CHAPTER 82

Histopathological Syndromes of Liver Allograft Rejection and Recurrent Disease

Anthony J. Demetris, Marta I. Minervini, Michael A. Nalesnik, Erin Rubin, Parmjeet Randhawa, and Eizaburo Sasatomi
Department of Pathology, Division of Transplantation and Hepatic Pathology, University of Pittsburgh Medical Center, Pittsburgh, PA, USA

Introduction

Liver transplantation is utilized to treat a broad spectrum of end-stage liver diseases. Hepatitic C virus (HCV), alcohol, and non-alcoholic fatty liver disease are leading indications in North America, Europe, and South America, whereas in Asia, hepatitis B virus (HBV)-induced cirrhosis accounts for the majority of transplants.

This chapter focuses on unique aspects of common diseases modified by transplantation as well as on conditions unique to allografts, such as rejection, small-for-size syndrome, and preservation–reperfusion injury. We employ tabular presentations for easier reference, including comprehensive tables prepared by the Banff Working Groups on acute and chronic rejection and late allograft dysfunction. The chapter complements Chapters 78 and 70, which deal with the clinical management of recurrent diseases of the liver and allograft rejection, respectively.

Deceased donor biopsy evaluation

Tissue for frozen section should be representative and obtained fresh, preferably in the presence of the pathologist who should also grossly inspect the organ. We routinely obtain three tissue samples if the gross appearance is uniform: two 2.0-cm 16-gauge needle cores, one each from the right and left lobes, and one 2.0-cm^2 subcapsular right lobe wedge biopsy. Cores are used to stage fibrosis; a wedge can be additionally helpful for evaluating arterial or arteriolar disease and steatosis.

Pitfalls to avoid during sample preparation include air-drying or storage in physiologic saline, which can cause hepatocytes to appear shrunken or necrotic. Also, absorbent substrates can leach fat out of the tissue resulting in underestimation of steatosis. Biopsies should be transported immediately to the frozen section room on a paper towel moistened with preservation solution or in a plastic specimen container.

Difficulty in sectioning should alert the pathologist to the possibility of steatosis. Recognition of hepatocytes in various stages of injury can be enhanced by staining sections for increasing lengths of time in eosin, which renders necrotic hepatocytes hypereosinophilic, also often allowing recognition of early karyorrhexis.

The pathologist should request additional information if biopsy findings do not correlate with known history or events. Donor biopsy evaluation is only one laboratory test; the pathologist is unable to predict organ function after transplantation based on donor frozen section evaluation in the absence of significant histopathologic findings.

Biopsy findings that usually disqualify organs include diffuse hepatocyte necrosis, severe macrovesicular steatosis (defined later), advanced intrahepatic atherosclerosis, and unequivocal bridging fibrosis [1–4]. Polarization microscopy offers a quick and accurate estimate of liver fibrosis without trichrome stain and represents a useful diagnostic adjunct.

Macrovesicular steatosis is typically defined as large fat globules (usually >1/2 nuclear diameter) associated with peripheral nuclear displacement, whereas small vacuolar or **microvesicular steatosis** is defined as multiple small fat globules (<1/2 nuclear diameter) associated with a centrally placed nucleus. Macrovesicular steatosis (>30%) increases susceptibility to preservation–reperfusion injury, impairs regeneration, and is associated with decreased graft survival [5–7]. Microvesicular steatosisis often occurs after a short period of warm ischemia and usually does not adversely affect outcome. However, one study associated "high grade" microvesicular steatosis with delayed graft function [8]. In our opinion, the severity of macrovesicular steatosis can be *roughly estimated* on hematoxylin and eosin (H&E) stained slides alone.

The interpretation algorithm at our institution is as follows. Mild donor macrovesicular steatosis (<10%) does not influence the decision-making process. Livers with moderate macrovesicular steatosis (10–30%) are usually still used, but other factors are also taken into consideration in the decision-making process (e.g. extended criteria donor (ECD) characteristics). Livers with >30%, or severe steatosis, are used only under special circumstances, such as when cold ischemic time is kept to a minimum (usually <8–9 hours) and there are very few or no other ECD risk factors. The outcome in such situation can be comparable to non-steatotic donor livers [9,10].

Necrosis in donor biopsies has negatively impacted recipient outcome in some [11,12], but not all studies [8,13]. In our experience, the liver is usually disqualified if >10% (roughly estimated) of hepatocytes are necrotic and the necrosis diffusely involves both the wedge and needle cores; the assessment should not be based on isolated subcapsular necrosis and should be correlated with donor liver injury test profiles.

HCV-postive donor livers at our institution undergo frozen section biopsy analysis. Those without bridging fibrosis (<3/6; Ishak scale) are offered to potential recipients after informed

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

consent. Other groups report one stage lower fibrosis cutoff (<2/6) [14].

A variety of neoplastic, infectious, and metabolic diseases have been inadvertently transferred from donors to recipients [15]. Examples that *might* be detectable by pathologists include various cancers, amyloidosis, hemochromatosis, fungal, viral, and parasitic diseases [15]. Metabolic diseases, such as familial amyloid polyneuropathy [16], oxalosis [17], and possibly α_1-antitrypsin deficiency [18] can be intentionally or unintentionally transferred with the donor organ in "domino" transplants.

Living donor biopsy evaluation

Living donor liver operations currently account for ≤5% of North American and European transplants, but for the vast majority of operations in Asia [19]. As major liver resection entails risk (mortality roughly of 2:700 [20], some centers routinely biopsy potential living donors to further minimize risk [21–24]; 20–50% of potential living donor biopsies show usually mild abnormalities.

The most common pathology and also the most common reason for donor disqualification is macrovesicular steatosis of variable severity in 14–53% [21–26]. Most programs limit macrovesicular steatosis in living donors to <30% because this level does not appear to adversely impact the course of either donor or recipient [23]. Other programs limit macrovesicular steatosis to <10% or 20% [26,27].

Other biopsy findings include low-grade chronic hepatitis of undetermined etiology, granulomas, and a variety other unexpected findings (e.g. unexpected early stage primary biliary cirrhosis (PBC)) [24]. Mild periportal hepatocellular iron deposits are present in ~17% of mostly male potential donors. This subclinical finding does not preclude transplantation. Unexplained portal tract eosinophilia can also occur and did not adversely affect the postoperative donor or recipient clinical course in two cases [24].

Determination of causes of graft dysfunction after transplantation (Table 82.1)

Post-transplant allograft needle biopsies

Allograft biopsy monitoring is used: (1) to determine the cause of dysfunction, if present; (2) assess the effect of therapy and/or progression of disease; (3) document the immunologic and architectural status to help guide immunosuppression therapy (IS). For native livers, the American Association for the Study of Liver Disease has recommended two passes with a 16-gauge needle for adequate assessment of fibrosis due to sampling error inherent with small biopsies (<20 mm long); additionally, those containing <11 portal tracts might not be representative (reviewed in [28]). Similar guidelines should be followed for liver allograft biopsies, particularly those obtained late after transplantation where assessment of fibrosis is important.

Most histopathologic studies can be completed on routinely processed formalin-fixed paraffin-embedded sections. A clinical differential that includes antibody-mediated rejection (AMR) optimally includes fresh frozen tissue for immunofluorescent staining for immunoglobulin and complement, but less sensitive formalin-fixed paraffin embedded samples can also be used for C4d staining [29,30]. Most frequently utilized special stains, ordered only on indication after review of the H&E slides, include trichrome, iron, and copper to detect chronic cholestasis. Cytokeratins 7 or 19 can help to localize bile ducts and ductular metaplasia of periportal hepatocytes [31] in cases with suspected ductopenia and chronic rejection.

It is often best to first complete the slide review and then correlate findings with the clinical history and laboratory results to generate a differential diagnosis. We also routinely compare current findings with findings in previous biopsies. This greatly assists with the interpretation, assessment of therapeutic intervention, and disease progression. Re-review of all liver allograft biopsies at a weekly clinicopathologic conference is an essential quality assessment tool that provides feedback to clinical physicians and pathologists.

Failed allograft evaluations

Gross examination of failed allografts should follow a standardized approach [32] with special attention paid to anastomotic sites: biliary, hepatic artery, portal and hepatic veins. At times this will require assistance of the operative surgeon to explain the surgical anatomy. Routine tissue sampling should include: (1) anastomoses, if present; (2) superficial and deep sections of the right and left lobes; (3) at least one deep hilar section with cross-sections of medium-sized bile ducts and arteries; and (4) any grossly obvious defects.

Preservation–reperfusion injury or primary non-function, vascular thrombosis, and patient death are the leading causes of allograft failure within the first few weeks after transplantation [33,34]. Very few allografts fail because of acute cellular rejection (ACR) or AMR [35,36]. Recurrent disease, delayed manifestations of technical complications, such as vascular thrombosis or biliary sludge syndrome, and patient death are most commonly responsible for late (>1 year) graft failures [37,38]. Chronic rejection is uncommon as a cause of graft failure [37,39]. Recurrent HCV-induced cirrhosis is a leading cause for allograft failure that challenges organ allocation algorithms [40].

Special considerations in reduced size and living-related liver allografts

Normal liver structure and function is dependent on optimal portal venous and hepatic artery inflow and adequate venous outflow and biliary drainage. Transplanting only a portion of the liver necessarily compromises at least one of these conduits, especially near the cut edge of the residual liver. It is therefore important for the pathologist to be aware of the technical details of the operation and the exact origin of the post-transplant biopsy because of non-representative and potentially misleading local alterations related to sampling site. For example, infarcted parenchyma or high grade biliary or venous outflow obstruction changes can be seen in biopsies obtained near the cut surface in otherwise well recipients with normal or near-normal liver injury tests.

Early after transplantation. reduced size and living donor allografts typically undergo robust regeneration and might be more susceptible to damage from needle biopsies [41] and AMR [42]. Late after transplantation, portal venopathy, low-grade ductular reactions, and nodular regenerative hyperplasia changes are fairly common in reduced size and living donor liver allografts [43].

Preservation–reperfusion injury

Preservation–reperfusion injury refers to manifestations of donor organ damage that result from the cumulative effects of agonal donor events (warm ischemia), cold ischemia, warm sanguineous reperfusion in the recipient, and perioperative events [44,45]. Donation after circulatory death (DCD) donors merit special mention because these organs all suffer an extended warm

Table 82.1. Approximate timing of common allograft syndromes (data from [260] and [156])

Syndrome	Clinical associations/observations	Peak time period
"Preservation" reperfusion injury	Long cold (>12 h) or warm (>120 min) ischemic time; older (>60 yr), hemodynamically unstable, DCD, "re-do" of anastomoses; poor bile production; prolonged cholestatic phase predisposes to biliary sludge syndrome	Recognized primarily in post-reperfusion biopsies and biopsies obtained within the first several weeks after OLTx. Changes can persist for several months depending on the severity of the initial injury
AMR	ABO-incompatible donor; high titer (>1 : 32) lymphocytotoxic cross-match DSA; presents with persistently low platelet counts and complement levels during first few weeks after transplantation	First few weeks to months after transplantation; later onset less common and not well-defined
Acute cellular rejection	Younger "healthier" female, and inadequately immunosuppressed recipients, long cold ischemic times, and those with disorders of dysregulated immunity (e.g. PSC, AIH, PBC)	Peak dependent on IS regimen; usually 3–40 days; later onset usually associated with inadequate IS
Chronic rejection	Usually occurs in inadequately immunosuppressed patients (e.g. infections, tumors, PTLD) and patients have a history of moderate or severe or persistent acute rejection episodes or are non-compliant	Bimodal distribution; early peak during first year and later increase in non-compliant and inadequately immunosuppressed patients
Hepatic artery thrombosis	Suboptimal anastomosis; pediatric/small caliber vessels; donor and/or recipient atherosclerosis; suboptimal or difficult arterial anastomosis; large difference in vessel caliber across anastomosis; hypercoagulopathy; suboptimal arterial flow (vasospasm from small-for-size syndrome	Bimodal distribution; early peak 0–4 weeks and later peak between 18 and 36 months (see text)
Biliary tract obstruction or stricturing	Arterial insufficiency or thrombosis; long cold ischemia, DCD, difficult biliary anastomosis; AMR; original disease of PSC	Variable, but timing can be used to determine etiology: <6 months usually mechanical, preservation–reperfusion injury (ischemic cholangiopathy) or AMR; >6 months recurrent disease, mechanical
Venous outflow obstruction	Difficult "piggyback" hepatic vein reconstruction; cardiac failure	Usually during the first several months
"Opportunistic" viral (CMV, EBV, adenovirus, etc.) and fungal infections (see text)	Seropositive donors to seronegative recipients (often pediatric); over-IS	0–8 weeks, much less common thereafter except for EBV-related PTLDs and other EBV-related tumors (see text)
Recurrent or new onset of viral hepatitis (e.g. HBV, HCV, HEV).	Original disease HBV, HCV, or acquired HEV-induced hepatitis in patients with contact with animals or culinary inconsistencies	Usually first becomes apparent 4–6 weeks after transplantation and persists thereafter; earlier onset (within 2 weeks) in aggressive cases
Recurrent AIH, PBC, and PSC	Original disease of AIH, PBC, or PSC (see text for risk factors)	Usually more than 6 months after transplantation; incidence of recurrence increases with time after transplantation
Alcohol abuse	Psychiatric co-morbidity/social instability; non-compliance with treatment protocols; γ-GTP : ALP ratio >1.4 (see text for risk factors)	Usually >6 months
NASH	Original disease NASH or cryptogenic cirrhosis; persistent or worsening risk factors for NASH in general population	Usually >3–4 weeks and increases with time if risk factors persist

AIH, autoimmune hepatitis; ALP, alkaline phosphatase; AMR, antibody-mediated rejection; CMV, cytomegalovirus; DCD, donation after circulatory death; DSA, donor-specific antibody; EBV, Epstein–Barr virus; γ-GTP, gamma-glutamyl transpeptidase; HBV, hepatitis B virus; HCV, hepatitis C virus; HEV, hepatitis E virus; HLA, human leukocyte antigen; HSV, herpes simplex virus; IS, immunosuppression; NASH, non-alcoholic steatohepatitis; PBC, primary biliary cirrhosis; PSC, primary sclerosing cholangitis; PTLD, post-transplant lymphoproliferative disorder; VZ, varicella-zoster virus.

ischemic insult. Even in the best of hands, considerable blood component sludging and subsequent damage occurs in the peribiliary plexus, which in turn predisposes to ischemic cholangiopathy [46–48].

Clinical presentation

Early signs of preservation–reperfusion injury include poor bile production and persistent elevation of serum lactate. This is usually associated with marked (>2500 IU/mL) elevations of serum alanine aminotransferase (ALT) and aspartate transaminase (AST) during the first few days after transplantation [3], followed by rapid ALT/AST normalization during the first week and a prolonged "cholestatic phase" characterized by persistent elevation of total bilirubin and gamma-glutamyl transpeptidase (γ-GTP). Recovery is accompanied by a gradual resolution of abnormal liver injury tests, but such grafts are also at risk for developing ischemic cholangiopathy and the biliary sludge syndrome [49,50].

Histopathologic findings

Post-reperfusion needle biopsies obtained within several hours of revascularization can reliably gauge the extent of preservation–reperfusion injury [3,51]. Mild damage is common and shows microvesicular steatosis, hepatocellular cytoaggregation (i.e. detachment of individual hepatocytes and "rounding up" of cytoplasm), and hepatocellular swelling [3,32]. Severe injury is characterized by zonal or confluent coagulative necrosis, which can be periportal, bridging, and combined with severe neutrophilic inflammation [3,51].

Mild injury is usually followed by hepatocellular mitoses, nuclear enlargement, and thickened trabeculae. Continuing injury manifests as typically co-existent mild centrilobular hepatocellular swelling and hepatocanalicular cholestasis, which often persist for several weeks. Severe injury is usually accompanied by marked centrilobular hepatocellular swelling and hepatocanalicular and cholangiolar cholestasis, which may persist for 1–2 months [3,32]. Cholangiolar proliferation is usually triggered by periportal and confluent bridging necrosis with reticulin framework collapse [3,32]. With recovery, normal architecture can be restored but risk for ischemic cholangiopathy remains.

Preservation–reperfusion injury of livers with >20% macrovesicular steatosis causes death of some fat-containing hepatocytes with lipid release into sinusoids. These fat droplets coalesce into larger globules, triggering local fibrin deposition, neutrophilia, congestion, and local sinusoidal obstruction [1]. If recovery occurs, the

large fat globules become surrounded by macrophages and eventually resolve over several weeks.

As hepatocytes require only 4–6 hours to undergo the entire apoptotic cycle, recognition of hepatocyte apoptosis or coagulative necrosis in a biopsy obtained more than several days after transplantation should arouse the suspicion of another, usually ischemic, insult [52].

Differential diagnosis

Biliary obstruction and pancreatitis, sepsis, AMR, and cholestatic hepatitis can produce histopathologic changes resembling preservation–reperfusion injury. Detailed donor information helps to determine the likely source of injury [35]. Preservation–reperfusion injury and operative technical difficulties most often prove to be the cause of liver injury early after transplantation.

Examination of true bile ducts and cholangioles provide useful clues in distinguishing between preservation–reperfusion injury and biliary tract obstruction or stricturing. The latter etiology usually causes at least some periductal lamellar edema surrounding true bile ducts or produces stellate-shaped septal bile duct lumens often containing intraluminal or intramural neutrophils. Preservation–reperfusion injury, in contrast, does not usually show "true" bile duct changes. Instead, neutrophils surround interface zone cholangioles. Centrilobular hepatocanalicular and cholangiolar cholestasis and intralobular neutrophil clusters are common to both disorders.

ACR superimposed on preservation injury is recognized by "typical rejection-type infiltrate" in portal and perivenular regions: blastic and smaller lymphocytes and especially eosinophils, which are an excellent marker of an early emerging rejection reaction, as is convincing lymphocytic cholangitis, and lymphocytic central perivenulitis.

Cholestatic hepatitis can be difficult to distinguish from preservation injury in the absence of clinical context. Cholestatic hepatitis has only been reported in patients infected with HBV or HCV and is distinctly unusual before 3–4 weeks after transplantation. Cholestatic hepatitis usually worsens with time unless the patient is specifically treated with decreased IS and/or antiviral therapy, whereas the trend is toward gradual improvement with preservation–reperfusion injury.

Portal hyperperfusion or "small-for-size" syndrome

Pathophysiology

Excessive venous inflow can injure portal venous and periportal sinusoidal endothelium [43,53] and contribute to allograft dysfunction referred to as the portal hyperperfusion (PHP) or small-for-size graft syndrome (SFSS). Increased portal venous flow causes adenosine washout and arterial constriction. This, in turn, predisposes to arterial thrombosis and ischemic cholangitis.

Liver regeneration [43] is dependent on portal blood and too little inflow can impair regeneration and cause graft steatosis [54,55]. Failure of liver regeneration is generally not a major problem unless also impeded by suboptimal hepatic venous drainage [56].

Clinical presentation

Dahm et al. [57] defined PHP/SFSS as at least two of the following complications on three consecutive days within the first few weeks after transplantation: elevated bilirubin (>100 μmol/L), INR >2, and grade 3–4 encephalopathy after exclusion of technical, immunologic, or infectious complications. PHP/SFSS probably also contributes to so-called technical complications, found with increased frequency in reduced size allografts [43].

Histopathologic findings

Denudation of portal vein and periportal sinusoidal endothelium may occur as early as 5 min following transplantation [43,53,58–60]. In severe cases, microvascular rupture at portal vein–sinusoidal junctions can cause portal stromal hemorrhage that can dissect into hepatic parenchyma [61,62]. Reparative changes occur if the allograft survives the initial crisis: endothelial cell hypertrophy, subendothelial edema, and in-growth of myofibroblasts and endothelial cells lead to fibrointimal hyperplasia/intimal thickening and luminal obliteration or recanalization of thrombi. Venous findings are uncommonly seen in biopsies. Instead, one often observes nonspecific centrilobular cholestasis, centrilobular hepatocyte steatosis, or hepatocyte atrophy with sinusoidal dilatation, and/or centrilobular hepatocyte necrosis and low-grade ductular reaction.

Hilar sections of failed allografts frequently show traumatic injury to larger portal vein endothelium, focal fibrointimal hyperplasia of vein branches, evidence of arterial vasospasm, and, in some cases, ischemic cholangitis, particularly if the hepatic artery has thrombosed [43]. Eventually, if the graft recovers, portal hypertension and ascites resolve over several weeks. This is accompanied by restoration of normal architecture, except that some grafts eventually develop significant nodular regenerative hyperplasia resulting from portal venopathy [43].

Differential diagnosis

Arterial thrombosis, stricturing, sepsis, hypotension, biliary tract obstruction and stricturing and ischemic cholangitis can cause histopathologic changes similar to PHP/SFSS. Preservation injury might also be a differential diagnostic consideration, but living donor grafts are usually not affected significantly. Biliary tract obstruction or stricturing alone is usually not accompanied by either portal tract connective tissue hemorrhage or centrilobular hepatocyte ischemic changes, or significant nodular regenerative hyperplasia.

Vascular complications

Hepatic artery thrombosis

Pathophysiology

Hepatic artery thrombosis (HAT) is the most frequent major vascular complication and usually occurs in 2–20% of transplants within 30 days of transplantation [63,64]. Because the hepatic artery supplies the extrahepatic and intrahepatic bile ducts, hilar and portal tract connective tissue, and hilar lymph nodes, these structures are preferentially damaged. The injury pattern is expressed in the generic phrase "ischemic cholangitis" [32,49] or "ischemic cholangiopathy" [50], which refers to ischemic damage to the biliary tree manifest as frank necrosis, poor wound/anastomotic healing, biliary leaks, and cholangitic abscesses, resulting in the biliary sludge syndrome [65].

Clinical presentation

Most early HAT manifests clinically as fever, leukocytosis, severe elevations in liver injury tests, and septic shock [63,64]. Late HAT can be asymptomatic or present insidiously with cholangitis, relapsing fevers, and sepsis related to hepatic infarcts, abscesses, ischemic cholangiopathy, and subsequent impaired bile flow

[63,64]. Ultrasonography can be used to screen hepatic arterial flow status, but angiography is the most reliable method of establishing the diagnosis with certainty.

Histopathologic findings

Hepatic artery thrombosis can be diagnosed on peripheral core needle biopsies, but not reliably because needle biopsies sample the subcapsular parenchyma, which is variably affected, leading to sampling issues [32,66]. Structures most commonly and reliably susceptible to ischemic injury, such as perihilar tissue and large bile ducts, are not routinely sampled.

Peripheral core needle biopsies can show centrilobular coagulative necrosis or marked centrilobular hepatocyte swelling and biliary tract complications, such as cholangiolar proliferation, acute cholangiolitis, and obstruction or stricturing. The biopsy might even be unremarkable, either because the patient has developed vascular collaterals or because biliary sludging secondary to hilar bile duct necrosis has not yet developed in the periphery. HAT can occasionally present as spotty acidophilic necrosis of hepatocytes or "ischemic hepatitis", mimicking acute viral hepatitis. Chronic suboptimal arterial flow can cause centrilobular hepatocellular atrophy and sinusoidal widening.

Failed allografts with HAT often show necrosis of hilar or perihilar bile ducts with bile leakage into surrounding connective tissue, biliary sludge, biliary abscesses seeded with fungi and bacteria, infarction of hepatic hilar lymph nodes, and patchy parenchymal infarction.

Differential diagnosis

As HAT or narrowing can mimic almost every liver allograft syndrome, a high index of suspicion should be maintained. Ischemic necrosis, often centrilobular, most reliably points toward HAT, but suboptimal flow can also result in centrilobular hepatocyte swelling, biliary tract obstruction and cholangitis. Chronic suboptimal arterial flow can cause biliary epithelial cell senescence changes that resemble chronic rejection. "Ischemic hepatitis" (spotty hepatocyte apoptosis) can be virtually indistinguishable from the lobular phase of acute viral hepatitis. The relationship between arterial thrombosis and biliary tract complications is so common that examination of hepatic arterial patency should be routinely considered when biliary tract complications are encountered.

Portal vein thrombosis

Pathophysiology

Portal vein complications are much less frequent than arterial complications and involve ~1–2% of recipients [67]. Long-surviving liver allografts with recurrent disease or cirrhosis are also are susceptible to portal vein thrombosis, as with any cirrhotic liver [67].

Clinical presentation

Portal vein thrombosis in a non-cirrhotic allograft can cause widespread necrosis and patients present with bleeding varices, fulminant hepatic failure, and portal hypertension with massive ascites and edema [67]. If obstruction is incomplete, small infarcts can develop or the liver can become seeded by intestinal bacteria resulting in relapsing fever.

Histopathologic findings

Complete portal venous obstruction early after transplantation often causes massive coagulative necrosis. Suboptimal portal vein flow because of strictures, kinks, or persistent collateral circulation can cause periportal or midzonal hepatocyte atrophy, coagulative necrosis, unexplained zonal or panlobular steatosis, nodular regenerative hyperplasia [68], or hepatic steatosis. Bacterial or fungal infection of a partial portal vein thrombus can result in miliary seeding of the liver with small abscesses.

Differential diagnosis

Suboptimal portal vein blood flow can be difficult to distinguish from suboptimal hepatic venous drainage. Linear zones of ischemic necrosis and hepatocellular atrophy favor the former, whereas red blood cell congestion within central veins and centrilobular sinusoids and obliterative central venopathy favors the latter. Ultrasonography and angiography are necessary to characterize the cause of the vascular abnormality. Cases of suboptimal portal vein flow presenting with intrahepatic steatosis need to be distinguished from recurrent or de novo steatosis or steatohepatitis.

Hepatic vein and vena caval complications

Complications involving the hepatic venous outflow are relatively uncommon. Significant stenosis or thrombosis of the outflow tract is mostly always associated with either significant clinical or histopathologic manifestations.

Clinical presentation

Severe stenosis or thrombosis presents as the Budd–Chiari syndrome including hepatic enlargement, tenderness, ascites, and edema; less severe stenosis might initially result only in histopathologic manifestations or an increase in portal vein–vena cava pressure gradient.

Histopathologic findings

Congestion and hemorrhage involving the hepatic venules and surrounding perivenular sinusoids are the most reliable histopathologic correlates of suboptimal venous drainage. Bland centrilobular hepatocyte necrosis and dropout are also usually present. Chronic changes can include nodular regenerative hyperplasia, perivenular fibrosis, and central vein occlusion, particularly if outflow obstruction is severe or of long duration, and venocentric cirrhosis. Chronic changes can also be accompanied by a prominent ductular reaction at the interface and perivenular areas, which can make it difficult to recognize architectural landmarks and to exclude biliary obstruction.

Differential diagnosis

If any of the above-mentioned changes are *not* accompanied by significant inflammation, a mechanical or outflow obstruction cause should be suspected. Conversely, if centrilobular changes are accompanied by significant lymphocytic, histiocytic or lymphoplasmacytic inflammation, an immunologically mediated cause of injury, such as acute or chronic rejection, autoimmune hepatitis (AIH), or drug-induced liver injury (less likely) should be suspected. However, perivenular inflammation can be transient in some cases of "immune-mediated" centrilobular injury and can present at a later stage when it is indistinguishable from mechanical causes of venous outflow obstruction [69]. Review of the clinical history and previous biopsies can help determine the underlying cause.

Bile duct complications

The biliary tree continues to be the "Achilles' heel" of liver transplantation with complications occurring in ~20% of recipients – an even higher incidence is observed in reduced-size allografts. The

distal-most portion of the extrahepatic donor bile duct is particularly vulnerable to ischemia and the peribiliary plexus vulnerable to both preservation–reperfusion injury and operative injury [70].

Strictures are the most common complication; they are categorized according to time after transplantation (early or late) and location (anastomotic, non-anastomotic, or intrahepatic) [71–75]. Intrahepatic strictures are further categorized into hilar or peripheral. Early (<1 year) non-anastomotic strictures are often associated with preservation-related injury [74,76] and usually occur in perihilar bile ducts. Late (>1 year) non-anastomotic strictures are usually peripheral and associated with immunologic risk factors, such as primary sclerosing cholangitis (PSC) as the original disease.

Histopathologic findings

Allograft biliary tract complications are histopathologically identical to those seen in native livers. Portal and periductal edema, predominantly neutrophilic portal inflammation, intraepithelial and intraluminal neutrophils within true bile ducts, an interface ductular reaction of varying severity, centrilobular hepatocanalicular cholestasis, and small clusters of neutrophils throughout the lobules are the typical findings of stricturing or obstructive cholangiopathy. Chronic biliary tract strictures, or intermittent obstruction, are often associated with mixed or predominantly chronic portal inflammation, biliary epithelial cell senescence changes, and low-grade ductopenia involving the small bile ducts. More than 1 year after transplantation, in addition to the classic features described above, biliary strictures are a relatively common cause of portal eosinophilia.

Biliary and vascular fistulas are recognized by red blood cells in lumens of bile ducts or bile concretions in blood vessels. Occasionally, inordinate elevations of serum bilirubin, beyond normal pathophysiologic ranges, can also be seen with a biliary-vascular fistula. In contrast, **periductal** hemorrhage surrounding small interlobular bile ducts is an inconsequential finding in asymptomatic patients when a biopsy is obtained within a day or so after transhepatic cholangiography [77].

Differential diagnosis

Within the first few weeks biliary obstruction or cholangitis can be difficult to distinguish from preservation–reperfusion injury and ACR, particularly if the patient was treated with increased IS before the biopsy was obtained.

Features that favor obstruction or stricturing over ACR early after transplantation include neutrophilic-predominant portal infiltrate, periductal edema, retention of the normal nuclear : cytoplasmic ratio and biliary epithelial cells, and an absence of perivenular mononuclear inflammation. Acute rejection is favored when mixed portal infiltrate comprised of blastic and small lymphocytes, plasma cells, and eosinophils; lymphocytic cholangitis, and increased nuclear : cytoplasmic ratio in biliary epithelial cells, and perivenular inflammation are seen. Portal eosinophilia in early acute rejection can be quite striking, especially in patients treated with steroid-sparing IS [78].

Late-onset and chronic biliary tract complications can occasionally present with predominantly mononuclear portal inflammation, and biliary epithelial senescence and low-grade ductopenia can develop [79]; they can also cause isolated portal eosinophilia, mimicking acute and chronic rejection, viral hepatitis, and recurrent disorders such as PSC.

Features that favor biliary strictures or recurrent PSC over chronic rejection include a history of biliary tract complications or PSC, periductal lamellar edema, stellate portal expansion, portal neutrophilia, a ductular reaction, and deposition of copper or copper-associated protein in periportal hepatocytes. Features that favor acute or chronic rejection include a previous history of rejection or inadequate IS, lymphoplasmacytic portal inflammation, small portal tracts, absence of a ductular reaction, and active central perivenulitis and perivenular fibrosis.

Additional findings in failed allografts can also be used to distinguish between biliary strictures or recurrent PSC and chronic rejection [80]. Chronically rejected livers are usually of normal or slightly increased weight, whereas those with obstructive cholangiopathy are usually significantly enlarged. In the hilar nodes, obstructive cholangiopathy usually causes bile-pigmented sinus histiocytosis, whereas chronically rejected nodes are usually atrophic or fibrotic. Perihilar arteries are either normal or show mild and focal eccentric fibrointimal hyperplasia, whereas foam cell arteriopathy and significant concentric fibrointimal hyperplasia are typical of chronic rejection. In obstructive cholangiopathy, extrahepatic and large intrahepatic ducts often show focal ulceration, periductal lymphoplasmacytic inflammation, fibrosis, whereas in chronic rejection ulceration is unusual. When the infiltrate in either a periphery needle biopsy or explant perihilar section of a large bile duct shows plasma cell-rich infiltrates, the possibility of recurrent or de novo IgG4 sclerosing disease should be considered [81].

Cholangitis favors a biliary tract complication whereas cholangiolitis and lobular disarray favor chronic hepatitis. The cholestatic liver injury tests profile favors obstructive cholangiopathy unless the patient has a cholestatic variant of viral hepatitis. Deposits of copper or copper-associated protein in periportal hepatocytes are not seen in chronic rejection alone.

Rejection

Antibody-mediated rejection

Crossing ABO blood group barriers in recipients with high titer isoagglutinins causes predictable and severe liver allograft injury [82] and is generally avoided in most North American programs because it leads to a high incidence (~60%) of significant AMR and graft failure [83]. ABO-incompatible liver allografts are still utilized in Asian programs where the donor pool is more limited. Plasmapheresis, vigorous anti-rejection, and microcirculatory protective therapy are needed to achieve reasonable results under these circumstances [84,85]. Even so, ABO-I recipients are still at risk for late complications such as ischemic cholangitis [83,86].

Clinical presentation

The most dramatic form of AMR has largely been eliminated by avoiding ABO-I transplants without pretreatment [84,85]. When it does occur, hyperacute rejection begins immediately after reperfusion and evolves over a period of hours to days, rather than minutes to hours, as in other allograft types [83]. Initial signs of dysfunction usually develop in the operating room after complete revascularization recognized by uneven reperfusion, swelling, dusky appearance, and cessation of bile flow in a liver that initially produced bile. These signs are often accompanied by coagulopathy [82]. Precipitous allograft failure is distinctly unusual.

A more common presentation is an increase or persistent elevation of serum bilirubin and ALT/AST during the first few days to weeks. This is often accompanied by persistence of the positive cross-match and/or donor-specific antibody (DSA), unexplained and often refractory thrombocytopenia, and low serum

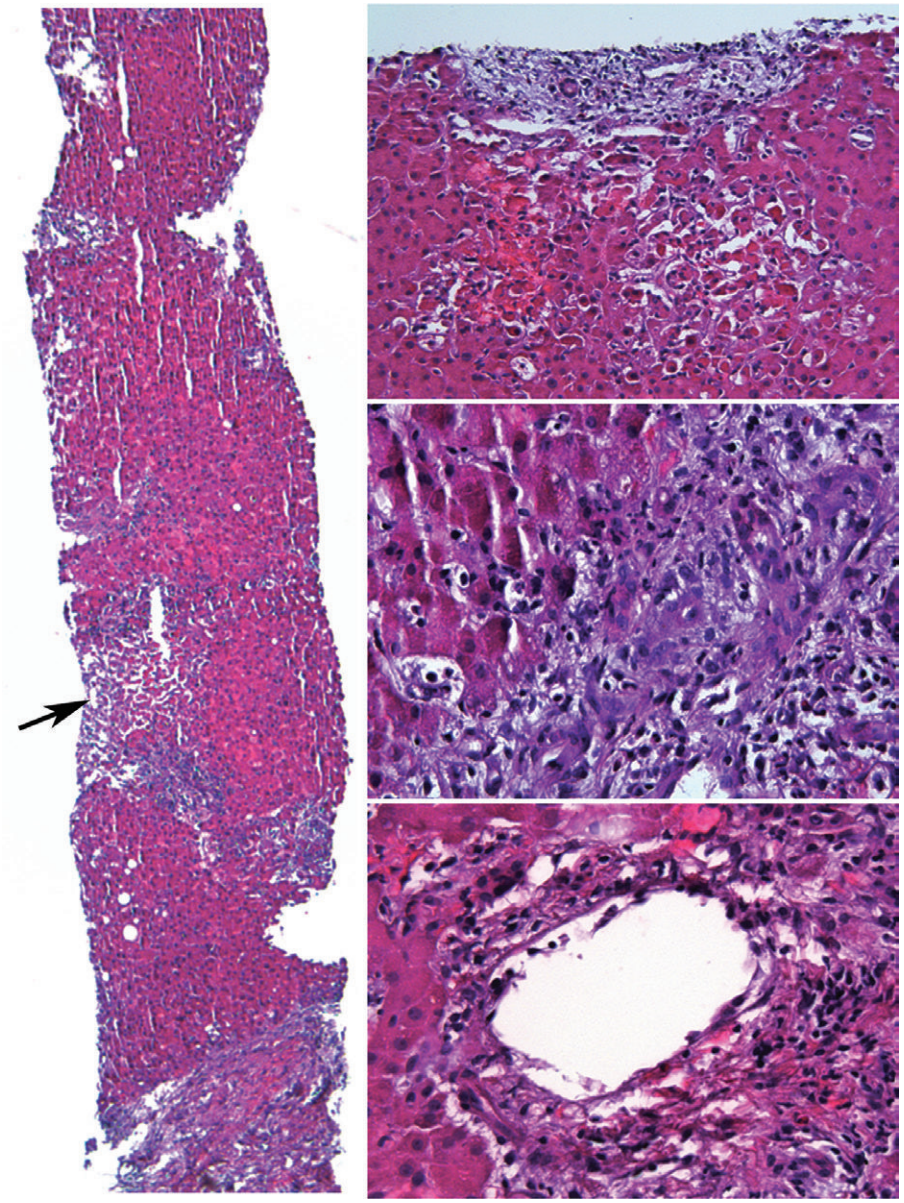

Figure 82.1. Acute antibody-mediated rejection (AMR). This biopsy was obtained from an ABO incompatible liver allograft 8 days after transplantation. The biopsy showed patchy areas of coagulative necrosis (arrow), which is illustrated at higher magnification in the right upper inset. Note also the mild mixed portal inflammation with neutrophils (right middle inset) and marked endothelial/hypertrophy reactivity of the terminal venule (right lower inset). AMR of an ABO-incompatible liver allograft tend to cause substantially more damage than lymphocytotoxic antibodies.

complement [30,87,88]. In severe cases, hepatic angiograms show segmental narrowing indicative of arterial vasospasm [83].

Histopathologic findings

Histopathologic manifestations of AMR are variable, with isoagglutinins usually causing more injury than anti-HLA or lymphocytotoxic antibodies (Figures 82.1 and 82.2).

High titer isoagglutinins (>1:64) [82,89,90] often cause prominent red blood cell and focal neutrophil sludging in the sinusoids, platelet-fibrin thrombi in periportal sinusoids, portal and central veins. Acidophilic hepatocyte necrosis can be seen within 2–6 hours after reperfusion in untreated recipients. This is often quickly followed portal or periportal edema, necrosis, focal hemorrhage, and C4d deposits in portal stroma [89] and diffuse endothelial C4d deposits in portal veins, capillaries, and sinusoids [35,89]. Confluent coagulative necrosis, prominent sinusoidal and venous congestion, and edema and hemorrhage into the portal tract connective tissue begin to appear within 1–5 days in peripheral core needle biopsies (Figure 82.1) [35,82,89]. Portal veins often show fibrin deposition. Medium-sized arteries are not often sampled in needle biopsies, but when present frequently show endothelial cell hypertrophy and evidence of arterial vasospasm, such as mural myocyte vacuolization, wrinkling of the elastic lamina, and thickening of the wall with narrowing of the lumen. Neutrophilic and necrotizing arteritis is only occasionally observed. Portal neutrophilia, cholangiolar proliferation, and

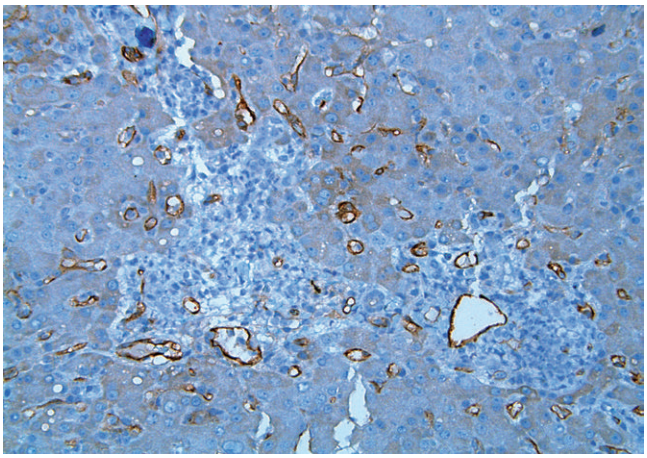

Figure 82.2. C4d staining of the same biopsy as illustrated in Figure 82.1. Note the strong C4d staining in the capillaries and venules of the portal tract as well as in the sinusoidal endothelium. C4d staining can be used to detect complement deposition in formalin-fixed paraffin-embedded tissue samples.

small areas of confluent hepatic necrosis usually begin to appear at 2–3 days. If untreated, progressive hemorrhagic infarction can occur in ABO-incompatible organs over a relatively short period of time (1–2 weeks).

ABO-I allografts that fail because of AMR are often grossly enlarged, cyanotic, and mottled with areas of geographic necrosis. Capsular ruptures, hepatic artery or portal vein thrombosis can be seen in extreme cases. Changes in the hilum–perihilar region can be particularly helpful in establishing a diagnosis of AMR. Included are congestion and leukocyte margination in the peribiliary vascular plexus, partially organized thrombi in arterial branches, focal mural necrosis of large septal bile ducts, and inflammatory and/or necrotizing arteritis. Late sequela of AMR include biliary sludge and stricturing with obstructive cholangiopathy, and obliterative arteriopathy and loss of small bile ducts, or chronic rejection [82,84,86,91,92].

Reperfusion biopsies from patients with high titer (>1:32) lymphocytotoxic antibodies show platelet aggregates in the portal or central veins more often than cross-match negative controls [2,87]. Spotty acidophilic necrosis of hepatocytes and centrilobular hepatocellular swelling, accompanied by cholangiolar proliferation and hepatocanalicular cholestasis, often appear during the first week after transplantation in those with high titer. Inflammatory or necrotizing arteritis is rarely present, but nearly diagnostic when found. The histopathologic changes closely resemble those seen in preservation–reperfusion injury. Clinicopathologic correlation with exclusion of other causes of dysfunction and staining for C4d and other immune deposits is needed to confirm the diagnosis (Figure 82.2) [29,30,35,93].

An AMR diagnosis in liver allograft should be based on all of the following:

1 Careful biopsy review showing changes consistent with a pattern of AMR injury;
2 Clinicopathologic correlation with exclusion of other insults;
3 Serologic evidence of DSA; and
4 Evidence of strong and diffuse antibody and/or complement (C4d) deposition within the injured allograft [35,82,87].

The latter is defined as strong portal vein and capillary and usually periportal sinusoidal endothelial staining involving the majority of portal tracts.

Compared with other allografts, however, a diagnosis of isolated liver allograft AMR because of anti-HLA antibodies is difficult to establish with certainty. Difficulties are encountered in establishing the diagnosis because:

1 Liver allografts are large, able to absorb high antibody loads, especially anti-class I HLA [94], and are resistant to AMR-related damage [3,83,87,95,96];
2 Immune deposits pointing toward an underlying injury cause are: (a) ephemeral [82,87]; (b) can be associated with other insults (see below); and (c) are more easily detected in frozen sections [97]; and
3 Clinicopathologic similarities exist between AMR and preservation injury, sepsis, and biliary or vascular complications [82,87].

Intrahepatic immune deposits are ephemeral in AMR, even when using the more sensitive technique of immunofluorescence on frozen tissue [30,82,87]. In severe cases, selective deposits of IgG, and/or IgM, C3, and C4 are usually detectable diffusely along the sinusoids and in perihilar arteries, portal veins, and peribiliary plexus [30,82,87]. Thereafter, immune deposits become patchy in distribution and may be difficult to distinguish from background staining unless antibody titers are quite high. Regardless, if AMR is suspected, saving frozen tissue for immunofluorescence testing can facilitate the diagnosis.

Interpretation and practical utility of C4d staining in liver allografts is more challenging than in kidney allografts [89,98–105]. This literature was recently reviewed by Bellamy [29]. Normal livers and liver allograft biopsies are usually C4d$^-$. Portal venous, arterial, and portal capillary and sinusoidal endothelial C4d has been detected in cross-match (XM) positive (XM+) recipients more often than XM negative (XM−) controls [103] and in those who developed isolated AMR [97,105]. Endothelial cell C4d staining might be most specific for AMR, but "portal C4d stromal" staining has also been described in ABO-incompatible AMR [89], ACR [103], and chronic rejection [93,106].

