary resources to support progress. • Align interdepartmental objectives around transplantation. • Provide a fiscal structure that supports the academic mission of the transplant program. • Foster pride of enterprise and a sense of shared responsibility and destiny among the various disciplines engaged in transplantation.	• Deliver high quality care that achieves excellent clinical outcomes • Operate as efficiently (cost-effectively) as possible. • Maintain full regulatory compliance. • Assure team-based multidisciplinary care with a focus on communication. • Center care on the patient. • Strive for the largest possible local market share.

ability to focus recruitment of desirable faculty around areas of common interest.

Although it is relatively easy to build a center or institute around the research and education components of the tripartite mission, it becomes more difficult to reconcile its clinical components. This problem mainly revolves around physician compensation. Different departments may use varying scales to measure physician productivity which can be difficult to assess in the setting of transplantation for reasons described in a previous section. Therefore, as the hospital's role in supporting the infrastructure increases with the evolution and growth of a transplant program, these issues become less about money and more about authority and control, can cause significant friction, and have been known to result in implosion of very active centers as individuals become unhappy and leave for what seem to them as greener pastures. It is incumbent upon the leadership of the institution to also establish a set of guiding principles (Table 126.2) that can be used to regulate funds flow, as well as allocation of resources. In this capacity, the transplant center's clinical mission should be viewed to provide:

1 high quality (clinical outcomes);
2 high value (cost efficient);
3 regulation compliance;
4 team-based, coordinated; and
5 patient-centered care.
6 In addition, delivery of care should strive to capture a high percentage of market share in the local market.

Depending on the level of integration of the delivery system, physicians may be either employed by the hospital, or act fundamentally as contractors for transplant services. As such, the actual contractual agreements may differ, but in the end, the objectives remain the same. The reader should note the absence of "innovation" in the previous list, although one could argue that it is indirectly implied in some of the other terms, including high quality and market share, given that a program might not be competitive without growth through innovation. However, transplant programs could be first movers or late adopters of innovative product lines. The reality is that most large academic hospitals are not focused on being first movers, but only in being late adopters if there are margins to be had. Instead, these institutions are much more interested in the more corporate elements of care, clearly enunciated in the previous list. This is where the more academic partner, the academic physician, has to provide the balance. We submit that neither of these two sets of guiding principles can be used in isolation. Instead, we propose that a transplant program that is built-to-last will incorporate elements of both.

Although it is clear that many established programs within the transplant center can function under the principles of HROs, achieving efficiency, quality, and consistency in proven therapies and processes and the resilience to overcome failures, require that the transplant center maintain an intrapreneurial identity to be able to conduct research and build new programs. Previous authors have made the compelling case for centers and institutes that cut across corporate boundaries and empower the clinician-scientists who built transplantation [26]. Expanding on that idea, we suggest that institutions should foster transplant centers and institutes which can conduct cutting-edge research and build new programs modeled on the intrapreneurial groups discussed earlier. In establishing the Skunk Works at Lockheed Martin, Kelly Johnson laid out 14 "rules and practices" he considered essential for the group's success [30]. "Kelly's 14 Rules" have become a guide for successful intrapreneurial groups. Although these rules are specific to a defense contractor, and more easily generalized to engineering, we have developed a new set of rules based on the original list. Following these rules will ensure that the research and new program development components of a transplant center (or institute) can thrive (Table 126.3). These rules are intended to assure the highest possible level of flexibility and accountability such that an intrapreneurial transplant center can innovate and lead within a corporate environment that assures high reliability for programs once they are up and running. The rules are also consistent with the lessons of new ventures described earlier [24] and the lessons of previous attempts to develop integrated health centers [31].

Finally, one essential element of a successful transplant center is strong leadership. This is critical for the entire leadership team: physician leader, administrator(s), medical directors, and managers and team leads. Truly exceptional transplant centers consistently have a single visionary physician leader, typically a surgeon. In *Good to Great: Why Some Companies Make the Leap. . . and Others Don't*, Collins identified that every company that made the leap from being merely a good company to being a great one was led by what he called a "Level 5 Executive". He noted that many of the storied corporate leaders, such as Lee Iacocca, were "Level 4 Effective Leaders", whom he described as "Catalyzes commitment to and vigorous pursuit of a clear and compelling vision, stimulating higher performance standards". This description will no doubt ring true for anyone looking at the majority of the giants of transplantation, as well as the leaders of many large transplant centers today. Having a Level 4 Leader is likely a requirement for a successful transplant center. However, in identifying Level 5 Executives, Collins described a model of truly transformational leaders, capable of taking organizations to the very highest level of achievement. In describing the levels and models of organizational leadership, Collins identified that Level 4 Leaders are often "a genius with a thousand helpers" — strong-willed leaders with great vision and myriad interchangeable managers to execute one person's plan. Conversely, the best companies have a Level 5 Executive team, in which a strong-willed leader surrounds himself with the best people and works with them to find the best way to develop and advance

Table 126.3. Northwestern's 14 Rules for an Intrapreneurial Transplant Center (right hand column) based upon "Kelly's 14 Rules" for Skunk Works at Lockheed Martin. Reproduced from [30]

Kelly's 14 Rules [30]	Northwestern's 14 Rules for an Intrapreneurial Transplant Center
1 The Skunk Works manager must be delegated practically complete control of his program in all aspects. He should report to a division president or higher.	1 The Center Director must be delegated practically complete control of his program in all aspects. S/he should report to the dean of the medical school and CEO of the hospital.
2 Strong but small project offices must be provided both by the military and industry.	2 A small but strong and empowered core administrative staff must be provided by the institution to ensure the center is nimble and responsive.
3 The number of people having any connection with the project must be restricted in an almost vicious manner. Use a small number of good people (10% to 25% compared to the so-called normal systems).	3 Membership in the center should be limited to faculty actively engaged in transplant research and new initiatives and who are held by the center director to specific goals.
4 A very simple drawing and drawing release system with great flexibility for making changes must be provided.	4 Project plans should be straightforward and high-level, with great flexibility for making changes.
5 There must be a minimum number of reports required, but important work must be recorded thoroughly.	5 There must be a minimum number of reports required, but projects should have clear performance metrics.
6 There must be a monthly cost review covering not only what has been spent and committed but also projected costs to the conclusion of the program.	6 There must be a regular cost and performance review covering status of projects along projected path and any changes required.
7 The contractor must be delegated and must assume more than normal responsibility to get good vendor bids for subcontract on the project. Commercial bid procedures are very often better than military ones.	7 The center must be empowered and expected to develop collaborations with other specialties to create projects at the intersection of diverse disciplines.
8 The inspection system as currently used by the Skunk Works, which has been approved by both the Air Force and Navy, meets the intent of existing military requirements and should be used on new projects. Push more basic inspection responsibility back to subcontractors and vendors. Don't duplicate so much inspection.	8 Institutional leadership must commit to facilitating and not impeding, research projects and new initiatives.
9 The contractor must be delegated the authority to test his final product in flight. He can and must test it in the initial stages. If he doesn't, he rapidly loses his competency to design other vehicles.	9 The center must be supported in efforts to rapidly but safely translate research discoveries into new clinical programs.
10 The specifications applying to the hardware must be agreed to well in advance of contracting. The Skunk Works practice of having a specification section stating clearly which important military specification items will not knowingly be complied with and reasons therefore is highly recommended.	10 The metrics for success and failure for any project must be agreed to in advance, and failures to meet these metrics and milestones remediated immediately or projects terminated and unspent funds returned.
11 Funding a program must be timely so that the contractor doesn't have to keep running to the bank to support government projects.	11 Committed funding for new programs must be fully available until the program meets its goals for self-sustainability or is eliminated due to inability to achieve goals.
12 There must be mutual trust between the military project organization and the contractor, the very close cooperation and liaison on a day-to-day basis. This cuts down misunderstanding and correspondence to an absolute minimum.	12 There must be mutual trust between the transplant center, medical school, and hospital with full transparency on finances, goals, and changes in strategy.
13 Access by outsiders to the project and its personnel must be strictly controlled by appropriate security measures.	13 Center faculty and staff must be able to manage projects within budget and plan free from burdensome external review and approval.
14 Because only a few people will be used in engineering and most other areas, ways must be provided to reward good performance by pay not based on the number of personnel supervised.	14 Because center faculty will work toward goals beyond usual metrics of physician productivity, the compensation scheme must allow center faculty to be rewarded for achieving these goals.

a vision. Collins characterized these Level 5 Leaders as people who prefer not to take credit for themselves, giving it instead to members of their team, at the same time taking blame on themselves for mistakes. He further portrayed them as acting with quiet and calm determination, setting inspiring standards, putting their organizations before themselves [32]. Organizations seeking transplant leaders would do well to identify, not only physicians with a vision who will lead their programs to new heights, but also the much rarer selfless leadership that sets Level 5 Leaders apart.