As in other allografts, C4d deposits are also often accompanied by ACR [35,89,93,98–105] and in some studies are directly proportional to the Banff grade [89,98–105]. Necrotic and steatotic hepatocytes can show non-specific C4d staining.

Portal vein and capillary C4d deposits can also be detected in other circumstances, including biliary obstruction [98], recurrent HBV infection [99], recurrent HCV infection [101], and de novo AIH [107]. C4d staining has also been described in portal venous and capillary, sinusoidal, central vein, and arterial endothelial cells, in lymphoid nodules, and in periductal and portal stromal cells in *native* pediatric livers with HBV, HCV, AIH, and overlap syndromes between AIH and PSC [108]. Endothelial C4d deposits in non-rejection-related allograft disorders are reportedly less widespread than in severe ACR or AMR. Similar to kidney and heart allografts, liver C4d deposits have also been associated with macrophage and plasma cell infiltrates [100].

Differential diagnosis

AMR should be suspected in a female liver allograft recipient with high titer, DSA, or lymphocytotoxic antibodies, who received a liver with a short cold ischemic time, but shows persistence of the antibodies after transplantation and develops graft dysfunction, refractory and otherwise unexplained thrombocytopenia, and

circulating low complement levels within the first few weeks after transplantation [30,35,87,88].

AMR should be favored over preservation–reperfusion injury when the following histopathologic findings are detected: (1) neutrophils, macrophages, and, to a lesser extent, lymphocytes, marginating on the luminal aspect and beneath the portal and central veins, along with marked and diffuse endothelial cell hypertrophy/reactivity; (2) edema, eosinophilia and microvasculitis, and (3) diffuse C4d staining in the microvasculature [35]. Portal or periportal edema, necrosis, and hemorrhage should raise the possibility of ABO incompatibility.

Precipitous allograft failure from severe AMR is currently rare, except in ABO-I livers. When it does occur, however, it can be difficult to distinguish from hemorrhagic liver necrosis caused by hypotension and poor perfusion, sepsis, or vascular thrombosis. Unless unequivocal evidence of AMR is detected, such as inflammatory or necrotizing arteritis and/or diffuse immunoglobulin and complement and C4d deposition combined with serologic evidence of antidonor antibodies, the cause of allograft failure can be extremely difficult to determine with certainty. More commonly changes diagnostic of AMR are not present and the diagnosis requires a thorough clinicopathologic correlation.

Acute (cellular or T cell-mediated) rejection

Acute (cellular) rejection is defined as "inflammation of the allograft, elicited by a genetic disparity between the donor and recipient, primarily affecting interlobular bile ducts and vascular endothelia, including portal and hepatic veins and occasionally the hepatic artery and its branches" [109]. Early acute rejection episodes rarely lead to allograft failure or permanent damage [39,110], whereas episodes occurring late after transplantation more often produce permanent allograft damage, possibly because there is a delay in treatment [111–114].

Clinical presentation

ACR usually presents clinically between 5 and 30 days after transplantation. Currently, ACR affects about 30% of liver transplant recipients [111]. Earlier presentations can be seen in presensitized patients or in those who receive less than optimal baseline IS. Later presentations can be seen in recipients treated with lymphocyte-depleting antibodies or in those with inadequate maintenance IS. Clinical findings are often absent early when tissue damage is mild. Later or with severe acute rejection, fever and allograft enlargement, cyanosis, and tenderness can occur. Early after transplantation when biliary T-tubes are in place, decreased bile flow and thin and pale bile are commonly seen. Ascites can occasionally develop because of increased intrahepatic hydrostatic pressure [115].

Histopathologic findings and grading

ACR is characterized by the following:

1 Predominantly mononuclear but mixed portal inflammation containing blastic or activated lymphocytes, neutrophils, and eosinophils;
2 Subendothelial inflammation of portal and/or terminal hepatic venules; and
3 Bile duct inflammation and damage [115,116].

Minimal diagnostic criteria needed to establish the diagnosis of acute rejection include at least two of the above histopathologic findings. The diagnosis is strengthened if greater than 50% of the ducts or terminal hepatic veins are damaged or if unequivocal endotheliitis of portal or terminal hepatic vein branches can be identified. Histopathologic evidence of severe injury, which is used for histopathologic grading, includes perivenular inflammation, centrilobular necrosis, arteritis, and inflammatory, usually central-to-central, bridging inflammation and necrosis [110,115].

Acute "rejection-type" infiltrates, described above, are encountered mostly in portal tracts (Figures 82.3 and 82.4) and occasionally

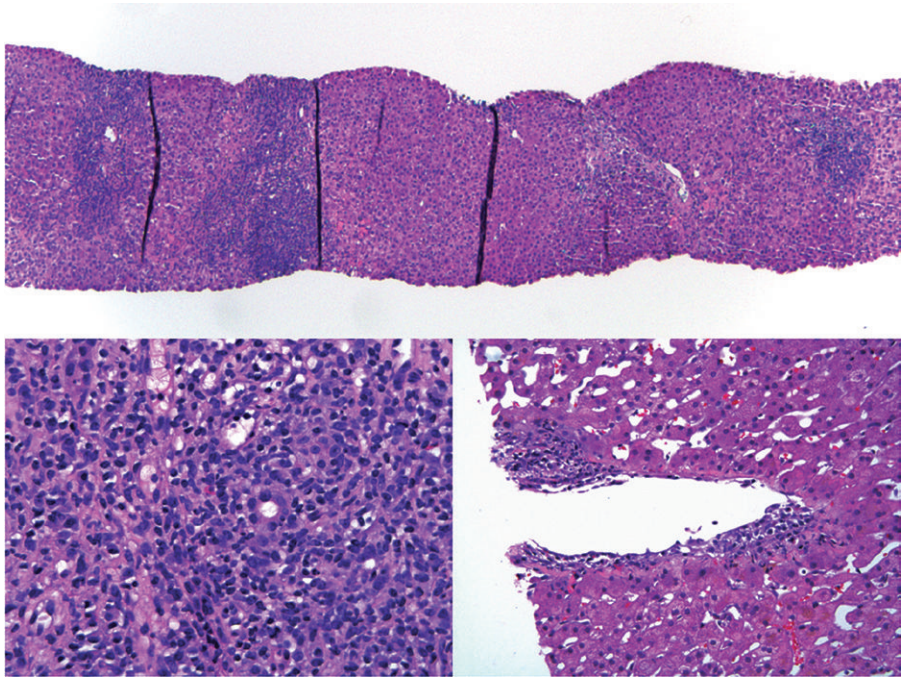

Figure 82.3. This biopsy shows histopathologic features of moderate acute T cell-mediated (cellular) rejection. As shown in this photomicrograph, most of the portal tracts show intense "rejection-type" portal infiltrate with bile duct inflammation and damage (left inset). The right inset illustrates classic "endothelialitiis," or infiltration of inflammatory cells into the subendothelial space.

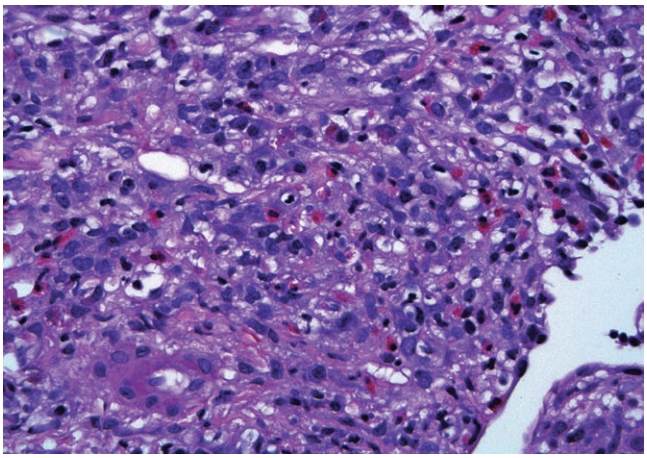

Figure 82.4. This photomicrograph illustrates the pleomorphic, typical, "rejection-type" infiltrate comprised of blastic and small lymphocytes eosinophils and neutrophils. This biopsy is the same biopsy as illustrated in Figure 82.3.

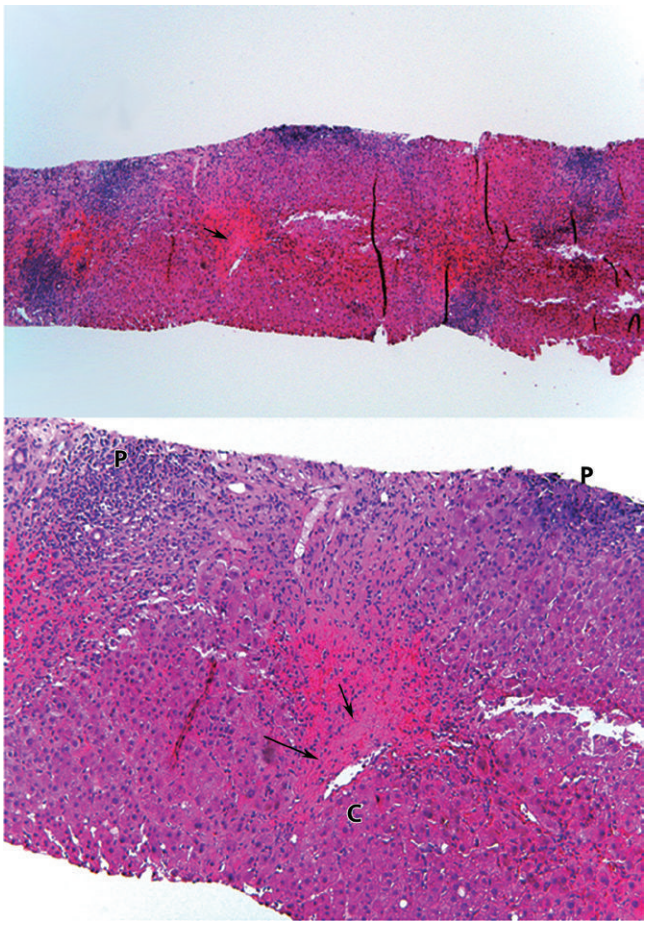

Figure 82.5. This example of severe acute T cell-mediated (cellular) rejection shows noticeable expansion of all of the portal tracts by a significant "rejection-type" infiltrate. There is also prominent central perivenulitis with widespread perivenular hepatocyte necrosis and dropout (arrows), which is also illustrated at higher magnification (bottom) (P, portal tract; C, central vein).

also around central veins. "Endotheliitis" or "endothelialitis" refers to lymphocytes underneath the portal and central vein endothelium (Figure 82.3). This characteristic feature of acute rejection can also occur with other causes of allograft dysfunction [117]. Immunophenotypic analysis of acute rejection infiltrates usually shows a predominance of T lymphocytes, as expected, and $CD8^+$ cells often surround and invade damaged bile ducts [118,119]. B cells usually comprise a minor fraction of the infiltrates. Macrophages and other leukocytes are also present and can predominate in severe acute rejection [118–120]. Routine immunophenotypic analysis of graft infiltrating lymphocytes is not useful for establishing the diagnosis of acute rejection, except when attempting to distinguish acute rejection (T-cell predominant) from a post-transplant lymphoproliferative disorder (B-cell predominant; see also Differential diagnosis).

Lymphocytic cholangitis involving small bile ducts (<30 μm diameter) is an important diagnostic feature. Lymphocytes are found inside the ductal basement membrane in association with evidence of biliary epithelial cell injury and response to injury. Included are paranuclear vacuolization, apoptotic bodies, and increased nuclear:cytoplasmic ratio, mitoses, and nucleoli. Cytoplasmic eosinophilia and multinucleation usually signal senescence-related changes and chronic injury [79]. Breaks in the basement membrane signify severe bile duct damage. Portal and peribiliary granulomas are not features of either acute or chronic rejection.

Inflammatory or necrotizing arteritis is a defining feature of severe acute rejection, but is rarely detected in needle biopsies and is poorly reproducible [121] and therefore is not generally included in grading schema. The interface zone is usually relatively unremarkable in typical early mild and moderate ACR. In severe acute rejection, portal inflammatory infiltrates spill over into the periportal sinusoids [113].

Rejection-type inflammation can also be seen in the connective tissue and perivenular sinusoids surrounding terminal hepatic venules – "central perivenulitis" [113], in up to 30% of acute rejection episodes. It is more frequent late (>100 days) after transplantation. Severe ACR is diagnosed only when typical portal changes of acute rejection are accompanied by perivenular inflammation with zonal centrilobular congestion, hemorrhage, and hepatocyte necrosis and dropout (Figure 82.5).

The Banff classification for acute and chronic rejection was constructed on data generated by recognized experts in liver transplant pathology, hepatology, and surgery from many of the major hepatic transplant centers in North America, Europe, and Asia (Tables 82.2 and 82.3) [116]. It is widely utilized [122], simple and easy to apply, reproducible [123], scientifically correct, and shown to have prognostic significance in prospective [110] and retrospective [124] studies.

The Banff classification includes descriptive grades of indeterminate, mild, moderate, and severe (Table 82.2), and a semiquantitative rejection activity index (RAI) (Table 82.3) [116]: a remnant of the European grading system [125] and conceptual equivalent of the hepatitis activity index [126]. RAI semiquantitatively scores the prevalence and severity of three separate histopathologic features on a scale of 0–3: portal inflammation, bile duct damage, and subendothelial inflammation. The individual components are then added together for a total RAI score.

There is a direct correlation between the total RAI score and descriptive rejection grade and an increased risk of persistent or

Table 82.2. Banff grading of acute liver allograft rejection (data from [261])

Global assessment	Criteria
Indeterminate	Portal rejection-type (see text) inflammatory infiltrate that fails to meet the criteria for the diagnosis of acute reject (see text)
Mild	Rejection infiltrate in a minority of the triads, that is generally mild, and confined within the portal spaces
Moderate	Rejection infiltrate, expanding most or all of the triads
Severe	As above for moderate, with spillover into periportal areas and moderate to severe perivenular inflammation that extends into the hepatic parenchyma and is associated with perivenular hepatocyte necrosis

NOTE: Global assessment of rejection grade is made on review of the entire biopsy, and only after the diagnosis of rejection has been established. It is inappropriate to provide a "rejection grade" when the diagnosis of rejection is uncertain.

Table 82.3. Acute rejection activity index (RAI) (data from [261])

Category	Criteria	Score
Portal inflammation	Mostly lymphocytic inflammation involving, but not noticeably expanding, a minority of the triads	1
	Expansion of most or all of the triads, by a mixed infiltrate containing lymphocytes with occasional blasts, neutrophils, and eosinophils	2
	Marked expansion of most or all of the triads by a mixed infiltrate containing numerous blasts and eosinophils with inflammatory spillover into the periportal parenchyma	3
Bile duct inflammation damage	A minority of the ducts are cuffed and infiltrated by inflammatory cells and show only mild reactive changes such as increased nuclear:cytoplasmic ratio of the epithelial cells	1
	Most or all of the ducts infiltrated by inflammatory cells. More than an occasional duct shows degenerative changes such as nuclear pleomorphism, disordered polarity, and cytoplasmic vacuolization of the epithelium	2
	As above for 2, with most or all of the ducts showing degenerative changes or focal luminal disruption	3
Venous endothelial inflammation	Subendothelial lymphocytic infiltration involving some, but not the majority of the portal and/or hepatic venules	1
	Subendothelial infiltration involving most or all of the portal and/or hepatic venules	2
	As above for 2, with moderate or severe perivenular inflammation that extends into the perivenular parenchyma and is associated with perivenular hepatocyte necrosis	3

Note: Total RAI score = sum of all component scores for portal inflammation, bile duct inflammation/damage, and venous endothelial inflammation.

recurrent acute rejection, chronic rejection, and graft failure [110]. The usual ranges of RAI scores are indeterminate (1–2), mild (3–4), moderate (5–6), and severe acute rejection (>6). The maximum possible total RAI score is 9, but biopsies rarely achieve this score [110]. Instead, most episodes are mild, have a total RAI <6, respond to increased IS, and do not lead to significant fibrosis, bile duct loss, or arteriopathy in subsequent or follow-up biopsies [110].

Additional IS given before a biopsy specimen is obtained can make histopathologic interpretation more difficult because resolution of some characteristic findings, such as subendothelial infiltration of veins, can occur within 24 h. Treatment before biopsy can also contribute to centrilobular hepatocyte swelling and hepatocanalicular cholestasis, causing further confusion. In general, 7–10 days are usually required for rejection-related changes to completely resolve after therapy.

Box 82.1. Banff descriptive grading of rejection presenting primarily in perivenular regions

Descriptor	Findings
Minimal/indeterminate	Perivenular inflammation involving a minority of terminal hepatic veins with patchy perivenular hepatocyte loss without confluent perivenular necrosis
Mild	As above, but involving the majority of terminal hepatic veins
Moderate	As above, with at least focal confluent perivenular hepatocyte dropout and mild moderate inflammation, but without bridging necrosis
Severe	As above, with confluent perivenular hepatocyte dropout and inflammation involving a majority of hepatic venules with central-to-central bridging necrosis

Late acute rejection (>100 days) shares many features of early acute rejection. However, slightly atypical features can also be seen (reviewed in [113]): fewer blastic lymphocytes, more necro-inflammatory type interface activity, less venous subendothelial inflammation, a higher incidence of perivenular inflammation, and slightly more lobular activity, which cause these biopsies to more closely resemble chronic hepatitis (reviewed in [113]).

Late acute rejection can also present as exclusively or predominantly perivenular inflammation and hepatocyte dropout with minimal or no portal tract changes (isolated central perivenulitis) [127–129]. These cases can later evolve into typical chronic rejection with ductopenia and perivenular fibrosis. In such cases, subendothelial inflammation of portal or central veins is not a required finding. Perivenular fibrosis and a Budd–Chiari or a veno-occlusive-like clinical syndrome can develop as a consequence of the severe perivenular injury [69,130]. The Banff Working Group proposed the descriptors in Box 82.1 for grading this reaction 8 [113]:

"Minimal" and "mild" cases, as described in Box 82.1, may resolve spontaneously [129]. More severe perivenular changes probably warrant more aggressive treatment, but no prospective studies on the effect of therapy have been carried out.

Differential diagnosis

ACR should be distinguished from preservation injury and obstructive cholangiopathy and cholangitis during the first several months after transplantation, discussed earlier.

Distinguishing acute rejection from recurrent HBV, HCV, and AIH can be especially difficult. The distinction can be achieved by closely examining the severity and prevalence of the bile duct damage, interface activity, lobular changes, and perivenular inflammation and hepatocyte dropout [131]. Features that favor ACR include inflammatory bile duct damage and perivenular inflammation involving the majority of the ducts and central veins, respectively; and low-grade or absent lobular and interface necro-inflammatory activity. Conversely, recurrent or new-onset viral or AIH is favored when the interface and lobular necro-inflammatory activity predominate over bile duct damage and perivenular changes.

Allograft AIH (reviewed in [132]) resembles viral hepatitis in most respects, except AIH more often shows conspicuous plasma cells as a component of the infiltrate and more commonly shows aggressive interface activity. Some allograft recipients with AIH also show prominent plasma cell-rich central perivenulitis involving the

majority of central veins, as with AIH in native livers. In such cases, severe interface activity, plasma cell predominance in the infiltrate, and relatively mild bile duct damage favor AIH over acute rejection.

Chronic rejection

Chronic rejection (CR) has been defined as immunologic injury that usually evolves from severe or persistent acute rejection and results in potentially irreversible damage to bile ducts, arteries, and veins (reviewed in [133]). "Chronic" implies a time parameter, but none is strictly intended [115] because it often occurs within several months and allograft failure can occur within the first year after transplantation (reviewed in [133]). Classically defined CR currently affects about 3–5% liver allograft recipients by 5 years after transplantation, which is a dramatic decrease from 15–20% in the 1980s [133]. CR does not appear to increase with time after transplantation, unless one includes idiopathic post-transplant hepatitis (IPTH) in this category.

However, CR still occurs and can be an important cause of late liver allograft dysfunction and failure, particularly if one includes patients with IPTH. CR is seen mostly in non-compliant patients, HCV-positive recipients treated with drugs such as α-interferon [134,135], and recipients who have IS lowered because of side-effects [136].

Clinical presentation

CR usually occurs in patients with a history of significant acute rejection, who develop progressive cholestasis and an increase in canalicular enzymes unresponsive to anti-rejection treatment [115]. Standard liver injury tests usually show preferential elevation of γ-GTP and alkaline phosphatase [115,137,138]. Persistent elevation of ALT and total bilirubin usually mark transition from acute to chronic rejection and can presage allograft failure [127,136,139]. Clinical symptoms, if present, resemble those of acute rejection until dysfunction becomes significant enough to cause jaundice. Biliary sludging, biliary strictures, hepatic infarcts, and loss of hepatic synthetic function, clinically manifest as coagulopathy and malnutrition, are other late findings that may presage allograft failure [115]. Hepatic angiograms often shows pruning of the intrahepatic arteries with poor peripheral filling and segmental narrowing [115,140].

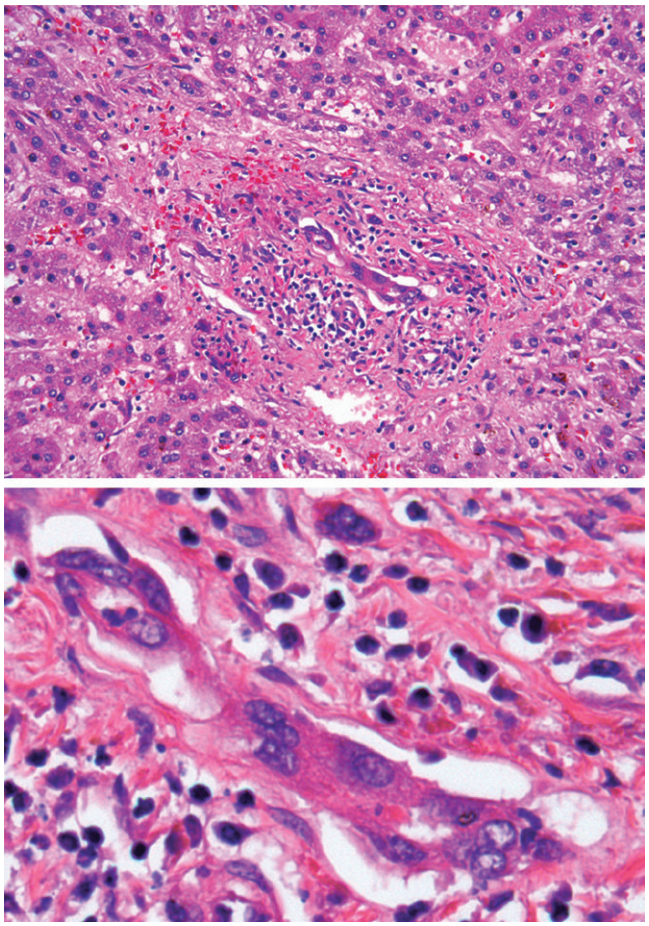

Figure 82.6. Early chronic rejection is characterized by duct damage with biliary epithelial senescence changes involving the majority of bile ducts. If mononuclear portal inflammation is present, it is usually concentrated around the small ducts as seen in this biopsy. If duct loss is present, it involves less than 50% of the portal tracts. The biliary epithelial senescence changes, which are illustrated at higher magnification (bottom), include eosinophilic transformation of the cytoplasm, an increased nuclear : cytoplasmic ratio, and uneven nuclear spacing.

Histopathologic findings and staging

Chronic rejection primarily affects portal tracts and perivenular regions and is divided into "early" (Figure 82.6) and "late" stages by the Banff classification (Table 82.4) [133]. Early CR is characterized by mild portal inflammation with lymphocytic cholangitis, biliary epithelial cell senescence changes involving a majority of small bile ducts, and variable small duct loss usually involving <50% of portal tracts (Figure 82.6). Compared with acute rejection, chronic rejection usually has less inflammation, fewer eosinophils, and an inflammatory infiltrate comprised primarily of lymphocytes, plasma cells, and mast cells [141].

Recognition of biliary epithelial cell senescence changes is critical to the diagnosis of early chronic rejection [79]: nuclear enlargement, hyperchromasia, and uneven spacing resembling cytologic dysplasia; syncytia formation; eosinophilic transformation of the cytoplasm; and bile ducts only partially lined by biliary epithelial cells (Figure 82.6). Immunohistochemical markers of senescence, such as p16 [142], $p21^{WAF1/Cip1}$, without co-existent Ki-67 expression, become up-regulated [79]. Down-regulation of epithelial junctional proteins combined with up-regulation of mesenchymal proteins can also occur, perhaps in response to injury [143]). Late stage chronic rejection is characterized by bile duct loss involving >50% of portal tracts; arteriolar loss can also be seen.

Crawford et al. [144] defined a portal tract as "a focus within the parenchyma containing connective tissue (by Masson's trichrome stain) and at least two luminal structures embedded in the connective tissue mesenchyme, each with a continuous connective tissue circumference." In normal livers, bile ducts and hepatic artery branches are detectable in 93 ± 6% and 91 ± 7% of portal tracts, respectively [144]. Lower figures were cited by others using larger tissue samples [145]. Using 2 standard deviations from the normal as a cutoff, bile duct loss is considered present when <80% of portal tracts contain bile ducts; arterial loss is considered present when <77% of the portal tracts contain hepatic artery branches. A similar approach has recently been advocated using the concept of bile duct–artery parallelism: ductopenia was defined by at least one unpaired artery in >10% of all portal tracts or two unpaired arteries in different portal tracts [146]. Unpaired arteries were defined as

Table 82.4. Features of early and late chronic liver allograft rejection (Reproduced from [133] with permission from John Wiley and Sons. Copyright © 2000 American Association for the Study of Liver Diseases)

Structure	Early chronic rejection	Late chronic rejection
Small bile ducts (<60 μm)	Bile duct loss in <50% of portal tracts Degenerative change involving a majority of ducts: eosinophilic transformation of the cytoplasm; nuclear hyperchromasia; uneven nuclear spacing; ducts only partially lined by biliary epithelial cells	Loss in ≥50% of portal tracts Degenerative changes in remaining bile ducts
Terminal hepatic venules and zone 3 hepatocytes	Intimal/luminal inflammation Lytic zone 3 necrosis and inflammation Mild perivenular fibrosis	Focal obliteration Variable inflammation Severe perivenular fibrosis, defined as central-to-central bridging fibrosis
Portal tract hepatic arterioles	Occasional loss involving <25% of portal tracts	Loss involving >25% of portal tracts
Other	So-called "transitional"* hepatitis with spotty necrosis of hepatocytes	Sinusoidal foam cell accumulation; marked cholestasis
Large perihilar hepatic artery branches	Intimal inflammation, focal foam cell deposition without luminal compromise	Luminal narrowing by subintimal foam cells Fibrointimal proliferation
Large perihilar bile ducts	Inflammation damage and focal foam cell deposition	Mural fibrosis

* "Transitional" hepatitis. Mild lobular disarray and spotty acidophilic necrosis of hepatocytes that can occur during evolution or transition from early to late stages of chronic rejection [151].

arteries without an accompanying bile duct within a radius of 10 hepatic artery diameters from the edge of the artery.

However, late chronic rejection can cause both bile duct and arterial loss [145,147], which can present difficulties when trying to apply these algorithms. Portal tract recognition should be based primarily on the location of the putative structure – cholestasis in chronic rejection is centrilobular.

A ductular reaction at the interface zone is unusual in chronic rejection, unless the liver is recovering from chronic rejection [139,148,149]. Cytokeratins 19 and 7 can be used to help substantiate bile duct loss and, with the latter stain, detect ductular metaplasia of periportal hepatocytes [31]. When a ductular reaction is easily noticeable by routine light microscopy, however, it signals either regrowth of bile ducts [139,148,149] or an underlying biliary stricture. The latter can be substantiated by periportal hepatocyte copper deposits, which are not seen in chronic rejection.

Early chronic rejection in terminal hepatic venules and surrounding perivenular parenchyma is characterized by subendothelial and/or perivenular mononuclear inflammation (Figure 82.6). The perivenular infiltrate usually consists of lymphocytes, pigment-laden macrophages, and plasma cells [133,150], often accompanied by perivenular hepatocyte dropout and mild perivenular fibrosis [133]. Spotty acidophilic hepatocytes, or "transitional hepatitis," can be seen during evolution from early to late chronic rejection [151].

Perivenular changes in late chronic rejection are characterized by severe (bridging) perivenular fibrosis with at least focal central-to-central or central-to-portal bridging and occasional obliteration of terminal hepatic venules [133]. Well-developed cirrhosis, primarily attributable to chronic rejection, is unusual until the very late stages when venous obliteration leads to areas of parenchymal extinction and venocentric cirrhosis [152]. True "regenerative" nodules are uncommon. Perhaps this is because a combination of venopathy and obliterative arteriopathy blunts any regenerative response [153]. Perivenular hepatocyte ballooning and dropout, centrilobular hepatocanalicular cholestasis, nodular regenerative hyperplasia changes, and intrasinusoidal foam cell clusters are other common findings in late chronic rejection.

A final diagnosis of classic chronic rejection should be based on a combination of the clinical, radiologic, laboratory, and histopathologic findings. In a biopsy specimen, minimal diagnostic criteria for chronic rejection are the following:

1 Senescent changes, affecting the majority of the bile ducts, with or without bile duct loss;
2 Convincing foam cell obliterative arteriopathy; or
3 Bile duct loss affecting greater than 50% of the portal tracts [94].

A diagnosis of chronic rejection is much easier to establish in an explanted **failed allograft** because characteristic diagnostic findings can be directly observed in the first, second, and third-order branches of the hepatic arterial tree in and around the liver hilum. Obliterative arteriopathy is usually seen in at least some perihilar arteries, except in cases characterized by duct loss or perivenular fibrosis alone. Accumulation of foamy macrophages usually first occurs in the intima, which triggers proliferation of intimal, and migration of medial donor-derived myofibroblasts. This eventually causes intimal thickening/luminal narrowing and medial thinning as arteries attempt to dilate and compensate for reduced arterial flow. Eventually, however, even compensatory mechanisms fail and the entire wall can be completely replaced by foam cells or the artery can undergo thrombosis causing necrosis of large bile ducts and ischemic cholangiopathy.

Foamy macrophages can also be seen around bile ducts and veins in the connective tissue. Large perihilar bile ducts can show focal sloughing of epithelium, papillary hyperplasia, mural fibrosis, and acute and chronic inflammation.

Staging of CR assumes that the diagnosis has already been correctly established [133]. **Early CR** implies that a significant potential for recovery exists if the source or cause of immunologic can be controlled or reversed. **Late CR** implies that the potential for recovery is limited and retransplantation should be considered, if otherwise clinically indicated. It is not well established that all patients proceed sequentially in an orderly fashion from early to late CR. Some patients appear to persist in the acute or early stage for months or years, while others rapidly develop severe fibrosis and late changes within the first year after transplantation or within weeks or months after the first onset. Some show predominantly or exclusively either bile duct loss or arteriopathy alone, but usually both features occur together [133].

The important practical implication of CR staging is that the biopsy findings do not absolutely define a point of no return. Instead they provide information about the likelihood of reversal, which should be correlated with other clinical and laboratory parameters, such as persistently elevated serum bilirubin

>20 mg/dL, progressive decline in synthetic function, superimposed hepatic artery thrombosis, and bile duct necrosis or biliary sludging.

Differential diagnosis

In needle biopsy specimens, a CR diagnosis is primarily based on damage and loss of small bile ducts and perivenular fibrosis. Arteries with pathognomonic changes are rarely present in needle biopsy specimens [133]. Duct injury and ductopenia can also occur because of non-rejection-related complications, such as obstructive cholangiopathy, hepatic artery stricturing or thrombosis, "cholangitic" drug-induced liver injury, and cytomegalovirus (CMV) infection. Perivenular fibrosis can also be caused by suboptimal hepatic venous drainage and other causes of perivenular injury. Therefore, a diagnosis of CR based on biliary epithelial senescence or loss or perivenular fibrosis alone should first exclude other non-rejection-related causes of ductal injury and loss or perivenular fibrosis.

CR can be very difficult to distinguish from biliary tract obstruction or stricturing, including recurrent PSC [80]. Features that favor obstructive cholangiopathy include the following:

1 Bile duct loss in some portal tracts accompanied by a ductular reaction in others;
2 Neutrophil clusters within lobules;
3 Bile infarcts;
4 Deposition of copper or copper-associated protein in periportal hepatocytes; and
5 Hepatocanalicular cholestasis out of proportion to the prevalence of ductopenia (<50%).

Features that favor CR include: (1) bile duct changes combined with central perivenulitis and/or fibrosis; and (2) absence of changes typical of recurrent PSC (described earlier). Cholangiography and/or angiography may be required in some case to distinguish between CR and biliary obstruction. Such studies usually show "pruning" and poor peripheral filling in CR.

Isolated ductopenia involving less than 50% of portal tracts can be seen without significant elevations of liver injury tests. Whether these uncommon cases are an early phase of CR is uncertain. Isolated perivenular fibrosis can be caused by mechanical outflow obstruction, drug-induced liver injury, and all causes of veno-occlusive disease and Budd–Chiari syndrome in native livers.

The safest approach to the diagnosis of CR in any setting is to review prior biopsies and closely correlate the histopathologic findings with the clinical course. The usual scenario is a history of severe or unresolved acute rejection preceding the development of histologic findings interpreted as CR.

Bacterial and fungal infections

Stress and tissue damage from the transplant operation combined with high IS needed to prevent acute rejection within the first 2 months after transplantation places the recipient at highest risk for serious "opportunistic" fungal and viral infections. After 6 months post-transplant, more typical bacterial infections occur. Fever, anastomotic or wound dehiscence, retransplantation, persistent abdominal pain, and vascular thrombosis are clinical situations, signs and symptoms that should further arouse suspicion of a serious infection.

Bacterial and fungal infections often arise in non-viable tissue; therefore, most necrotic tissue should be routinely subjected to special stains for bacteria and fungi. Co-existent acute and chronic inflammation and granulomas are always good surrogate markers of infection but might not appear because of heavy IS. Histopathologic manifestations of deep fungal and bacterial infections are familiar to most pathologists and beyond the scope of this chapter.

"Opportunistic" hepatitis viruses

Cytomegalovirus hepatitis

Clinical presentation

Any organ system can be involved depending on the extent of viral dissemination, but the most common signs and symptoms of active CMV infection or disease arise from gastrointestinal involvement and include fever, diarrhea and gastrointestinal ulcers, leukopenia, and low-grade hepatitis with modestly elevated liver injury tests [154,155]. Respiratory insufficiency, pneumonia, and retinitis are signs of severe disseminated disease. CMV can also occasionally cause a syndrome that mimics Epstein–Barr virus (EBV) associated post-transplant lymphoproliferative disorder (PTLD) with lymphadenopathy, fever, and atypical lymphocytosis (reviewed in [156]).

Histopathologic findings

CMV hepatitis has become rare because of serologic monitoring, prophylactic and pre-emptive antiviral therapy [154,155]. CMV hepatitis, when it occurs, is usually characterized by spotty lobular necrosis, Kupffer cell hypertrophy, mild lobular disarray, and patchy lobular inflammation (described later). Inclusions tend to be limited to patients who are over-immunosuppressed and not adequately monitored or treated. Any cell type can be infected. Diagnostic features include large eosinophilic intranuclear inclusions surrounded by a clear halo accompanied by small basophilic or amphophilic cytoplasmic inclusions. CMV alone does not cause submassive or massive necrosis [156].

Infected cells are often surrounded by neutrophilic microabscesses or clusters of macrophages and lymphocytes – "microgranulomas." CMV hepatitis can also be associated with mild lymphoplasmacytic portal inflammation showing bile duct infiltration and damage that can superficially resemble acute or early CR. In fact, bile duct loss and CR have been associated with persistent allograft CMV infection (reviewed in [154,155]).

Because of medical therapy, "fragmented" nuclear CMV inclusions are seen, which are difficult to recognize without immunostain or in situ hybridization to detect viral antigens or nucleic acid, respectively. Rapidly dividing tissues such as young granulation tissue, proliferating cholangioles, edges of infarcts, abscesses, or other intraparenchymal defects are fertile soil for CMV growth [32]. .

Differential diagnosis

Subtle clues raising the possibility of CMV hepatitis that enable distinction from early acute HBV or HCV include less lobular disarray and hepatocyte swelling with CMV. In addition, microabscesses or microgranulomas are not generally seen with the early or lobular phase of HBV or HCV. A definitive diagnosis of CMV hepatitis requires either characteristic inclusions, which are rarely present, or specific detection of viral antigens or viral nucleic acids.

CMV hepatitis can superficially resemble EBV hepatitis because each has mild lymphoplasmacytic portal and lobular inflammation and both occasionally contain blastic and atypical lymphocytes. In such cases, EBV hepatitis usually demonstrates more lymphoplasmacytic cytologic atypia, whereas CMV hepatitis usually causes more intralobular inflammation (e.g. microgranulomas and

microabscesses). Deeper sections, staining for EBV and CMV viral antigens and in situ hybridization for EBV nucleic acids, are usually required to make the distinction.

Herpes simplex and varicella-zoster viral hepatitis

Histopathologic findings

Recognition and prompt reporting of herpes simplex virus (HSV) and varicella-zoster (VZ) hepatitis on needle biopsy evaluation is essential because effective therapy is available and, without treatment, infection can be rapidly fatal. Two patterns of HSV hepatitis have been described: localized and diffuse [157]. Both cause characteristic circumscribed areas of coagulative-type necrosis showing no respect for lobular architecture (reviewed in [156,157]). The center of the necrotic zones is occupied by hepatocyte "ghosts," intermixed with neutrophils and nuclear debris, whereas more viable hepatocytes rimming the periphery usually contain recognizable HSV or VZ inclusions, if present. Infected cells are usually slightly enlarged and contain "smudgy" ground glass nuclei or characteristic Cowdry type A eosinophilic inclusions. Multinucleate cells are occasionally present, but, not infrequently, diagnostic inclusions of HSV or VZ will be absent on the H&E slides.

In our experience, antibody preparations used to detect HSV I and II show can show cross-reactivity with each other and with VZ, making it difficult to distinguish among these viruses. Antibodies used to detect VZ precursor and mature glycoprotein may be more discriminating in this circumstance.

Differential diagnosis

If a histopathologic diagnosis of HSV or VZ virus hepatitis is considered on H&E sections, regardless of whether the diagnosis is confirmed, the clinical physician should be immediately notified [158]. This will prompt effective antiviral therapy that can be discontinued if the diagnosis is not confirmed on immunostaining. Necrotic lesions of HSV and VZ hepatitis are distinguished from infarcts by examining viable cells at the edge of the necrotic lesions for characteristic viral inclusions. Frequently, however, only cells with smudged nuclear chromatin are seen at this location. It is our policy to "over-diagnose" HSV hepatitis on H&E sections followed by HSV II and II and VZ immunostains to confirm or exclude the diagnosis.

The histopathologic differential diagnosis of CMV and HSV hepatitis has been discussed earlier.

Human herpes virus-6

Human herpes virus-6 (HHV-6), a member of the β-Herpesviridae subfamily of human herpes viruses, is a ubiquitous virus. Reactivation infection occurs in 15–80% of liver allograft recipients, usually during the first 2–8 weeks after transplantation, often precipitated by heavy IS [159].

Indirect effects attributed to HHV-6 include exacerbation of CMV disease, increased severity of HCV recurrence, increased risk of other opportunistic infections, allograft dysfunction, and ACR [159].

Liver allograft biopsy shows variable findings: moderate lymphocytic portal and patchy lobular inflammation, microabscesses [160,161], and syncytial giant cell hepatitis [162]. ACR has been seen at time of disease [160,161]. Consistent with the known biology of the virus, immunoperoxidase stains for HHV-6 viral antigens decorated mononuclear inflammatory cells [160] and hepatocyte syncytial giant cells in a single case report [162].

Human herpes virus-8

Human herpes virus-8 (HHV-8) is a lymphotropic gammaherpes virus family member exerting a pathogenic role in Kaposi's sarcoma, multicentric Castleman's disease, and primary effusion lymphoma [163–165].

Primary infection might be more severe and can result in variable manifestations, including liver dysfunction, multiorgan failure, multicentric Castleman's disease, and Kaposi's sarcoma [163–165]. Liver biopsy findings are typical for acute viral hepatitis: lobular disarray, ballooning, hepatocyte swelling and apoptosis, and variable ductular reaction. When multicentric Castleman's disease, Kaposi's sarcoma, or an unexplained acute hepatitis is recognized, one should include HHV-6 and HHV-8 in the differential diagnosis.

Epstein–Barr virus

EBV infection "immortalizes" B lymphocytes and lies dormant in B lymphocytes and possibly some epithelial cells [166–168]. Potent immunosuppression increases the risk of various EBV disease manifestations ranging from self-limited mononucleosis-like syndromes to aggressive clonal post-transplant lymphoproliferations and overt lymphomas [166–168]. These are currently all subsumed under the generic heading of PTLD.

Histopathologic findings

"Typical" EBV hepatitis manifests as mild portal lymphoplasmacytic inflammation combined with sinusoidal lymphocytosis comprised of small or mildly atypical lymphocytes. "Lining-up" of lymphocytes in the sinusoids should suggest an EBV-related disorder, as in native livers. Lobular changes include focal hepatocellular swelling, mild acidophilic necrosis of hepatocytes, and mild lobular disarray and regenerative activity.

In the liver, PTLDs usually present with cytologically atypical lymphoplasmacytic portal infiltrates. In early or polymorphic lesions, atypical cells are usually intermixed with small and blastic lymphocytes, plasmacytoid lymphocytes, and plasma cells. In monomorphic lesions atypical cells predominate, and involvement manifests as map-like enlargement of portal tracts because of sheets of atypical immunoblastic cells that obscure normal portal architectural landmarks. Some cases are accompanied by significant hepatic necrosis. Hodgkin's-like lymphoma PTLDs with classic Reed–Sternberg cells can also occur and be associated with bile duct loss, as in native livers. Subendothelial localization of lymphocytes in portal or central veins can mimic acute rejection.

Diagnosis of any EBV-related disorder is confirmed by in situ hybridization for EBV RNA (EBER sequence), which should be liberally employed to evaluate any suspicious infiltrate. Our routine workup also includes immunohistochemical stains or in situ hybridization for kappa and lambda light chains, and CD20 to determine possible responsiveness to anti-CD20 antibodies [168]. Occasionally, we also examine EBV antigen expression, and if enough fresh tissue is available, a portion is also submitted for flow cytometry and molecular analyses, which enable a more detailed phenotypic characterization and immunoglobulin gene rearrangements studies.

Differential diagnosis

Features that favor acute rejection over EBV-related disorders include pleomorphic "rejection-type" portal and/or perivenular inflammatory infiltrates, including conspicuous eosinophils; and severe and prevalent bile duct damage that is proportional to the

severity of inflammation. Features favoring EBV over acute rejection include relatively monomorphic portal infiltrates consisting primarily of activated and immunoblastic mononuclear cells, many of which show features of plasmacytic differentiation and some of which show atypical cytologic features; and patchy or mild inflammatory bile duct damage less than would be expected based on the severity of the portal infiltrate.

HCV and EBV hepatitis can both show sinusoidal lymphocytosis, but EBV-related disorders usually contain at least occasional atypical cells. In contrast, lymphocytes associated with HCV hepatitis are usually small, round, and inactive-appearing and form nodular aggregates in the portal tracts [169–172]. Clinical suspicion and increased peripheral blood EBV levels also point toward the correct diagnosis.

In most cases, the final diagnosis of any EBV-related disorder is heavily dependent on in situ hybridization for EBV RNA (EBER), but results should be interpreted with caution [173] because rare EBER-positive cells are not uncommon even in lymphoid tissues from the general population. In our opinion, however, clustering of EBER-positive cells into aggregates, or the presence of EBER-positive cells in tissues showing other histopathologic features of EBV-associated disease, is indicative of enhanced EBV replication and such patients are at increased risk of developing EBV-related disease.