Summary

The incremental implementation of the provisions of the Affordable Care Act (ACA) will undoubtedly result in evidence-based, team-based, coordinated, longitudinal, accountable, and value-driven care. The ongoing dialogue and debate over future delivery and payment reform underlines the many features and key success factors of the current models of both delivery and payment in transplantation. The direction that the rest of healthcare in the US seems to be taking emulates what transplantation has achieved over the past couple of decades. However, there has been no emphasis on innovation. Instead, the focus seems to be primarily on regulation, incentives for value, and models of care that reward coordinated and integrated care for patients. Although these are all laudable objectives, the biggest and mostly neglected victim is likely to be innovation and research with training and education being a distant second. Who will pay for innovation, and how will we make sure that regulations and the search for novel treatments are not mitigated by the dogged determination to bend the cost curve by replacing quantity with quality? Healthcare reform may foreshadow the demise of the entrepreneurial spirit, adding further to the challenge of transplant leaders and the need for intrapreneurial initiatives within organizational frameworks.

CHAPTER 127

Transplant Quality Programs

Christian Morath, Peter Schemmer, and Martin G. Zeier
University of Heidelberg, Heidelberg, Germany

Introduction

As detailed in Chapters 103 through 110, the overall outcomes of all solid organ transplants have improved consistently over the past decades. According to international and national registries, more than half a million of kidneys and more than 100 000 liver and heart transplantations have been performed [1]. For kidney transplant recipients, patient and graft survival has improved continuously over the decades even though the co-morbidities of end-stage renal disease patients have increased, as has the age of the recipient at time of transplantation [2]. In non-renal organ transplantation patient and graft survival improved as well over the past decades. In liver transplantation patient and graft survival has improved despite a diminishing in the general condition of liver transplant candidates [3]. The success of heart transplantation is continuously increasing, despite an increase of donor age [4]. The estimated half-life for heart transplants over the time period of 1982 to 2009 is 11 years. The number of heart transplants is more than 3700 per year according to the International Society for Heart and Liver Transplant (ISHLT) registry [5]. Since organ transplantation is growing worldwide, the treatment modalities (immunosuppression, surgical technique) are manifold, and the expectations for outcomes are escalating, standards for quality assessment are increasingly required.

This chapter provides a listing of the major indices that should be prospectively tracked to maintain cognizance of the quality of a transplant program. The information technology evolving to assist with capturing and reporting these metrics is covered in Chapter 132. For the purposes of the present chapter, focus is given in an organ specific and chronologically-specific (relative to the time of transplant) manner to the major metrics impacting quality.

Transplant outcome quality: the role of registries

The transplant community has been a pioneer in periodic review of clinical outcomes to ensure the optimal use of limited donor organs [5]. Organ transplantation is constantly developing and is influenced by changing external and intrinsic parameters. These include surgical techniques, perioperative care, post-transplant follow-up, new immunosuppressive drugs and the combination of immunosuppressive medication. Without follow-up data analyzed by registries it is difficult to assess quality standards in this high-level treatment modality. Results from large registries influence the quality of organ transplantation and impact new developments. Although registries deal with retrospective analysis, the high number of patients and a high percentage of follow-up allow effective conclusions (also see Chapter 133 for registry data use). There are a number of national and international registries that accumulate and calculate patient and graft survivals. A large international registry is the Collaborative Transplant Study which follows more than 350 000 kidney, 60 000 liver, 11 000 pancreas, and 50 000 heart, transplant recipients worldwide [1]. In the past two to three decades the Collaborative Transplant Study produced several landmark papers on patient and graft outcome in comparison to a specific variable, such as HLA-system, type of immunosuppression and long-term care of transplant recipients. For example, one paper on blood pressure and its impact on graft survival [6] show that the quality of blood pressure control is strongly associated with the long-term outcome after kidney transplantation. The largest national registry is the United Network for Organ Sharing (UNOS), which follows the data of recipients with solid organs in the US. Another important national database is the United States Renal Data System (USRDS). The USRDS publications continuously impact the quality of outcome after kidney transplantation. A list of international and national registries and their websites is summarized in Table 127.1.

Guidelines

The primary role of globally accepted guidelines is to achieve a certain quality standard in organ transplantation despite geographic disparity. Many national and international transplant societies place significant emphasis on the improvement of transplant outcome quality. However, the suggested way to improve the quality of organ transplantation is naturally biased by local practice patterns, ethnic background, local medical peculiarities (e.g. endemic infections, cardiovascular comorbidity etc.), and the socio-economic conditions encountered.

An example of an international guideline collection is the Kidney Disease Improvement of Global Outcome (KDIGO) guidelines for kidney transplant recipients. This is the first initiative, initiated by the International Society of Nephrology and executed by the National Kidney Foundation, to establish globally applicable guidelines for the care of kidney transplant recipients. Two generalizations were made in the establishment of these guidelines: an evidence-based approach was to be taken, and guidelines were to

be formulated such that they could be applied any place in the world [7]. What is the benefit of such a guideline initiative? In terms of quality assessment, guidelines give a basis for the standard of care. In addition, they are helpful when requesting the economic resources needed to establish a transplant program on a scientific based quality level. For non-renal transplantation there are guidelines from various national and international transplant societies available. Guidelines may also be downloaded from the national and international societies mentioned in Table 127.1.