Adenoviral hepatitis

Pathophysiology

Adenoviral-related disease after liver transplantation is largely restricted to pediatric recipients with primary infections [174,175], although occasional cases have been reported in adults [176,177].

Histopathologic findings

Considerable experience is required to diagnose adenoviral hepatitis on H&E sections because the disease is uncommon and typical nuclear inclusions are difficult to recognize with certainty. Typical cases show"pox-like" granulomas consisting of macrophages with or without neutrophils spread randomly throughout the parenchyma; in other cases granulomas surround small map-like areas of necrosis [174–176]. Typical adenoviral inclusions are usually found in nuclei of viable hepatocytes near the edge of the necrotic zones or granulomas. Infected cells show a "smudgy" appearance with crowding of chromatin towards the nuclear membrane, which makes the nucleus look like a "baked muffin." Immunohistochemical staining is usually required to confirm the diagnosis and given 52 serotypes it seems prudent to employ antibodies reactive with the hexon protein common to all serotypes of adenovirus (e.g. MAB805, blend of clones 20/11 and 2/6; CHEMICON International Inc., Temecula, California, USA) [177].

Differential diagnosis

On H&E sections, characteristic inclusions can be used to distinguish adenoviral hepatitis from other causes of focal hepatic necrosis and hepatic granulomas such as HSV and VZ, infarcts, and deep fungal or mycobacterial infections. HSV/VZ and CMV hepatitis can also have granulomatoid infiltrates and focal necrosis, respectively. However, adenovirus usually causes less necrosis than either HSV or VZ hepatitis. Granulomas associated with adenovirus are much larger than "micro-granulomas" typical of CMV hepatitis and multinucleated giant cells are rare in adenoviral hepatitis. CMV hepatitis, in contrast, causes cytomegaly and produces eosinophilic intranuclear inclusions, surrounded by a clear halo, and basophilic or amphophilic small cytoplasmic inclusions. Adenovirus does not cause cytomegaly, the nucleus assumes a "smudgy-appearance," and cytoplasmic inclusions are not seen.

Ultimately, however, immunostaining or in situ hybridization for adenoviral antigens is usually needed to confirm the diagnosis, often in conjunction with stains to exclude HSV/VZ, and CMV viral antigens and/or nucleic acids.

Considerations involved in the evaluation of late liver allograft dysfunction and protocol biopsies

A broad spectrum of insults can cause dysfunction and many show overlapping clinical, serologic, and histopathologic features. These issues were addressed by the Banff Working Group for liver allograft pathology who constructed a consensus document to help guide interpretation of such biopsies (Tables 82.5 and 82.6) [113].

Leading causes of late liver allograft dysfunction include recurrence of original disease and obstructive cholangiopathy [137,178]; acute and/or chronic rejection was detected in only 4–38% of late biopsies. Most (~75%) biopsies from recipients surviving more than 1 year with abnormal liver tests or symptoms show significant abnormalities [113,137,178], usually attributable to recurrent disease or biliary strictures, some of which are clinically occult. About 25% biopsies from long-surviving asymptomatic recipients with normal liver tests also show significant abnormalities, particularly if the original disease is one that commonly recurs (e.g. HCV, PBC, and AIH [113,137,178]).

Minor histopathologic abnormalities occur in about 60–70% of symptomatic patients even in the absence of recurrent disease with (near-) normal liver tests. Common minor abnormalities include portal venopathy, nodular regenerative hyperplasia, thickening and hyalinization of small hepatic artery branches, and "non-specific" portal and lobular inflammation. The significance of these unexplained findings is currently under scrutiny.

Many late post-transplant biopsies show portal-based mononuclear inflammation with variable necro-inflammatory-type interface activity, even in patients without recurrence of chronic necro-inflammatory diseases [113]). Even after extensive analysis, the underlying cause of the inflammation may not always be apparent. Rendering a definitive diagnosis, therefore, particularly during the early stages of a disorder, might not be possible. In such cases, using "features suggestive of early" emphasizes a tentative diagnosis [113].

Laboratory tests used to establish a diagnosis before transplantation may not have the same significance after transplantation [113]. Antimitochondrial antibodies (AMA) and antinuclear antibodies (ANA) often transiently disappear, only to reappear at lower titers after transplantation in patients with PBC or AIH – even without histopathologic evidence of recurrent disease. Patients without AIH before transplantation can develop autoantibodies either as a complication of otherwise typical rejection [179–181], or in association with new-onset AIH [113,132].

Recurrent diseases and diseases induced by transplantation

Recurrent original disease is the most common and significant cause of late liver allograft injury and dysfunction. This is covered in detail in Chapter 78 and includes infectious diseases (e.g. viral hepatitis A, B, C, D, E), disease of dysregulated immunity (AIH,

Table 82.5. Histopathologic features most commonly detected with various causes of late liver allograft dysfunction* (Reproduced from [113] with permission from John Wiley and Sons. Copyright © 2006 American Association for the Study of Liver Diseases)

Histopathologic features	AIH†	Acute rejection	Chronic rejection	Chronic viral hepatitis types B and C	PBC	PSC/BD strictures
Distribution, severity and composition of portal inflammation	Usually diffuse predominantly mononuclear of varying intensity Often prominent plasma cell component	Usually diffuse, variable intensity Mixed "rejection-type" (see text) infiltrate	Patchy, usually minimal or mild lymphoplasmacytic	Patchy, variable intensity; predominantly mononuclear; nodular aggregates	Noticeably patchy and variable intensity; predominantly mononuclear; nodular aggregates and granulomas	Usually patchy to diffuse depending on stage; mild neutrophilic, eosinophilic, or occasionally mononuclear predominant
Presence and type of interface activity	Usually prominent and defining feature: necro-inflammatory-type; often plasma-cell-rich	Focally present and mild necro-inflammatory type	Minimal to absent	Variable, usually not prominent: necro-inflammatory and (ductular-type)	Important feature later in disease development: ductular and necro-inflammatory-type with copper deposition	Prominent and defining feature: ductular-type with portal and periportal edema
Bile duct inflammation and damage	Variable; if present involves a minority of bile ducts	Present and usually involves the majority of bile ducts	Focal ongoing lymphocytic bile duct damage; inflammation wanes with duct loss	Variable; if present involves a minority of bile ducts	Granulomatous or focally severe lymphocytic cholangitis is diagnostic in proper setting	Periductal lamellar edema, "fibrous cholangitis," acute cholangitis, multiple intraportal ductal profiles
Biliary epithelial senescence changes and small bile loss	Absent or involves only a minority of ducts/portal tracts, but may be focally severe	Absent or involves only a minority of ducts	Senescence/atrophy/atypia involve the majority of remaining ducts (see text)	Absent or involves only a minority of ducts	Small bile duct loss associated with ductular reaction	Small bile duct loss associated with ductular reaction
Perivenular mononuclear inflammation and/or hepatocyte dropout	Variable, can involve the majority of perivenular regions, similar to rejection (see text); may be plasma-cell-rich	Variable, if defining feature should involve the majority of perivenular regions; may also show subendothelial inflammation of vein (see text)	Usually present, but variable	Variable, but generally mild, if present involves a minority of perivenular regions	Variable, but generally mild, if present involves a minority of perivenular regions	Absent
Lobular findings and necro-inflammatory activity	Variable severity; rosettes may be present and/or prominent	Variable, if present, concentrated in perivenular regions	Variable; if present, concentrated in perivenular regions	Disarray variable Variable severity necro-inflammatory activity	Mild disarray, parenchymal granulomas Periportal copper deposition and cholatestasis are late features	Disarray unusual Neutrophils clusters ± Cholestasis
Pattern of fibrosis during progression toward cirrhosis	Usually macronodular, post-hepatitic pattern	Rare	Uncommon, if present usually a venocentric pattern; may evolve to biliary pattern over time	Usually macronodular, hepatitic pattern; may be micronodular (see text)	Biliary pattern	Biliary pattern

AIH, autoimmune hepatitis; BD, bile duct; PBC, primary biliary cirrhosis; PSC, primary sclerosing cholangitis.
*The histopathologic findings in this table should be combined with clinical, serological, radiographic, and important exclusionary criteria listed in Table 82.2 to arrive at a final diagnosis.
†The same findings apply to recurrent and de novo AIH.

PBC, PSC, and overlap syndromes), malignancies (hepatocellular and cholangiocarcinomas), toxic insults, such as alcohol abuse and drug-induced liver injury and hepatic-based metabolic diseases such as α_1-antitrypsin deficiency and Wilson's disease and extrahepatic metabolic disorders (e.g. metabolic syndrome, hemochromatosis, Gaucher's disease).

Numerous other uncommon diseases of uncertain etiology (-ies) also can recur after liver transplantation including sarcoidosis [182,183], idiopathic granulomatous hepatitis [137], post-infantile giant cell hepatitis [184], and Budd–Chiari syndrome [185–187]. Liver transplantation can transmit diseases such as familial amyloidosis, polyneuropathy [16], and oxalosis [17] when these genetically diseased, but phenotypically normal, livers are used as "domino" transplants.

Hepatitis virus infections

Hepatitis A

Several case reports show that hepatitis A virus (HAV) can persist or recur after transplantation, as determined by detection of genomic HAV RNA by reverse transcription polymerase chain reaction (RT-PCR) in liver tissue, serum, and stool at the time of transient graft dysfunction and in one case of apparent HAV-induced allograft failure [188,189]. Biopsy findings showed changes generally attributable to hepatitis: variable hepatocyte apoptosis, degenerative changes of hepatocytes with cholestasis, mild portal inflammation with variable bile duct damage, and ductular cholestasis [188,189]. However, HAV RNA can be detected in liver tissue of patients with otherwise typical acute or chronic rejection [188–191]. The diagnosis, therefore, of recurrent or persistent HAV after

Table 82.6. Inclusionary and exclusionary criteria for the diagnosis of recurrent and new-onset chronic necro-inflammatory diseases after liver transplantation and timing of first onset and pattern of liver test elevations* (data from [113]and [260])

Diagnosis	Original disease	Serology/molecular testing†	Timing and liver injury test profile‡	Important exclusionary criteria
Recurrent AIH	AIH	Autoantibodies (ANA, ASMA, ALKM) usually in high titers (>1:80); raised serum IgG	>6 months Hepatocellular	Acute and chronic rejection, HBV, HCV, HEV infection, as determined by third generation ELISA assay and/or by serum or tissue PCR
Plasma Cell Hepatitis (De novo AIH)	Other than AIH	Same as above	>6 months Hepatocellular	Same as above
Recurrent HBV or HCV	HBV- or HCV-induced cirrhosis	HBV or HCV infection using standard, third generation serologic criteria and/or positive molecular testing for HBV or HCV nucleic acids	Usually 6–8 weeks, but as early as 10 days Usually hepatocellular; but may be cholestatic	Acute and chronic rejection AIH
Recurrent PBC	PBC	Positive AMA, but little additional benefit because AMA remains elevated in the majority of patients after transplantation	>1 year Cholestatic	Biliary tract obstruction/strictures
Recurrent PSC	PSC	NA	Usually >1 year Cholestatic	HA thrombosis/stenosis, chronic (ductopenic) rejection, abnormal surgical anatomy, anastomotic strictures alone, non-anastomotic strictures occurring < 90 days after OLTx, and ABO incompatibility
Acute rejection	NA (see text for risk factors)	NA	Any time Usually hepatocellular; may be mixed if superimposed on chronic rejection	Inadequate IS usually, but not always present (see text) Important exclusions: biliary tract obstruction/strictures, HBV, HCV, AIH
Chronic rejection	NA (see text for risk factors)	NA	Any time, but usually <1 year Cholestatic; rarely hepatocellular in veno-occlusive variant (see text)	Inadequate IS usually, but not always present (see text) Important exclusions: biliary tract obstruction/strictures, HBV, HCV, AIH
Idiopathic post-transplant hepatitis	Non-viral and non-AIH	Negative testing for HBV, HCV, and HEV infection and autoantibodies	>1 year Usually hepatocellular	Acute and chronic rejection, all other causes of chronic hepatitis, and biliary tract obstruction/strictures reasonably excluded. All attempts should be made to determine a cause before establishing this diagnosis

AIH, autoimmune hepatitis; ALKM, anti-liver–kidney microsomal antibodies; AMA, antimitochondrial antibodies; ANA, antinuclear antibodies; ASMA, anti-smooth muscle antibodies; HBV, hepatitis B virus; HCV, hepatitis C virus; HEV, hepatitis E virus; IS, immunosuppression; PBC, primary biliary cirrhosis; PCR, polymerase chain reaction; PSC, primary sclerosing cholangitis.

*See Table 82.5 for compatible histopathologic findings.

†Timing = usual timing of first onset;

‡Sustained elevation for more than 1 month: hepatocellular = ALT and/or AST > ALP and/or GGTP; cholestatic = ALP and/or GGTP > AST and/or ALT.

transplantation should be based on complete clinicopathologic and serologic correlation.

Hepatitis B and Delta

Clinical presentation

Untreated recipients, largely of historical interest, show that HBV reinfection of the allograft occurs immediately after transplantation. Clinical manifestations first become obvious about 6–8 weeks as otherwise unexplained elevations of ALT and AST [192,193]. More significant hepatitis is accompanied by nausea, vomiting, jaundice, and, in rare cases, fulminant hepatic failure. In the liver transplant setting, recipients treated with too much IS can develop severe disease because of fibrosing cholestatic hepatitis. In contrast, rapid tapering or withdrawal of IS should also be avoided in HBV-positive recipients with evidence of active viral replication. This maneuver can "re-arm" the immune system and cause severe immunologically mediated liver injury and fulminant hepatic failure.

Histopathologic findings

The histopathologic manifestations of untreated HBV infection of hepatic allografts are similar to that seen in native livers, except for the rare occurrence of the fibrosing cholestatic variant [193,194], which has largely been eliminated because of effective therapy.

HBV-related disease typically begins with acute hepatitis usually recognizable within 4–6 weeks after transplantation. A small percentage of untreated HBV-positive recipients will develop confluent/bridging, and even submassive necrosis, especially if IS is rapidly reduced [192]. Delta antigen can be detected by immunohistochemical staining [195].

Cirrhosis can develop rapidly within 12–18 months after transplantation in untreated recipients [192,193]. Lobular findings in the chronic phase are usually much less conspicuous than during the acute phase and include ground glass hepatocytes or hepatocytes with sanded nuclei that stain positively for hepatitis B surface and core antigen, respectively, mild disarray and low grade necroinflammatory activity.

Massive HBV replication because of over-immunosuppression and major histocompatibility complex (MHC) non-identity between liver and recipient can lead to the development of fibrosing cholestatic hepatitis; it can also occur with the emergence of viral mutants [193,196]. Findings include marked hepatocyte swelling, lobular disarray, and cholestasis combined with prominent ductular and fibrotic-type interface activity often with minimal or mild portal and lobular inflammation. Swollen and degenerating hepatocytes usually show massive hepatocellular expression of hepatitis B core and/or surface antigen, suggesting that HBV is directly cytopathic under these circumstances [193,197].

Delta agent co-infection of HBV-positive recipients usually results in a lower incidence of recurrent disease compared to HBV-positive/delta-negative recipients, particularly in pharmacologically

treated recipients [198]. Effects of HDV on HBV-related pathology in untreated recipients would be expected to be similar to that seen in the general population [199].

Differential diagnosis

Acute HBV should be distinguished from other causes of acute hepatitis, such as CMV, HCV, and EBV and other conditions such as "ischemic" hepatitis and portal and so-called "transitional" hepatitis that accompanies the transition from acute to chronic rejection. The most reliable method of distinguishing acute HBV hepatitis from the other insults is a review of the clinical, histopathologic, immunohistochemical, and serologic profile.

Chronic HBV hepatitis needs to be distinguished from other causes of chronic hepatitis such as HCV, AIH, and drug-induced liver injury. Detection of ground glass hepatocytes or viral antigens or nucleic acid in the blood or tissues, in the absence of other causes, favors chronic HBV. Detection of viral antigens or nucleic acids in the blood or tissues combined with histologic features of active lobular hepatitis, in the absence of other causes, favors recurrent HBV, but does not exclude other causes [193].

Features used to distinguish between acute rejection and acute or chronic hepatitis have already been discussed (see Acute rejection, Differential diagnosis).

Hepatitis C virus

Liver damage from recurrent HCV is mediated via a combination of viral replication and immune-mediated damage: either can damage the liver [200]. Rapid tapering of IS is associated with more rapidly progressive recurrent HCV [201–203], probably related to "re-arming" of the immune system at a time of high HCV replication. This triggers a more aggressive immune-mediated hepatitis [201–203], as noted decades ago for HBV-induced chronic liver disease. Slower tapering of IS, particularly in long-surviving recipients, seems to be more advisable [201–203].

In keeping with fibrogenesis models [200], any insult in addition to HCV (e.g. co-existent steatosis, high viral replication and oxidative stress, iron deposits, or co-existent damage from preservation–reperfusion injury, biliary structuring, or acute rejection) will accelerate disease progression. This concept also explains why use of extended criteria donors in HCV-positive recipients has offset the recent improvements in medical management of HCV leading to no net improvement in long-term outcomes [200,204,205].

Clinical presentation

The clinical presentation of HCV hepatitis is similar to that seen in the general population. Acute hepatitis, which develops in most recipients, is often asymptomatic, recognized primarily by elevation of ALT and AST to 4–8 times baseline levels [200]. This usually becomes apparent 3–6 weeks after transplantation; earlier onset within 10–14 days can be associated with more aggressive disease.

Fibrosing cholestatic hepatitis (FCH) HCV is associated with "over IS" and characterized clinically by malaise, jaundice, and marked and preferential elevations of bilirubin, alkaline phosphatase, and γ-GTP.

Histopathology

Usual variant. The usual appearance and evolution of HCV in liver allografts is similar to that seen in native livers. In allografts, however, the acute phase generally shows less portal and lobular inflammation; the chronic phase less often shows nodular aggregates of portal-based lymphocytes; and there is more ductular-type interface activity [200,206].

Focal inflammatory bile duct damage can be seen, but is neither severe nor widespread, involving a minority of bile ducts, and duct loss is not seen. Inflammation in and around the central veins can be seen in a minority of lobules. However, central perivenulitis is neither severe nor widespread in recurrent HCV.

Plasma cell-rich "autoimmune" variant of HCV. Recurrent chronic HCV can present with aggressive plasma-cell-rich interface and perivenular necro-inflammatory activity resembling AIH (Figure 82.7) [132,200,207]. More studies are needed to determine whether this represents an "autoimmune variant of HCV," acute rejection, actual AIH, or a combination of these possibilities [132,200,207].

Immunosuppressive therapy can lessen the severity of liver damage in patients with plasma cell-rich HCV in the general population [208] and in allograft recipients with plasma-cell-rich interface and perivenular necro-inflammatory activity [207,209]. However, this can occur at the expense of enhancing HCV replication and impeding eventual HCV clearance [208].

Perivenular necro-inflammatory activity involving the majority of central veins, plasma-cell-rich or not, is a feature of acute rejection and AIH, but not of recurrent HCV. Central perivenulitis is usually responsive to increased IS, regardless of whether the patient is HCV-positive, and regardless of whether the patient is an allograft recipient [132,200,207].

Fibrosing cholestatic hepatitis. FCH HCV usually occurs within the first year after transplantation in the context of over-IS. It is typically characterized by homogeneous viral quasi-species and massive HCV RNA levels in the peripheral circulation (usually >30–50 million IU/mL). The most common features of FCH include cholestasis, hepatocyte ballooning degeneration, fibrosis (periportal, portal, and bridging), and ductular reaction [210]. Spotty apoptosis/necrosis and mild mixed or even neutrophilic-predominant portal inflammation are also often seen. FCH HCV occurs as a spectrum of severity: mild cases show only mild hepatocyte swelling, slightly more mononuclear portal inflammation, and only a low grade or minimal ductular reaction.

Diagnosing co-existent conditions in the context of recurrent HCV

Establishing a histopathologic diagnosis of acute or chronic rejection in the context of recurrent HCV is often difficult. The most frequent mistake is to over-diagnose ACR, leading to unnecessary increases in IS [131,200]. Features attributable to acute and chronic rejection include the following:

1 Mononuclear inflammatory bile duct damage and/or biliary epithelial senescence, respectively; and
2 Central perivenulitis and fibrosis, involving the majority of bile ducts or terminal hepatic veins, respectively.

Features attributable to recurrent or new-onset HCV include lobular necro-inflammatory activity and necro-inflammatory and ductular type interface activity. The key to establishing a final diagnosis is to determine which constellation of findings predominates.

Most clinically significant rejection episodes occurring in the context of recurrent HCV are graded as "moderate" according to the Banff criteria [116]. Biliary epithelial cell senescence involving the majority of bile ducts leads to a diagnosis of CR, which is often associated with a reduction in IS or treatment with an immune

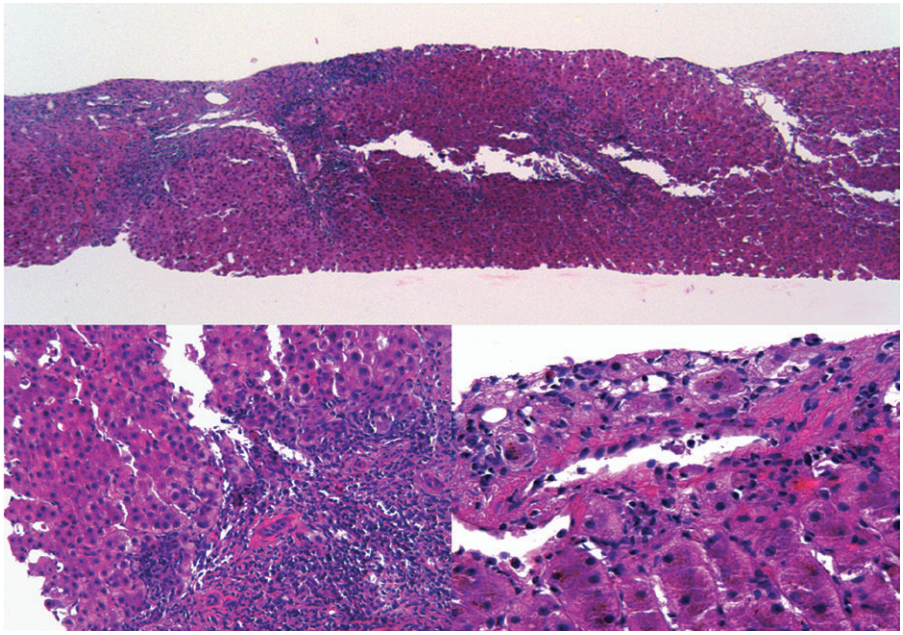

Figure 82.7. Recurrent HCV appears usually similar to that seen in native livers. Some cases of recurrent HCV, however, show "autoimmune" features such as plasma-cell-rich portal inflammation, aggressive interface activity (bottom left), and plasma cell-rich perivenular inflammation (bottom right). This biopsy was obtained about 26 months after transplantation from a female recipient who was HCV RNA-positive, but also had serologic evidence of co-existent autoimmunity. It is difficult to distinguish between acute cellular rejection and autoimmunity in such cases. Both will respond to increased immunosuppressant, but also usually show an increase in HCV RNA levels.

stimulator like α-interferon [200,211]. When either acute or chronic rejection is the predominant process the changes should be obvious. In addition, clinically significant rejection episodes occurring in the context of recurrent HCV are usually, but not invariably, associated with relatively low peripheral blood HCV RNA levels (<1–5 million IU/mL), suggesting that immunologic mechanisms associated with rejection also contribute to viral clearing [131,205].

Differential diagnosis

The differential diagnosis for acute and chronic HCV includes acute and chronic rejection, recurrent non-HCV hepatitis (e.g. HBV, CMV, EBV), and recurrent or new-onset AIH, PBC, and PSC, and biliary tract obstruction or stricturing [200,206]. C4d deposits and HCV protein and nucleic acid expression have been employed to assist with the differential diagnosis with limited success [200,206]. It is important to recognize other causes of injury occurring in the context of recurrent HCV. HCV is an uncommon cause of allograft dysfunction during the first several weeks after transplantation except for rare cases that begin as early as 10–14 days. Most cases occur 3–8 weeks after transplantation. Most acute rejection episodes, in contrast, occur within the first 30 days, with a median of 8 days [212].

Distinguishing HCV from other causes of chronic hepatitis also requires evaluation of the complete clinical, biochemical, and serologic profile. Viral antigen and/or nucleic acid detection, ground glass cells, or sanded nuclei distinguish HBV from HCV. Confluent necrosis is rarely, if ever, seen in HCV, alone. Recurrent or de novo AIH is recognized by sheets of plasma cells in the portal and perivenular inflammation with confluent perivenular necrosis, especially when combined with autoantibodies and hypergammaglobulinemia. In contrast, low-grade periportal and mid-zonal steatosis and portal lymphoid aggregates favor recurrent HCV.

FCH HCV can be difficult to distinguish from bile duct obstruction and hepatic artery thrombosis. Portal edema and portal or periportal neutrophilia are common in duct obstruction and acute cholangitis. A prominent ductular reaction and acute cholangiolitis without portal edema is more characteristic of non-obstructive cholestatic hepatitis. Lobular disarray and marked hepatocellular swelling are usual for viral hepatitis, but uncommon in duct obstruction alone.

Hepatitis E virus

Hepatitis E (HEV) is a single-stranded non-enveloped hepatotropic RNA virus endemic in Southern Asia and Africa. HEV infection in liver recipients has been associated with acute and chronic hepatitis [213–220]. Some cases spontaneously resolve, but up to 60% of chronically infected liver allograft recipients (defined as HCV RNA+ in the stool or serum for 6 months) develop chronic hepatitis and 15% of those progress toward cirrhosis [217]. Importantly, lowering IS can lead to resolution of infection and favorably influence chronic hepatitis [217], which is of potential importance for drug minimization trials.

Histopathologic findings and differential diagnosis

Similar to HBV and HCV, acute and chronic phases are described [213,215,218,220]. The acute phase is characterized by predominantly lobular inflammation and spotty hepatocyte necrosis and apoptosis. Portal tracts show mild to moderate expansion by inflammation composed mainly of lymphocytes and mild necroinflammatory-type interface activity [213].

Biopsies from patients with chronic infection show typical chronic viral hepatitis, characterized by variable lymphocytic and lymphoplasmacytic portal infiltrates with variable necroinflammatory-type interface activity and progressive fibrosis [213,

215,218,220]. The same criteria used to distinguish chronic HBV or HCV from acute and chronic rejection can be employed for HEV.

Disorders of dysregulated immunity

Disorders of immune regulation commonly recur after liver transplantation; the approximate incidence is about 25% by 5 years. The rate of progression of recurrent disease, however, might be less rapid than the same disease before transplantation [221,222]. Long-term graft and patient survival has not yet been significantly influenced by recurrent disease. However, there appears to be a progressive increase in the incidence of recurrent disease with time. Therefore, it is likely that diseases will begin to negatively impact long-term morbidity and mortality [222].

Primary biliary cirrhosis

Clinical presentation

Programs that conduct protocol biopsies most often detect recurrent disease from asymptomatic patients who often have (near-) normal liver injury test profiles [223]. In the large Mayo experience, only 12% of patients with recurrent PBC reported disease-related symptoms, with fatigue and pruritus most common [223]. In programs where biopsies are done by indication, recurrent PBC is usually first suspected because of increased alkaline phosphatase and γ-GTP as part of routine serologic monitoring.

Recurrent PBC can progress after liver transplantation, but retransplantation for recurrent PBC is rare and long-term patient and graft survival results are excellent [223]. AMA are of little additional benefit in establishing the diagnosis because AMA transiently decline shortly after transplantation and then recur in the vast majority, even without recurrent disease.

Histopathologic findings

Histopathologic diagnosis of recurrent PBC is based on the same clinicopathologic criteria as before transplantation. Diagnostic lesions include non-infectious non-caseating granulomatous bile duct damage or severe lymphocytic cholangitis producing breaks in the ductal basement membranes – referred to as florid duct lesions [223]. Patchy dense portal plasmacytic infiltrates at 1 year after transplantation presage later development of full-blown disease [224].

Patients often present with patchy mononuclear portal inflammation with focal lymphocytic cholangitis accompanied by portal lymphoid nodules and prominent ductular type interface activity resulting in a "biliary" gestalt. This refers to a ductular reaction at the interface zone, periportal "clearing" or edema, cholatestasis, accumulation of copper or copper-associated pigment in periportal hepatocytes, and patchy small bile duct loss. Such cases are "strongly suggestive" of recurrent PBC if they occur in proper context, which includes an original disease of PBC with no other reasonable explanation for the biliary pathology and preferential elevation of the γ-GTP and alkaline phosphatase.

The diagnosis of recurrent PBC is less certain in biopsies without significant lymphocytic cholangitis or a biliary gestalt. For example, "possible" recurrent PBC might first present as unexplained chronic hepatitis [137,225] because sampling problems may have missed the bile duct damage or the patient is presenting with an overlap syndrome with AIH [225], or as AIH alone [226].

As in native livers, lobular findings in recurrent PBC are usually mild.

Differential diagnosis

The differential diagnoses for recurrent PBC includes acute and chronic rejection, chronic obstructive cholangiopathy, chronic viral, autoimmune, or idiopathic hepatitis, and drug-induced liver injury. These same disorders can also co-exist with recurrent PBC. Other causes of granulomatous cholangitis, such as fungal or acid-fast bacterial infections and HCV, should be reasonably excluded.

A "biliary gestalt," described previously, is one of the most helpful constellations of findings that can be used to distinguish biliary tract pathology from other causes of dysfunction. Neither acute nor chronic rejection shows a significant ductular reaction biliary fibrosis or cirrhosis. Rejection-associated portal inflammation and lymphocytic cholangitis usually involve the majority of portal tracts and preferentially involves small bile ducts ($<20\,\mu m$ in smallest diameter). PBC-associated portal inflammation and lymphocytic cholangitis, in contrast, is typically patchy and preferentially involves medium-sized bile ducts ($>40–50\,\mu m$ in shortest diameter).

Patients with PBC can also develop de novo AIH or an overlap syndrome after liver transplantation [226]. Clinical, serologic, and histopathologic criteria used to establish the diagnosis of AIH and overlap syndrome before transplantation can also be used after transplantation, but are more difficult to apply.

Recurrent PBC can be quite difficult to distinguish from obstructive cholangiopathy because both produce a biliary gestalt. Histopathologic features that favor obstructive cholangiopathy over recurrent PBC include the following:

1. Edema and/or neutrophilic inflammation in and around the true bile ducts in the middle of the portal connective tissue;
2. Centrilobular hepatocanalicular cholestasis;
3. Bile infarcts; and
4. Intralobular neutrophil clusters.

In some cases, cholangiography may still be required to exclude a mechanical problem.

PBC can be difficult to distinguish from chronic viral and AIH, particularly because recurrent HCV can show a prominent ductular reaction. In such cases, careful examination of the bile ducts for evidence of significant lymphocytic or granulomatous duct damage and small bile duct loss can be helpful. Portal granulomas have been reported with recurrent chronic HCV [227]. However, this observation is uncommon and the granulomas rarely cause noticeable or severe ductal damage. Finally, copper and copper-associated protein stains can be used to distinguish between ductular reactions attributable to chronic cholestasis and those related to other insults.

Recurrent and new-onset "autoimmune" hepatitis

Establishing a diagnosis of recurrent or de novo AIH after transplantation is even more difficult than before transplantation. This is because: (1) serologic abnormalities either persist or transiently decline and then reappear without association to disease recurrence; and (2) histopathologic evidence of liver injury from other causes of allograft injury can mimic AIH [228,229]. The Banff Working Group advocated relatively strict criteria [113] to establish the diagnosis AIH after transplantation, but more study is needed.

Histopathology and differential diagnosis

Native liver, de novo, and recurrent AIH are indistinguishable and characterized in the typical case by aggressive, often plasma cell-rich necro-inflammatory-type interface and variable perivenular necro-inflammatory activity. Some patients with recurrent AIH present with plasma cell-rich central perivenulitis (see Acute

rejection). Distinguishing between centrilobular-based acute rejection and AIH can be problematic in such cases. A high percentage of plasma cells (>30%) favors AIH, whereas inflammatory bile duct damage or biliary epithelial senescence changes involving the majority of ducts favors rejection.

Patients who develop de novo bile salt export pump (BSEP) antibodies present histologically with cholestasis, hepatocyte multinucleation/giant cells, prominent interface ductular reaction, and fibrosis, which can lead to allograft failure. Aggressive plasma cell-rich interface or perivenular necro-inflammatory activity or inflammatory bile duct damage has *not* been described [230–232].

Once a "hepatitic" pattern of injury is established, examination of the clinicopathologic and serologic profiles are needed to: (1) support an autoimmune etiology (e.g. anti-nuclear antibodies (ANA), anti-smooth muscle antibodies (ASMA), liver-kidney microsomal (LKM), serum gamma globulins); and (2) reasonably exclude other causes of a chronic hepatitis, such as HBV, HCV, HEV, PBC, as well as obstructive cholangiopathy [178,228,229].

Distinguishing AIH from conventional acute and chronic rejection uses the same criteria as those used to distinguish acute and chronic rejection from viral hepatitis (see Hepatitis C virus). Distinguishing AIH from obstructive cholangiopathy and PBC was discussed in the sections on biliary tract complications and PBC, respectively.

Recurrent primary sclerosing cholangitis

The early stage of recurrent PSC usually first comes to clinical attention more than 6–9 months after transplantation because of selective elevation of alkaline phosphatase and γ-GTP. Non-anastomotic intrahepatic biliary strictures that develop *before* 90 days after transplantation are usually not attributable to recurrent disease and therefore other causes should be sought.

Histopathologic findings

Histopathologic features of recurrent PSC are identical to those described for native livers and cannot be reliably distinguished from other causes of biliary tract obstruction or stricturing in a needle biopsy. Findings typical of early stage include mild non-specific acute and chronic "pericholangitis" and variable low-grade interface ductular reaction. A "biliary" gestalt appears as the disease becomes well-developed. Included are irregular stellate fibrous expansion of most portal tracts accompanied by variable portal edema, periductal lamellar edema, stellate-shaped lumen of septal bile ducts, intraepithelial or intraluminal neutrophils within bile ducts, fibrous cholangitis, focal small bile duct loss, pigmented macrophages in portal connective tissue, ductular-type interface activity surrounded by edema, and periportal deposition of golden pigment and copper and copper-associated protein. As is typical for biliary diseases, the spatial relationship between the expanded portal tracts and the central veins remains intact until well-developed cirrhosis appears.

Lobular findings in early recurrent PSC include variable cholestasis, lobular neutrophil clusters, and mild nodular regenerative hyperplasia changes. Later stage are characterized by the development of biliary cirrhosis, cholestasis, intralobular foam cell clusters, marked deposition of copper and copper-associated protein, and Mallory's hyaline at the edge of nodules.

Differential diagnosis

Histopathologic recognition of the "biliary" gestalt, preferential elevation of γ-GTP and alkaline phosphatase points toward "biliary" pathology. However, extensive clinicopathologic and radiographic correlation are needed to determine whether recurrent PSC or one of the many other causes of biliary tract pathology is responsible for the changes observed. This distinction is not possible based on peripheral core needle biopsy findings alone. Instead, recurrent PSC should be diagnosed only after a complete analysis of clinical, histopathologic, and radiographic findings, including important exclusionary criteria.

Metabolic diseases and toxic insults

Jaffe [233] devised an algorithm to separate metabolic diseases into three categories for the purpose of understanding the impact of liver transplantation on the disease process and the possibility of recurrent disease (Table 82.7). As more medical therapies appear

Table 82.7. Summary of metabolic disease treated by liver transplantation classified according the system of Jaffe et al. [233] (see text)

Liver is the site of the primary metabolic defect and liver is usually diseased (see text)	Liver is the site of primary metabolic defect, but liver is usually normal or near-normal	Site of primary metabolic defect is probably extrahepatic and liver transplantation decreases morbidity and mortality associated with liver disease
α_1-Antitrypsin deficiency [234,262]	Branched chain amino acid deficiencies (reviewed in [234])	Cystinosis [233]. Does not generally cause liver disease; one patient developed intrahepatic crystal deposits in liver with perivenular fibrosis and recurrent disease in the allograft [233]
Bile acid synthesis defects [234]	Crigler–Najjar syndrome [263,264]	Cystic fibrosis; cures liver disease, and if liver transplant is performed early, lung function can improve [234]
Carbohydrate metabolism defects (reviewed in [234])	FAP [265]. Mild liver abnormalities: amyloid deposits in portal tracts and nerve trunks; use of FAP-affected liver is controversial	Porphyria (reviewed in [266,267])
Familial intrahepatic cholestasis syndromes (reviewed in [234])	Familial hypercholesterolemia [233]	Hemochromatosis or (inadvertent transplantation of donor with hemochromatosis) (reviewed in [268])
Glycogen storage disease, types I and Ib, III, IV [234,269,270]	Hemophilia A and B [233]	Niemann–Pick disease [233,234]
Hemochromatosis, neonatal (reviewed in [234])	Oxaluria, type I [233,234]	Sea-blue histiocyte syndrome [271]
Mitochondrial defects, limited to liver (reviewed in [234])	Urea cycle enzyme deficiencies [233,234])	
Tyrosinemia [234,272]		
Wilson's disease [234,273]		

FAP, familial amyloid polyneuropathy.

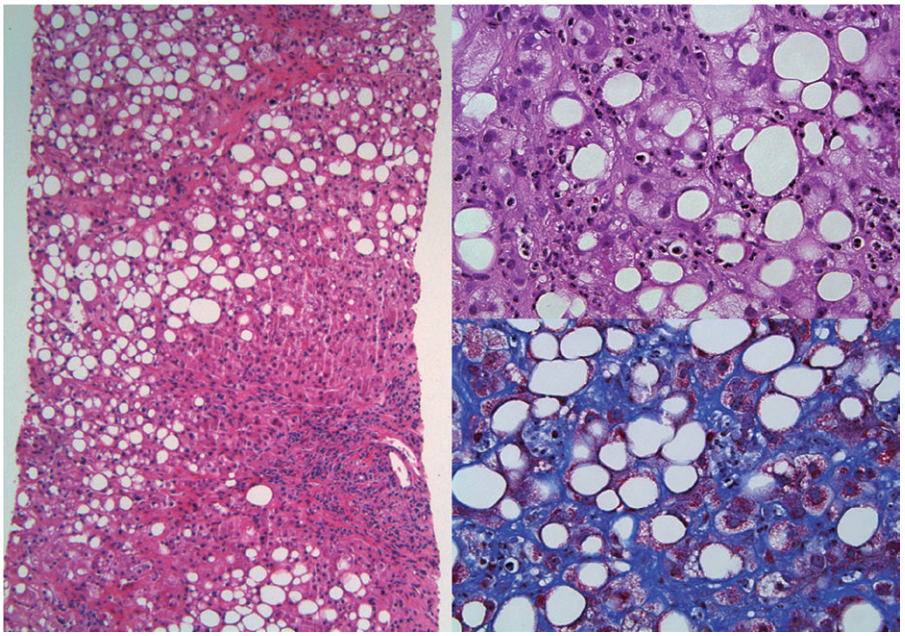

Figure 82.8. Recurrent alcoholic liver injury is a relatively uncommon cause of significant allograft injury. Although it is difficult to distinguish alcoholic from non-alcoholic fatty liver disease, the strict perivenular distribution of steatosis (left) with so-called "foamy" degeneration of hepatocytes (right upper inset) and neutrophilic inflammation are more typical of recurrent alcohol use. This can lead to subsinusoidal fibrosis (right lower inset).

the need for liver replacement therapy is decreasing, but is still effective when required [234]. Patients in the first group who failed medical or other surgical therapy, if available, are prime candidates for liver transplantation because the cirrhotic liver is replaced by a genetically and structurally normal one that generally cures the disease. Some familial intrahepatic cholestasis syndromes, however, recur after transplantation because of de novo antibodies that develop in response to mutated non-inherited proteins that are introduced with the donor organ (see AIH section) [230–232].

The liver is structurally normal or near-normal in the second group. The liver allograft is vulnerable to recurrent disease in the third group because the metabolic disorder persists after transplantation. Improved survival and/or quality of life issues, however, justify liver replacement [233].

Recurrent alcoholic liver disease

Clinical presentation

Problems with recidivism are usually detected because of elevation of liver injury test results that are routinely obtained in liver transplant populations [235], missed medical appointments [236], inappropriate social behavior [137], and non-compliance with IS (reviewed in [235,237]). A high γ-GTP : alkaline phosphatase ratio might provide biochemical evidence of alcohol recurrence [137,235], but blood alcohol levels are more definitive proof of relapse. A small minority of patients experience a rapid downhill course after transplantation because of recidivism and recurrent steatohepatitis [238–240]. However, most alcoholics do not relapse badly enough to cause significant alcoholic liver disease in the allograft.

Histopathologic findings and differential diagnosis

The histopathologic findings in alcoholic allograft liver disease are identical to those seen in native livers and will not be discussed in detail here. The most common histopathologic presentation is small and large droplet steatosis involving primarily centrilobular hepatocytes. The zonal distribution pattern of the steatosis is usually distinctive (Figure 82.8). More significant abuse can lead to so-called "foamy" degeneration of centrilobular hepatocytes, followed by fully developed "alcoholic hepatitis" with Mallory's hyaline, and ballooning degeneration of hepatocytes, with associated lobular neutrophilic inflammation.

For differential diagnosis, see the section on Non-alcoholic steatohepatitis.

Recurrent non-alcoholic steatohepatitis

Clinical presentation

Non-alcoholic fatty liver disease (NAFLD) is currently the third leading indication for liver transplantation in the United States, but is on trajectory to become the most common indication [241]. Those who undergo liver replacement for NAFLD are likely to be older, female, and have a higher body mass index.

A significant proportion of patients who underwent liver transplantation for cryptogenic cirrhosis will also develop NAFLD after transplantation [242–245]. Presumably, these patients also had undetected NAFLD before transplantation, but the histopathologic features were not obvious in the explant cirrhotic liver.

Recurrent NAFLD is usually first detected on protocol or indicated in allograft biopsies in asymptomatic patients. Many patients have multiple risk factors for NAFLD. A minority of otherwise healthy recipients develops unexplained NALFD after transplantation; in these patients metabolic testing for insulin resistance and a search for more esoteric causes is warranted.

Histopathology and differential diagnosis

A detailed description of the histopathology of hepatic steatosis and steatohepatitis are known to most pathologists and appear similar

to native livers. Readers, therefore, are referred elsewhere for an excellent review [246].

Determining the underlying cause of steatohepatitis in allografts can be particularly difficult in a minority of allografts. As in native livers, steatohepatitis is seen most commonly with morbid obesity, diabetes, insulin resistance, and alcohol abuse. However, it can also be associated with a number of other causes, and reference to standard medical texts is recommended. In the case of allografts, abnormalities of hepatic blood flow are an important cause of hepatic steatosis and steatohepatitis especially when it first appears within a few months after transplantation.

A thorough clinicopathologic correlation is needed to substantiate a suspicion of alcohol relapse or metabolic abnormalities leading to NAFLD. Awareness of the original disease(s), detailed clinical history, including current alcohol use, blood alcohol levels, and the ratio of γ-GTP : alkaline phosphatase can be used to distinguish between these possibilities.

Idiopathic post-transplant hepatitis

Pathophysiology and clinical presentation

Idiopathic post-transplant hepatitis is a diagnostic term coined by Hubscher [247] to describe chronic hepatitis changes on allograft biopsy (i.e. mononuclear portal inflammation with variable interface activity) without clinical or serologic evidence of viral hepatitis infection, autoimmunity, or drug-induced liver injury (reviewed in [113,248]). According to the definition, features used to diagnose acute rejection, such as bile duct damage and venous endothelial inflammation, are neither severe nor widespread [113,248].