Quality assessment of different organ transplants

Kidney transplantation

Kidney transplantation (summarized in Table 127.2) is the treatment of choice for end-stage renal disease patients. Although the perioperative risk is higher for transplanted patients, compared to age-matched dialysis patients, the long-term outcome of kidney transplant recipients is much better [8].

The outcome data for quality assessment on a national level is primarily restricted to patient and graft survival, as registry data are insufficiently granular to gain more in-depth quality measures. At a local level, however, much more granular data are available (as discussed in depth in Chapter 132). With the aid of local databases, it is also important to document primary function or the rate of delayed graft function, the quality of organ function (e.g. s-creatinine or glomerular filtration rate = GFR), the number and severity of rejection episodes, the number and type of surgical complications (e.g. lymphocele, vascular complications, ureteral leakage) and the immunosuppression associated morbidity and mortality. This specific assessment of graft function and patient morbidity has an important impact on the long-term graft survival.

Table 127.3. Quality data for pancreas transplantation

Primary quality data	patient- and graft survival, graft function (free of insulin)
Secondary quality data	rejection, surgical complications, blood glucose, HbA1c, regression of diabetes associated long-term complications

Table 127.4. Quality data for liver transplantation

Primary quality data	patient- and graft survival
Secondary quality data	30-day mortality, rejection, surgical and non-surgical complications, retransplantation, INR, bilirubin

Pancreas transplantation

In most cases (>90%) the pancreas is transplanted together with a kidney, a combined kidney-pancreas transplantation (Table 127.3). The quality standards for pancreas transplantation thus typically include the quality standards of kidney transplantation.

The outcome data for the kidney in combined kidney-pancreas transplantation are the same as mentioned above. Additional quality standards specific to the pancreas transplant include clinical and biochemical data. The clinical parameters contain the surgical technique (e.g. bowel drainage of the exocrine pancreas, arterial anastomosis, and the venous drainage either systemic or portal). Additional clinical information includes postoperative pancreatitis due to ischemia/reperfusion injury and pancreas fistula (e.g. due to explantation trauma, see Chapter 60 for major technical issues unique to the pancreas transplant). The number of rejections should be recorded, and in this context, a biopsy program to diagnose a rejection episode of the pancreas should be a quality feature of a pancreas transplant program. For long-term follow-up clinical quality data should include the progression of diabetic lesions such as retinopathy, angiopathy, and polyneuropathy. They are associated with the absence of insulin application (full endocrine function), the blood glucose levels, and oral glucose challenge and glycosylated hemoglobin.

Liver transplantation

The main causes for liver transplantation (Table 127.4) are end-stage liver disease, hepatocellular carcinoma, liver metastasis from neuroendocrine tumors, acute liver failure, and rarely, inborn errors of metabolism.

A liver transplant quality program should include the 1-year patient and graft survival, including the 30-day mortality and the rate of retransplantation. The 30-day mortality reflects the in-hospital mortality, and both are significantly influenced by recipient condition at the time of transplantation. This should be captured through the MELD score, with specific note of dialysis or ventilator dependence at the time of transplantation. The length of patient stay in the intensive care unit, the length of respirator

Table 127.5. Quality data on heart transplantation

Primary quality data	patient- and graft survival
Secondary quality data	1-year patient and 1-year graft survival, 30-day mortality, retransplantation, rejection

Table 127.6. Quality data on lung transplantation

Primary quality data	1-year patient survival and 30-day mortality
Secondary quality data	pO_2/FiO_2 at 6 hours post-transplantation, extra-corporal membrane oxygenation

treatment, and total duration of the hospital stay are also important metrics for consideration. The number of rejection episodes should be recorded, as should antirejection treatment. Biochemical parameters should reflect the excretory function of the liver (bilirubin) and marker for synthesis, e.g. INR, albumin.

Heart transplantation

Heart transplantation (Table 127.5) is a routine treatment for end-stage cardiac failure. It is of particular note that cardiac failure patients bear a specifically high risk when they go for transplantation and that they are at high risk for perioperative mortality.

The heart quality program should include 1-year patient and organ survival, including the 30-day mortality. An additional quality item is the number of retransplantations. Like for liver transplant recipients, the pretransplant general condition significantly impacts the outcome after transplantation, and should be captured by detailing specific co-morbidities including renal failure and ventilator dependence. The number of biopsy proven and treated rejections are an additional quality item.