As with other idiopathic disease categories, the expectation is that the diagnosis of IPTH will gradually dwindle as the underlying etiology is discovered: cases reassigned an etiology of chronic HEV infection, discussed above, is one example. Another small subgroup probably represents recurrent AIH, although strict criteria for AIH might not always be met [247]. The underlying cause of chronic hepatitis still cannot be determined in substantial percentage of cases. More study is clearly needed on this topic, but current thinking suggests that a substantial percentage of IPTH cases represent a variant of late-onset acute rejection [113,178,248,249].

Histopathology and differential diagnosis

IPTH is characterized by chronic portal inflammation, variable interface and lobular necro-inflammatory activity, but without prominent or prevalent bile duct damage or central perivenulitis. Prevalent lymphocytic cholangitis and central perivenulitis are more suggestive of an active rejection reaction. Significant plasma cell inflammation comprising >30% of the infiltrates is uncommon and suggests recurrent or de novo autoimmune hepatitis. Other causes of chronic hepatitis, such as HBV, HCV, HEV, and recurrent or de novo AIH should be excluded using clinical, serologic, and molecular diagnostic parameters.

The differential diagnosis for IPTH is the same as that for HBV or HCV infection or AIH (see earlier).

Considerations in immunosuppression optimization protocols

Clinical presentation

Evaluation of allograft biopsies has an important role in IS minimization or optimization, including complete withdrawal of IS in a small number of highly selected recipients [113,178,248,250]. This is a unique aspect of liver transplantation compared to other organs because: (1) liver allografts are more "tolerogenic" than other solid organ allografts [111]; and (2) if rejection does occur during or after weaning, it is usually rapidly reversible with current IS regimens without significant fibrosis or loss of function [111,113,178,248,250].

Histopathology and differential diagnosis

Pre-weaning biopsies are usually considered mandatory in IS minimization trials [248]. Biopsy findings associated with successful weaning include: (1) less portal inflammation [251,252]; (2) fewer $CD3^+$ and $CD8^+$ lymphocytes, but more $CD45RO^+$ lymphocytes within the lobules [6,252], more portal fibrosis in HCV-positive recipients [253], and less prevalent microvascular C4d deposits [251].

Follow-up biopsies are usually obtained during or after IS weaning, triggered by an elevation in liver tests [248,250]. However, liver test elevations are non-specific and weaning of IS can worsen recurrence of the underlying original disease [248,250]. γ-GTP elevation might be the most specific and sensitive indication of ACR after weaning [254,255].

The routine histopathologic appearances of ACR during weaning from IS most often resembles "classic" ACR, but atypical or incomplete presentations are common [113,248,250] and can include: (1) less prevalent and severe inflammatory bile duct damage; (2) more prevalent and severe interface and lobular necro-inflammatory activity; and (3) less portal venous subendothelial inflammation in the former. Therefore, biopsies might resemble low-grade chronic hepatitis [248,250], making differential diagnosis difficult, especially as interface hepatitis can also be seen after weaning in patients with underlying AIH or PBC, probably as a manifestation of recurrent disease.

Early and rapid weaning of IS from HCV-positive [203] and some HCV-negative recipients [256] treated with lymphocyte-depleting antibodies can "rearm" the immune system (immune reconstitution syndrome) [203], which manifests as aggressive hepatitis with rapid progression of fibrosis [203].

Development of progressive rejection-related fibrosis is of particular concern [113,248]. To monitor for this complication, the Banff Working Group encouraged adequate (two passes with a 16-gauge needle >20 mm and >11 portal tracts [28]) protocol biopsies in patients who do not develop symptoms or biochemical evidence of liver injury at 1, 3, 5, and 10 years after major decreases or total withdrawal of IS.

Findings in follow-up biopsies that should elicit concern for close follow-up include any noticeably increased inflammation, biliary epithelial cell damage, fibrosis, perivenular necro-inflammatory activity, or obliterative arteriopathy.

Long-term changes not readily explained by recurrent disease

Some histopathologic changes in long-surviving allografts cannot be attributed to recurrence of a specific disease and might represent adverse side-effects of medications or the effects of long-term engraftment and abnormal graft physiology [113,137,178]. Included are portal venopathy and nodular regenerative hyperplasia; thickening and hyalinization of small hepatic artery branches [137,257], subsinusoidal fibrosis, and "non-specific" portal and lobular inflammation [113,137,178]. Older livers placed into younger recipients

continue to age at the same or an accelerated rate (unpublished observation) and do not appear to experience any rejuvenation by being placed into a young body [258]. If nodular regenerative hyperplasia changes are detected early (<4 years) after transplantation progression to portal hypertension can occur [259]. As long-term survival after liver replacement is becoming increasingly common, more studies on these issues are needed.

Conclusions

Histopathologic evaluation of the liver is among the most diverse in transplantation, and the pathologist should be considered an integral part of the clinical liver transplant team. Indeed, real-time histopathologic assessment is required to inform the clinical management of the transplant recipient from organ acceptance through the life of the allograft, incuding retransplantation when necessary. The types of injuries commonly seen post-transplant include preservation–reperfusion injury small-for-size syndrome and rejection, and these give way to recurrent disease entities and viral hepatitis with time. Alterations in immune management also lead to alterations in hepatic histology. In general, changes in allograft status should prompt a biopsy, which in turn should prompt a critical assessment by a pathologist with specific experience in the spectrum of transplant-related disease.

CHAPTER 83

Histopathological Syndromes of Heart Allograft Rejection and Recurrent Disease

E. Rene Rodriguez and Carmela D. Tan
Department of Anatomic Pathology, The Cleveland Clinic, Cleveland, OH, USA

Introduction

Orthotopic heart transplantation is an effective therapy for end-stage heart disease of coronary and non-coronary etiology. Survival has continued to increase over time. The most common indications for cardiac transplantation in the adult have not changed in the last three decades: non-ischemic cardiomyopathies (53.3%) and ischemic disease (37.7%) [1]. In the pediatric age group, congenital heart disease is the most common indication for recipients <1 year of age. while cardiomyopathies account for more than 50% of the diagnosis in patients 1 year or older [2]. The current 10-year survival rate after cardiac transplantation is 50% and better in high-volume centers [1,2].

In this chapter, we focus on the technical, morphologic, and interpretive aspects of the anatomic pathology of the graft. We discuss the evolution and current status of the International Society for Heart and Lung Transplantation Working Formulations of 1990, 2005, and 2011 (ISHLT-WF-1990, ISHLT-WF-2005, and ISHLT-WF-2011) for the pathologic evaluation of transplant biopsies. This is followed by some comments about the pitfalls and caveats likely to be found, as well as controversial issues in the diagnosis of rejection in heart allografts. The chapter complements Chapters 71 and 79, which detail the clinical diagnosis and management of heart allograft rejection and recurrent disease, respectively.

Endomyocardial biopsy

The endomyocardial biopsy (EMB) remains the gold standard diagnostic tool for rejection surveillance in the heart transplant patient. It has a high sensitivity and specificity for the diagnosis of acute cellular rejection [3,4]. No other current modality of cardiac imaging, serum markers, or molecular diagnostics have higher sensitivity and specificity with a very short turnaround time to replace the performance of surveillance biopsies in the post-transplantation care and management of these patients [5]. While molecular testing has been developed for diagnosis, the biopsy is, at present, far more accessible for decision-making in real time.

Timing of the biopsy. In an ideal situation, a baseline donor biopsy should be obtained at the time of the transplant to provide assessment of the donor organ and rule out myocarditis, ischemic injury, or other pathologic changes. In most heart transplant centers, surveillance protocol biopsies are performed once a week for the first month, every 2 weeks for the second month, and every 4–8 weeks from the third to the twelfth month.

Procurement of the tissue. Bioptomes are used from either the jugular or femoral vein to sample the right ventricular septal wall. Bioptomes are available in different sizes (Figure 83.1), so the size of the piece of tissue retrieved will differ slightly. The common sizes used are 7 F (French) and 9 F in adults, and 3 F, 5 F, and 7 F in pediatric patients [6]. The cutting "jaws" procure adequate samples of subendocardial myocardium, usually from the interventricular septum.

Minimum number of tissue samples. As acute cellular rejection is not uniformly distributed in the heart, it is important to take multiple samples during the biopsy procedure. Pomerance and Stovin [7] showed that if three biopsy pieces taken show no rejection, there is a 5% and 0% chance of missing a mild and moderate–severe rejection, respectively. However, if four pieces are examined, the false-negative rate of mild rejection is further reduced to 2% [8]. Other investigators have emphasized that the extent of infiltration is also important, given that if at least three of the four fragments are graded separately as mild rejection, with a calculated frequency of 13.57% of the time, the probability of missing moderate–severe rejection is as high as 25% [9].

The ISHLT-WF-1990 required four pieces of tissue examined and optional procurement of one piece of tissue for freezing and one for electron microscopy [10]. In comparison, the ISHLT-WF-2005 formulation calls for the examination of at least three pieces, and preferably four (or more) of myocardium, 50% of which must be evaluable myocardium and not biopsy site or scar [11]. Specimens that do not meet these criteria should be diagnosed as "inadequate biopsy" [10]. The revised working formulation does not require a separate piece of frozen tissue or tissue routinely fixed for electron microscopy [11].

Pathologic evaluation of the biopsy. Optimal preservation of the tissue for diagnostic analysis can easily be done in the heart biopsy suite. The tissue should be fixed immediately in the desired fixative which has been allowed to reach room temperature of 25°C. Cold fixative enhances contraction band artifact. The tissue should not be allowed to sit on filter paper, gauze, or any other surface

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

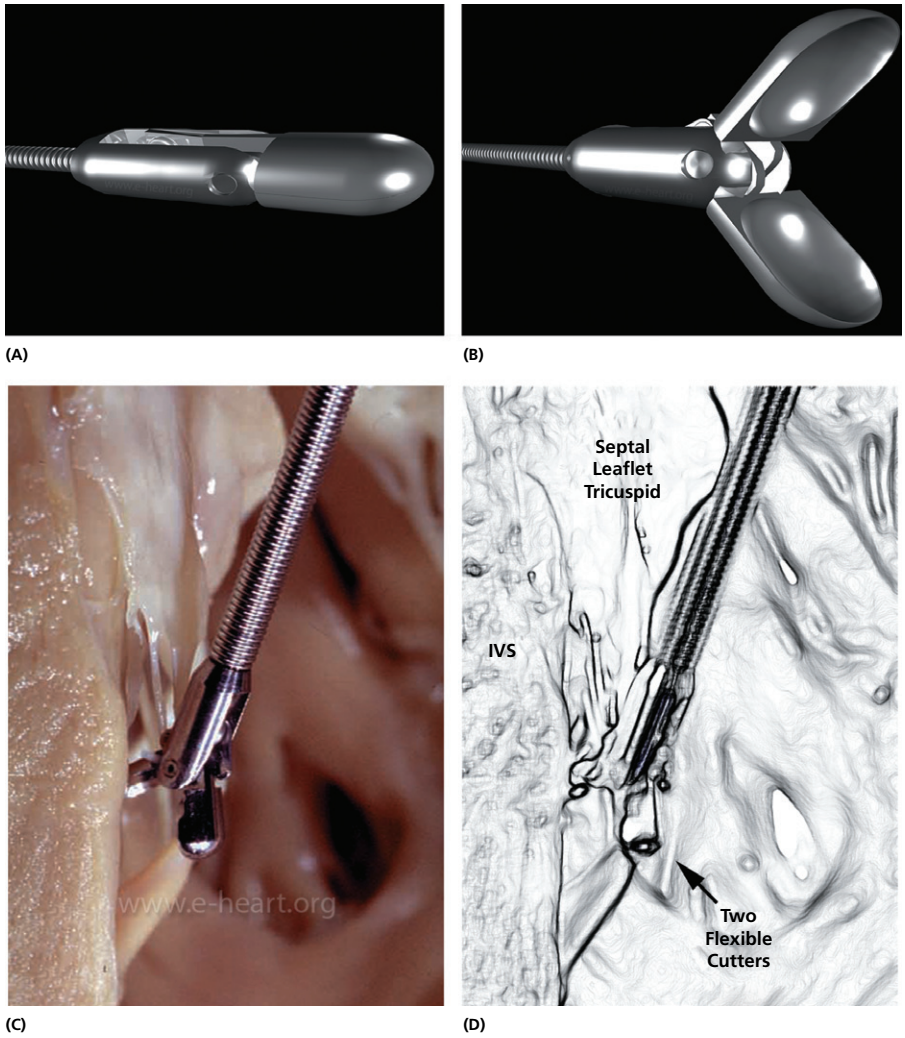

Figure 83.1. The bioptome (A,B) is the instrument used to procure endomyocardial biopsies. In North America, most biopsies are procured from the right side of the heart via transjugular approach. The target is the interventricular septal myocardium (C,D). The two spoon-shaped cutters provide adequate myocardial samples with minimal artifact.

impregnated with saline for a long period of time. Saline is a very poor solution to preserve the morphology of myocardium and readily creates artifacts. Other fixatives or preservatives that maintain tissue antigens in a better state for immunohistochemistry or immunofluorescence studies can also be used. For research protocols, one or more pieces of tissue can be snap frozen for molecular studies.

Gross examination. The gross description should include the demographic data of the patient, the number of tissue pieces, the average size, and color. In most instances careful gross examination provides important information regarding the presence of myocardium, thickened endocardium, adipose tissue, chordae tendineae [12], and blood clot or small endocardial thrombi. In our institution, we require that the number of pieces submitted be stated in the requisition form, verified on gross examination, and always correlated with the number of pieces present in the glass slides for microscopic examination.

Handling of the tissue. The tissue should be handled gently and not with forceps during gross examination in the pathology laboratory. It can be safely transferred directly from the specimen container into a mesh bag and then securely folded into the processing cassette. Do not triage the tissue. All the pieces obtained should be submitted, as they may have valuable information when examined with the microscope. Pieces that look white, suggesting that they are made up of thick endocardium, may actually be curled up, thus concealing some myocardium that will be visible on histologic sections (see section on Pitfalls and caveats). Likewise, pieces that look like blood clot may harbor a piece of myocardium in their core.

In our center, which is the third largest heart transplant center in the United States, the entire biopsy (i.e. all four or more pieces) is processed as a frozen section specimen. This procedure allows us to evaluate the sample for both acute cellular rejection and antibody-mediated rejection (AMR) in all the pieces, with a turnaround time of only a few hours. Careful preparation of the specimen prevents

Table 83.1. Acute cellular rejection (data from [10,11])

ISHLT-WF-1990	ISHLT-WF-2005
Grade 0 (no acute rejection)	Grade 0R
Grade 1A (focal, mild acute rejection) Grade 1B (diffuse, mild acute rejection) Grade 2 (focal, moderate acute rejection)	Grade 1R Mild (interstitial and/or perivascular infiltrate with up to 1 focus of myocyte damage)
Grade 3A (multifocal moderate rejection)	Grade 2R Moderate (two or more foci of infiltrate with associated myocyte damage)
Grade 3B (diffuse, borderline severe acute rejection) Grade 4 (severe acute rejection)	Grade 3R Severe (diffuse infiltrate with multifocal myocyte damage ± edema, ± hemorrhage ± vasculitis

freezing artifacts such as ice crystals forming in the sarcoplasm of the myocytes.

Cardiac allograft rejection: morphologic aspects

After more than a decade of widespread use, the ISHLT-WF-1990 working formulation [10] was revisited during the Heart Session of the Banff Allograft Pathology group meeting in 2001. The meeting consensus was that although the working formulation had withstood the test of time, some areas for refinement in the cellular rejection grading approach existed, and the lack of standard diagnostic criteria for AMR needed to be addressed [13]. The formal revision was published in 2005 and it is the current working formulation for acute cellular rejection [11]. The ISHLT-WF-2005 provided for the first time the criteria for diagnosis of AMR [11,14] (Table 83.1). A further revision of the working formulation for the diagnosis of AMR was published in 2011 (ISHLT-WF-AMR-2011) [15]. Like in any other solid organ, cardiac allograft rejection can be divided into humoral and cellular rejection. These can in turn be subclassified into hyperacute, acute, and chronic rejection on the basis of mechanism and duration of the process.

Hyperacute rejection consists of a violent complement-mediated immune attack to the graft that is triggered by preformed antibodies and occurs very quickly, usually within minutes to hours, after the implantation of the graft. Mechanistic specifics of hyperacute rejection can be found in Chapter 6. Predisposing factors that may have a role are preformed antibodies to epitopes of the ABO and human leukocyte antigen (HLA) systems, multiple pregnancies, multiple surgeries with the use of blood products, and even previous cardiac transplantation. The activation of the complement cascade produces severe endothelial cell damage as well as platelet activation, followed by the clotting cascade and thrombosis. The morphologic findings include swelling of the endothelial cells (not easily documented by light microscopy), microthrombi, extravasation of red blood cells and even microscopic hemorrhages, interstitial edema, and subsequently polymorphonuclear inflammatory infiltrates, followed by tissue necrosis. On gross examination, the changes may be inconspicuous or may show hemorrhages or the combination of pallor and hemorrhages. Immunohistochemical studies may show deposits of IgM, IgG, and complement in the vessel walls as well as interstitial fibrin. Unfortunately, the pathologic examination of this type of rejection is usually carried out during the autopsy [16].

Acute cellular rejection: effector cells. Morphologically, acute cellular rejection is a mononuclear inflammatory response, predominantly lymphocytic, directed against the cardiac allograft. Its mechanistic features are detailed in Chapter 5. In severe cases, there is also participation of the granulocytes in the rejection process. The subtleties and variations of this response are used in the grading of rejection. The rejection grades proposed in the working formulation are based mainly on the amount of inflammatory infiltrate and the presence of myocyte damage; the pattern of inflammatory infiltration plays a minor part. Studies that have characterized the phenotype of lymphocytes in cardiac biopsy tissue have shown no good correlation between the extent and composition (CD4:CD8 ratio) of T lymphocytes infiltrating the graft and the histologic grading of rejection [17,18]. However, other studies report a good correlation between the mean number of $CD8^+$ T cells and the severity of rejection grade [19]. The discrepancy in these studies may be related to the fact that the immune response to the allograft is a continuous process in flux that is usually dissected in small "time-lapsed" views for pathologic study. Some support to this notion is provided by the observation that if subsets of T lymphocytes are further classified on the basis of the presence of naive cells (CD45RA) and memory or activated cells (CD45RO), naive cells of the CD4 phenotype are more abundant in biopsy tissue during mild rejection. A shift toward activated CD8 phenotype is seen in moderate rejection [20]. An increase in the number of antigen-presenting cells (i.e. macrophages and dendritic cells) is also observed as a function of the severity of rejection [21–24]. The role of regulatory cells in human cardiac allograft rejection is not well defined. However, recent quantitative methods in biopsy material will allow better characterization of this subtype of T cells in cardiac allografts [25].

B-cell infiltrates are rarely present in mild rejection. However, a substantial increase in activated B lymphocytes and natural killer cells are seen in moderate rejection, suggesting their important role as promoters and effectors of cellular rejection [24].

Grading of acute cellular rejection in endomyocardial biopsies

The rejection grades in the current ISHLT-WF-2005 have the added suffix R after the grade (Table 83.1), to indicate that these are the "revised" grades as follows [11]:

Grade 0R (no acute cellular rejection). In Grade 0 R, there is no evidence of mononuclear (lymphocytes/macrophages) inflammation or myocyte damage (Figure 83.2).

Grade 1R (mild, low-grade, acute cellular rejection). Mild or low-grade rejection may manifest in one of two ways. First, perivascular and/or interstitial mononuclear cells lymphocytes/histiocytes) are present. In general, these cells respect myocyte borders, do not encroach on adjacent myocytes, and do not distort the normal architecture (Figure 83.3). Second, one focus of mononuclear cells with associated myocyte damage may be present.

Grade 2R (moderate, intermediate-grade, acute cellular rejection). In Grade 2R, two or more foci of mononuclear cells (lymphocytes/macrophages) with associated myocyte damage are present. Eosinophils may be present. The foci may be distributed in one or more than one biopsy fragment. Intervening areas of uninvolved myocardium are present between the foci of rejection (Figure 83.4). Low-grade rejection can be present in other biopsy pieces.

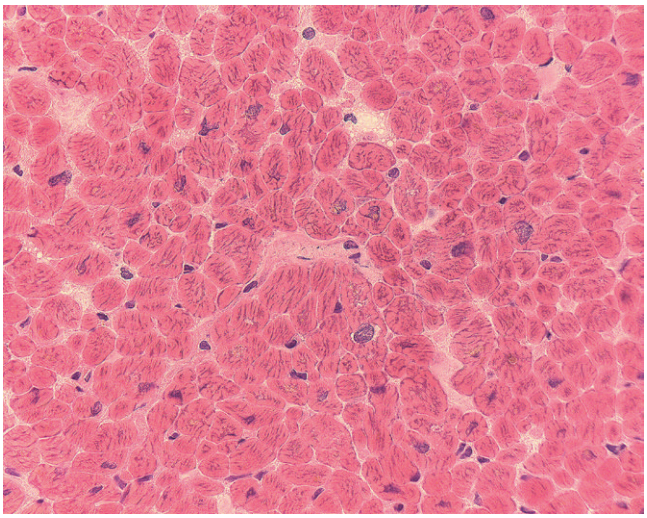

Figure 83.2. Endomyocardial biopsy of an allograft with rejection Grade 0R. The myocytes show minimal hypertrophy with enlarged hyperchromatic nuclei, but no evidence of any inflammatory infiltrates in the interstitium or around a small arteriole seen in the center of the image (H&E, original magnification ×400).

Grade 3R (severe, high-grade, acute cellular rejection). A diffuse inflammatory process, either predominantly lymphocytes and macrophages, or a polymorphous infiltrate, is present (Figure 83.5). In most cases, the majority of biopsy fragments are involved, although the intensity of the infiltrate may vary between pieces. Multiple areas of associated myocyte damage are present. In the most severe forms of cellular (and humoral) rejection, edema, interstitial hemorrhage, and vasculitis may be present.

Additional information to be included in the biopsy report (non-rejection biopsy findings) (Table 83.2)

Statement on adequacy of biopsy. The term inadequate biopsy should be used when the specimen consists of less than three pieces [10,11]. In addition, the term inadequate biopsy should also be used even when the number of pieces examined under the microscope is four, but the myocardium present in one or more of these pieces is less than 50% of the piece. The inadequate pieces usually consist of mostly or only endocardium, thrombus, granulation tissue from a previous biopsy site, or adipose tissue. However, it should be recognized that in some instances, valuable information such as rejection is present in the other adequate biopsy pieces. Although a diagnosis of rejection cannot be rendered, the findings can be

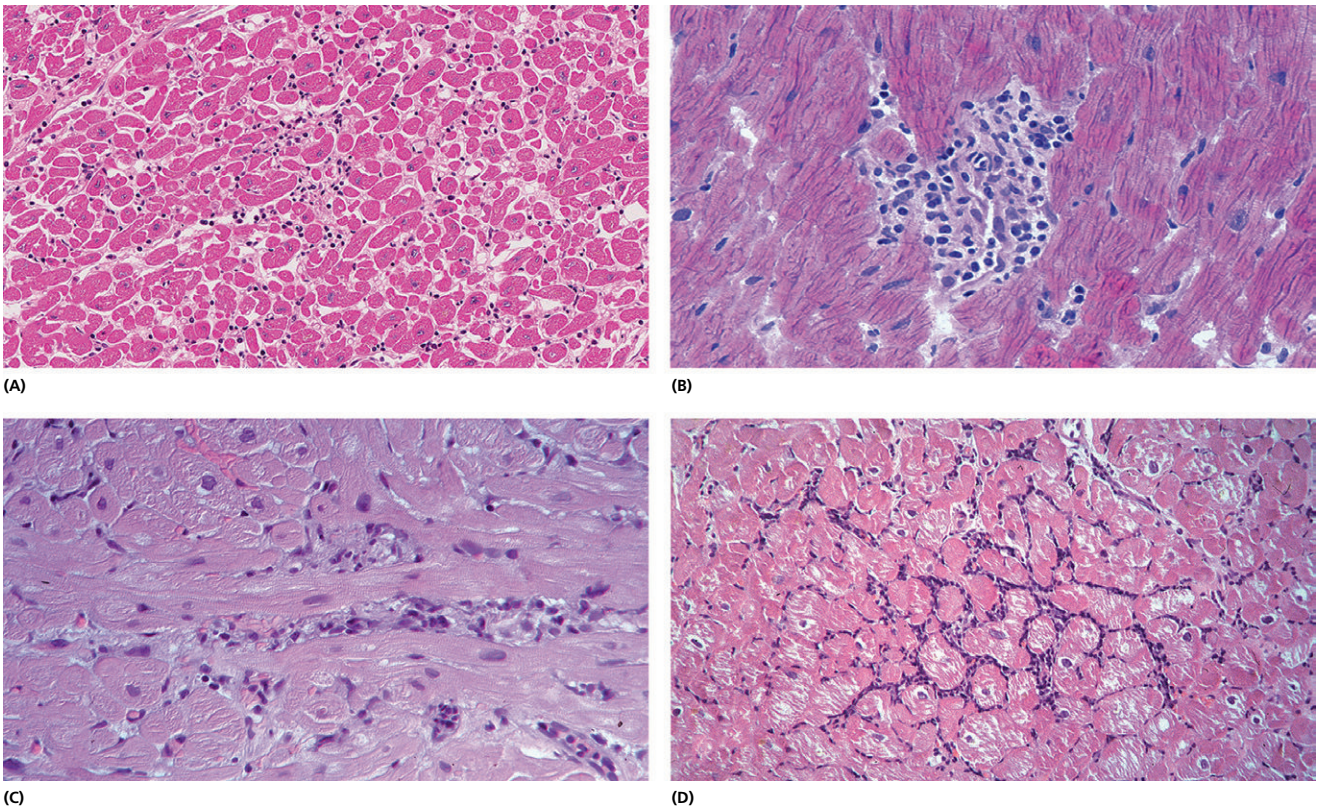

Figure 83.3. Rejection Grade 1R. (A) Light micrograph showing scant but conspicuous lymphocytes in the interstitium of the myocardium without evidence of necrosis, injury, or dropout of the myocytes (H&E, original magnification ×100). (B) A cluster of lymphocytes is present surrounding a small arteriole and also extending into the interstitial space. The infiltrate is discrete and clearly "vasculocentric" (H&E, original magnification ×200). (C) A slightly different pattern of lymphocytic infiltrate present in both perivascular and interstitial pattern (H&E, original magnification ×200). (D) This micrograph shows a more abundant infiltration, with the lymphocytes distinctly surrounding individual myocytes in their perimysial spaces. This "chickenwire" pattern was designated as the 1B pattern in the ISHLT-WF-1990 (H&E, original magnification ×150).

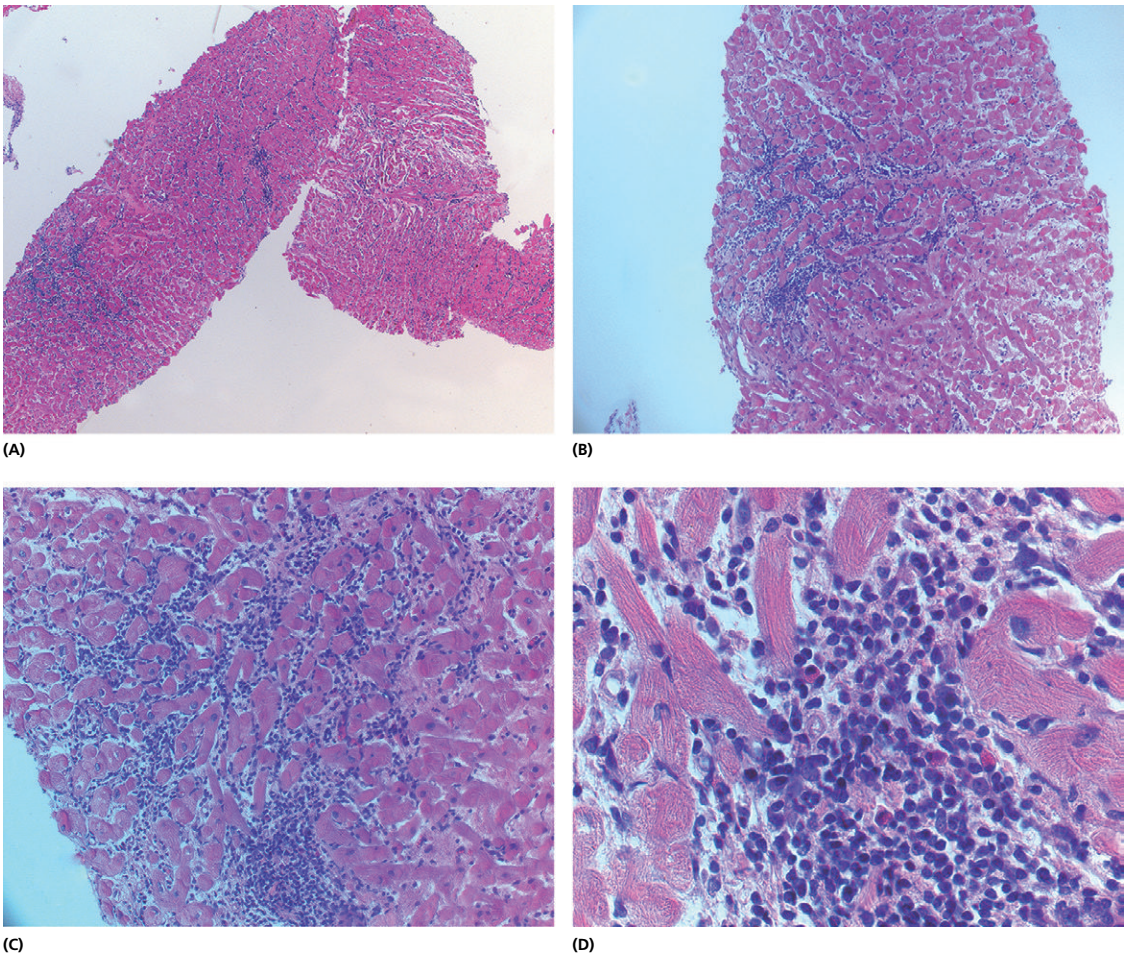

Figure 83.4. Rejection Grade 2R. (A) This biopsy shows multifocal lymphocytic infiltrates that expand the interstitial space. Two distinct foci of more abundant inflammatory infiltrates with an intervening area of myocardium without inflammation are shown (H&E, original magnification ×20). (B,C) Myocyte dropout is clearly present as well as distinct encroachment of the myocytes by the lymphocytic infiltrates (B, H&E, original magnification ×40, and C, original magnification ×200). (D) In this close up of C, the expansion of the inflammatory infiltrate clearly replaces myocytes (dropout) and in addition shows some eosinophils (H&E, original magnification ×400).

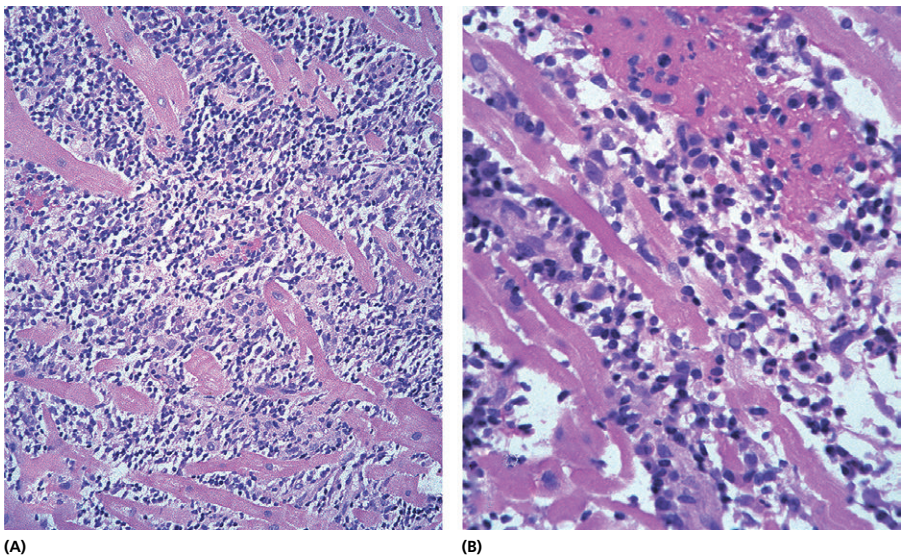

Figure 83.5. Rejection Grade 3R. (A) The myocardium is diffusely and extensively infiltrated by dense mononuclear inflammatory cells. These represent a grade 3B in the ISHLT-WF-1990 (H&E, original magnification ×100). (B) The extensive inflammation can progress to the stage in which neutrophils and even vascular necrosis can be seen. In addition, marked interstitial edema accompanies the inflammatory infiltrate (H&E, original magnification ×400).

documented in the report as part of the histologic description or as a note.

Perioperative ischemic injury. This is an early process of ischemic injury related to prolonged ischemic time and characterized by contraction band necrosis or coagulation necrosis (Figure 83.6A,B). Early perioperative necrosis may be due to events that affect the donor such as catecholamine discharge, pressor therapy given during acute care, severe donor trauma, reimplantation damage, or early postoperative damage [26]. A biopsy of the septum taken at the time of implantation is informative although the changes can be very subtle. During allograft monitoring, the working formulation makes a distinction between ischemia commonly seen up to the third week post-transplant representing perioperative injury and late ischemia that occurs after 3 months or more. Morphologically there is clear evidence of myocyte necrosis, usually coagulative type, with hypereosinophilic myocytes, pyknotic nuclei, and even some karyorrhexis. Myocyte necrosis is usually out of proportion to the inflammatory infiltrate; myocyte vacuolization may be seen. Healing may be delayed due to immunosuppression [26]. Although this type of necrosis can be clinically silent, these changes can compromise the function of the graft in various degrees if severe. These areas are usually conspicuous, especially when stained with Masson trichrome. Calcification of myocytes sometimes occurs (Figure 83.7). Myocyte vacuolization and fat necrosis may also be seen [26]. As healing ensues, the biopsy may show mixed inflammatory infiltrates, including neutrophils, lymphocytes, macrophages, and eosinophils. This phenomenon may be seen in biopsies

Table 83.2. Non-rejection findings (data from [10,11])

ISHLT-WF-1990	ISHLT-WF-2005
Ischemic injury	*Ischemic injury*
A = up to 3 weeks post-transplant	Early – up to 6 weeks post-transplant
B = late ischemia	Late – related to allograft coronary disease
Quilty effect	*Quilty effect*
A = no myocyte encroachment	
B = with myocyte encroachment	
Infection	*Infection*
Lymphoproliferative disorder	*Lymphoproliferative disorder*

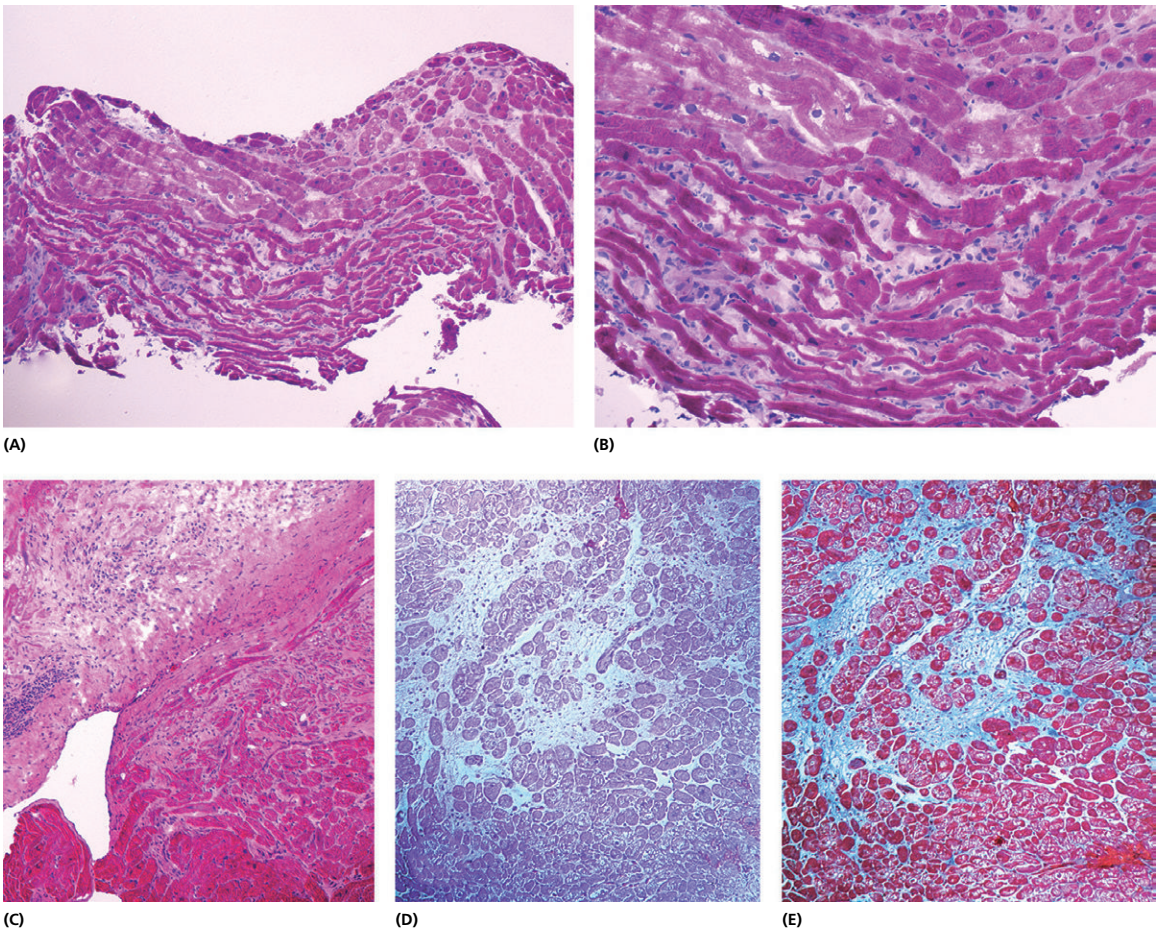

Figure 83.6. Ischemic injury. (A,B) Hypereosinophilic wavy thinned myocytes with distinctly pyknotic nuclei and/or loss of nuclei which represent acute ischemic injury (H&E, A original magnification ×40; B original magnification ×200). (C) Healing ischemic focus with loose granulation tissue and mild lymphocytic infiltrates (H&E, original magnification ×40). (D,E) Replacement and interstitial fibrosis representing healed areas of ischemic injury are shown. When present late in the post-transplant period, they should always raise the suspicion for the presence of allograft vasculopathy (D, Masson's trichrome, original magnification ×40).

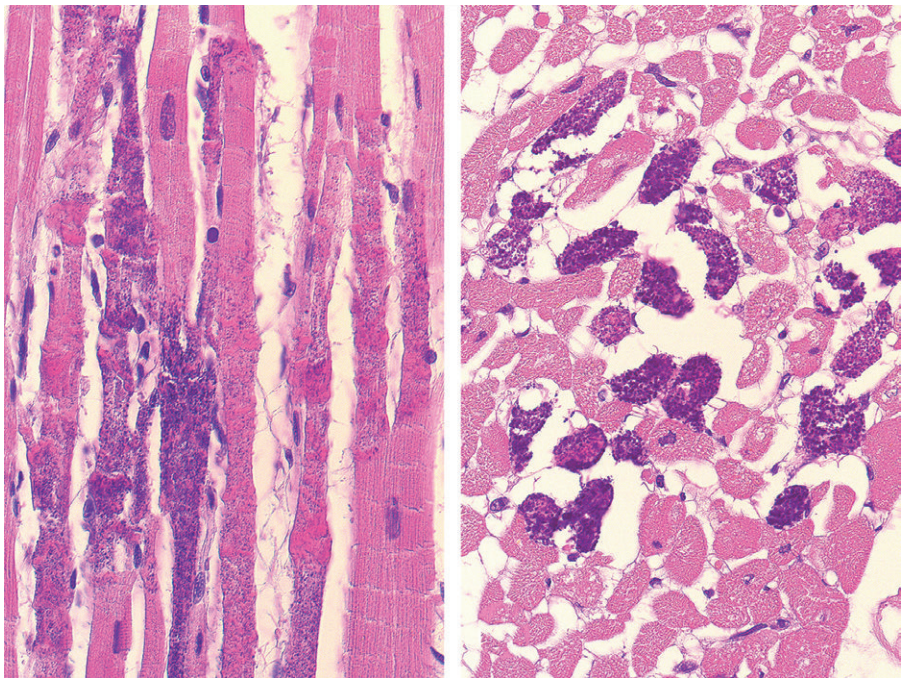

(A) (B)

Figure 83.7. Calcification of myocyte mitochondria in ischemic injury. Mitochondrial calcification can be recognized as basophilic sarcoplasmic granules in these necrotic myocytes. (A) The myocytes in longitudinal section show that the basophilic mitochondria are in register with the striations of the sarcoplasm (H&E, original magnification ×400). (B) In cross-section, the pattern of distribution of the calcified mitochondria in the sarcoplasm is more haphazard (H&E, original magnification ×400). As a function of time, the myocytes become completely calcified (see Figure 83.12).

during the first 6 weeks. The injury to the myocytes is greater than the inflammatory infiltrate in this lesion [11].

A possible early injury to the allograft during the peritransplant period is the development of interstitial fibrosis [27]. The only way to ascertain that the fibrosis may be the result of peritransplant ischemic injury is to obtain a baseline biopsy piece at the time of implantation of the graft. Another caveat with regard to fibrosis is the fact that the size of the actual myocardial piece may influence the perception of the amount of fibrosis [28].

Late ischemic injury. Assessing the arterial changes of allograft vasculopathy is usually precluded by the lack of vessels large enough to permit such an evaluation in the biopsy specimen. However, secondary myocardial changes, such as colliquative myocytolysis and coagulation necrosis, can be easily identified. In the setting of cardiac allograft vasculopathy, ischemic foci are not associated with any significant mononuclear infiltrates. Thus, the diagnosis of late ischemic injury may be helpful in ruling out other potentially treatable etiologies that are part of the differential diagnoses for cardiac failure in transplant recipients, such as acute cellular rejection or AMR [11].

Endocardial lymphocytic infiltrates (Quilty effect). Endocardial lymphocytic infiltrates [29], also known as "Quilty effect" [30], are collections of T and B cells with histiocytes [31] seen in the endocardium of transplanted hearts (Figure 83.8). Plasma cells are present in about half of these lesions. Occasional eosinophils and neutrophils may be seen [32]. Capillaries with red blood cells and sometimes prominent endothelial cells may be seen within the infiltrate. They vary in size from 0.007 to 1.89 mm^2 [29]. Several hypotheses have been proposed to explain the pathogenesis of these infiltrates which include the use of cyclosporine [33] to concomitant infection with Epstein–Barr virus [34], low local levels of cyclosporine in the areas of endocardium where Quilty effect infiltrates develop [35], and idiosyncrasy to cyclosporine [33] but none of these has been proven. However, one striking observation is that the Quilty effect does not occur in the hearts of patients who are taking cyclosporine as a result of having received other organ transplants (i.e. liver, kidney) [36]. It seems to be a phenomenon that only occurs in the endocardium of cardiac allografts.

Quilty effect infiltrates may or may not be associated with rejection. The size of these infiltrates varies greatly, from a small cluster of mononuclear cells to grossly visible 2 mm lesions. Two morphologic patterns were recognized in the ISHLT-WF-1990: types A and B. Type A was confined to the endocardium. Type B extended into the subjacent myocardium [10] (Figure 83.8C,D). The ISHLT-WF-2005 removed the requirement to classify the Quilty effect lesions into A and B, because there is no clinical relevance to the distinction of these two patterns [11]. However, there is a third rarely seen pattern in which lesions identical to Quilty effect lesions are found deep in the myocardium besides the typical endocardial lymphocytic infiltrates.

Quilty effect and moderate rejection. The possible confusion of Quilty infiltrates with rejection [37] has been a problem for pathologists because of the obvious implications for therapy. One may imagine how a tangential section through the deeper myocardial end of a biopsy may show inflammatory infiltrates that look like rejection if only a few levels of section are examined. However, if deeper sections are made, or better yet, if all the biopsy tissue is

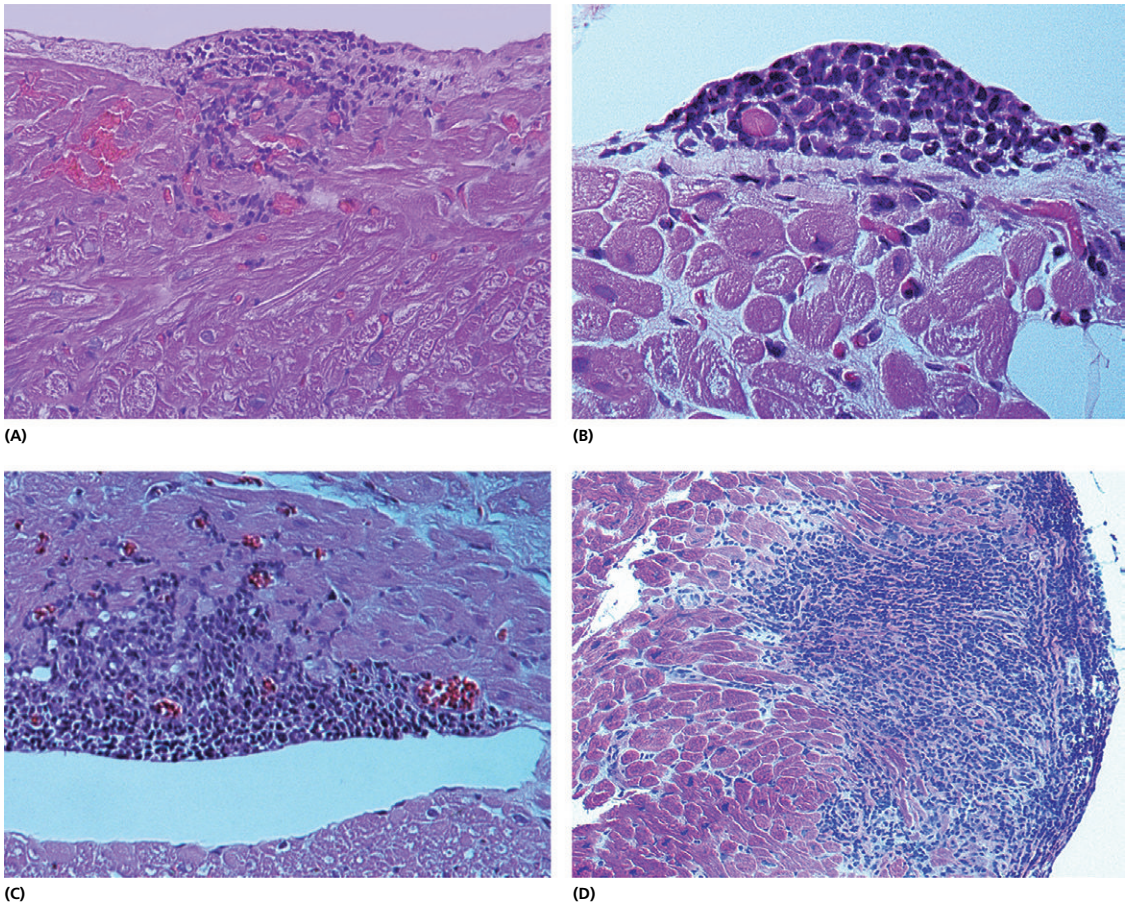

Figure 83.8. Endocardial lymphocytic infiltrates (Quilty lesions). (A) Lymphocytic infiltrate contained within the endocardium and extending into the myocardium is shown in this biopsy (H&E, original magnification ×150). (B) This Quilty lesion is distinctly contained within the endocardium and does not penetrate the subjacent myocardium. Such lesion used to be called Quilty type A in the ISHLT-WF-1990 (H&E, original magnification ×400). (C) This infiltrate is clearly within the endocardium and showing early infiltration of the myocardium. In addition, it shows conspicuous blood vessels filled with red blood cells. These are very characteristic and common in Quilty lesions. However, in frozen sections, these vessels may not be as conspicuous (H&E, original magnification ×200). (D) In this biopsy, the lymphocytic infiltrate clearly extends into the subjacent myocardium with finger-like projections. This used to be called Quilty B in the ISHLT-WF-1990 (H&E, original magnification ×100).

examined, it would soon become very obvious that the inflammatory infiltrate in the myocardium is connected to a Quilty type lesion in the endocardium.

Quilty effect and lymphoid neoplasms. Exuberant Quilty lesions can be easily distinguished from lymphoid neoplasms by their cellular composition and location. Lymphoid neoplasms are reported to occur in 6% of all transplanted patients [38]. The role of Epstein–Barr virus in the pathogenesis of post-transplant lymphoproliferative disorders (PTLD) is established [39–42] but not necessarily the sole cause of this disorder [43,44]. In most instances, these neoplasms are monoclonal B-cell type [45] and their clinical presentation involves the lymph nodes, the central nervous system, systemic organs, or the transplanted organ itself [39]. Nevertheless, T-cell lymphomas also occur [46], but primary cardiac presentation of these neoplasms is not common [39]. Development of multiple myeloma is rare [47]. Additional discussion of PTLD and malignancies post-transplant can be found in Chapters 93 and 95, respectively.

In summary, endocardial lymphocytic infiltrates (Quilty effect) are lesions that are commonly seen in cardiac transplant biopsies but until now lacked any clinical relevance. In a recent report including 217 adults and 22 children studied for 10 years, the authors show that 49% of adults and 68% of children show these infiltrates [30]. The important points in this study are that there seems to be no association between the endocardial infiltrates and: (1) grade of rejection; (2) subsequent development of vasculopathy (vascular chronic rejection); (3) development of lymphoma; and (4) viral infections (cytomegalovirus or Epstein–Barr virus). Lastly, because there is no difference whether the infiltrate is type A or type B the ISHLT-WF-2005 no longer requires this distinction [11].

Pitfalls and caveats

Although an enormous effort has been made to create a standard method for grading rejection [10,11], there are several controversial points that are often identified by both pathologists and cardiologists in using the working formulation.

Myocyte injury. A difficult issue in the interpretation of endomyocardial biopsies from human allografts has been the inability to obtain consensus about the definition of myocyte damage even among experienced pathologists trained in, and dedicated to,

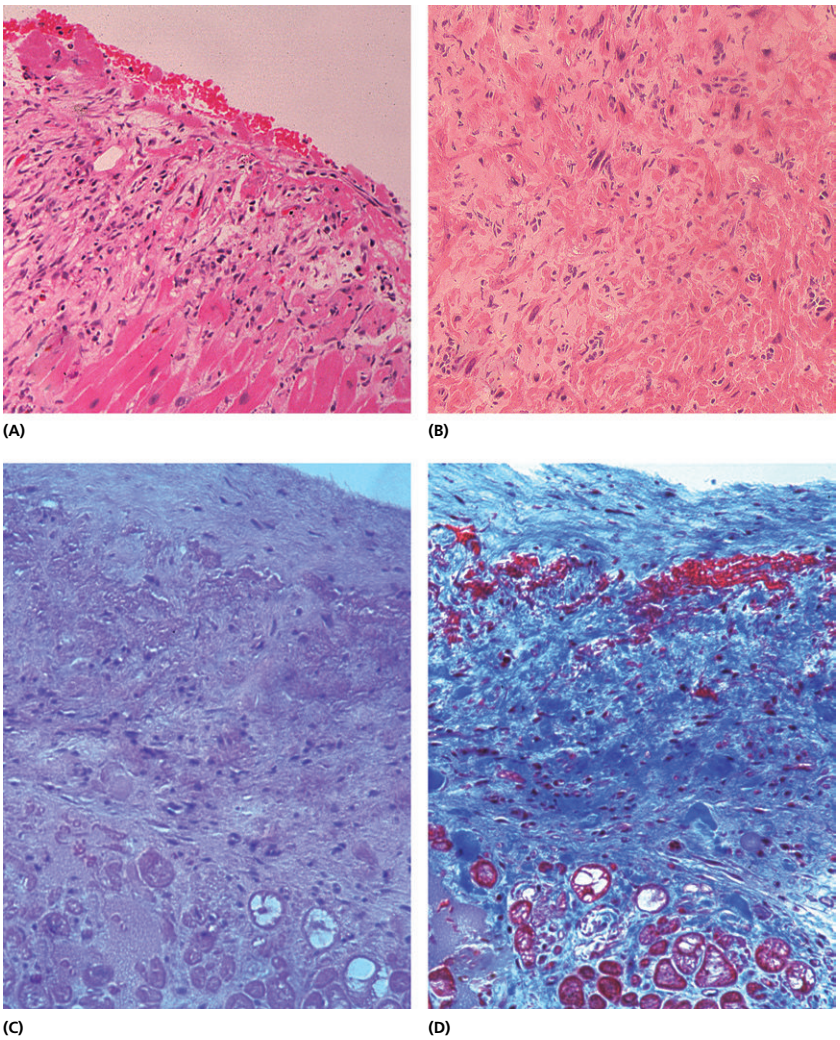

Figure 83.9. Previous biopsy sites. (A) This image illustrates an area of granulation tissue in the endocardium with abundant fibroblasts and some red blood cells on the surface. The fibrous tissue is still loose. It represents an area of healing from a recent previous biopsy site (approximately a week old) (H&E, original magnification ×100). (B) This area of granulation tissue shows further healing, with somewhat fewer fibroblasts and distinct maturing denser fibrous tissue than the lesion in A. Note the mild disarray of myocytes within the scar shown in this field. This lesion may represent a healing biopsy site of approximately 2–3 weeks' evolution (H&E, original magnification ×200). (C,D) These two images show a well-healed previous biopsy site with endocardial thickening and subjacent scar. The trichrome stain in D shows a distinct increase of dense fibrous tissue forming the scar (C, H&E, original magnification ×200; D, Masson's trichrome, original magnification ×200).

cardiovascular pathology [13]. The suggestion at the Banff 2001 conference was to focus on terminology that was more precise for pathologists, such as myocyte injury [13]. On light microscopic examination, this type of injury can encompass a spectrum of subtle to ominous changes. The subtle changes are more difficult to be noticed by the occasional observer. In a strict sense, simple changes in the myocytes such as vacuolization, hydropic change, or perinuclear halos [48] are at the somewhat milder end of the spectrum whereas coagulation necrosis, myocytolysis, and nuclear pyknosis are at the very worse end of the spectrum. Thus, the term damage is rather ambiguous. Unless there is clear coagulative necrosis or fragmentation of the sarcoplasm or typical nuclear changes such as pyknosis in the myocytes, the identification of "damaged" cells in hematoxylin and eosin stained paraffin sections is a subjective matter. Ultrastructural studies have clearly shown that subtle myocyte damage is present [49]. Myocyte degeneration is easily distinguished from necrosis. Damage to endothelial cells, basal lamina, or other components is also easily recognized [50]. Myocyte necrosis as defined by ultrastructural criteria is common in humoral rejection, whereas myocyte degeneration with the potential for recovery is more common in cellular rejection [51]. Ultrastructural studies have suggested that some of the myocyte damage seen during rejection may actually be a reversible process [49,52]; however, by light microscopy some of the myocyte changes that represent sublethal damage are indistinguishable from actual early necrosis.

Previous biopsy site. This is a common finding in transplant monitoring biopsies (Figure 83.9). In fact, it can be seen in 53–69% [53,54] of biopsies. This high frequency is because, for a given patient, the anatomy of the inflow tract to the right ventricle is constant. During the biopsy procedure using the jugular approach, the ridges of the atrial anastomotic site, the right ventricular trabeculations, and the moderator band all contribute to guide the tip of the bioptome towards the same site in the interventricular septum. Gross examination at autopsy may show a patch of thickened endocardium measuring 1–2 cm in diameter in the mid-third of the right ventricular septum in patients who survived several months to years after the transplant. On light microscopy, the findings of this repetitive sampling of a small area of the septum vary with the interval between biopsies.

Opportunistic infections. It is well-known that chronic immunosuppressive drug therapy predisposes transplant recipients to a large number of opportunistic infections including viruses, bacteria, fungi, and protozoa. This is covered in detail in Chapters 92,

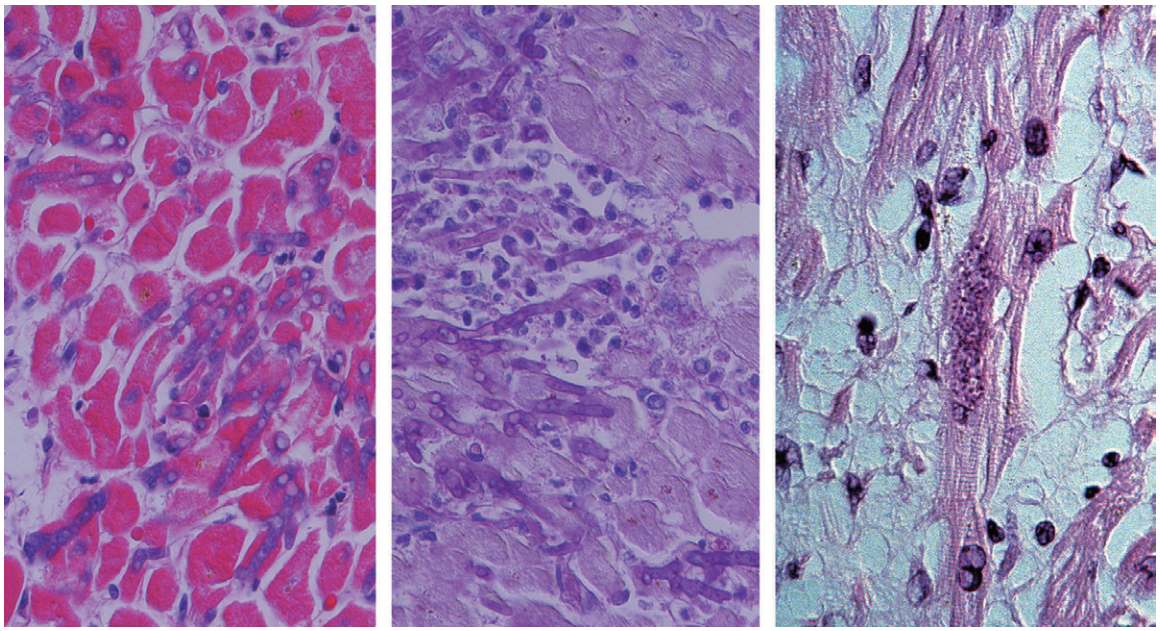

Figure 83.10. Agents in endomyocardial biopsy. (A,B) *Aspergillus* species hyphae growing in the myocardium (A, H&E, original magnification ×400; B, PAS stain, original magnification ×400). (C) In this biopsy there is a myocyte showing a sarcoplasmic cyst filled with bradyzoites of *Toxoplasma* (H&E, original magnification ×800).

93, and 94. Bacterial infection is the most common type of infection [55]. Viral infections are second in frequency, with fungal and protozoal pathogens being responsible for the rest [56,57]. The two most commonly reported opportunistic infections seen in EMB specimens are *Toxoplasma* and cytomegalovirus [58–60]. Other organisms reported to occur in heart transplant patients include the following:

Viruses: hepatitis B [61], hepatitis C [62], enteroviruses, parvovirus B19 [63], Epstein–Barr virus [63] and other herpes viruses, adenovirus [63].

Bacteria and mycobacteria [64–66].

Fungi: Aspergillus [67,68], *Candida* [68], *Nocardia* [55], *Mucor* [69] (Figure 83.10A,B).

Protozoa: Pneumocystis [70], *Toxoplasma* (Figure 83.10C) [71], *Leishmania* [72] reactivation of Chagas' disease [73].

In the pediatric heart transplant population, the pathogens reported include viruses (cytomegalovirus, herpes simplex, varicella-zoster, respiratory viruses, and Epstein–Barr virus), bacteria (mycobacteria, Gram-positive and Gram-negative), toxoplasmosis, and pneumocystis [68,74,75].

It should be noted that the identification of micro-organisms in endomyocardial biopsy is difficult and should never be the only method to rule out infection. When examining a biopsy, always look for hints of infection such as unusual inflammatory infiltrates. Unusual in this context may be the presence of granulocytes, plasma cells, and/or macrophages in a focus of inflammation without overt myocyte necrosis or dropout. Areas like these may harbor intracellular parasites (such as *Toxoplasma*) or fungal organisms, which can be elusive on hematoxylin and eosin stain. Special stains for micro-organisms should then be performed as needed. The pathologist should also look for viral inclusions in the nuclei of endothelial cells, smooth muscle cells, or miscellaneous perivascular cells. Viral inclusions visible by light microscopy within the cardiac myocytes are quite rare.

Adipose tissue: perforation and infiltration. Adipocytes are normal cellular components of the heart mostly present in the epicardium. Microscopic foci of adipose tissue are usually present in the subendocardium and within the myocardium. These foci can be seen in all chambers but are more commonly found in the right ventricular wall in obese patients and patients taking steroids. Thus, the pathologist should bear in mind that finding adipose tissue per se is not pathologic. An attempt should be made to define whether the adipose tissue seen in an endomyocardial biopsy is part of the ventricular wall because it may also come from the epicardium (Figure 83.11). Although the aim of a right ventricular biopsy procedure is to obtain samples from the right side of the interventricular septum, the bioptome may actually sample the right ventricular free wall. Therefore, when a focus of adipose tissue is found in an endomyocardial biopsy, the pathologist should make an effort to determine if this is subendocardial or subepicardial adipose tissue. This can sometimes be easily determined by looking for the presence of mesothelial cell lining, which indicates the surface is actually epicardium (Figure 83.11B). The presence of ganglion cells or nerves is not indicative of perforation. However, because of the fibrinous and eventually fibrous pericarditis that usually develops after the transplant, it may be difficult to find mesothelial lining. In the latter case, the presence of nerves and ganglion cells may be suggestive of epicardial location, as these types of peripheral nerve tissue are common in the epicardium. However, a few weeks after the transplant, the organized pericarditis usually forms a dense protective layer around the myocardium that prevents the development of tamponade if there is perforation. The presence of adipose tissue in endomyocardial biopsies has been reported [76]

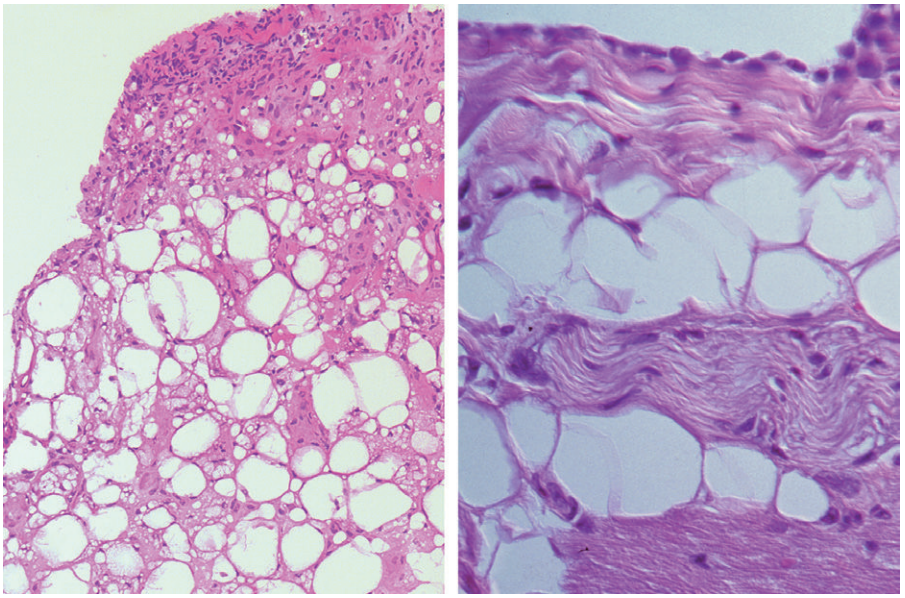

Figure 83.11. Adipose tissue in endomyocardial biopsy. (A) Endomyocardial biopsy showing abundant adipose tissue with macrophages (H&E, original magnification ×100). (B) Cuboidal mesothelial cells are present (top) as well as adipose tissue and nerve fibers in this biopsy. These findings distinctly indicate perforation of the myocardial wall and sampling of epicardial structures such as mesothelial cells and epicardial nerve fibers (H&E, original magnification ×400).

and classified [77] in non-transplant patients. The presence of adipose tissue has been reported to occur in 4.62% of transplant biopsies in one study [77]. In transplant biopsies, there is also some tendency to see fat deposits in areas of previous biopsy site or perhaps foci of healing ischemic damage. Whether the use of steroids for the treatment of rejection increases the amount of adipose tissue in the endocardium is not known.

Other artifacts: contraction bands. This is a very common artifact seen in transplant and non-transplant heart biopsies. Several factors may influence the presence of contraction bands in the biopsy (Figure 83.12A). It may be the result of trauma to the myocardium induced when the bioptome cuts the tissue. It may also be induced by poor osmolarity of the medium in which the biopsy is placed before and during fixation, as well as the cold temperature of the medium of fixative (i.e. 4°C or 22°C). Because of the high likelihood of finding contraction bands, they alone should never be the only criterion used to make a diagnosis of myocyte necrosis or ischemic injury.

Pinching or forceps artifact. This represents mechanical distortion of the tissue due to manipulation (Figure 83.12B). The bioptome itself can induce this artifact, specifically if its cutters are not very sharp (in the case of reusable bioptomes). It can also be induced during processing of the tissue in the pathology laboratory. An effort should be made to handle it with care because this artifactual deformation may render the specimen uninterpretable.

Foreign bodies. Occasional foreign bodies introduced at the time of the transplant can be seen, such as gel foam. It is also possible that the bioptome may actually sample fragments of indwelling catheters or the soft plastic cover of pacemaker leads.

Pseudohemorrhage. During the biopsy procedure,the spoon-shaped cutters of the bioptome can trap red blood cells and, at the time of biopsy, embedd these cells into the myocardium by the pressure of the bioptome on the tissue (Figure 83.12C). This produces artifactual pools that mimic hemorrhage. They are usually not accompanied by inflammatory cells or pathologic changes in the myocytes, thus making the distinction between artifact and rejection fairly easy.

"Telescoping" or intussusception of small arteries. This occurs when a small muscular artery is sampled by the bioptome. Just before the bioptome cutters actually cut the tissue, the small artery is stretched and, as soon as it is cut, recoils into its own lumen. This can give the appearance of an occluded vessel or a small artery with vasculopathy. However, the elastic lamina if present in small arteries is usually determinant in showing that there is an intussusception of the artery, thus making the distinction from vasculopathy rather obvious. It is uncommon to see this artifact occur in arterioles (Figure 83.12D).

Dystrophic calcification. There have been reports of various forms of calcification in the heart after transplantation (Figure 83.12E). In some patients, radiographic evidence of calcification has been shown in the native atria [78,79] and in biopsy tissue [78]. In our experience, it is also uncommon to see dystrophic calcification of the ventricular myocardium in biopsies (Figure 83.7). In most other reports, the myocytes and specifically the mitochondria show calcification. On light microscopy, the dystrophic calcification of the mitochondria is easily recognized as dark blue granular material within the myocytes. These granules are 1–2.5 μm in diameter. The granules may be seen in perinuclear location and also following the pattern of the sarcomeres. When abundant, they follow the contour

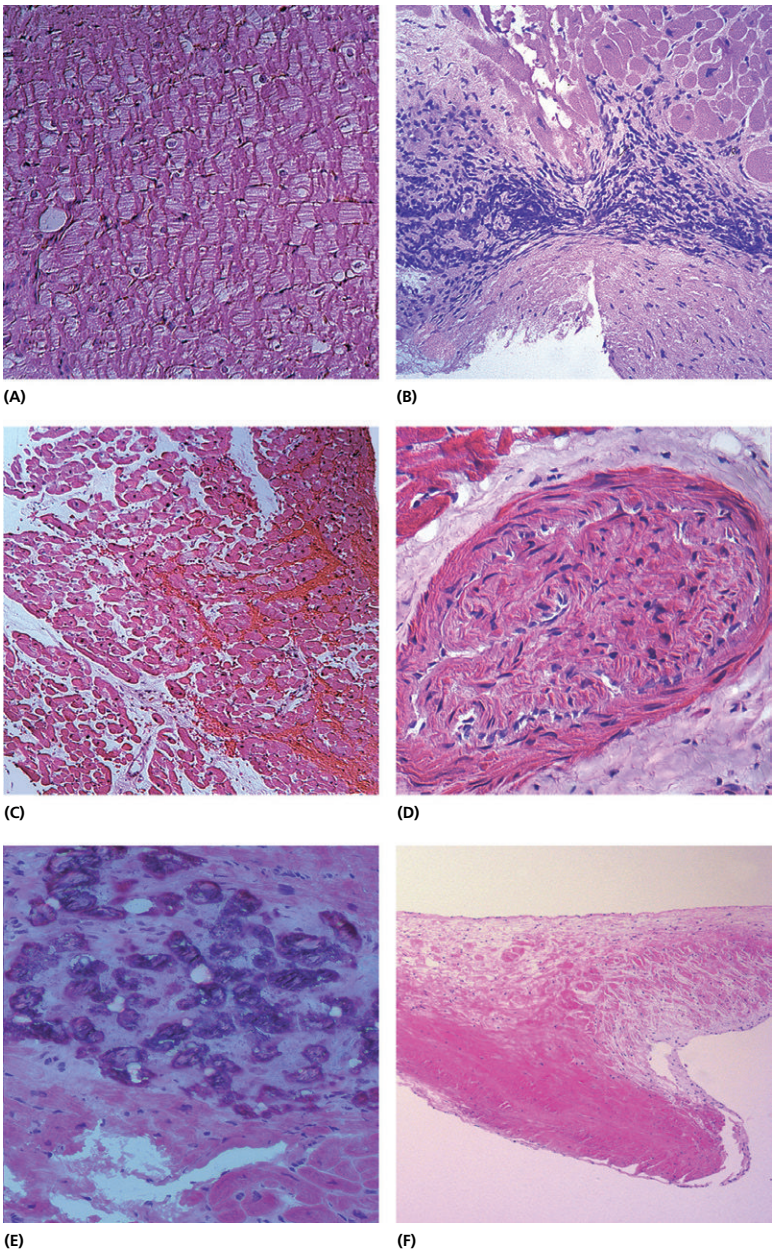

Figure 83.12. Miscellaneous artifacts in endomyocardial biopsies. (A) Contraction band artifact is relatively common in endomyocardial biopsies (H&E, original magnification ×100). (B) Pinching artifact with distortion of the tissue can occur when the bioptome does not cut the tissue, but instead compresses it. This image shows extreme distortion of a Quilty type lesion in the endocardium. Creating crushing artifact of the lymphocytes in the Quilty lesion (H&E, original magnification ×200). (C) Pseudohemorrhage. The cutters of the bioptome can trap blood and embed these into the myocardium, creating the false impression that there is a hemorrhagic infiltrate (H&E, original magnification ×100). (D) Occasionally, arterioles and small arteries can be sampled by the bioptome. In some instances, these arteries can be overstretched as the biopsy piece is cut and they recoil into their own lumen forming an intussusception or "telescoping" artifact. This should not be misinterpreted as allograft vasculopathy (H&E, original magnification ×400). (E) Dystrophic calcification of entire myocytes is also possible (H&E, original magnification ×300). (F) Chordae tendineae tissue can be cut by the bioptome, as many of the chordae tendineae from the septal leaflet of the tricuspid valve insert directly into the interventricular septum (H&E, original magnification ×20).

of the whole myocyte. In some cases, a relationship between calcification of the mitochondria and cyclosporine therapy has been suggested [80]. Some conditions that have been associated with dystrophic calcification are sepsis, temporary uremia, hypomagnesemia, steroid therapy, alcoholism [78], and ischemic injury.

Chordae tendineae and valvular tissue. Fragments of chordae tendineae (Figure 83.12F) are occasionally seen as part of the biopsy specimen [32]. They should be described and processed along with the biopsy. The clinical significance with regard to tricuspid dysfunction secondary to chordal rupture is varied [12,81].

Biopsy-negative allograft dysfunction. The concept of biopsy-negative rejection or biopsy-negative allograft dysfunction has appeared in the heart transplant literature in recent years. It refers to cases in which there is nil or no cellular rejection in a biopsy to explain dysfunction of the allograft. Thus, suggesting that in those instances the dysfunction may be secondary to AMR [82]. However, in those centers that routinely evaluate biopsies for cellular and AMR and rule out these two entities [83], the concept of true biopsy-negative allograft dysfunction usually indicates that cardiac allograft vasculopathy may be the process responsible for the dysfunction and not cellular or AMR.

Antibody-mediated rejection (humoral arm of the rejection immune response)

AMR is an immunopathologic process in which donor-specific antibodies bind to antigen within the graft, leading to activation of the complement system and, in turn, result in injury to the graft (see Chapter 6). This type of rejection was first recognized as a distinct clinicopathologic entity in kidney transplant patients as an acute

allograft rejection associated with the production of anti-donor reactive antibodies and poor prognosis [84]. AMR is poorly responsive to conventional immunosuppression, which targets the cellular arm of the immune response. It has been postulated that the allorecognition and production of antibody may occur in any transplant and can span from subclinical to fully overt clinical AMR [85]. Old terminology in heart transplant literature such as vascular rejection, microvascular rejection, and humoral rejection should be avoided, as it has only led to confusion in the literature. The preferred terminology is AMR. For many years, it was said that AMR occur early post-transplant (i.e. in the first 3 months) and the ISHLT-WF-1990 recommends AMR monitoring by immunofluorescence on all biopsies only up to 6 weeks post-transplant. This is clearly incorrect, as it is now known that AMR can and most commonly occurs months and even years after transplantation [83,86,87].

Risk factors for developing AMR include pregnancy, previous transplantation, blood transfusions, sensitization by OKT3 induction therapy, use of ventricular assist devices, use of homografts in infants, presence of positive B-cell flow cytometry cross-match, and elevated panel-reactive antibodies [11,88,89]. The long-term outcome of AMR is not yet fully established in heart transplantation but it has been suggested that an association exists with the development of cardiac allograft vasculopathy (CAV) and decreased survival [90,91].

The ISHLT-WF-1990 did not provide a detailed pathologic classification of "humoral rejection" in biopsies (Table 83.3). Consequently, the true incidence of AMR was unknown and recognition of AMR as a real entity was not widely accepted. For more than a decade, there was no uniform set of diagnostic criteria provided to guide different transplant programs in the detection of this entity until the Banff Allograft Pathology group stressed the need for defined criteria for AMR [13]. In turn, the ISHLT-WF-2005 defined an initial set of standards to guide heart transplant centers around the world on how to evaluate endomyocardial biopsies for AMR (Table 83.3). This set included histologic and immunopathologic features. It suggested that the histologic features of AMR (see below under Diagnostic criteria of AMR) should be identified in biopsies and this should prompt the use of immunopathologic examination [11,14]. However, soon after the ISHLT-WF-2005 was published, there was evidence that the histologic criteria had rather low sensitivity and specificity for AMR [92].

The antibodies used in immunofluorescence evaluation for the diagnosis of AMR were varied and included antibodies to detect IgG, IgM, C3, C1q, fibrinogen, fibrin, and HLA-DR. But the presence of these antibodies did not always correlate with hemodynamic compromise or incidence of CAV and thus resulted in decreased usefulness of this test [93]. Furthermore, a recent survey of North American centers regarding their diagnostic approach to AMR showed a chaotic situation with many more immunopathologic markers that have not been evaluated in large cohorts for sensitivity or specificity [94]. Evidence from large heart transplant centers in North America shows that while many markers such as immunoglobulins and some complement components (C3, C3c, C1q) may be detected in biopsies, the specificity and sensitivity of the immunoglobulins, and some complement components, are low as diagnostic [86] and prognostic markers of AMR [95,96] .

Diagnostic criteria of AMR. The histologic features that allow for the identification of this type of rejection on endomyocardial biopsies as defined in the ISHLT-WF-2005 and its companion article on AMR [11,14,32] include capillary injury with endothelial cell swelling and intravascular macrophage accumulation. Interstitial edema and hemorrhage can be present together with neutrophils in and around capillaries. Intravascular thrombi and myocyte necrosis without cellular infiltration can also be identified [11,14].

However, the sensitivity of histologic criteria (i.e. light microscopic features such as endothelial cell swelling, intravascular macrophages) is too low to serve as screening parameters for AMR [92]. The authors thus recommend the addition of immunostaining to screen for the presence of AMR.

Immunohistochemical staining of endomyocardial biopsies recommended in ISHLT-AMR-WF-2011 [15]*:* For immunohistochemistry (IHC) on paraffin-embedded tissue, the latest working formulation recommends C4d or CD68 (or other appropriate macrophage marker), alone or combined. A concern is the lack of experience by pathologists in the interpretation of CD68 in the context of AMR. The potential for misinterpretation is based on the fact that only intravascular macrophages should be interpreted as indicative of AMR. The interstitial macrophages should not be interpreted as indicative of AMR.

Use of C4d and C3d immunofluorescence has shown excellent correlation with AMR [83] in large transplant centers (Figure 83.13). The use of these two markers in immunohistochemistry has not been extensively evaluated in many high-volume centers [15].

The ISHLT-AMR-WF-2011 states that initial immunostaining should be avoided in the first 2 weeks because of theoretical perioperative considerations such as the presence of necrotic myocytes

Table 83.3. Antibody-mediated rejection (AMR) (data from [10,11,15])

ISHLT-WF-1990	ISHLT-WF-2005	ISHLT-WF-2011
Humoral rejection Positive immunofluorescence, vasculitis or severe edema in the absence of cellular infiltrate	**Antibody-mediated rejection** AMR 0 = Negative for acute antibody-mediated rejection AMR 1 = Positive for AMR Histologic features of AMR Positive immunofluorescence or immunoperoxidase staining for AMR (Positive CD68, C4d)	**Antibody-mediated rejection** pAMR 0 = Negative for pathologic AMR: both histologic and immunopathologic studies are negative pAMR 1 (H+) = Histopathologic AMR alone: histopathologic findings present and immunopathologic findings absent pAMR 1 (I+) = Immunopathologic AMR alone: Immunopathologic findings present and histologic findings absent pAMR 2 = Pathologic AMR: both histologic and immunopathologic findings present pAMR 3 = Severe pathologic AMR: Rare cases of severe AMR with histopathologic findings of interstitial hemorrhage, capillary fragmentation, mixed inflammation, endothelial cells pyknosis, karyorrhexis, marked edema

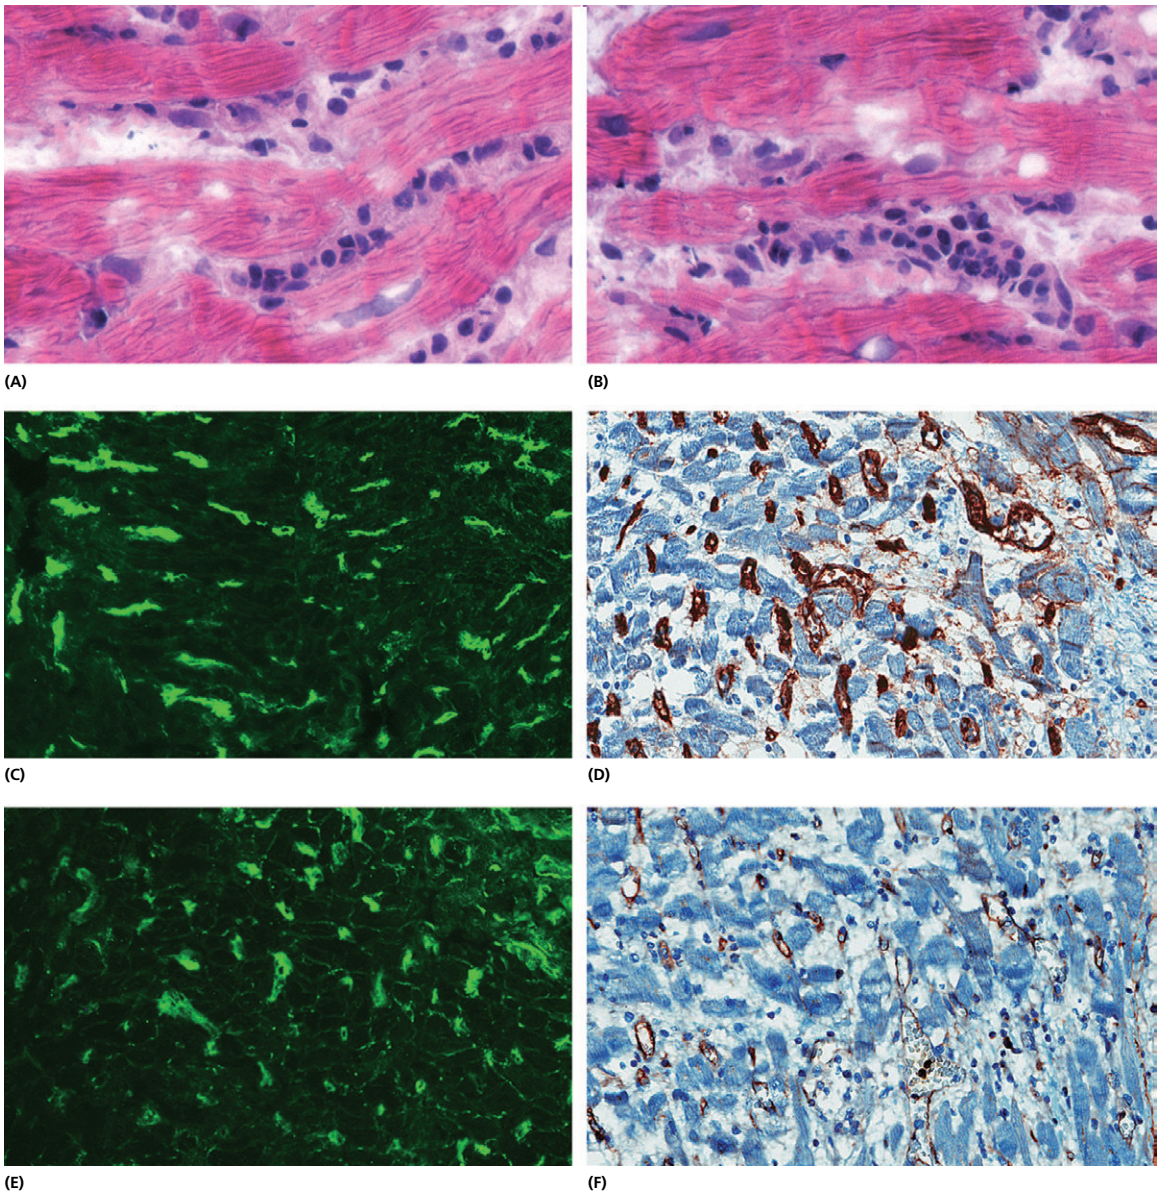

Figure 83.13. Antibody-mediated rejection. (A) This biopsy shows endothelial cell swelling and occasional intravascular macrophages (H&E, original magnification ×600). (B) In this field, a small arteriole distinctly shows intravascular macrophages (H&E, original magnification ×600). (C) Immunofluorescence for C4d shows an intense capillary pattern deposition of this complement split product in this frozen endomyocardial biopsy tissue (C4d immunofluorescence, original magnification ×300). (D) The same complement split product is present in a biopsy fixed in formalin. The pattern of positive deposition of C4d is identical (linear capillary staining) to the pattern seen on immunofluorescence (immunohistochemistry for C4d, original magnification ×300). (E,F) The same linear pattern of capillary staining is now demonstrating the presence of C3d in these two biopsies. (E) Immunofluorescence for C3d (original magnification ×300). (F) Immunohistochemistry for C3d (original magnification ×300).

binding complement early in the post-transplant period and ischemic injury [97] as potentially responsible for activating complement. However, the pattern of staining of capillaries in AMR is distinctly different from the sarcoplasmic staining of necrotic myocytes. This should not be a reason for not performing immunofluorescence during this period, particularly in highly sensitized patients.

The grading system for the latest iteration of the Working Formulation pAMR 0. Negative for pathologic AMR: both histologic and immunopathologic studies are negative.

pAMR 1 (H+). Histopathologic AMR alone: histopathologic findings present and immunopathologic findings absent.

pAMR 1 (I+). Immunopathologic AMR alone: immunopathologic findings present and histologic findings absent.

pAMR 2. Pathologic AMR: both histologic and immunopathologic findings present.

pAMR 3. Severe pathologic AMR: rare cases of severe AMR with histopathologic findings of interstitial hemorrhage, capillary fragmentation, mixed inflammation, endothelial cells pyknosis, karyorrhexis, marked edema.

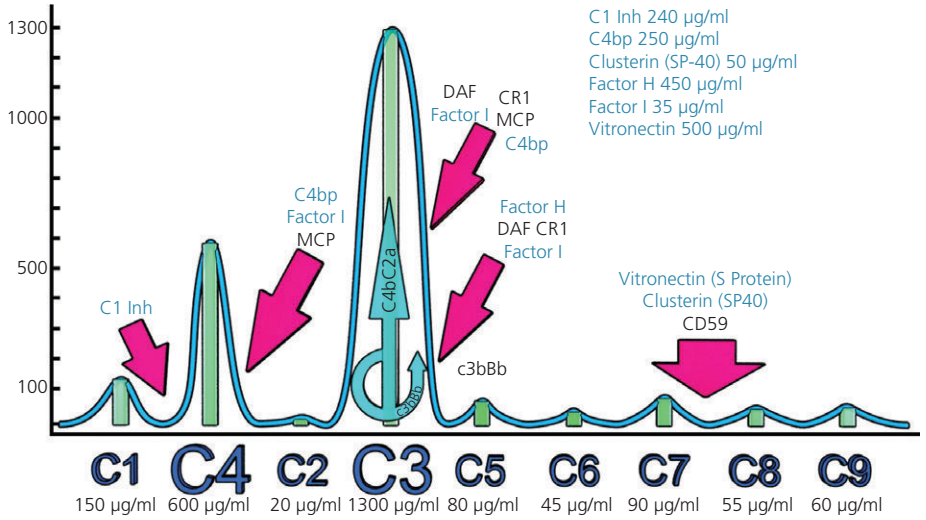

Figure 83.14. Serum concentration of complement components and regulators of complement activation. The serum concentration of the different complement factors in serum is shown in micrograms per milliliter. The activation of C3 is critical as it augments both cellular and humoral immune response. C3 is enzymatically cleaved and activated by C4b2a of the classic pathway and C3bBb through an amplification loop of the alternative pathway. Its activation is an important amplification step because C3 is present in a larger molar amount and, once activated, it can further increase the activation of the rest of the cascade. Regulators of complement activation are composed of both plasma (blue letters) and membrane (black letters) proteins that inhibit the proteolytic subunits of classic and alternative pathways, thereby preventing the progression of the complement pathway to the membrane attack complex formation. C1 Inh, C1 inhibitor; C4bp, C4 binding protein; CR1, complement receptor 1; DAF, decay accelerating factor; MCP, membrane co-factor protein.

While the ISHLT-WF-2005 recommended that these patients undergo assessment for circulating antibodies to HLA class I or II as well as non-HLA donor antigens, the ISHLT-WF-AMR-2011 does not require correlation of the histologic or immunopathologic findings with the presence of donor-specific antibodies or allograft dysfunction. An EMB with no histologic or immunopathologic evidence of AMR is graded 0 (pAMR 0). If the immunofluorescence or immunohistochemical staining supports the histologic features of AMR, the biopsy is considered positive (pAMR 2). The presence of either histologic or immunopathologic findings only is considered pAMR 1 with a qualifier of H+ or I+. Note that occurrence of severe pathologic AMR or pAMR3 is very rare in current practice. The precise clinical correlation for each of these pathologic grades will continue to be established.