Lung transplantation

Lung transplantation (Table 127.6) is a standardized treatment in specialized centers. Indications for lung transplantations are mucoviscidosis, pulmonary hypertension, primary lung fibrosis, and less commonly, emphsema.

The most important indicator in lung transplantation is the 1-year patient survival and the 30-day mortality. As with other life sustaining organs, recipient condition at transplantation significantly influences patient outcome, and in the case of lung transplantation, ventilator dependence and pulmonary infection/colonization are particularly telling indices. Additional quality factors are the duration of postoperative respirator treatment, the pO_2/FiO_2 co-efficient six hours post-transplantation, and the number of patients who required extra corporal membrane oxygenation (a marker of delayed graft function). In the long-term follow-up the appearance of broncho-obliterative syndrome is of critical importance.

The impact of pretransplant risk factors for the outcome in solid organ transplantation

Patient and graft survival are strongly impacted by the pretransplant condition of the transplant recipient [9]. This differs for the various organs in terms of alternative methods to bridge the organ failure (e.g. dialysis) or in terms of urgency for transplantation (e.g. heart and liver patients on the waiting list). For kidney patients, survival on the waiting list is normally guaranteed by the dialysis treatment; however, time on the waiting list has a specific impact on patient and graft survival and the number of rejection episodes [10]. Furthermore, almost every sixth patient on the kidney waiting list awaits a retransplant, which increases the risk for rejection (e.g. immunization) and early graft loss [11]. For liver and heart transplant patients on the waiting list, the waiting time is even more critical. Since there are not enough solid organ donors and living related donation is only done in a minority of liver patients, normally the most critically ill patients [12] have a chance to receive an allograft. These are important factors that influence the quality of a transplant program and this is summarized in Box 127.1.

Box 127.1. Pretransplant risk factors with significant proven influence on patient and graft survival in solid organ transplantation

- Age of the recipient (<16 and >65 years)
- Retransplantation
- Presensitization
- Time duration on the waiting list
- General health assessed by indices (e.g. Karnovsky etc.)
- Permanent hospitalization pretransplant (liver and heart candidates)

Access to organ transplantation

Access to transplantation varies for the different solid organs. In liver and heart transplantation the access to a transplant program is highly dependent on the current status of the patient. Due to the organ shortage only patients with advanced liver or heart failure are considered for transplantation. Quality programs should assure that patients who are not treated at hospitals with a concomitant organ transplant program should have the same access to a transplantation center. In this context it is important that a transplant center offers regular teaching opportunities for surrounding hospitals.

Scientific publications of the past 30 years document that many patients meeting the criteria for solid organ transplantation remain excluded from transplant waiting lists. For the kidney transplant waiting list barriers to listing include: low social status, a lesser degree of school and professional education, a history of non-adherence and many other variables. It is also thought that female patients have a lesser chance being wait-listed compared to male transplant candidates. Further barriers include the physicians prejudice, such as, not to wait-list an end-stage liver patient with a history of alcohol abuse. Therefore, transplant centers should provide information material on the different solid organ transplantations at their center. They should provide in-house meetings with referral centers to maximize the information for primary care-takers. Specific relationships with referring physicians is covered in Chapter 34. Primary care-takers should be encouraged to refer every potential solid organ recipient for individual counseling to a transplantation center, and indeed, the referral rate is a quality metric for nephrologists providing dialysis care. Information material such as flyers, booklets and videos are available from almost every national and international transplant society.

Organ procurement and organ quality programs

The number of patients on the waiting list is manifold higher than donor organs available for transplantation. The number of donors

per population varies widely between different countries and sometimes between different parts of a nation. The success in organ donation is related to evidence-based education. An example is the Transplant Procurement Management (TPM), an international project on organ donation and transplantation. The program started in 1991 under the auspices of the University of Barcelona and the National Spanish Transplant Organization. In 1994, TPM became international and was initiated in 1997 in Italy, and in 2006 in France. National training courses were organized adapting the same methodologies as the advanced international TPM courses. In 2002 the e-learning platform program was launched to facilitate the education of professionals. In 2005, an international master's degree was created at the University of Barcelona under the Life-long Learning Institute. In 2006, the courses were expanded to include pregraduate health science faculties with the International Project on Education and Research in Donation at the University of Barcelona. Finally in 2007, the European-funded European Training Program on Organ Donation project was started. Currently, TPM offers face-to-face, e-learning, and blended international courses. As of 2008, TPM has trained 6498 professionals in 89 countries on five continents [13]. Another example is the Southern California Organ Procurement Center. This program managed a significant increase of organ donors over the past years. They applied successfully educational strategies similar to the TPM. The number of deceased donor organs per year should regularly be recorded and published as a quality marker for the transplantation center.