Mixed acute cellular rejection and AMR. Although most AMR episodes are associated with absent or at most mild acute cellular rejection, mixed rejections have also been reported to carry a significant risk of mortality [98,99]. Mixed rejection may occur early or late [100] in the course of transplantation and is also associated with allograft dysfunction.

Practical issues in the diagnosis of AMR. Some diagnostic considerations about complement split products are germane. Immunofluorescence methods for detection of AMR in tissues have evolved in the last decade. Some complement components, specifically C3d and C4d, are found to be more readily detected than antibodies and serve as very sensitive markers of rejection in endomyocardial biopsies for several reasons [101]. Antibodies bind to antigens with different avidity and either dissociate at varying rates or are eliminated by shedding or internalization. In contrast, the process of complement activation yields split products of C4 and C3 that bind to the tissue where complement was activated. This increases the sensitivity of complement detection by prolonging their half-lives. Among the components of the complement system, C3, followed by C4, are present in the highest concentration in serum, therefore their split products are also deposited in tissues in the largest quantities (Figure 83.14) [32]. Furthermore, the amplification steps in the complement cascade results in the generation of more C3 split products [102].

While complement is activated through antibody in the classic pathway, one must remember that complement can also be activated during procedures such as extracorporeal circulation during surgery [103,104], by ischemia–reperfusion injury, and by induction therapy before transplant with antithymocyte globulin [97]. Thus, the mere presence of C4d alone or C3d alone in capillaries should not be equated with AMR.

In our experience, the use of C4d immunostaining alone is not a reliable tool. Instead, evaluation of endomyocardial biopsies for AMR should include staining for both C4d and C3d [83,86], because the presence of both markers correlates highly with allograft dysfunction and the presence of elevated donor-specific antibodies.

Discrepancy between pathology and clinical presentation. Activation of the complement cascade detected by immunostains for C4d and/or C3d is not always accompanied by dysfunction of the graft. Some authors have referred to this apparent lack of graft injury despite evidence of complement activation as "accommodation" in animal models [105] and in ABO-incompatible renal transplants [106]. One possible explanation is that complement activation is interrupted by a protective mechanism in the host. This suggests that unless the complement cascade proceeds to the formation of the membrane attack complex (MAC), there is no expected injury to the allograft. This complex is needed to form a "pore" that leads to loss of integrity of the cell membrane. In humans, it is well known

that there are regulators of complement activation (RCA) that can prevent the completion of the complement cascade at different stages of activation.

Regulators of complement activation. RCA exert their effects at different points in the complement activation cascade, whether the activation occurs through the classic, alternate, or mannose-binding lectin pathways. All these pathways converge at the point of generation of the enzymatic complexes known as the C3 convertases which, in turn, proceed to activate the remaining complement components required for the formation of the MAC. There are two main types of proteins that can regulate the activation of complement: membrane-bound and soluble types. In humans, the membrane-bound regulators are CD35 or complement receptor 1 (CR1), CD46 or membrane co-factor protein (MCP), CD55 or decay-accelerating factor (DAF), CD59 or protectin, and C8-binding protein or homologous restriction factor (C8bp/HRF) [107,108]. The soluble factors include the C1 inhibitor, C4 binding protein (C4bp), factor I, factor H, clusterin, and S-protein (vitronectin). Their points of action are shown in Figure 83.14 [32].

There is little information about the expression of these RCA molecules in human heart transplantation. A recent study shows that DAF or CD55 is expressed locally in the myocardium in heart transplant patients [109]. In this study, a group of patients with complement deposition in endomyocardial biopsies was studied. The biopsies were stained by immunofluorescence for C4d, C3d, and DAF. There were two subgroups identified on the basis of allograft dysfunction present or absent. All patients had biopsy-proven C4d and C3d deposits. Patients with good response to therapy and resolution of the AMR episode showed intense tissue expression of CD55 in the endothelium of the allograft. Patients with poor outcome had low or absent tissue expression of CD55. Thus, the local expression of DAF correlates with absence of allograft dysfunction in spite of C4d and C3d deposition in capillaries (Figure 83.15).

Complement staining artifacts. Common artifactual staining seen in immunofluorescence microscopy of transplant biopsy includes autofluorescent lipofuscin deposits and non-specific binding to collagen in the interstitium and to the internal elastic lamina of arteries. Necrotic myocytes likewise bind complement.

Platelets and coagulation factors in rejection. The combination of antibodies and complement with inflammatory cells has great potential to injure the endothelial and smooth muscle cells of the vessels of the allograft [110]. It is known that stimulation through receptors for IgG or complement split products can activate macrophages, but stimulation through combinations of these receptors generates synergistic results. Thus, the effect of antibodies and complement efficiently integrate the activation of endothelial cells, platelets, and macrophages [110].

Alloantibodies can induce exocytosis of von Willebrand factor and P-selectin from endothelial cells and attachment of platelets within minutes. Consequently, platelets also adhere to and stimulate leukocytes, which is potentiated by complement activation. After attachment, platelets degranulate and release preformed mediators stored in their granules such as platelet factor 4 and CXCL4 [111]. These effects may also have a role in the pathogenesis of CAV (see section on CAV below).

Thrombolytic and coagulation factors have also been implicated in allograft rejection and CAV. The notion that a hypercoagulable state may have a role in CAV has been supported by the finding that early elevation of tissue factor and fibrin and reduction of tissue plasminogen activator (tPA) and antithrombin in human cardiac allografts are associated with both onset and severity of CAV and graft failure. As expected, impairment of fibrinolysis has also been correlated with CAV [112].

Cardiac allograft vasculopathy

The most difficult obstacle to long-term successful outcome in cardiac transplantation is the development of graft vasculopathy [32]. The clinical manifestations of CAV are covered in detail in Chapter 79. This problem is not unique to the heart and occurs in any solid organ graft to some degree [113]. Allograft vasculopathy

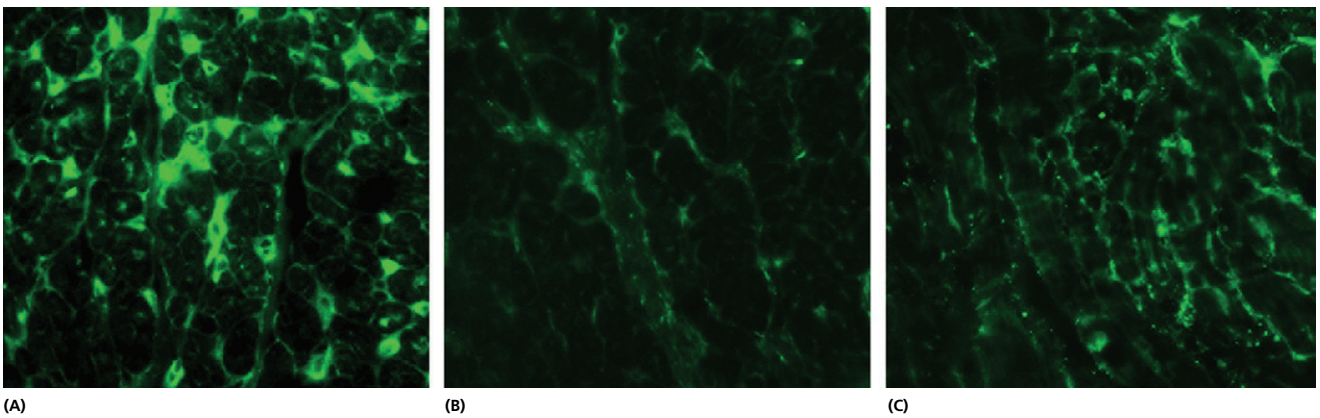

Figure 83.15. C4d positivity alone is not antibody-mediated rejection. (A) This biopsy shows distinct intense linear immunofluorescence for C4d in capillaries (immunofluorescence for C4d, original magnification ×400). (B) Staining for C3d is negative, showing no staining of capillaries (immunofluorescence for C3d, original magnification ×400). (C) Decay accelerating factor (CD55) is present in the capillaries and myocytes of this micrograph (immunofluorescence for CD55, original magnification ×400). The presence of CD55 is interpreted as the mechanism preventing progression of activation of the complement cascade from activation of C4 into activation of C3, and consequently no activation of the membrane attack complex.

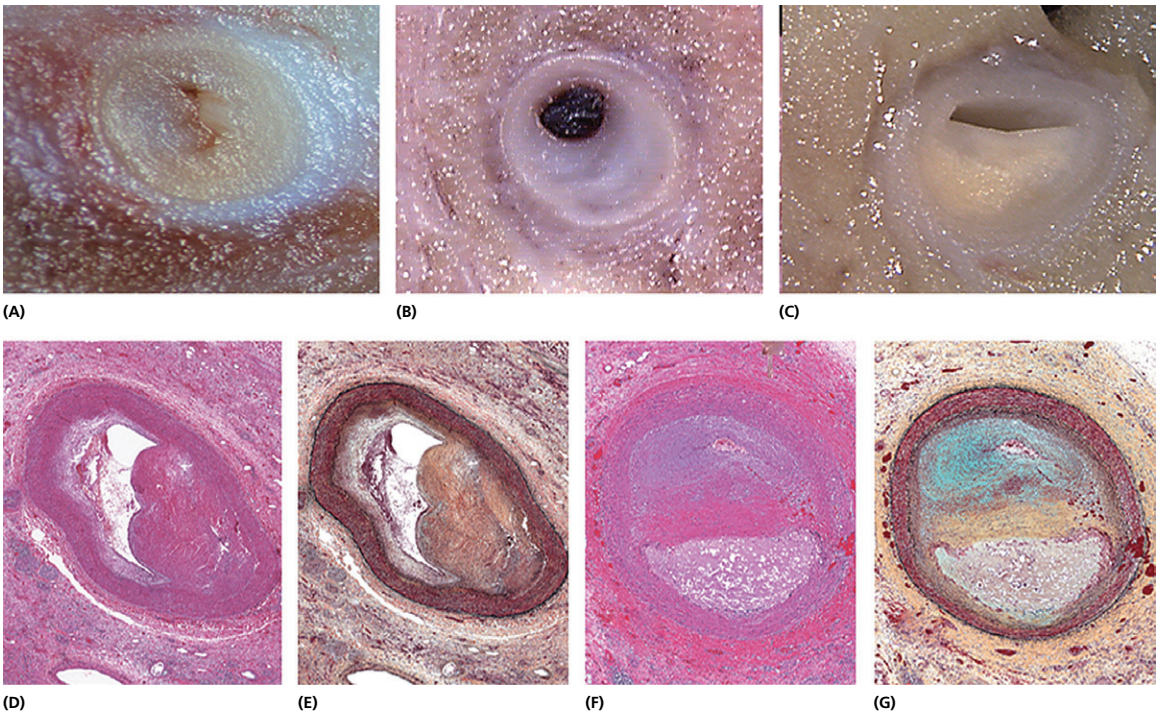

Figure 83.16. Cardiac allograft vasculopathy (CAV) I. (A) Epicardial coronary artery showing the "typical" concentric narrowing of the lumen by proliferative intima. (B) Eccentric lesions are also commonly seen. Note the pearl-white myxoid matrix of the intima. (C) If there is coronary atherosclerosis in the donor, the CAV lesions (pearl-white) are commonly superimposed upon the atheromatous plaque (yellow). (D) Microscopic examination of an eccentric plaque showing the proliferative intima in the right half of the vessel (H&E, original magnification ×10). (E) The proliferative intima in this case is formed of mature fibrous tissue (yellow). The internal elastic lamina (black) is intact, and the media of the vessel is also intact (dark red) (Movat pentachrome, original magnification ×10). (F) This light micrograph shows an almost complete occlusion of the lumen by a combination of atheromatous plaque (lower half of the image) and superimposed CAV (H&E, original magnification ×10). (G) The same artery stained with a Movat pentachrome shows the atheroma, the fibrous cap (yellow), and the proliferative neointima of the CAV process as a proteoglycan-rich extracellular matrix (green) (Movat pentachrome, original magnification ×10).

(also called chronic rejection, accelerated graft arteriosclerosis, or transplant coronary artery disease) develops, over time, in practically all transplanted hearts. In some patients it develops in a few months, while in others it develops after several years. The events leading to this vascular process are complex and include at least some of the following: native donor atherosclerosis [114], ischemic time of the graft [115], endothelial damage of diverse origins [116,117], histocompatibility issues [118], arteritis [119], chronic humoral and cellular immune attack [120–123], fibrinolysis [124,125], viral infections [126], serum lipids [127], and hormonal milieu [128]. The problem of vasculopathy is also seen in the pediatric population and follows a course similar to the one seen in adults [129,130].

Vasculopathy involves both epicardial and intramural coronary arteries [32]. To understand the pathology, one should remember that the coronary vessels have three layers: the adventitia, the media, and the intima. In turn, each one of these anatomic layers is made of many different cellular and extracellular components. There is evidence that during the development of vasculopathy a concerted series of events occurs that produce varying degrees of damage to each one of these structures (intima, media, adventitia and vasa vasorum).

On gross examination, rejection may be evident as areas of myocardial discoloration ranging from pale tan to red. Examination of the epicardial coronary arteries may reveal a combination of focal eccentric lesions and, in other areas, uniform concentric thickening of the wall (Figure 83.16). However, in some instances, while there may be little or no gross evidence of vasculopathy in these epicardial coronary arteries, there is abundant pathology in the intramyocardial vessels. Careful examination of the cut surfaces of the ventricles often reveals thickened arteries (with a diameter range of 0.2–0.5 mm) with abundant perivascular fibrosis. These vessels are quite prominent on gross examination (Figure 83.16A–C). Some allografts may show clear evidence of epicardial coronary atherosclerosis that was present in the donor prior to the transplant (Figure 83.16D–G) [32,114,131]. In these cases, the allograft vasculopathy is superimposed over the atherosclerosis. If pre-existing atherosclerotic plaques are present, the morphology of the lesion may be eccentric with more features of atheroma such as destruction of the internal elastic lamina, amorphous lipid-rich plaque, and cholesterol clefts. Long-term lesions of the epicardial coronaries may eventually look like conventional atherosclerosis and be indistinguishable from it.

The light microscopic morphology of the lesions seen as a result of vasculopathy is slightly different in epicardial from in medium or small arteries [32,132]. If no atherosclerotic plaques are present, the typical vasculopathy lesions show concentric intimal proliferation (Figure 83.17) composed of smooth muscle cells and less differentiated cells (myofibroblasts or "myointimal" cells). There is deposition of connective tissue components such as collagen and

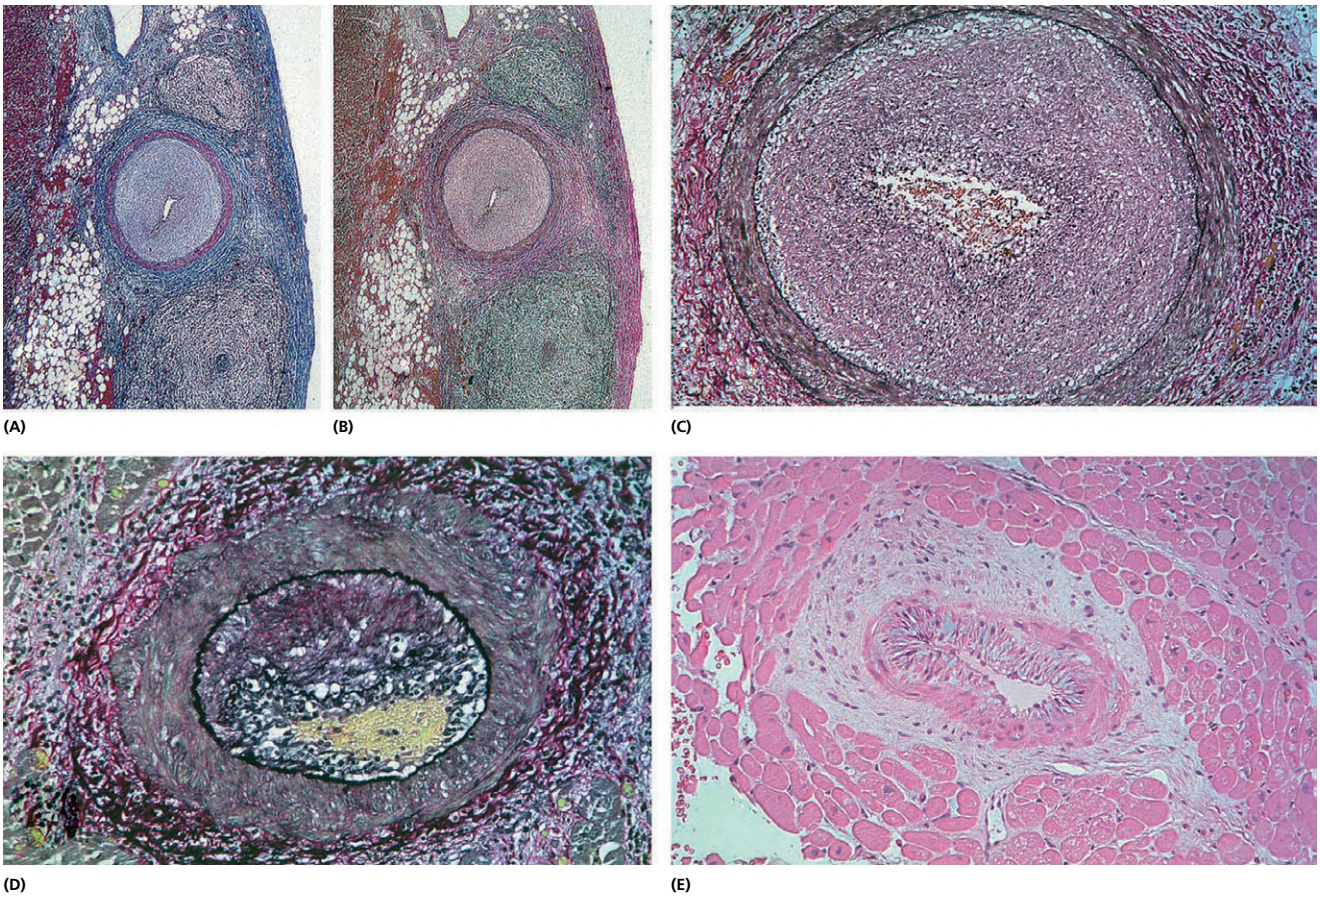

Figure 83.17. Cardiac allograft vasculopathy II. (A) Light micrograph showing an epicardial coronary artery with marked narrowing of its lumen by intimal proliferation of cells and deposition of connective tissue (red–blue). The adventitia is fibrotic and stains blue. The smooth muscle of the media and the myocardium (left) are stained red. There are two large foci of lymphocytic infiltrate flanking the coronary artery (Masson's trichrome, original magnification ×1.25). (B) An adjacent section shows the delimitation of the media and the intima with more clarity (darker red media and light pink–red intima) (Verhoeff–Van Gieson elastic stain, original magnification ×1.25). (C) Higher magnification showing the intima, media, and adventitia. The intima shows marked proliferation of cells which almost completely narrows its lumen. Note that the elastic laminae are intact (Verhoeff–Van Gieson elastic stain, original magnification ×4). (D) A smaller intracardiac coronary artery shows an eccentric lesion in the intima that partially occludes its lumen (>60%). There is a small thrombus with entrapped erythrocytes (yellow cells) in the lower part of the arterial lumen (Verhoeff–Van Gieson elastic stain, original magnification ×10). (E) Small intracardiac coronary artery shows early proliferative disease in the intima and abundant proteoglycan accumulation (light blue discoloration subjacent to the endothelial cells). Note the abundant fibrosis of the adventitia (H&E, original magnification ×20).

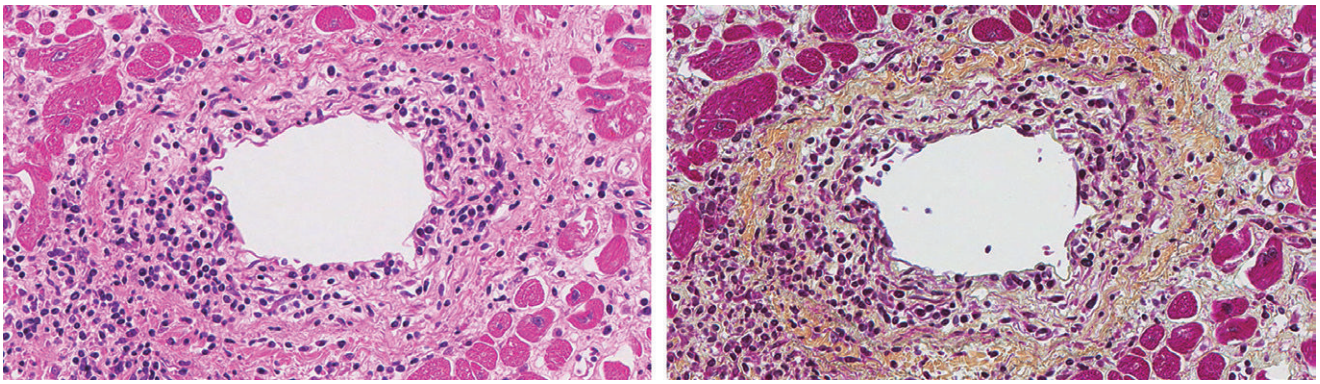
proteoglycans. The intramural coronary arteries usually show concentric uniform lesions consisting of intimal smooth muscle proliferation with or without lipoprotein deposition within the proliferating cells. The internal elastic lamina is usually intact or only focally disrupted, the media shows little to no lipoprotein deposition and there usually is an adventitial cuff of fibrous tissue with or without mononuclear inflammatory infiltrates. The pathology of CAV in children is practically identical [133].

In some patients, frank vasculitis has been documented (Figure 83.18) [120]. This usually affects the distal coronaries. Active vasculitis shows lymphocytes, plasma cells, and occasionally polymorphonuclear leukocytes. Fibrinoid necrosis may be seen in early stages. Thrombosed and recanalized vessels may represent healed vasculitis with thrombosis (Figure 83.19). Although small arteries or arterioles with vasculopathy may be seen in endomyocardial biopsies, there is no consistent correlation with the anatomic or functional status of epicardial coronary arteries [134]. Despite this lack of correlation, the presence of vasculopathy in the biopsy specimen, if any, should be recorded in the final report.

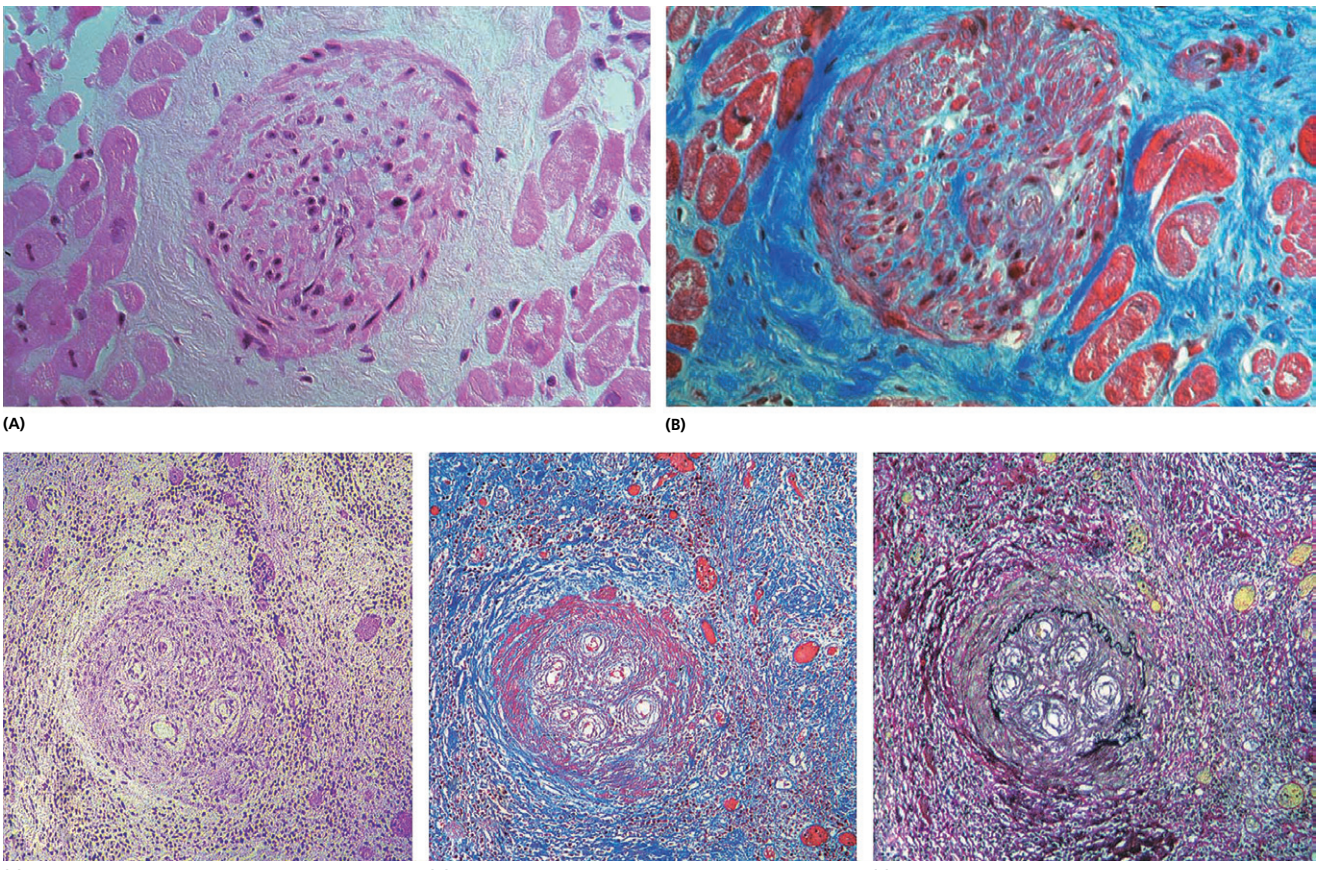
Recurrent diseases in the allograft and the patient

A number of cardiac conditions have been shown to recur in the transplanted heart, including infections [73] and amyloidosis [135]. These are discussed further in Chapter 79. Depending on the cause of iron overload leading to heart transplantation [136], the iron overload may recur in the allograft [137]. Giant cell myocarditis [138,139] can also rarely recur despite immunosuppression [140], as does sarcoidosis [141,142]. Administration of amiodarone pretransplant has been described to cause QT prolongation in the allograft [143]. Systemic disorders associated with genetic predisposition for recurrence have been reported as in the case of recurrent thrombotic complications in a patient homozygous for



(A) (B)

Figure 83.18. Allograft vasculopathy with frank vasculitis. In some instances, the cellular rejection process distinctly affects all layers of the arteries. (A) Transmural mononuclear infiltrates (occasionally with eosinophils) are noted to involve the adventitia, media, and intima of this intramural coronary artery (H&E, original magnification ×40). (B) The same artery shows that the media has been disrupted by the inflammatory infiltrate. The adventitial fibrosis is highlighted as yellow connective tissue (Movat pentachrome, original magnification ×40).



(A) (B)

(C) (D) (E)

Figure 83.19. Allograft vasculopathy in the intramural coronary arteries. (A) Occlusive proliferation of smooth muscle cells in a small intramural coronary artery. Note the adventitial fibrosis (H&E, original magnification ×40). (B) This stain proves that most of the luminal narrowing is secondary to smooth muscle proliferation (red staining cells) and little accumulation of collagen. The adventitial fibrosis is also well demonstrated (Masson's trichrome, original magnification ×40). (C) Recanalized intramural coronary artery may be secondary to healed vasculitis or thrombosis (H&E, original magnification ×20). (D) The same artery as shown in C shows marked adventitial and intraluminal accumulation of fibrous tissue (Masson's trichrome, original magnification ×20). (E) Staining for elastic fibers shows distinctly a fragmented elastic lamina suggestive of earlier vasculitis (Verhoeff–Van Gieson elastic stain, original magnification ×20).

prothrombin G20210A single nucleotide polymorphism [144] or recurrent aortic dissection after heart transplantation in a patient with Marfan's syndrome [145]. Vascular pathology complicated the postoperative course of a patient with Behçet's disease who developed a large pseudoaneurysm at the aortic anastomotic site [146]. Cardiac transplantation for unresectable primary cardiac sarcomas is controversial because of risks for local recurrence or metastatic disease. For instance, local recurrence of primary cardiac sarcomas has been described in both native right atrium [147] and in the left pulmonary artery [148]. Recurrent Epstein–Barr virus-related leiomyosarcoma has been described in young patients [149].

Examination of the allograft after failure

Gross examination. This type of examination takes place either during retransplantation or during postmortem examination. These two circumstances provide different kinds of specimens. During retransplantation, the specimen will consist of the ventricles and a small portion of atria, aorta, pulmonary artery, and in some instances the previous anastomotic sites. These should be described accordingly. Our current procedure to examine the heart is described below; it assumes that the examination is performed during the autopsy. Depending on the postmortem interval, one should decide whether some tissues may be harvested for cell culture or nucleic acid extraction. Most postmortem specimens yield useful material for DNA extraction; however, RNA is rapidly degraded after death.

The prosector should make every effort to retrieve the specimen without mutilation as there are often dense fibrous adhesions of the pericardium to the heart, the sternum, and mediastinal pleurae. This can be easily achieved with only a few more minutes of careful dissection. The heart and mediastinal structures should be inspected in situ before dissecting and sectioning the following vessels:

1 Superior vena cava at least to the level of the external jugular veins;
2 Branches of the aortic arch to the level of the common carotids and to the level of the clavicle bilaterally;
3 Aorta transected in its thoracic portion as it approaches the diaphragm;
4 Right and left pulmonary arteries to their lobar branches as they enter the lung;
5 Pulmonary veins as they arise from each of the pulmonary lobes; and
6 Inferior vena cava dissected through the diaphragm and sectioned as close to the liver as possible.

If there are any catheters or pacemaker electrodes, each of them can be secured to the respective vessel where they enter the heart (preferably by a small suture) and then cut. In this manner, the prosector will not alter the location of these devices within the heart. As an option, the prosector may choose to tie all the vessels as they are dissected and sectioned. This allows for a very clean work area and guarantees a successful harvesting of the heart in those cases in which the autopsy consent limits the autopsy to the operative incision or to the heart only.

After sectioning the major vessels, the heart can be retrieved. Any vessel tie is removed before fixing the specimen overnight in 10% buffered formalin in a container that is at least 10 volumes larger than the specimen itself (a 12-L bucket is optimal). The dissection continues the following morning. The parietal pericardium will show variable degrees of adhesion to the visceral pericardium (epicardium) (Figure 83.20). Blunt dissection is started from the anterior wall first towards the apex, then moving laterally towards the right and left ventricles and around them into the diaphragmatic surface of the heart. This will free most of the pericardial sac around the ventricles and part of the atria. Subsequently, the dissection moves into the region of the great vessels and into the native atria. Once the anastomotic sites are identified, the dissection of these structures is usually not more difficult than in a normal heart. The approach to open the heart may differ from case to case.

Depending on the expected pathology, it may be needed to open the heart through the traditional "blood flow" approach. Alternatively, a four-chamber view or even transverse sectioning may be indicated (Figure 83.20). In our laboratory, we often use the four-chamber view to section the heart because it allows us to quickly perform a very thorough examination of all the chambers, the valves, the interatrial and interventricular septa, and anastomotic suture lines. Furthermore, using this approach we can easily obtain excellent photographs of the heart for documentation and teaching purposes. In any case, examine all chambers for dilatation and hypertrophy. Note the endocardium for discoloration, thrombosis, vegetations, or fibrin deposits. Locate any cannulas catheters or pacemaker leads. Inspect the anastomotic sites (recent, healed, endothelialized) for kinks and narrowings. Describe the myocardial cut surface for any discoloration (focal, diffuse, size, location), hemorrhage or scars (perivascular, subendocardial, transmural). Record the presence of endocardial scars secondary to previous biopsy sites in the septum or mural thrombosis. The valvular apparatus integrity is checked for evidence of infection, fibrosis, or chordal rupture. The ventricles can then be thoroughly examined and if needed cut in cross-sections. In cases when the clinical history or the examination of the coronary arteries or the cut surface of the ventricles suggest ischemic disease, we prefer to proceed with transverse sections of the ventricles. This may reveal areas of necrosis, hemorrhage, or reperfusion injury. The coronary arteries and any bypass grafts are sectioned in close intervals to look for stenosis, occlusive thrombosis, and calcifications.

Occasionally, the pathologist is confronted with an unusual surgical procedure that requires modification of the dissection technique during the autopsy. For example, to examine the chest in patients with biventricular assist devices requires more extensive dissection in situ and modification of the gross examination of the heart to demonstrate the pathology and allow proper study and preservation of the specimen. In these cases, it is important to take extra time in the examination of the heart in situ. Plan the dissection method for retrieval of the heart and attached devices. Once harvested, the heart can usually be studied very thoroughly. We find it very useful to stage the study of the heart beginning with adequate fixation for a minimum of 18–24 hours after retrieval of the heart. Stages of the dissection are documented with photographs. In some instances, unusual findings will prompt to stop the dissection until photographs of good quality are available. This should not necessarily take a long time because access to a high quality digital photography system is available in most academic centers.

Conclusions

Histopathologic diagnosis is critical for proper management of cardiac allograft recipients. Indeed, given the paucity of early clinical features for allograft injury and the gravity of the consequences thereof, it is arguable that no area of transplantation is so dependent on the pathologist for care delivery. As such, protocol biopsy interpretation is an integral part of post-transplant care in all centers.

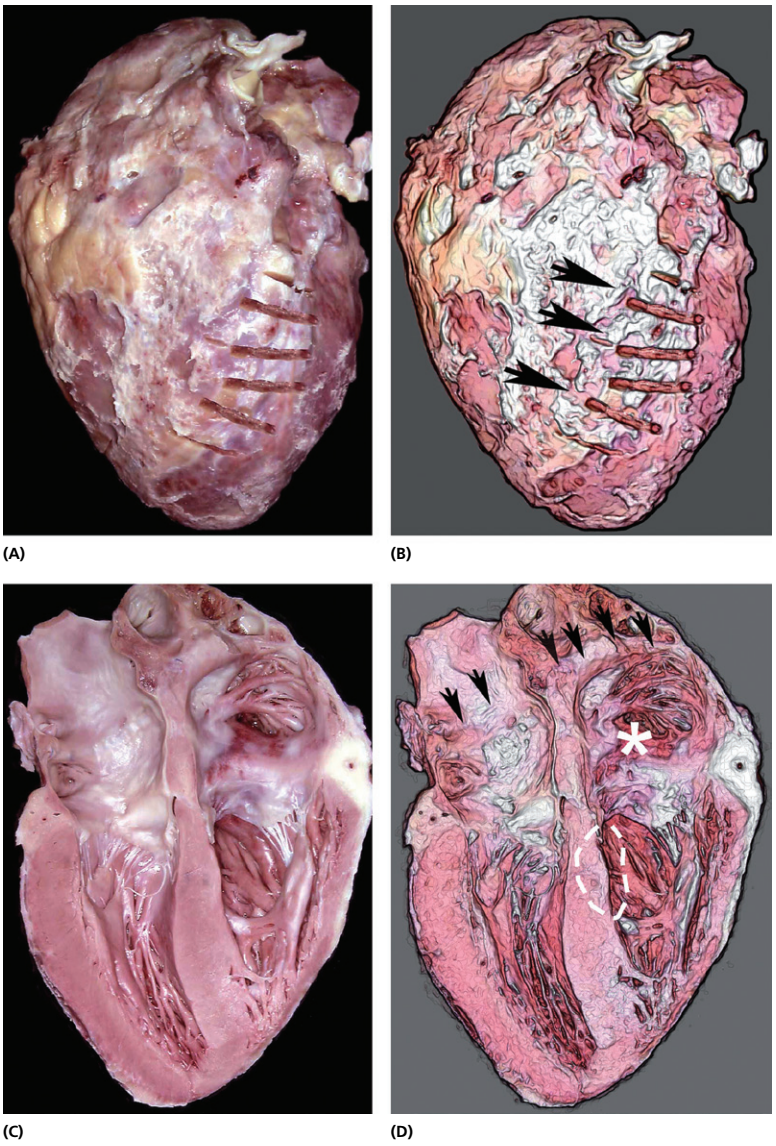


Figure 83.20. Failed allograft. (A,B) Fibrous organized pericarditis in a 16-year-old patient who died suddenly 15 months post-transplant. The coronary arteries have been sampled extensively (arrows). (C,D) Four-chamber view of the heart showing the fully endothelialized atrial anastomotic sites. Obviously, the atrial chambers are large, as they represent part of the recipient atria and the donor atria anastomosed. There is a focus of endocardial thickening (white patch) representing previous biopsy site in the trabeculae of the right ventricle (dashed line). There is ecchymosis in the endocardium of the donor right atrium (asterisk). The left ventricle shows mild hypertrophy.

The biopsy represents the intersection of mechanistic understanding and clinical effect, and its study will provide substantial insight into the biology influencing transplant outcome and should inspire the clinician to engage the immunosuppressive armamentarium with specificity.

CHAPTER 84

Histopathological Syndromes of Lung Allograft Rejection and Recurrent Disease

Carol Farver[1] and W. Dean Wallace[2]

Introduction

Allograft rejection is a common and clinically serious problem in the lung. Compared to other organs, the incidence of acute cellular rejection in the lung allograft is quite high. The reported incidence in the first year post-transplantation ranges from 36% [1,2] to 55% [3]. This compares to 40% for the heart [4] and 11% for the kidney [5]. These episodes are rarely fatal but their accumulative effect on the lung results in the chronic rejection of the vessels and, more importantly, of the airways, ultimately leading to graft failure. Details on the clinical presentation and differential diagnosis of lung allograft rejection can be found in Chapters 72 and 80.

Because of the ongoing potential for rejection-related graft injury, lung allograft recipients undergo routine monitoring for clinical and pathologic signs of acute rejection. Bronchoscopic biopsy is the main diagnostic tool used to evaluate the allograft for acute rejection and its sensitivity to detect rejection if present is greater than 80% [6]. Through this procedure both histologic and cytologic specimens can be obtained and evaluated for morphologic evidence of acute rejection. As with other allograft teams, comprehensive lung transplant teams require a strong relationship with the pathology team for optimal patient management. This chapter reviews the specific histopathologic features of lung allograft rejection that are important for the clinical lung transplant physician or surgeon to comprehend to facilitate dialogue between the clinical and pathology services.

Histologic grading of lung allograft rejection

The classification system used to grade histologic rejection in these biopsies was first put forth by the Lung Rejection Study Group of the International Society for Heart and Lung Transplantation (ISHLT) in 1990 and is now in its third iteration [7]. The original Working Formulation was developed by pathologists in active lung transplantation centers to allow for the comparison of outcomes data among these institutions and to be a simple, reproducible, and easily taught system. This original schema, which used a grading system of A and C for vascular rejection and B and D for airways rejection, was adopted by most of the centers and used for the subsequent 5 years with considerable success. In 1995, an expanded group of pathologists convened to further improve the grading schema to respond to new developments in the field. The second Working Formulation, published in 1996, was based on published data and practical experience of the multiple centers and emphasized that the pathologic data needed to be interpreted within a broad clinical context to provide the optimum patient care. Most specifically, infection and other sources of inflammation in the biopsy tissue needed to be excluded clinically for more accurate and reproducible grading [7].

The most recent revision of this grading system was published in 2007 and continues to be used today (Table 84.1). The major changes in this document were the revision of the acute airway rejection grading system from a four-tier system (B1–B4) to a two-tier system with low and high grades and the grading of chronic airway rejection (C) without reference to the presence of inflammation. Finally, though recommendations were made for the pathologic evaluation of antibody-mediated rejection (AMR), there was no consensus as to its role or diagnostic criteria in lung allograft rejection [7].

General recommendations

Appropriate technical handling of the transplant biopsies is important to obtain optimal information from the tissue and recommendations for this have been standardized in the ISHLT classification system [7]. The biopsies should be fixed in buffered formalin and undergo paraffin embedding. Paraffin tissue sections are cut and placed on microscopic glass slides (2–3 sections per slide; total three slides) and stained with routine hematoxylin and eosin stains. Two additional slides are cut and one is stained with silver to evaluate for fungal organism, including *Pneumocystic jiroveci*, and the other stained for elastic fibers to highlight evidence of fibrosis, a marker of chronic rejection, especially in the airways. Additional studies for other infectious organisms including immunohistochemical studies for cytomegalovirus (CMV) and Epstein–Barr virus (EBV) can be performed, if clinically needed.

The number of tissue fragments needed in the biopsy for an adequate evaluation for the presence of rejection is not definitively stated in the most recent (2007) Revision of the Lung Rejection Study Group (LRSG) Working Formulation. The original 1990 Working Formulation and its successor in 1997 recommended that five pieces of alveolated lung or at least 100 alveoli were needed to evaluate for the presence of rejection and that standard is continued

Table 84.1. 2007 Revision of the Working Formulation for the classification and grading of pulmonary allograft rejection

A. Acute rejection	Grade 0 – None Grade 1 – Minimal Grade 2 – Mild Grade 3 – Moderate Grade 4 – Severe
B. Airway inflammation–lymphocyte bronchiolitis	Grade 0 – None Grade 1R – Low grade Grade 2R – High grade Grade X – Ungradeable
C. Chronic airway rejection–bronchiolitis obliterans	Grade 0 – None Grade 1 – Present
D. Chronic vascular rejection–accelerated graft vascular sclerosis	

Based on [7] Stewart S, Fishbein MC, Snell GI, et al. Revision of the 1996 Working Formulation for the standardization of nomenclature in the diagnosis of lung rejection. *J Heart Lung Transplant* 2007;26:1229–1242. Copyright 2007, with permission from Elsevier.

by most centers today [8]. For those biopsies that have insufficient tissue for evaluation, a definitive diagnosis on the presence of absence of rejection is usually not given (see later).

Histologic features of acute rejection

Acute cellular rejection in the lung is graded using two scales: A for vascular rejection and B for airway inflammation, the latter not labeled definitely as rejection because it may be a result of acute rejection of the airways, but may also have other etiologies. Rejection in the vessels is usually accompanied by rejection in the airways, especially in cases of moderate and severe vascular rejection [9] but vascular rejection is the clinical trigger that prompts therapy even in the absence of airway rejection.

Acute vascular rejection is graded on an A0–A4 scale, each increment representing an increasing amount of inflammation, first surrounding the vessels and then infiltrating out into the alveolar walls. The infiltrate is composed of lymphocytes, some with reactive faintly eosinophilic or "transformed" nuclei, macrophages, eosinophils, and neutrophils, the latter two acute inflammatory cell populations usually seen only in grade A2 and above. A diagnosis of acute rejection has no minimal number of vessels involved, requiring only a single vessel to show histologic evidence of rejection. Veins and venules are more commonly involved than arteries and arterioles. Finally, though the vascular rejection may include a spectrum of grades, the grade given to the biopsy represents the highest grade present in the tissue.

Grade A0 (no acute rejection) is the grade given to the biopsy when no acute vascular rejection is seen and adequate tissue is available for grading.

Grade A1 (minimal acute rejection) indicates the presence of lymphocytes encircling the vessels in layers 2–3 cells thick in the adventitia (Figure 84.1). Though previous Working Formulations have accepted incomplete vascular cuffing consistent with rejection, the most recent Working Formulation states that the infiltrate must completely surround the vessel [7]. Unlike higher grades of acute rejection, no eosinophils or neutrophils are seen in this grade. Though subtle, this pathology can usually be seen even at low magnification if the tissue is free of artifacts.

Grade A2 (mild acute rejection) also has a mononuclear infiltrate around vessels, containing lymphocytes, many activated and plasmacytoid variants, as well as eosinophils. The infiltrate is more prominent than in Grade A1 with cell layers of 3–5 cells thick and easily visible at low magnification (Figure 84.2). There may be subendothelial involvement of these mononuclear cells (endothelialitis). In addition, though airway inflammation is not commonly see in Grade A1, it is commonly found co-existing with Grade A2 [10]. No extension of this mononuclear infiltrate into the alveoli is seen in this grade, which distinguishes it from Grades A3 and A4.

Grade A3 (moderate acute rejection) consists of a dense mononuclear infiltrate cuffing the vessels, with frequent eosinophils and neutrophils and a prominent endothelialitis. The infiltrate, by definition, must extend into the adjacent alveolar walls, involving airspaces and septa and in some cases can cause features of early acute lung injury including reactive Type 2 pneumocyte hyperplasia and intra-alveolar fibrin. This infiltrate commonly extends into the alveolar space resulting in clusters of alveolar macrophages, lymphocytes, and occasionally focal fibrin deposition, giving

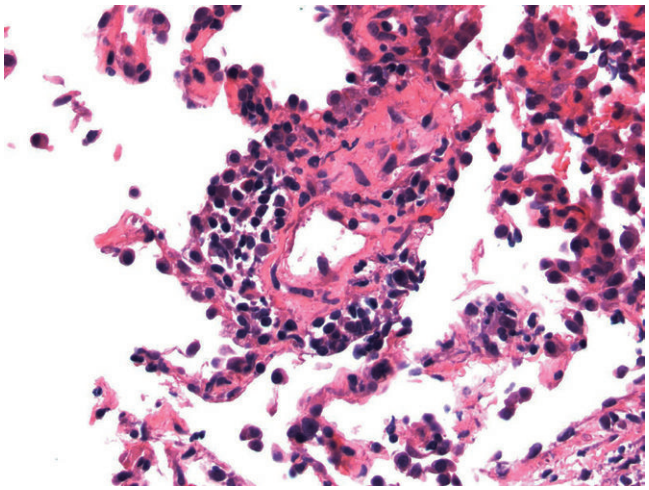

Figure 84.1. Acute cellular rejection Grade A1 (minimal). A small vessel is cuffed by plasmacytoid and transformed lymphocytes present in a layer of 2–3 cells (hematoxylin and eosin).

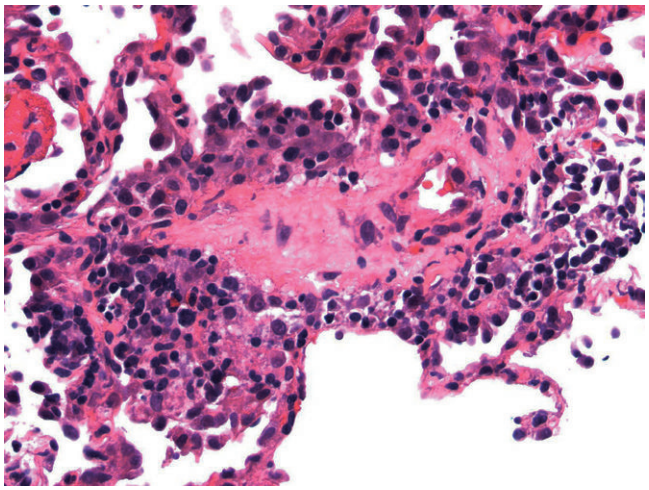

Figure 84.2. Acute cellular rejection Grade A2 (mild). Inflammatory cells greater than three layers thick surround a small vessel. This infiltrate includes lymphocytes and scattered eosinophils and neutrophils (hematoxylin and eosin).

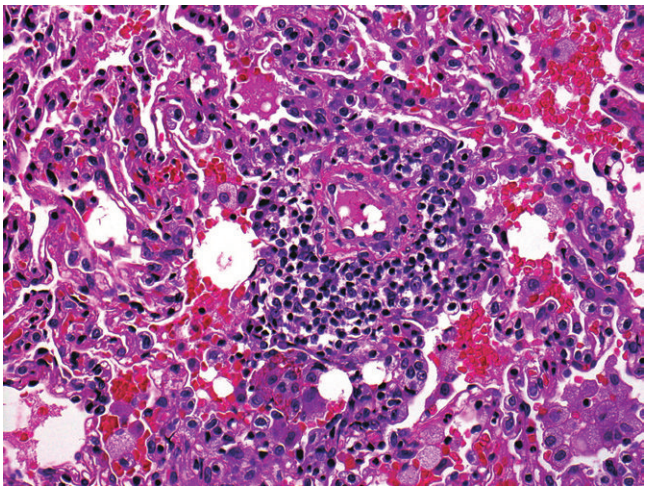

Figure 84.3. Acute cellular rejection Grade A3 (moderate). An inflammatory infiltrate with lymphocytes, eosinophils, and neutrophils extends into the alveolar septa (hematoxylin and eosin).

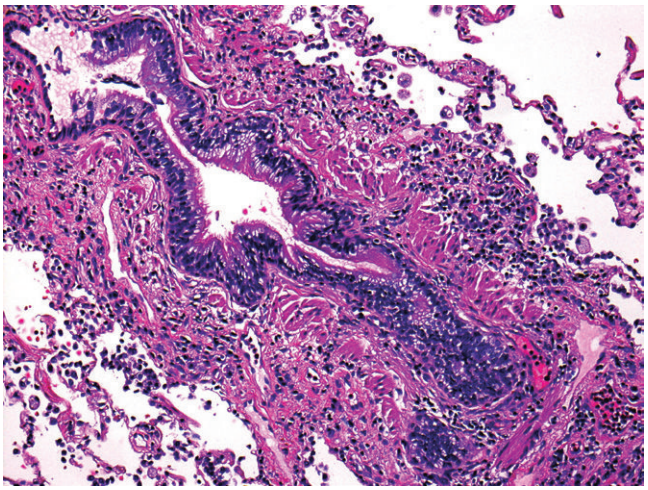

Figure 84.5. Low-grade lymphocytic bronchiolitis Grade B1R. Lymphocytes are present in a band-like infiltrate in the submucosa and as single cells infiltrating the overlying bronchiolar epithelium (hematoxylin and eosin).

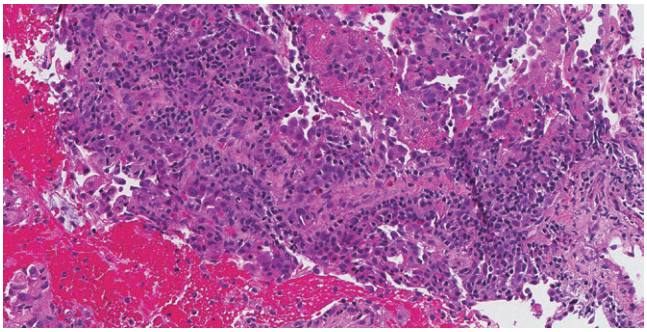

Figure 84.4. Acute cellular rejection Grade A4 (severe). Diffuse perivascular, interstitial, and air space infiltrates are present with evidence of acute lung injury and hemorrhage (hematoxylin and eosin).

the lung parenchyma a more inflamed and atelectatic appearance (Figure 84.3).

Grade A4 (severe acute rejection), a grade seldom seen in transbronchial biopsies, is defined as diffuse involvement of the lung vessels and alveoli with mononuclear cell infiltrates and severe acute lung injury. The histologic features are those of diffuse interstitial pneumonia with intra-alveolar macrophages, fibrin, and perivascular inflammation with areas of both necrosis of the parenchyma and fibrinoid necrosis of the vessels (Figure 84.4). The alveolar space may be filled with macrophages, fibrin, hemorrhage, and hyaline membranes and the abundance of neutrophils is characteristic of Grade A4 rejection. The vasculitis and perivascular prominence of the inflammation may be helpful in distinguishing Grade A4 acute rejection from diffuse alveolar damage. The latter has multiple etiologies including infection or reperfusion injury in the immediate post-transplantation period [11]. Both the reactive Type 2 pneumocyte hyperplasia and the endothelialitis are more prominent than that seen in Grade A3. With Grade A4 acute rejection, the inflammation commonly spills over into the adjacent large and small airways, resulting in infiltration of the epithelium with these inflammatory cells and ulceration [12]. Because of the abundance of acute inflammation including neutrophils, the primary differential diagnostic consideration to Grade A4 rejection is usually an infectious process. Organism stains and clinical information is often necessary to support the correct diagnosis.

For biopsies that have fewer than five pieces of tissue and are insufficient to evaluate for rejection, a Grade of AX is given.

Grading of the small airways for acute rejection is based on the extent of a lymphocytic infiltrate of the airway and epithelium injury and is applicable to small airways only [7]. In the original 1990 Working Formulation, acute airway rejection was simply listed as present or absent, at the discretion of each institution [12]. In the 1996 revision, the grading of airway inflammation expanded to include B0 (no inflammation) to B4 (severe airway inflammation) [12]. However, not all members of the LRSG were convinced that the inflammation could be used solely to grade rejection because it was also found in other settings (most notably infection) [13], thus, the consensus was that this schema would need ongoing study. In the 2007 revision, the difficulty in discriminating the causes for the inflammation (predominantly rejection or infection) was officially acknowledged with the introduction of the generic term "airway inflammation" into the grading schema. In addition, because a consensus could not be reached regarding the criteria needed to reproducibly separate the airway inflammation into four separate grades, it was decided to collapse the grading schema down to a two-tier system, B1R and B2R (R for revised grade), retaining B0 for the absence of inflammation and BX for those biopsies in which the inflammation could not be adequately assessed for a number of reasons. These included cases in which no airways were present for evaluation, other inflammatory processes capable of producing the inflammation were present (such as infection), or tangential cuts of the tissue or crush artifact obscured the small airway present [7].

In airways with Grade B1R, there are mononuclear cells forming patches or, in more prominent cases, a band within the submucosa of the small airways. The infiltrate may extend into the muscular wall of the bronchiole but does not tend to involve the overlying bronchiolar epithelium and no significant epithelial injury is present (Figure 84.5). Grade B2R has a much more exuberant infiltrate and forms a dense band of more activated

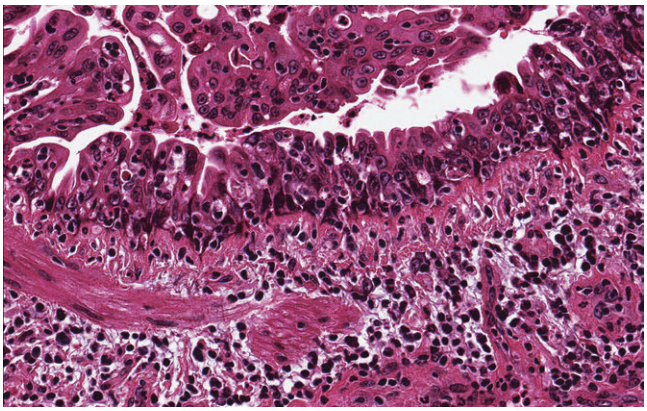

Figure 84.6. High-grade lymphocytic bronchiolitis Grade B2R. Lymphocytes are present in the submucosa with extensive infiltration into the overlying epithelium producing extensive epithelium injury (hematoxylin and eosin).

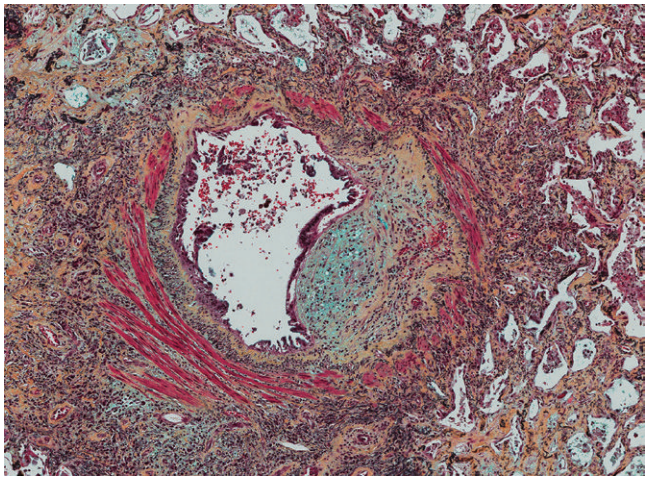

Figure 84.7. Chronic airway rejection–bronchiolitis obliterans Grade C1. A small airway has early fibrosis and asymmetrical narrowing of lumen (Movat).

lymphocytes with plasmacytoid variants and significant numbers of eosinophils and neutrophils. This inflammation infiltrates the overlying bronchiolar epithelium causing significant epithelial injury, taking the form of both apoptotic cells and areas of frank ulceration with cellular debris (Figure 84.6). The acute inflammatory cells make it difficult to distinguish high-grade rejection from infection; however, a more prominent presence of neutrophils within the epithelium and lumen of the airway may be evidence of infection rather than rejection. Viral bronchiolitis may induce a similar degree of airway-centered inflammation and epithelial injury. In these cases, careful review of the injured epithelial cells may reveal viral inclusions and immunohistochemistry studies, especially for CMV and herpes simplex virus, may demonstrate the viral inclusions.

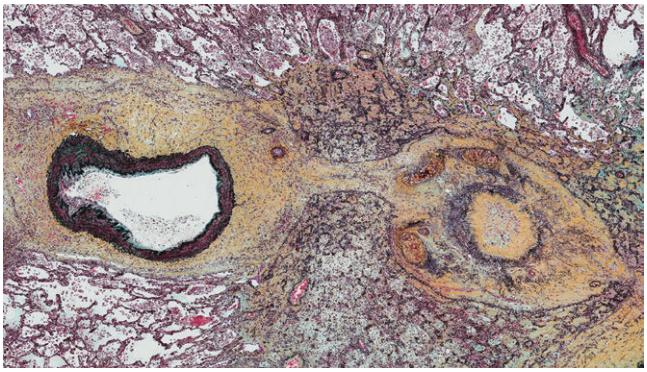
Given the importance of the transbronchial biopsy in assessing rejection and dictating treatment, it is important to examine research that has studied the validity and reproducibility of the current classification system by assessing the interobserver variability. Studies show that agreement between expert lung pathologists for acute rejection is variable from poor (kappa 0.183) [13] to moderate (kappa 0.47–0.79) [8,14,15], with most disagreement occurring for Grade A1 (minimal acute rejection) and most concurrence for Grade A2 (mild acute rejection). For airway inflammation, there was predominantly poor interobserver variability (kappa 0.035–0.25) [14,16] with significant concurrence occurring for Grade B0, no airway inflammation. These data argue for continued education to optimize and increase uniformity of the pathologic grading of acute rejection and for ongoing refinement of the criteria to further enhance diagnostic reproducibility [13].

Chronic rejection

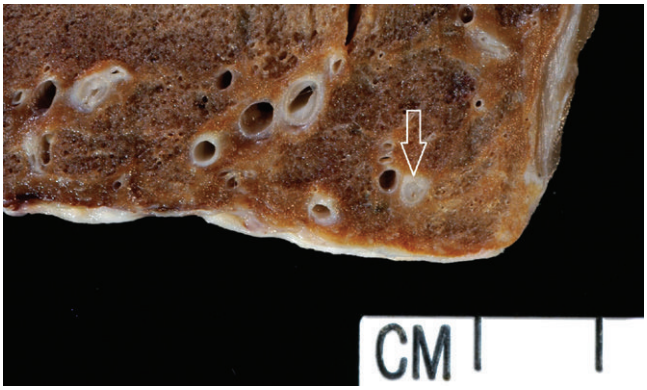
As with acute rejection, the histologic features of chronic rejection in the lung allograft are most clearly defined in the vessels and the airways, with the latter currently thought to be the most clinically significant. Chronic airway rejection, or obliterative bronchiolitis (OB), is a process by which collagenous type fibrosis occurs in the small airways as a sequela of the lymphocytic bronchiolitis, perhaps as a result of the airway inflammation of acute rejection [17–19]. This abnormal repair reaction may be mediated via transforming growth factor-beta (TGF-β) over-expression in response to acute injury and inflammation [19]. This airway fibrosis may appear anywhere from a few months to several years after transplantation. The median time to presentation is 16–20 months [20]. The sensitivity of transbronchial biopsy (TBB) for the detection of chronic airway rejection at most centers ranges 15–40% [3,21] because of its patchy nature in the allograft. This sensitivity may increase with the number of tissue fragments, the experience of the bronchoscopist and the pathologist, but it remains a less sensitive measure than pulmonary function testing and it is more expense and invasive [20]. Therefore, surveillance TBBs for OB are no longer performed in most clinical transplant centers. Instead, a standardized formulation for the clinical diagnosis of OB or bronchiolitis obliterans syndrome (BOS), developed by the ISHLT and based on pulmonary function test results, is used to dictate therapy [22].

The primary histologic marker for chronic airway rejection is the presence of dense hyalinizing fibrosis comprised of type 3 collagen in the subepithelial area of the bronchiolar mucosa [19]. This may be either concentric or eccentric and it gradually narrows (Figure 84.7) and eventually occludes the small airways (Figure 84.8). As the fibrosis increases, the bronchiolar epithelium is lost and identification of the obliterated airway may be difficult. Its proximity to a pulmonary artery or residual smooth muscle from its wall may be helpful in finding it. Also, connective tissue stains such as elastic or pentachrome stains are helpful in highlighting the elastica of the obliterated airway as well as identifying evidence of early fibrosis. Though previous Working Formulations considered the amount of chronic inflammation in the schema, the most recent grading system does not include this and consists of just two grades: Grade C0 if absent and Grade C1 if present.

Chronic inflammation, fibrosis, and eventually bronchiectasis may be present in large airways in lung allografts with both acute and chronic small airway rejection. These histologic findings may represent chronic injury from a number of insults that the allograft has suffered, including infection and aspiration as well as rejection.



(A)



(B)

Figure 84.8. (A) Chronic airway rejection–bronchiolitis obliterans with early chronic vascular rejection Grade C1D. Remnants of a cartilaginous airway (right), outlined by elastic fibers (black), is completely obstructed by collagenous fibrosis. The pulmonary artery (left) shows some evidence of intimal fibrosis consistent with an early chronic vascular rejection. (Movat). (B) Chronic airway rejection. A transplanted lung resected for chronic airway rejection has small airways some partially narrowed and others completely obliteration by fibrosis (arrow) (Gross).

Because these pathologic findings are not specific for rejection, they are not included in the 2006 Working Formulation and are not graded as chronic airway rejection.

The pathologic features of chronic vascular rejection have not received significant attention because the transbronchial biopsy does not reliably sample these lesions and the clinical significance of this pathology is not yet clear. The pathologic features of chronic vascular rejection have not been well documented. Features described include intimal fibrosis and variable transmural chronic inflammatory infiltrates (Figures 84.8 and 84.9). One report states that the intimal proliferation could be non-laminar eccentric and concentric and that the media of vessels can demonstrate mild extracellular matrix deposition with smooth muscle atrophy [23]. Grading chronic vascular rejection is similar to chronic airway rejection in that only its absence (Grade D0) or presence (Grade D1) is noted.

The concurrence of chronic airway and chronic vascular rejection is well-documented leading to speculation regarding a causal link [24]. Recent research suggests that intimal fibrosis of the small vessels that supply the airways, the pathology seen in chronic vascular rejection, may correlate with the presence of OB [25,26].

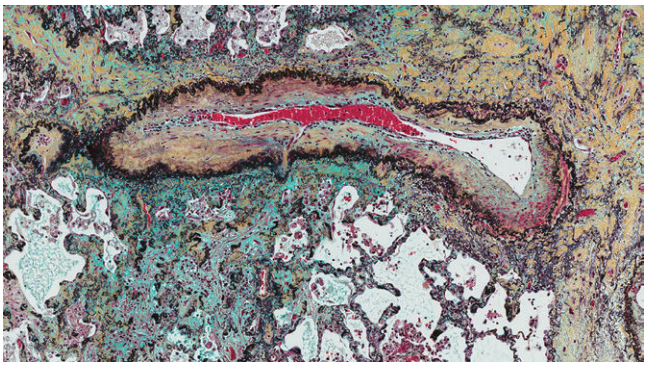


Figure 84.9. Chronic vascular rejection: vein. A large vein within an interlobular septa in a transplanted lung resection for chronic rejection shows marked intimal fibrosis (Movat).

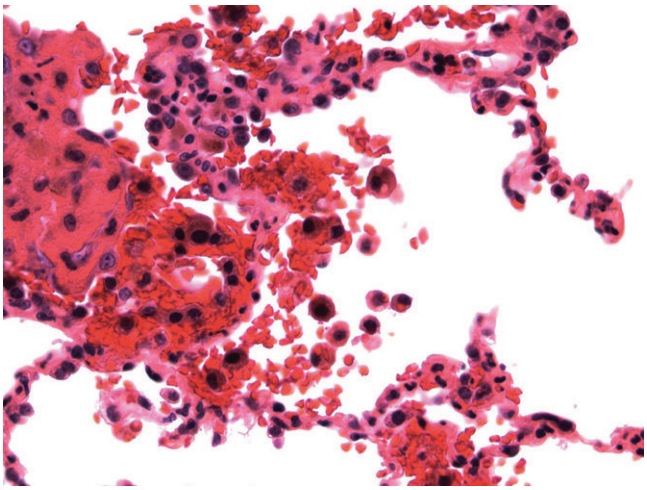
Because the bronchial circulation, the high pressure circulation that supplies the oxygen to the lung, is not reconnected during the transplantation procedure, the lung tissue including the small airways, are more susceptible to hypoxic injury [27]. These studies suggest that the pathologic changes of chronic vascular rejection may further compromise oxygenation in the lung allograft small airways, leading to epithelium injury, fibrosis, and eventually OB. Early studies suggest that in lungs where the bronchial circulation has been reconnected, there is a decreased incidence of OB [28]. Further studies of the chronic vascular changes and their effects in lung allografts are needed to clarify these findings.

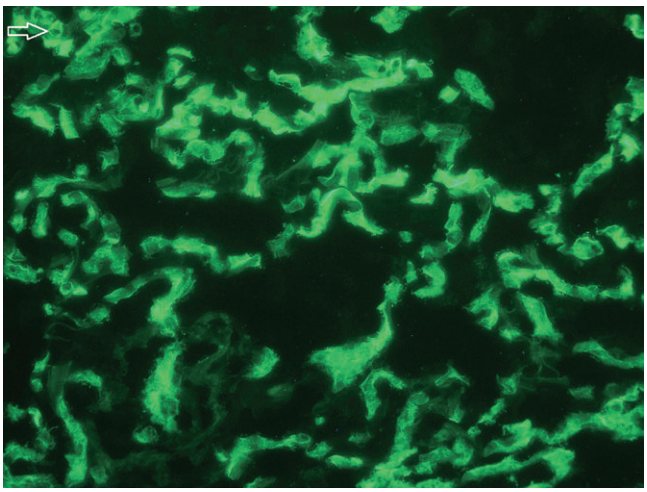
Antibody-mediated rejection

Antibody-mediated rejection (AMR) results from injury to the allograft from donor specific anti-HLA antibodies post-transplantation [29]. This form of allograft rejection is clinically important in other solid organ transplants such as kidney and heart [30]. However, its clinical significance in the lung allograft including its effect on allograft survival is not known. The detection of HLA antibodies among lung transplant recipients has been shown to decrease lung allograft survival [31,32] and humoral rejection in the form of so-called hyperacute rejection in the lung, resulting from preformed antibodies in the recipient directed against donor HLA antigens has been well-documented [33]. In the latter, the most common pattern of injury takes the form of diffuse alveolar damage (DAD) and may also reveal evidence of vascular injury such as thrombi formation in vessels and neutrophils and necrosis within alveolar septal capillaries [30,34]. In the two previous Working Formulations, AMR was not in the classification or grading for lung rejection [12] and though the current Working Formulation includes a discussion of AMR, it concludes that the pathologic features for AMR in the lung are not yet definitive and require further studies. Further, it introduces the term capillary injury (in place of capillaritis) and suggests this may be the pattern of injury for AMR but may have a wider etiologic spectrum including infection and high grades of cellular rejection [7].

Currently, the focus of study on AMR in the lung has been on defining both the clinical and the pathologic features. The working group from the National Conference to Assess Antibody-Mediated Rejection in Solid Organ Transplantation has proposed a general



(A)



(B)

Figure 84.10. (A) Antibody-mediated rejection. Lung parenchyma shows features of acute lung injury including reactive pneumocytes and intra-alveolar fibrin. Neutrophils are present with the septal capillaries (hematoxylin and eosin). (B) Antibody-medicated rejection. Immunofluorescent staining for C4d shows capillaries with linear deposition and areas of cross-sectional vessels with a characteristic "donut" like pattern of staining (arrow) (polarized light).

classification system for humoral rejection that proposes four necessary features for humoral rejection: detection of circulating HLA or donor-specific antibodies; C4d deposition in the allograft tissue; the presence of tissue pathology; and graft dysfunction [30]. Studies that have focused on defining the tissue pathology have found that, in general, it includes neutrophils within alveolar septal capillaries if not definitive necrosis or evidence of pulmonary hemorrhage (Figure 84.10), features at least suggestive of pulmonary capillaritis [35]; however, C4d staining was not performed. In studies where C4d staining was performed, the results have been somewhat discrepant. Some studies have found evidence of C4d deposition in lung allografts with this pattern of injury [36–39], while others have not seen C4d deposition in this setting of capillaritis [40]. These discrepancies may be a result of differing methodologies, nonspecific staining of elastic tissue and fibrin, or the extremely low incidence of capillary-specific C4d positivity in lung allograft biopsies. Currently underway are large-scale multi-institutional studies with standardized protocols, including those for C4d tissue staining, to help gather more conclusive data regarding the pathologic features of AMR in the lung [41].

Role of bronchoalveolar lavage fluid in the diagnosis of lung allograft rejection

The use of bronchoalveolar lavage fluid (BALF) analysis in monitoring rejection in the lung allograft remains an area of controversy. The monitoring of the active cellular dynamics between the lung parenchyma including alveoli and the interstitial compartment and the small and large airways becomes possible with bronchoscopy and bronchoalveolar lavage (BAL) through the counting and immunophenotyping of inflammatory cells within the BALF. Through lavaging the lung allograft, it is estimated that over 1 million alveoli may be sampled [42], a considerably larger area of the lung than TBB can access. This would seem to give BAL a considerable advantage over TBB given the patchy nature of rejection. However, though BAL is a primary tool used in assessment of the lung for infection [43] and is a common tool used when infection is suspected in lung transplantation patients [44], the promise of BAL as a more sensitive tool for diagnosing rejection has not been borne out for a number of reasons.

First, the cellular composition of the BALF changes during the post-transplantation period. In the immediate aftermath of surgery, the total cell count is elevated, especially the neutrophils, probably as a result of a number of inflammatory insults including reperfusion injury [44,45]. This cell count may remain elevated for years, making it difficult to establish a firm baseline with which to compare subsequent samples. Second, though acute rejection in the lung allograft is characterized by an increase in mononuclear inflammatory cells within the interstitium and the airspaces that increases with the grade of both acute vascular and airway rejection [7], granulocytes (eosinophils and neutrophils) also increase [46] making it difficult to separate infection from rejection. Studies that compared the inflammatory cell findings in TBB specimens with those in BALF, found the inflammatory cells in TBB are highly specific for rejection. However, the cellular changes in the BALF from lungs with rejection had increased proportions of lymphocytes in early rejection and neutrophils in later occurring rejection but were not specific for rejection [47,48].

To assess for features of AMR in BALF, one study evaluated soluble C4d with C4d fragment enzyme immunoassay and correlated the findings with tissue C4d deposition and anti-HLA donor-specific antibodies. The study found positive correlation of soluble C4d with tissue C4d deposition and donor-specific antibodies, but the findings were not specific and a high false-positive result was found in the setting of CMV infection [49]

Finally, given the importance of T cells in rejection [50], studies that focused on subtypes of T cells in the BALF did show some correlation with $CD4^+$ and $CD8^+$ ratios with the presence of acute cellular rejection in the lung allograft [51] and with the development of chronic airway rejection [43,52]. However, further studies to confirm these findings are needed before BALF is useful clinically in diagnosing rejection.

Conclusions

Lung transplant recipients remain at risk of alloimmune-mediated rejection of their grafts throughout life. This manifests as either

overt acute rejection or indolent chronic injury in the form of OB and its related BOS. Continuous patient surveillance supported by histopathologic diagnosis of tissue, or BALF analysis remains a critical part of lung transplantation.

CHAPTER 85

Histopathological Syndromes of Pancreas and Islet Allograft Rejection and Recurrent Disease

Cinthia Beskow Drachenberg and John C. Papadimitriou
University of Maryland School of Medicine, University of Maryland Hospital, Baltimore, MD, USA

Introduction

In patients with type 1 diabetes mellitus, insulin independence can be achieved either through whole pancreas transplantation (WPnTx) or with islet transplantation (IT). Successful β-cell replacement positively impacts quality of life for the diabetic patient [1] and, if long-term normoglycemia is maintained, can lead to improvement of secondary diabetic lesions that were previously considered irreversible [2,3].

The first pancreas transplant was performed in 1966, but achievement of acceptable results with this procedure has been slow – mostly because of a series of technical and immunological difficulties [4–8]. Since the 1990s, however, results for WPnTx have continuously improved and this procedure is currently considered a standard treatment for selected patients [9]. Routine histological evaluation of pancreas allograft biopsies and standardized interpretation of the pathology findings have contributed to better outcomes in WPnTx [5,10–15]. A thorough discussion of the procedural evolution and long-term benefits and outcomes in pancreas transplantation can be found in Chapter 107.

Since the first series of successful IT reported in 2000, excellent short-term results have been achieved; however, most patients require insulin therapy within 5 years post-transplantation. Despite this serious setback, other metabolic advantages such as disappearance of hypoglycemic episodes and overall improvement of glycemic control appear to persist longer in IT recipients [16,17]. Islet transplant outcomes are discussed in detail in Chapter 108.

In comparison to other types of transplants, systematic histopathological analysis of WPnTx and IT have been limited largely by technical limitations of obtaining suitable graft tissue by percutaneous biopsy. The interpretation of pancreas biopsies is still in a developmental phase, but continuous research efforts are increasing our understanding of the mechanisms of graft loss. Although the fundamental pathways of graft loss may differ in these two types of transplants, both eventually suffer a steady and irreversible deterioration of graft function that correlates with progressive graft fibrosis and sclerosis in WPnTx, and loss of a sufficient islet mass in IT [14,16–18]. The islets of Langerhans, the essential component in both these transplant modalities, can be affected by common processes (i.e. allograft rejection, recurrence of type 1 diabetes, amylin deposition, and susceptibility to cytomegalovirus (CMV) related effects) [18–21].

Principles and practical aspects of histopathological diagnosis of allograft rejection in whole pancreas transplants

Immunological aspects of rejection

Histopathological features of acute allograft rejection in the pancreas are not different from those in other solid transplants [6,8,22–24]. Acute T-cell-mediated rejection (ACMR) and antibody-mediated rejection (AMR) are characterized by tissue infiltration by effector inflammatory cells and by antibody and complement deposition in the vascular walls, respectively; these fundamental mechanisms are discussed in Chapters 5 and 6, respectively. In both of these pathways, graft injury typically results from antigen-specific immune damage in combination with other non-specific factors [22–24].

Graft rejection depends highly on the degree of incompatibility between recipient and donor major histocompatibility complex (MHC) antigens [24]. The MHC Classes I and II are expressed differentially in exocrine and endocrine pancreatic tissues, both in normal and inflammatory conditions (Table 85.1) [13,25–27]. MHC disparities, specifically in Class II, have been associated with an increased risk of AMR and graft loss [28].

In the early post-transplantation period, histopathological manifestations related to ischemia and surgical trauma predominate [24,29–31]. The development and progression of ACMR have been characterized in various animal models. ACMR manifests with inflammatory infiltrates in the interstitium, involvement of small veins, and variable more heterogeneous involvement of ducts [32–39]. Acinar inflammation and acinar cell damage, including apoptosis, is also characteristic of acute rejection [5,12,32,35–39]. The severe, more advanced forms of ACMR manifest with intimal arteritis, necrotizing vasculitis, thrombosis, and eventual parenchymal necrosis [14,36,39].

Although islets are not a primary target in ACMR, severe rejection leading to extensive parenchymal necrosis is typically associated with secondary islet damage or necrosis and hyperglycemia [40]. Furthermore, repeated or untreated episodes of ACMR lead to chronic injury characterized by acinar damage or dropout and chronic vascular injury both associated to a fibrogenic reaction that obliterates the pancreatic architecture and leads secondarily to loss of adequate islet function. Graft sclerosis represents the main feature of chronic rejection [41,42].

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Table 85.1. Class I and II HLA expression in normal and abnormal pancreas tissue

Cell type	Normal pancreas histology sections		Tissue culture – inflammatory milieu (β-IFN, γ-IFN, IL-2)		Diabetes mellitus (DM)	
	Class I	Class II	Class I	Class II	Class I	Class II
Acinar cells	–	–	+ Aberrant expression	+ Aberrant expression	n/a	n/a
Ductal cells	++	–	++	+ Aberrant expression	n/a	n/a
Islet cells	+/– (Weak)	–	++ Over-expression	++ Aberrant expression	++ all islet cells Over-expression, (with insulitis – early DM)	+ ß cells Aberrant expression, +/– insulitis)
Capillary endothelium	++	++	n/a	n/a	n/a	n/a
Large vessel endothelium	++	Variable	n/a	n/a	n/a	n/a

In AMR, deposition of antibodies in the vascular walls cause direct injury by activation of the complement cascade and also through antibody-dependent cell-mediated toxicity (ADCC) [28,43,44]. Therefore, vascular injury and necrosis, development of thrombosis, and secondary ischemic parenchymal necrosis typically characterize well-developed acute AMR; hyperacute rejection is the most extreme example of this process [24,43,45,46]. Although initially thought to be associated only with immediate graft loss in the form of hyperacute rejection, more protracted forms of AMR (acute and chronic active) are now recognized. Macrophages and neutrophils are recruited in abundance in AMR; however, these cell types can be present also in the more severe forms of T-cell mediated rejection as well as in any form of severe parenchymal injury [11,45,47–49]. Several documented cases of AMR have presented with hyperglycemia, suggesting that the islets may be susceptible to microvascular injury associated with antibody deposition in this form of rejection [11,47,50,51].

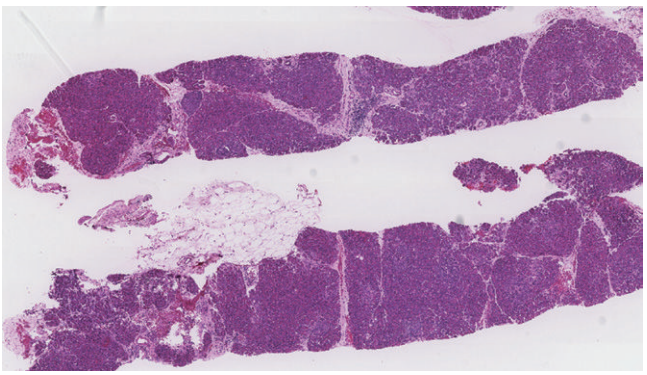

Figure 85.1. Low power view of a pancreas transplant biopsy stained with hematoxylin and eosin. The majority of the tissue sampled consists of exocrine pancreas (acinar lobules) separated by thin connective tissue septa. There is negligible septal fibrosis (i.e. graft sclerosis) in this biopsy (Stage 0).

Histological diagnosis of allograft rejection

Important efforts are being made to discover and validate non-invasive biomarkers that could potentially circumvent the performance of allograft biopsies [52–54]; however, tissue sample evaluation continues to be the gold standard for the diagnosis of acute pancreas rejection. ACMR and AMR cannot be distinguished from each other on clinical grounds alone. A complete discussion of the clinical recognition of pancreas and islet transplant rejection is found in Chapter 73. With both processes, patients present most commonly with exocrine abnormalities or a combination of exocrine and endocrine abnormalities; isolated endocrine dysfunction (hyperglycemia) is a less common indication for allograft biopsy (<10%) [10,11,47,55,56].

An ideal pancreas allograft biopsy contains at least three lobular areas and the associated interlobular connective tissue septa to allow for the evaluation of septal structures including ducts, veins, and smaller arterial branches, which are typically affected in T-cell-mediated rejection (Figure 85.1). The larger arterial branches are sampled with more difficulty. The absence of arterial branches in the biopsy core should be noted in the pathology report due to the diagnostic importance ascribed to the arterial lesions [14].

The biopsy is first examined at lower magnification for assessment of the overall lobular architecture and semiquantitative determination of the amount of septal and interacinar collagen (fibrosis), if present. Inflammation in the septal areas is identified easily at lower magnifications; however, acinar inflammation requires more detailed, systematic evaluation as the inflammatory cells tend to blend with the acinar cells, particularly in early forms of rejection [51,57].

Biopsy types

Percutaneous needle core biopsies are usually performed under ultrasound or computer tomographic guidance, with 18 or 20 gauge needles [12,15,58–63]. Adequate tissue can be obtained in 88–90% of instances [15,58–61,64–66]. Significant complications have been reported in 2–3% of cases (e.g. bleeding, mild pancreatitis), none leading to graft loss [59,60].

Performance of a laparoscopic biopsy is an alternative to the percutaneous approach when access to the graft is impossible, particularly in enteric-drained grafts (e.g. interposition of bowel loops) [67,68]. Pancreas transplantation with retroperitoneal portal-enteric drainage may allow for better access through the percutaneous route [69,70].

Cystoscopic transduodenal pancreas biopsies were often used in the past when bladder drainage was commonly utilized. Pancreatic tissue could be obtained in only 57–80% of cases and therefore interpretation relied also on the examination of duodenal mucosa from the grafted duodenal cuff [71–74]. Enteroscopic biopsy of

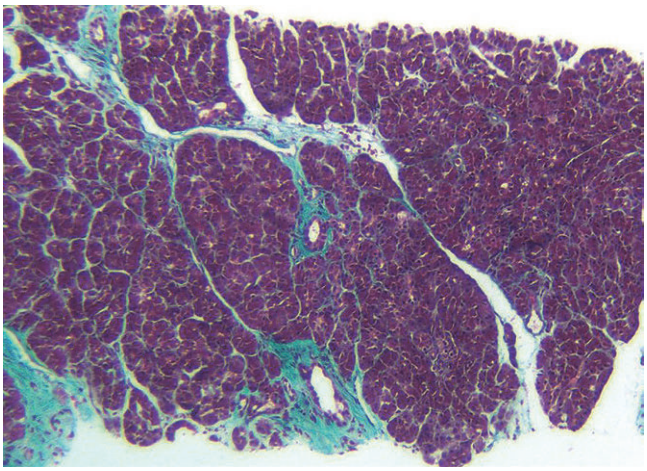

Figure 85.2. Masson's trichrome stain demonstrates thin delicate fibrous septa each of which contains branches of pancreatic ducts.

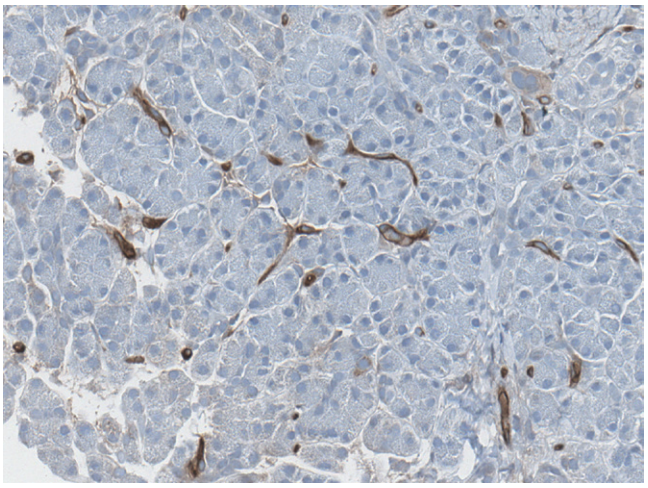
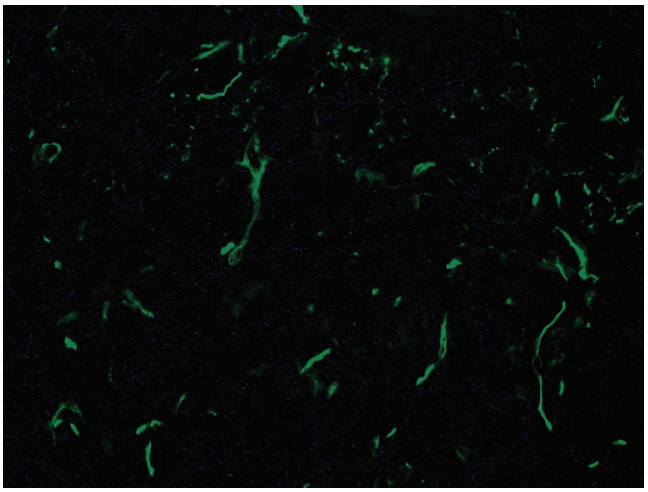


(A)



(B)

Figure 85.3. C4d stains using the immunohistochemical (A) and immunofluorescence (B) techniques demonstrate a similar staining pattern of the interacinar capillaries (IAC) in antibody-mediated rejection (AMR).

pancreas allografts, similarly, relies on the evaluation of mucosa from the duodenal cuff obtained with upper gastrointestinal endoscopy [75]. This is considered further in the section on Duodenal graft pathology.

Open (surgical) biopsies carry a higher risk of parenchymal leak and related complications, so they are performed only in selected cases when all other methods fail to provide tissue adequate for diagnosis [76].

Histological evaluation: technical guidelines

Routine light microscopy includes evaluation of at least two hematoxylin and eosin stained sections from different levels of the core. Intervening sections are stained for C4d (see diagnosis of antibody-mediated rejection below), and Masson's trichrome stain (Figure 85.2). The latter is a collagen stain used for quantitation of fibrosis and it also aids in the identification of specific structures or pathological changes (e.g. arterial walls, fibrinoid necrosis) [13,14]. With respect to the C4d stain, comparable results have been obtained with paraffin-embedded/immunohistochemical and frozen section/immunofluorescence methods (Figure 85.3) [13].

In patients biopsied due to hyperglycemia, it is essential to perform stains for *insulin and glucagon* to rule out selective loss of β cells [77–79]. Additional stains should be evaluated as needed (e.g. Epstein–Barr virus (EBV), CMV stains) [80,81].

Congo red stain is required for the identification of amylin (islet amyloid) [82] (see section on Banff pancreas allograft rejection).

If frozen tissue is available, deposition of immunoglobulins and complement in vascular walls can easily be demonstrated with immunofluorescence studies. These studies can be useful in cases suspected to represent hyperacute or fulminant acute AMR [42]. Electron microscopic preparations may be used to demonstrate selective β-cell loss in recurrence of type 1 diabetes or β-cell degeneration in calcineurin inhibitor toxicity [83].