Living organ donation — quality program for the donor

The perennial solid organ shortage has impelled a continuous increase in the use of living donors. Particularly in renal transplantation where the relative number living related transplants makes up 30–50% of transplants performed. Before a living related organ transplantation can be considered, all possible measures should be done to put the transplant candidate on the deceased donor waiting list. A standardized protocol is necessary to inform the potential donor on all short-and long-term risks (currently known from the scientific literature and annually updated) to guarantee informed consent. The information on risk and benefit should include the surgical (open vs. laparoscopic), the anesthesiological and the immediate postoperative risk. The evaluation of living donors for kidney and liver transplantation are covered in Chapters 23 and 24, respectively.

All solid organ donors should be included in a life-long follow-up program according to national or international guidelines. In some countries there are specific laws forcing the transplantation center to follow a living organ donor at least annually. These are followed to varying degrees worldwide, and are most problematic in countries without nationalized healthcare systems.

Living donation puts an enormous pressure on the donor and the family. Although the majority of donors are satisfied with their decision to donate an organ, a minority may have somatic complaints (incision site, medical problems, etc.). In addition, there are a number of donors who suffer from adaptive disorders. A predonation counseling as well as a postoperative counseling offer should be at hand. The quality program should have a predonation document referring to the result of the counseling process and this should compare to a similar psychological assessment after organ donation. Misinterpretations and a possible diversity in the estimation of the predonation psychological status are measurable and should impact the predonation work-up in the future

The donation of a solid organ (e.g. kidney) or a part of an organ (e.g. liver, lung) has an impact on the long-term function of the remaining organ. Quality standards are mandatory to avoid donors with occult dysfunction of the potential donor organ and/or exclude an underlying disease. This is of particular importance in patients with inherited diseases (e.g. polycystic kidneys or Alport syndrome in kidney transplantation).

Organ quality

It is a common experience that the donor age for solid organs has increased gradually, commensurate with a generally aging population in most countries [14]. For all solid organs, the age of the donor directly impacts the graft survival, and for heart and liver transplantation it also impacts patient survival [15]. The assessment of organ quality is therefore an important task; however this question is not completely solved at present. For example for renal transplantation the size of the kidney, scarring of the parenchyma, unexpected cysts and other possible malformations need care and attention. The more interesting question in this case is, however, are there microscopic tissue changes, such as interstitial fibrosis, arteriolar hyalinosis and global glomerular sclerosis? It is of great importance to have a representative biopsy size (number of glomeruli) to give an estimate of the quality of the donor organ. Similar questions are raised for a liver graft. The histological hallmarks are the macrovesicular steatosis, fibrosis and inflammatory changes, all of which are important quality criteria for a liver graft [16]. To assess the quality for either a kidney or a liver transplant a 24 hour pathology stand-by is required. There are also clinical and biochemical organ quality markers, diuresis in the past 24 hours, the course of the s-creatinine in kidney grafts, and serum sodium concentration, INR and bilirubin in liver allografts. Specific considerations on donor organ assessment are covered in depth in Chapter 53.

After the declaration of the brain death, organ procuring is the first of many steps toward successful organ transplantation. The quality of the organs procured from a deceased donor is of critical importance for the outcome of the transplants. The experience of the procurement team, and in particular, of the surgeon leading the team is critical. In the UK, a surgical procurement specialist has been created to assure a high quality standard of organ procurement [17]. In a study from Sweden the performance for liver and kidney procurement teams was reported. The most important findings related to missed information concerning organ abnormalities or organ damage from the procurement operation [18]. Damage to procured organs is naturally organ specific.

In the process of diagnosing brain death and the procurement surgery an experienced team is necessary to do all medical measures to stabilize the condition of the potential donor. Transplant centers should provide special trained physician and nurses who are able to deal with this specific situation. Blood pressure monitoring and a thorough volume balance are extremely important to avoid hypo or hypertensive insults to the donor. Quality assessment also includes the treatment of associated complications such as infections, which could significantly impact the potential donation (e.g. nephrotoxic antibiotics). Specific treatment of procurement methods is found in Chapters 21 and 22 for brain dead and heart beating cadavers, respectively.

Medical quality assessment post transplantation

Successful solid organ transplantation starts with an optimal surgical result; however, most of the challenges arise in the days and weeks following surgery. Thus, properly trained (see Chapter 130) transplant physicians should follow all transplant recipients in addition to the surgeon during the hospital stay and the immediate outpatient follow-up. This requires that transplant centers have access to a broad array of medical specialties to deliver quality care. Quality criteria for a physician trained for organ transplantation should include the diagnosis of rejection (including biopsy procedures), experience with immunosuppressive drugs and their interaction (either with other immunosuppressive medication or non-immunosuppressive medication) and the peculiarities with viral, bacterial and fungal infections of transplanted patients. Physicians should understand the potential of late surgical complications and their management, together with the surgical transplant team. The medical quality post transplantation critically depends on the availability of a team of transplant immunologists, particularly when sensitized patients are transplanted. Treatment options should be discussed with the immunological specialist. To assure a high quality for the diagnosis of rejection a specialist in transplant pathology (e.g. kidney, liver, and heart) is mandatory. Quality assessment includes regular biopsy conferences. A department of virology and microbiology with a 24 hour presence is required to treat infections early and with the appropriate antibiotic. Finally a clinical laboratory must be available at any time.

The above mentioned multidisciplinary approach is necessary to provide quality care and thus means of multidisciplinary staff communication are required to facilitate the exchange of knowledge. These include regular in-house teaching rounds or conferences, a written or electronic document where all the relevant process details are accessible to all members of the team, and morbidity and mortality conference for all disciplines involved. The disciplines include not only surgery and medicine, but should include specially trained pathologists and transplant-immunologists. As a quality goal in our unit, we measured the reduction of cold ischemia time. An optimized interaction between surgery, transplant-immunology and anesthesiology reduced the cold ischemia time by almost 20% [19]. Another part of this information chain is to provide the referring physician (e.g. nephrologist, hepatologist) with the present status of the patient. It is fairly common that the referring physician has additional information that makes the work of the transplant team easier.

Clinical pathways differ between the different types of solid organ transplantation. Though this is true, several pathways are similar for all types of organs. This comprises the laboratory control, including immunosuppressive trough levels, as well as bacteriology and virology. Laboratory results should be accessible to all physicians and nurses involved in the postoperative care of transplanted patients. Regular patho-anatomy conferences should be held to interact with the pathologist. These conferences exchange details difficult to relate in the written report, exposes the pathologist to clinically relevant information, and creates an environment to raise research questions.

The experience and the number of transplants for quality assessment

Quality programs for a number of surgical procedures show a reduction in mortality when more than 200 procedures per year are performed. For cardiac transplantation a learning curve has been readily documented: for the first five heart transplants the postoperative mortality is 20%, beyond this number the mortality rate decreases to 12%. It is of particular note that the surgical experience did not improve the chance of survival; it was the association of a transplant-experienced cardiologist in the team [20]. In another study, the number of liver transplants was compared and the authors differentiated between low volume (<20 cases/year) and high volume (>20 cases/year) centers. The mortality rate in low volume centers was almost 26% compared to 20% in high volume centers [21]. Another study from Europe (European Liver Transplant Registry) showed an 1-year survival of 74% in centers with less than 25 liver transplants per year and a 1-year survival of 79% in centers with more than 90 liver transplants per year [22]. A similar effect is also notable in kidney transplantation. Data form the UNOS registry has been used to compare graft survival data between the top 20 transplant centers and the bottom 20 as assessed by transplant volume. A comparison was made for HLA-matched and HLA-non-matched allografts. The graft half-life for unmatched grafts for the top 20 centers was 11.8 years versus 8.9 years for the bottom 20 centers. It is if particular interest that in the time period of 1994–1999, the graft half-life for unmatched allografts in top 20 centers was 15.7 years and in the bottom 20 centers 12 years for HLA-matched kidney recipients [23]. In kidney transplantation the center effect has an even higher impact on graft outcome than HLA-compatibility. Another important aspect is whether a transplant center offers a single transplant program (e.g. kidney) or a multi organ transplant program, which includes for example all visceral organs (liver, pancreas, kidney, if specialized also small bowel).

The quality of long-term follow-up following solid organ transplantation

Recipients of solid organs need a life-long follow-up to record the quality of graft function and the transplantation associated complications. Although the risks in the early months post-transplantation are higher (e.g. surgery, higher degree of immunosuppression, hospital readmission), it is of critical importance to follow the patient with the allograft over the many years. Quality assessment should include the organ specific measurements for the functional capacity and the potential loss of organ function over the follow-up period. Typical organ general and organ specific measurements are shown in Tables 127.7 and 127.8.

Immunosuppressive blood levels should be monitored, although the number of measurements will be less frequent beyond the first year post-transplantation. A specialized outpatient clinic should

Table 127.7. Summary of the surgical quality criteria of organ procuring

Liver	Portal vein length, aberrant arteries (in 15%). Avoiding the denudation of the bile duct. Sufficient cuff of donor caval vein. Avoiding parenchymal injuries
Kidney	Additional or aberrant arteries or veins. Particularly veins which vanish in the fat tissue of the hilus. No denudation of the ureter.
Pancreas	Very careful preparation of the pancreas (risk of pancreatic fistulas). Sufficient length of the splenic and the superior mesenteric artery for back-table reconstruction. Sufficient length of the portal vein. Avoiding injuries of the duodenal segment for the pancreatic drainage
Small bowel	Completeness of organ perfusion. Avoiding hematoma of the intestinal mesentery. Avoiding vascular injury

Table 127.8. Specific quality parameters which are required for the long-term follow-up of solid organ recipients.

Kidney	Glomerular filtration rate, blood pressure, diabetes, bone complications, infection and cancer rate
Liver	Laboratory work: AST, ALT, LDH, bilirubin, INR. Technical work: vascular duplex (hepatic artery)
Heart	Troponin, ventricular ejection fraction, protocol biopsy for occult rejection
Lung	FeV1 (forced expiratory volume in the first second)
Pancreas	Free of insulin, blood glucose, HbA1c

Table 127.9. General quality parameters which are required for the long-term follow-up of solid organ recipients

Blood levels of immunosuppressive medication
Blood pressure
Diabetes
Renal function (glomerular filtration rate)
Number of infections with hospitalization
Type and treatment of malignancy

council the patients in all matters referring to the transplant specific treatment (e.g. drug interactions with immunosuppressive medication, intercurrent illness or surgery, contraception and in female patients the possibility of pregnancy). Quality assessment includes also the number of infections requiring hospitalization and immunosuppressive associated malignancies.

In the context of long term follow-up, the quality assessment of adherence with particular emphasis on the transition period (adolescents) is included. Non-adherence of immunosuppressive mediation is a common cause of allograft loss (and is covered in depth in Chapter 120). The level of adherence affects clinical outcomes, and is associated with early and late allograft rejection. The suspicion to non-adherence should be raised, when missed appointments and fluctuating blood drug concentration occur in the renal transplant recipient. Non-adherence is, however, beyond the intake of immunosuppressive drugs. Additional areas of non-adherence that influence graft survival include exercise, tobacco, alcohol and drug abuse and the self-monitoring of vital signs. Non-adherence occurs early and/or late after transplantation. Non-adherence is particularly common during the transition from pediatrics to internal medicine (see Chapter 121 for a detailed discussion of this topic). How can the quality of adherence be measured in an individual patient? There are several measures which can be applied to assess the quality of adherence: self-reporting medication, collateral reporting by relatives or caretakers, patient diaries, laboratory tests (drug and metabolite levels), medical record review, prescription refills, monitoring pill counts, and electronic monitoring devices. There are several approaches to improve adherence they are summarized in the Kidney Disease: Improving Global Outcomes (KIDGO) guidelines [24].

The assessment of quality of life of patients after transplantation

Organ transplantation encompasses many aspects in the life of allograft recipient. Beside the need for surgery and the regular intake of immunosuppressive medication, there is often co-morbidity or treatment associated morbidity (e.g. infections, cancer). All these distresses taken together increase the psychological burden of an individual patient. Beside these sorrows, the organ transplant recipient knows that an organ from another person is within his or her body. Such patients understand that another person has died (in the case of a deceased organ donation) or that a relative or a friend has voluntarily donated an organ (in most cases a kidney). Therefore, it is important to offer psychological counseling for organ transplant recipients. A quality program of transplant center should actively ask patients about their psychological wellbeing. There are some questionnaires out to assess the psychological status of an organ recipient. Examples are the SF-36 Quality of Life Questionnaire or the Transplant Effects Questionnaire TxEQ-D. Other instruments, which are more organ specific comprise the Kidney Transplant Questionnaire (KTQ), The Heart Transplant Checklist, the End stage Renal Disease Symptom Checklist (ESRD-SCL) or Bone Marrow Transplantation Symptoms List.

Table 127.10. Important milestones to improve the quality of organ transplantation

Critical review of outcome results (registries)
Implementing the evidence based knowledge of guidelines
Optimization of process sequences
Assessment and enhancement of patient adherence
Organ quality measurement
The role of minimum quantity
Quality of organ procurement
Quality of life of organ transplant recipients

Summary

Solid organ transplantation is a complicated treatment for critically ill patients. The past decades have provided us with many new immunosuppressive drugs and a significant reduction in the acute rejection rate. Today tong-term survival with a transplanted organ is reality. Despite this success, the results for solid organ transplantation can be further improved. Transplant centers should understand that the treatment options (surgery, medication, diagnostic procedures) alone will not achieve this goal. They should measure the milestones (Table 127.10) and verify whether these milestones are considered in their transplantation center.