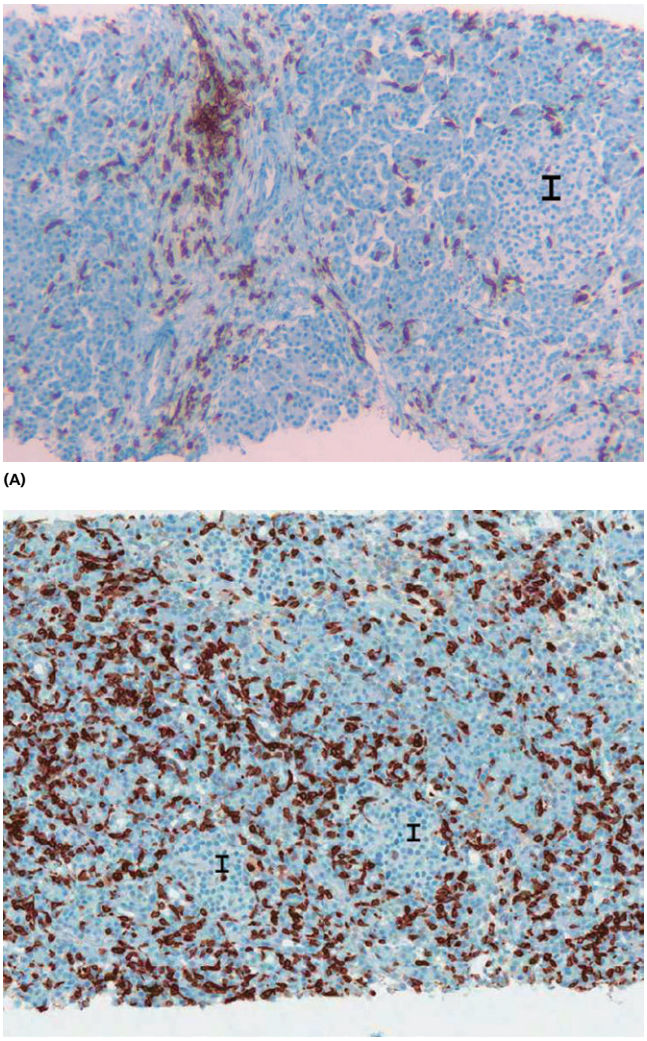
Acute T-cell-mediated allograft rejection

ACMR is characterized by septal inflammation and edema, venulitis, ductitis, and focal of diffuse "spilling" into adjacent or discontinuous acini (acinitis) [10,12,14,61]. Arterial lesions in pancreatic ACMR are morphologically identical to their counterparts in other solid organ transplants and by definition are classified with the more severe rejection grades due to their association with immediate or late graft thrombosis [14,84].

C4d staining in interacinar capillaries (≥5%) is not present in stereotypical ACMR [11].

Inflammatory cell types in ACMR

ACMR is defined by the presence of T-cell infiltrates. In milder forms of ACMR, more dense T-cell accumulation is predominantly confined to the septal areas (Figure 85.4A); in contrast, diffuse parenchymal T-cell infiltration is seen in extensive severe ACMR (Figure 85.4B). Eosinophils are commonly seen in acute ACMR and may even predominate in some cases [85]. Similar to ACMR in the kidney, macrophages are also present, but typically do not predominate unless there is a concurrent process present, such as ischemic pancreatitis or peripancreatic abscess. [86]. Plasma cells are uncommon in early acute ACMR but tend to accumulate along with the other mononuclear cells in protracted or partially treated or late acute-on-chronic rejection. Significant B-cell infiltrates are not characteristic of ACMR in the early post-transplantation period,



(A)

(B)

Figure 85.4. (A) Mild acute cell-mediated rejection (ACMR) (Banff Grade I). CD3 stain demonstrates heavier T-cell infiltrates in a septal area, with milder involvement of the acinar areas. (B) Severe ACMR (Banff Grade III) can present with various types of changes (see Banff schema). In this example, there is diffuse T-cell acinar inflammation as demonstrated by the CD3 stain. Note that in both images the islets (I) are to a large extent spared, because they are not specifically targeted by the inflammatory cells in ACMR.

but they commonly appear, often forming aggregates, in chronically inflamed grafts. B cells tend to increase with time, particularly in patients with previous episodes of rejection or ongoing ACMR. Their role is complex and poorly understood in the kidney and has not been systematically studied in pancreas allografts [87–89].

Therapeutic implications

Excellent response is achieved in most cases of ACMR with standard anti-rejection treatment (pulse steroids, antilymphocytic antibody). Conflicting results in the earlier series, where a significant proportion of severe ACMR rejection cases characterized by parenchymal and vascular necrosis were unresponsive to anti-rejection treatment, may have actually represented acute AMR [65,90]. Additional discussion on rescue therapy in general, and treatment of pancreatic acute rejection specifically are found in Chapters 67 and 73, respectively.

Differential diagnosis of ACMR

Negative or minimal pathological findings

For patients biopsied for graft dysfunction who have a "non-diagnostic" biopsy lacking obvious inflammation, the possibility of a sampling error should be considered. Unusual cases of mild ACMR may present with absence of septal infiltrates but focal acinar inflammation that may be underestimated at low-power evaluation [8,14]. Similarly, mild early AMR may present with extremely subtle acinar inflammation which may not be appreciated at first glance [13,91].

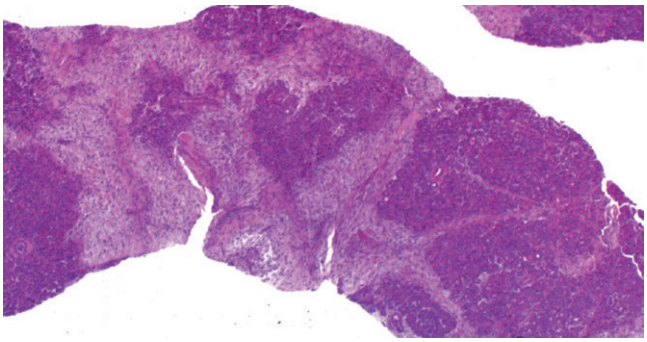
Septal and/or acinar inflammation with features different from ACMR

The main differential diagnosis includes peripancreatitis, CMV infection and post-transplant lymphoproliferative disorders (PTLD).

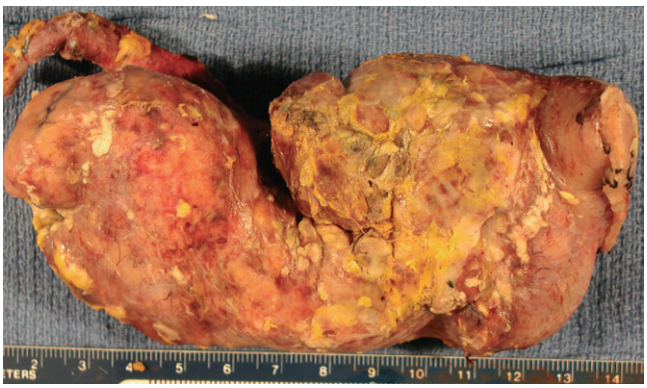
Infectious peripancreatitis, fluid collection, or peripancreatic abscess is a relatively common early complication of pancreas transplantation often secondary to ischemic graft pancreatitis [92,93]. Needle biopsies obtained from the grafted pancreas during post-transplantation laparotomy show variable degrees of mixed inflammation, predominantly septal. A typical finding in these biopsies is the presence of dissecting bundles of active tissue culture-like connective tissue with abundant fibroblasts. The fibrous bands run between the exocrine lobules giving the biopsy a "cirrhotic" appearance (Figure 85.5). The fibrosis becomes more pronounced as time passes if the peripancreatic infected fluid collection persists. The main differential diagnosis in biopsies from grafts with intra-abdominal or peripancreatic abscesses is with acute and with chronic rejection. In order to distinguish each of these processes it is necessary to integrate the histological and clinical information, including imaging and microbiological studies. From the morphological point of view, active fibrosis (or any active septal fibroblastic proliferation) is not typically found in acute ACMR unless there is an underlying component of chronicity. Overall preservation of the exocrine lobules is found in peripancreatitis whereas extensive atrophy of the central parts of the exocrine lobules is typically found in chronic rejection or graft sclerosis [14,41,86]. Although the degree of septal fibrosis seen in biopsies from patients who require one or more re-laparotomies may be very pronounced, these changes are usually confined to the periphery (surface) of the graft and therefore superficial fibrotic biopsies may not represent the status of the whole organ. In contrast to ACMR, the acinar parenchyma typically shows proportionally little inflammation and acinar damage in peripancreatitis [86].

Necrotizing infectious duodeno-pancreatitis with abscess formation can present at any time post-transplantation, but occurs more often in the first months. A variety of organisms can be cultured from these grafts, most commonly enterobacteria and methicillin-resistant *Staphylococcus aureus* (MRSA). Fungal infections, more often from *Candida* sp. and mixed bacterial and fungal infection, are not uncommon [94,95].

CMV allograft pancreatitis has become a rare diagnosis with the widespread use of antiviral prophylaxis. Klassen et al. [80] reported biopsy-proven CMV pancreatitis in four patients with the diagnosis made 18 weeks to 44 months after transplantation. With prolonged ganciclovir treatment, clinical and histological resolution of the infection was achieved in all patients [80]. On percutaneous needle



(A)



(B)

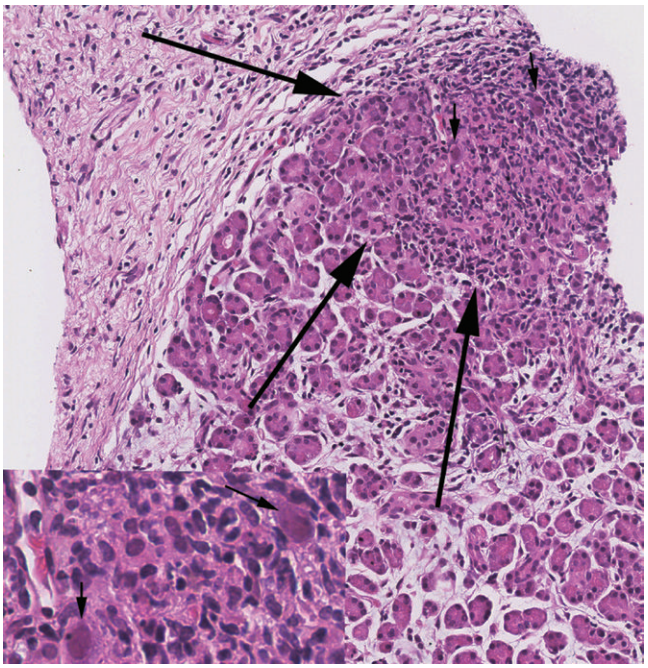
Figure 85.5. (A) Microscopic image of post-transplant peripancreatitis often shows mixed, predominantly septal inflammation and active septal fibrosis. The fibrous bands run between the exocrine lobules giving the biopsy a "cirrhotic" appearance. The inflammatory and fibrotic changes involve the peripheral areas of the graft. (B) Macroscopic appearance of pancreas transplant resected due to post-transplant peripancreatitis. The organ is partially covered by purulent exudates.

biopsies, both ACMR and mild CMV pancreatitis may present with modest, predominantly lymphocytic, acinar inflammation (Figure 85.6). Eosinophils are more common in rejection but may be present in small numbers in CMV infection as well. Neutrophils may be present in association with areas of necrosis or acinar cell damage in both rejection and CMV pancreatitis. Multiple tissue sections and CMV stains should be performed if deemed necessary to rule out viral infection [80,86].

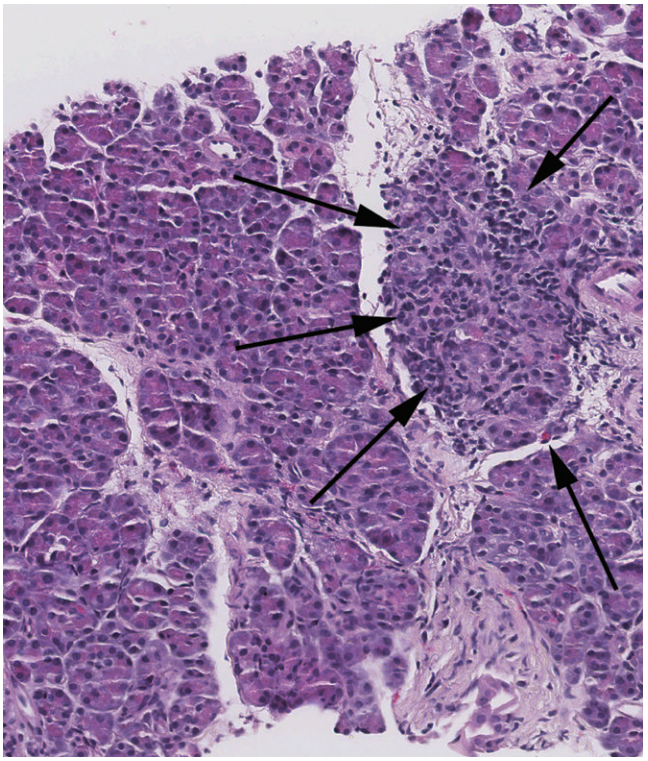
The clinical presentation of CMV graft pancreatitis is indistinguishable from acute rejection (e.g. increase in serum amylase and lipase). Severe cases of CMV infection may present with intractable gastrointestinal hemorrhage or duodenal-cuff perforation [96–100]. Necrotizing CMV infection with abscess formation and development of a CMV-related arteriovenous fistula have been reported [101–103].

Post-transplant lymphoproliferative disorder

PTLD occurs in 1–3% of pancreas transplant recipients [81,104–106]. Most PTLD is EBV-related, and of B-cell lineage. EBV-related PTLD includes a wide range of processes from benign hyperplastic to overtly malignant lymphoid proliferations. At the most benign end of the spectrum (plasmacytic hyperplasia), graft biopsies usually do not have a role in the diagnostic work-up. Graft involvement is not unusual in the other forms of PTLD (polymorphic



(A)



(B)

Figure 85.6. (A) Inflammatory focus due to CMV infection (large arrows). Enlarged cells with cytomegalovirus (CMV) cytopathic changes (small arrows) are present in the main image and in (B). Note the overall similarity with a focus of acinar inflammation due to ACMR, also marked with large arrows in (B).

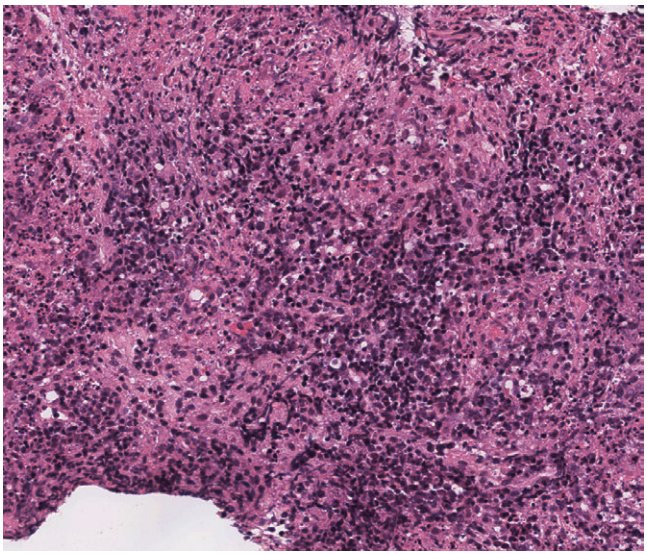


Figure 85.7. Post-transplant lymphoproliferative disorder (PTLD) is characterized by cytologically atypical immunoblastic or plasmacytoid infiltrates that infiltrate the parenchyma with a destructive expansive pattern. Necrosis, which is represented here in the lighter staining areas of the section, is commonly found in the more aggressive forms of PTLD.

B-cell hyperplasia/lymphoma, immunoblastic lymphoma) [81,107, 108]. The diagnosis of PTDL is more problematic in the earlier stages, particularly if there is a component of concurrent acute rejection. Evaluation of T-cell and B-cell markers (e.g. CD3, CD20) can aid in the evaluation of the infiltrates. Acute rejection is characterized by a predominant population of T cells (typically more than 75%) and a minor population of B cells that form aggregates no larger than a few hundred microns. In contrast, the identification of large confluent nodular B-cell aggregates are strongly suggestive of graft involvement by PTLD. The presence of marked cytological atypia, in infiltrates predominantly composed of immunoblastic and plasmacytoid cells, also favors a diagnosis of PTLD (Figure 85.7). Eosinophils are present in variable proportions both in acute rejection and in PTLD. Immunoglobulin light chain restriction is typically found in lymphoma [81,107,108]. EBV-related PTLD is confirmed with in situ hybridization for EBV-encoded RNAs (EBER) which marks a significant proportion of the atypical cells. Also, stain for LMP-1 (EBV latent membrane protein) is usually positive in a variable proportion of the cells. The random involvement seen in cases of PTLD with areas of parenchyma that may be completely free of infiltrates contrasts with the more diffuse involvement of the pancreas seen in the severe forms of cell-mediated acute rejection [5,81,107].

Acute antibody-mediated allograft rejection

There is a wide spectrum of histological changes in AMR, ranging from very mild inflammation to diffuse coagulation necrosis [43]. Intimal arteritis (endarteritis), a lesion that was considered typical of ACMR, is now recognized to also be associated with acute AMR [48,109,110].

C4d staining in >5% of interacinar capillaries is typically present in cases of acute AMR (Figure 85.3). C4d staining is characterized as focal (>5–50%) or diffuse (>50%), according to the extent of interacinar capillary staining in the lobular surface areas [11,13].

Box 85.1. Histological severity grading of acute antibody-mediated rejection (AMR) (see Banff grading schema in Box 85.2 for other diagnostic components)

Grade I, mild acute AMR
Well-preserved architecture, mild monocytic–macrophagic or mixed (monocytic–macrophagic/neutrophilic) infiltrates with rare acinar cell damage

Grade II, moderate acute AMR
Overall preservation of the architecture with interacinar monocytic–macrophagic or mixed (monocytic–macrophagic/neutrophilic) infiltrates, capillary dilatation, capillaritis, congestion, multicellular acinar cell dropout, extravasation of red blood cells

Grade III, severe acute AMR
Architectural disarray, scattered inflammatory infiltrates in a background of interstitial hemorrhage, multifocal and confluent parenchymal necrosis, arterial and venous wall necrosis and thrombosis

Table 85.2. Morphological features in acute T-cell-mediated rejection (ACMR) and antibody-mediated rejection (AMR)

	ACMR	AMR
Septal infiltrates	+++	− to +
Eosinophils	+ to +++	− to +
Neutrophils	− to ++	+/− to +++
T lymphocytes	++ to +++	+/− to +
Macrophages	++	++++
Venulitis	++	−
Ductitis	++	−
Acinar cell injury	+/− to ++	+++
Acinar inflammation	− to +++	+ to +++
Acinitis (mononuclear infiltrates within the basement membrane of individual acini)	+ to +++	− to +/−
Interacinar capillaritis	− to +/−	+ to +++
Intimal arteritis	+	+
Necrotizing vasculitis/thrombosis	− to +	+++
Confluent hemorrhagic necrosis	− to ++	+++

Inflammatory cell types in acute AMR

Mononuclear cells of monocyte–macrophage type constitute the most predominant cell type in the inflammatory infiltrates in acute AMR. Neutrophils are commonly also present and are proportional to the extent of tissue damage or necrosis. T lymphocytes are typically present, scattered throughout the parenchyma, but clearly represent a minority of the infiltrates. Rare eosinophils may be present (Box 85.1) [13,14,39,86,91].

Treatment implications

Histological grading of acute AMR (mild, moderate, or severe) is based on the extent of the interacinar infiltrates or capillaritis and tissue damage (Table 85.2) [13]. Severe acute AMR with diffuse vascular thrombosis and parenchymal necrosis is essentially untreatable [5]. Early, mild, or more indolent forms of acute AMR are potentially amenable to treatment but, as with other solid organs, results vary considerably. AMR in pancreas allografts continues to present a formidable therapeutic challenge [18].

Differential diagnosis of acute AMR

Negative or minimal pathological findings

Minimal early AMR can be very subtle and the biopsy may be erroneously considered "non-diagnostic" unless the sample is evaluated with a high degree of suspicion for identification of incipient

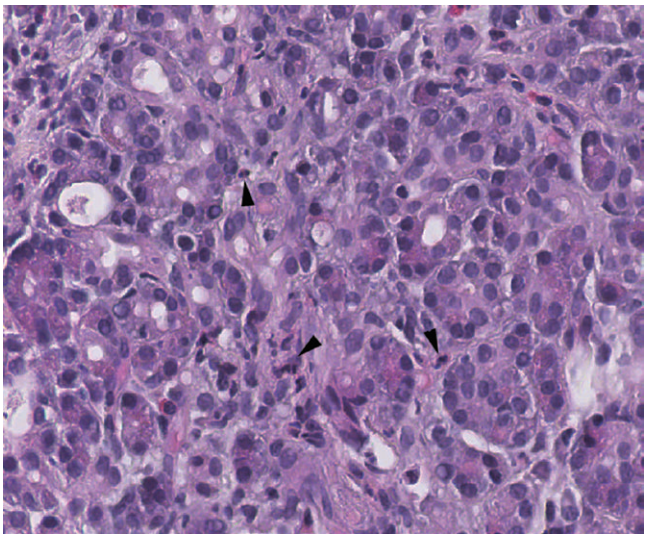

Figure 85.8. Mild ischemic pancreatitis is characterized by acinar cell injury (swelling, dropout of isolated or multiple cells) and mild neutrophilic (arrowheads) and macrophage infiltrates. This entity should be differentiated from acute AMR.

lobular infiltrates, accompanied by C4d staining and correlation with donor-specific antibody (DSA) status [13].

Recurrence of autoimmune diabetes [111], or other islet-related abnormality [83], should be considered in biopsies with minimal or absent inflammation, isolated insulitis, and particularly in patients with hyperglycemia [112].

Post-transplantation pancreatitis

AMR characterized by mixed lobular inflammation with or without microscopic or confluent hemorrhages, or cases with vascular thrombosis, require differentiation from ischemic pancreatitis. Critical evaluation of the samples is necessary for distinction of these entities [42].

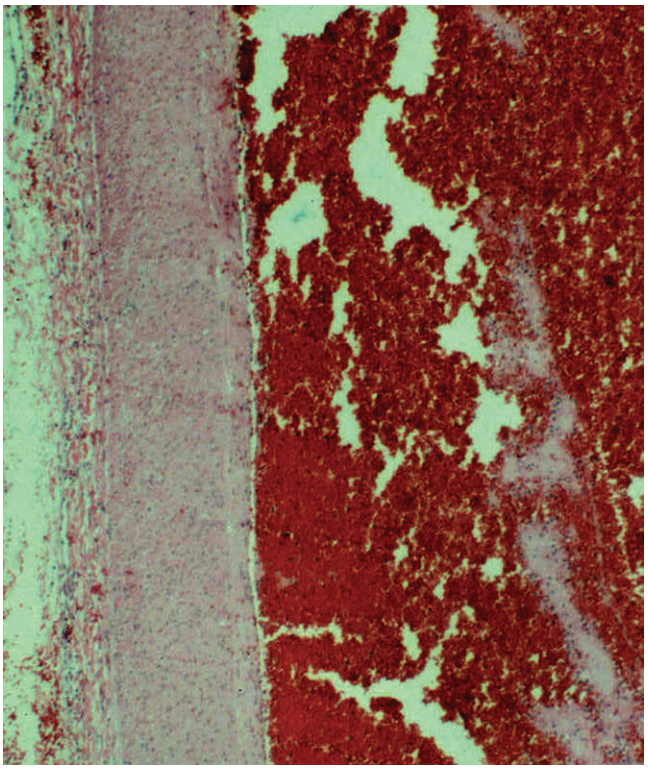
Mild ischemia–reperfusion injury is characterized by spotty acinar cell dropout, spotty apoptosis, flattening of the acinar cells, and otherwise minimal inflammation (Figure 85.8) [30,113,114]. In the absence of AMR, biopsies with ischemic pancreatitis fail to demonstrate C4d staining in interacinar capillaries. C4d stains often highlight necrotic cells and necrotic tissue in a non-specific manner but this is not diagnostic of AMR [13]. Another manifestation of ischemia is the presence of marked acinar and islet cell cytoplasmic swelling and vacuolization which should be distinguished from islet drug toxicity.

The incidence and severity of graft pancreatitis correlates with the length of cold ischemia time and is directly related to disturbances of the microcirculation in the reperfusion period [29,92,94,115].

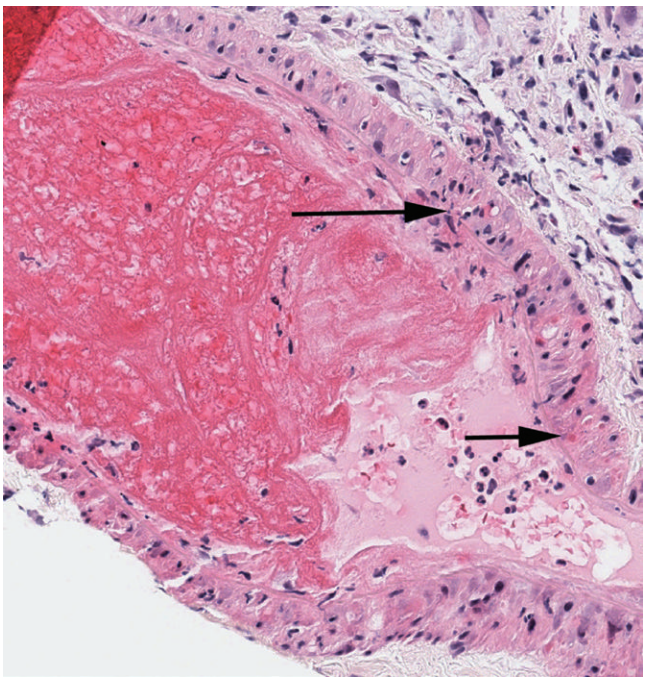
Graft thrombosis

Pancreas graft thrombosis occurs in different settings, including the following:

- *Early graft thrombosis in otherwise normal pancreas* (true technical failure) typically occurs within the first week post-transplantation [42]. In these grafts the only pathological changes consist of recent vascular thrombosis and bland ischemic parenchymal necrosis. There is no underlying vascular pathology or any other specific histological change (Figure 85.9A).



(A)



(B)

Figure 85.9. (A) Large vessel thrombosis due to "technical failure." The arterial wall is completely normal. (B) Arterial thrombosis in association with severe rejection. The arterial wall shows areas with loss of nuclei (necrosis, lower arrow) and intramural inflammatory infiltrates (upper arrow).

Perioperative inflammation and edema, as well as microvascular and endothelial damage relating to donor or procurement factors and organ preservation, all contribute to an increased incidence of early graft thrombosis [42,116].

- *Thrombosis in association to acute rejection* may occur at any time post-transplantation and is typically the result of acute or chronic vascular injury (endarteritis, transmural arteritis, transplant arteriopathy). Both AMR and ACMR can present with necrotizing arteritis (Figure 85.9B). Transmural inflammation and various degrees of intimal arteritis (endarteritis) are more common in ACMR. Systematic histological evaluation of failed grafts is necessary for accurate classification of the cause of graft loss, including generous sampling of large vessels, sections from the parenchyma to include an adequate number of medium-sized and small vessels and C4d staining [8,13,14,42,86]. High level panel reactive antibody (PRA) and circulating DSA were identified retrospectively in early cases of severe AMR with fulminant graft thrombosis [5,42].
- *Late graft thrombosis* is a recognized cause of late graft loss. This process is also associated with underlying vascular pathology that may be immune-mediated (acute or chronic active allograft rejection) or may be non-immune-related (e.g. atherosclerosis) [42,84].

Chronic allograft rejection and graft sclerosis in whole pancreas transplants

Despite excellent and prompt response to anti-rejection treatment, variable degrees of irreversible parenchymal fibrosis may develop after acute ACMR. Scarring is directly proportional to the extent of the inflammatory infiltration and to the severity of the acinar cell damage. Whereas pure septal inflammatory infiltrates (mild or Banff Grade I ACMR) may disappear without sequelae, confluent acinar inflammation and necrosis is invariably followed by secondary collagenization of the interacinar areas and eventual loss or disappearance of the exocrine component in the affected area [41].

Acute AMR refractory to treatment leads to graft failure in a short period of time (weeks or months), mostly due to widespread microvascular and large vessel obliteration and thrombosis. Thrombosis and ischemic necrosis predominate in severe acute AMR due to diffuse arterial and venous necrosis [43]. In more protracted forms of AMR, graft failure results from acute or chronic immunoglobulin and complement-induced smoldering microvascular injury and remodeling that eventually leads to graft fibrosis [13,117].

In general terms, chronic rejection is manifested histologically with progressive parenchymal sclerosis, defined by progressive fibrous expansion of the interlobular connective tissue septa and proportional degrees of atrophy of the acinar lobules. All exocrine tissue is eventually lost, with some areas becoming unrecognizable except for occasional residual islets embedded in the dense scar tissue. Disappearance of the acinar component forecasts progressive disappearance of islets as well, and eventual loss of glycemic control [41,118]. Narrowing of the arterial branches due to proliferative intimal endarteritis or transplant arteriopathy is also characteristic of the process [32,34,41,42].

In patients with long-term grafts immunosuppressed with calcineurin inhibitors (cyclosporine, tacrolimus), there may be widespread arteriolar hyalinosis, but it is not clearly established whether this contributes to the process of graft sclerosis [8]. Furthermore, in patients with generalized atherosclerotic disease, atheroemboli have been demonstrated to lodge in the pancreas allograft causing late pancreatitis and further ischemic compromise [119]. Criteria for staging of chronic rejection and graft fibrosis are described below (diagnostic category 6 of the Banff grading schema) (Box 85.2).

Duodenal graft pathology

In whole organ pancreas allografts, the exocrine drainage anastomosis is typically carried out through a segment of the graft duodenum [4]. A variety of pathological processes can affect the duodenal graft segment including technical problems (e.g. ischemia, anastomotic leak), CMV infection, and rejection.

Biopsy types

Cystoscopic duodenal biopsies were often performed in the 1990s when pancreas transplant exocrine secretions were routinely managed through bladder drainage. Significant experience was developed with the interpretation of these samples during that period [34,66,71,73,74,120,121]. Duodenal tissue can be also obtained fortuitously through the percutaneous route.

More recently, there has been renewed interest in the evaluation of duodenal samples from enteric-drained pancreas allografts with anastomosis to the proximal jejunum and obtained through upper gastrointestinal endoscopy. The technique for this type of enteroscopic graft biopsy is described in detail in the study of Margreiter et al. [75] who indicate that the duodenal cuff (area of duodenal-enteric anastomosis) was not accessible in 25% of cases; however, adequate duodenal material could be obtained in the remaining cases (76 out of 102 procedures, 75%). Microscopic pathology was identified in approximately one third of samples ranging from inflammation of undeterminate significance to severe rejection. CMV enteritis and *Giardia lamblia* infection were identified, one case of each. When the procedure was performed for suspected pancreas allograft rejection, the duodenal sample confirmed rejection in 65% of cases [75].

Pathological findings in the grafted duodenal cuff

Technical issues (duodenal leak): infections

Ischemia and poor surgical technique may lead to dehiscence of the anastomosis between the duodenal cuff and the urinary bladder or small intestine [94]. Pathological examination of grafts resected for this reason may show specific causes such as CMV-related perforation or may only show non-specific changes such as necrosis in the area around the anastomosis and acute inflammation. The adjacent peritoneal surfaces typically show acute fibrinous or purulent serositis [122].

Acute allograft rejection

From early experience with pancreas allografts drained externally (cutaneous graft duodenostomy) it was concluded that inflammation of the exposed segment of the graft duodenum correlated with acute rejection in the pancreas proper [123]. This was confirmed with earlier studies of duodenal and pancreatic samples which showed that acute rejection in the duodenum commonly occurred concurrently with pancreas rejection (72–100% concordance) [71,73]; but discrepant results with respect to rejection and even CMV infection could be observed in each of these organs [71,124].

Studies in dogs [125], pigs [126], and rodents [127] demonstrated a high degree of concordance between rejection in the duodenum and the pancreas but, interestingly, treatment response

Box 85.2. Banff pancreas allograft rejection grading schema, 2011 update diagnostic categories*

1. Normal
Absent inflammation **or** inactive septal, mononuclear inflammation not involving ducts, veins, arteries, or acini. There is no graft sclerosis. The fibrous component is limited to normal septa and its amount is proportional to the size of the enclosed structures (ducts and vessels). The acinar parenchyma shows no signs of atrophy or injury

2. Indeterminate
Septal inflammation that appears active but the overall features do not fulfill the criteria for mild cell-mediated acute rejection

3. Acute T-cell-mediated rejection‡
Grade I, mild acute T-cell-mediated rejection
Active septal inflammation (activated, blastic lymphocytes, ± eosinophils) involving septal structures: venulitis (subendothelial accumulation of inflammatory cells and endothelial damage in septal veins, ductitis (epithelial inflammation and damage of ducts)
and/or
Focal acinar inflammation. No more than two inflammatory foci† per lobule with absent or minimal acinar cell injury.
Grade II, moderate acute T-cell-mediated rejection (requires differentiation from AMR)
Multifocal (but not confluent or diffuse) acinar inflammation (≥3 foci† per lobule) with spotty (individual) acinar cell injury and dropout
and/or
Mild intimal arteritis (with minimal, <25% luminal compromise)
Grade III, severe acute T-cell-mediated rejection (requires differentiation from AMR)
Diffuse (widespread, extensive) acinar inflammation with focal or diffuse multicellular /confluent acinar cell necrosis
and/or
Moderate or severe intimal arteritis, >25% luminal compromise.
and/or
Transmural inflammation – necrotizing arteritis

4. Antibody-mediated rejection (see diagnostic components below*)
***Confirmed circulating donor-specific antibody**
***Morphological evidence of tissue injury (interacinar inflammation/capillaritis, acinar cell damage swelling/necrosis/apoptosis/dropout, vasculitis, thrombosis)**C4d positivity in interacinar capillaries (≥5% of acinar lobular surface)
- *Acute AMR:* three of three diagnostic components*
- *Consistent with acute AMR:* two of three diagnostic components*
- *Requires exclusion of AMR:* one of three diagnostic components*

See separate table for histological grading of acute AMR†

Chronic active antibody-mediated rejection
Combined features of categories 4* and 6 in the absence of features of category 3.

5. chronic allograft arteriopathy
Arterial intimal fibrosis with mononuclear cell infiltration in fibrosis.

6. Chronic allograft rejection/graft fibrosis
Stage I (mild graft fibrosis)
Expansion of fibrous septa; the fibrosis occupies less than 30% of the core surface but the acinar lobules have eroded irregular contours. The central lobular areas are normal
Stage II (moderate graft fibrosis)
The fibrosis occupies 30–60% of the core surface. The exocrine atrophy affects the majority of the lobules in their periphery (irregular contours) and in their central areas (thin fibrous strands criss-cross between individual acini)
Stage III (severe graft fibrosis)
The fibrotic areas predominate and occupy more than 60% of the core surface with only isolated areas of residual acinar tissue and/or islets present

7. Islet pathology
Recurrence of autoimmune diabetes mellitus
- Insulitis
- Selective β-cell loss
- Islet amyloid (amylin) deposition
- Islet cell drug toxicity

8. Other histological diagnosis
Pathological changes not considered to be due to acute and/or chronic rejection (e.g. CMV pancreatitis, PTLD)

AMR, antibody-mediated rejection; CMV cytomegalovirus; PTLD, post-transplantation lymphoproliferative disorder.
* Categories 2–8 may be diagnosed concurrently and should be listed in the diagnosis in the order of their clinicopathological significance.
† Histological grading of acute AMR (see Box 85.1).
‡ Histological features of stereotypical ACMR and AMR (see Table 85.2).
See Box 85.3 for morphological definition of specific lesions and Table 85.3 for other histological diagnosis.

occurred promptly in the duodenum but not in the pancreas in rodents [127].

Criteria for grading allograft rejection in the duodenal cuff mucosa have not been defined. In general terms, mild acute duodenal rejection is manifested by an increase in the inflammatory cells in the lamina propria, including neutrophils, with mild villous blunting and apoptosis of epithelial cells (Figure 85.10). In severe rejection there is confluent epithelial necrosis with total loss of the epithelial lining. Necrosis can extend to all layers, including the muscularis propria. Arterial involvement (e.g. endarteritis, necrotizing arteritis), which is diagnostic of rejection in the pancreas, may be seen also in the duodenum [71]. A case of duodenal perforation caused by acute rejection has been reported [128].

Chronic rejection and graft fibrosis

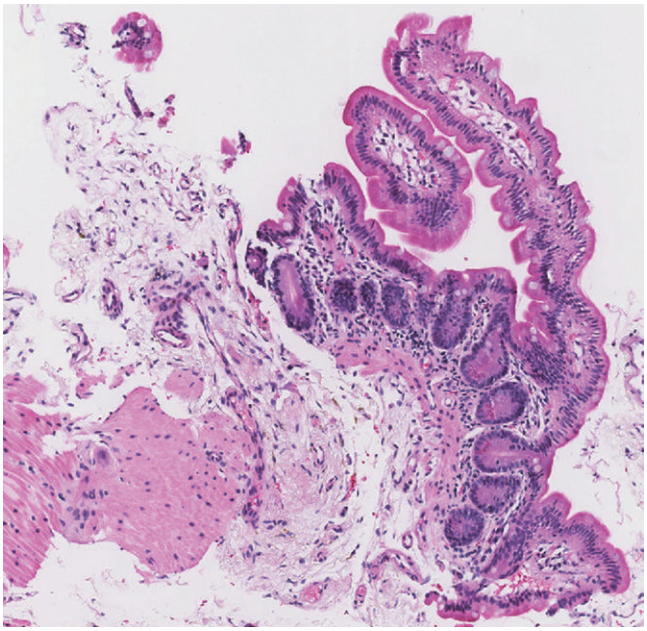
Examination of failed pancreas allografts with advanced chronic rejection and fibrosis consistently demonstrate similar sclerotic changes in the duodenal cuff (Figure 85.11). The latter typically shows marked flattening, atrophy, and attenuation of the duodenal mucosa, which may be reduced to the thickness of a few layers of reactive epithelial cells. The deeper muscular and connective tissue layers are irregularly replaced by fibrotic tissue and often contain scattered inflammatory infiltrates similar to those found in the pancreatic parenchyma itself.

The specific features of acute and chronic allograft rejection in the duodenal cuff are poorly defined. Systematic studies of the features of ACMR and AMR in the grafted duodenum are necessary to definitely determine if this type of tissue can be used as a reliable surrogate of the pancreatic parenchyma itself. Current studies in this area are underway as part of the Banff 2013 pancreas task groups [129].

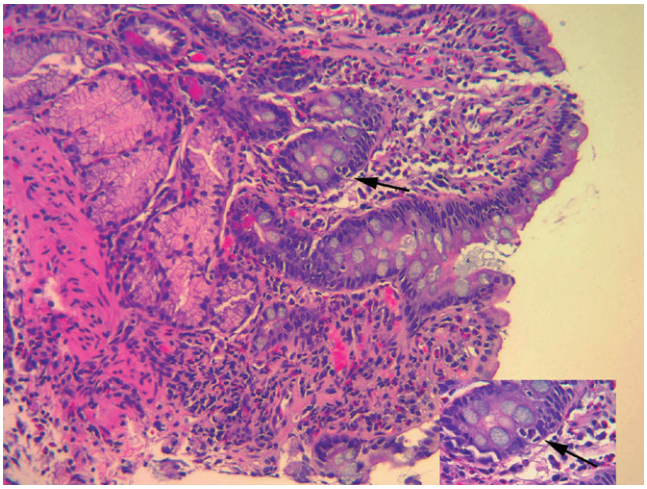
Banff pancreas allograft rejection: Banff working grading schema (2011 update, Box 85.2)

Diagnostic categories: specific considerations

The Banff schema includes eight diagnostic categories that cover the range of histopathological changes that can occur in pancreas allografts. Similar to other transplanted organs, two main forms of allograft rejection are recognized: T-cell mediated and antibody-mediated [13,14,22,23,45]. For each rejection type, acute and chronic histological manifestations are identified and criteria



(A)



(B)

Figure 85.10. (A) Fragment of duodenal mucosa from the grafted duodenal cuff in a patient with normal graft function. The duodenal mucosa has preservation of the intestinal villi and a normal amount of infiltrates in the lamina propria. There is no evidence of acute rejection. (B) Mild acute rejection in duodenal cuff mucosa shows blunted intestinal villi, increase in the inflammatory cells in the lamina propria including numerous eosinophils, and occasional apoptosis of enterocytes (arrows, insert).

defining severity grades are presented. The specific histological features utilized in the pancreas Banff schema are presented in Box 85.3.

Normal

Inflammatory infiltrates are absent, or very sparse, inactive, mononuclear (small lymphocytes, rare plasma cells). If there is slight inflammation, this is focal and confined to the septa with lack of involvement of any of the septal structures (vessels, ducts, nerves) (Figure 85.2).

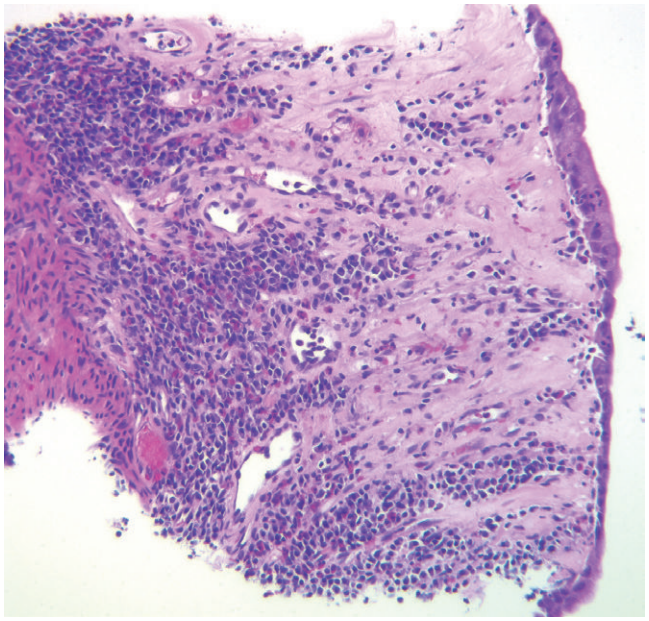


Figure 85.11. Advanced chronic rejection of the duodenal cuff segment. There is complete flattening of the intestinal villi, marked fibrosis and sclerosis of the lamina propria, and chronic inflammatory infiltrates with large numbers of plasma cells.

An adequate biopsy with these histological characteristics practically rules out a diagnosis of ACMR. Accordingly, these types of findings are more often encountered in protocol biopsies of well-functioning grafts [65,90,130]. "Normal"-appearing biopsies may also be encountered under other clinical circumstances. Specifically, in patients biopsied for hyperglycemia, the differential diagnosis includes:

1 Late phase of recurrent autoimmune disease (i.e. after resolution of isletitis) [111];
2 Drug toxicity, characterized by vacuolization or damage of islet cells [83]; and
3 Early or mild AMR [51].

Indeterminate for rejection

This category is defined by the presence of focal septal inflammation that displays features of activation (blastic changes ± eosinophils), but the overall features do not fulfill the criteria for mild rejection (e.g. partial cuffing of a septal vein or duct but lacking any evidence of endothelial or epithelial involvement) (Figure 85.12).

These histological features can be seen in protocol biopsies of well-functioning grafts as well as in patients biopsied for graft dysfunction. Similar to the "borderline" category in the kidney, these changes may represent early as well as treated acute rejection, or alternatively may be entirely non-specific [90,130].

The treatment of patients with biopsies showing "indeterminate" features may vary depending on the indication for biopsy, and ultimately depends on clinical judgment. In accordance with the heterogeneous nature of the "indeterminate" histological changes, response to treatment varies significantly in comparison to biopsies with definite acute cell-mediated rejection which are usually responsive to treatment [90].

Box 85.3 Histological definition of lesions used for the diagnosis of rejection

Acinar cell injury-necrosis. Cytoplasmic swelling and vacuolization and/or nuclear pyknosis, apoptotic bodies, lytic necrosis leaving empty spaces equaling the size of individual cells (cell dropout)
Acinar inflammation. Inflammatory infiltrates with characteristics similar to the septal infiltrates amidst the exocrine acini
Acinar inflammatory lesion/focus. Collection of ≥10 lymphocytes/eosinophils within an acinar area
"Active" transplant arteriopathy. Narrowing of the arterial lumen by a subendothelial proliferation of fibroblasts, myofibroblasts, and smooth muscle cells with infiltration of the subintimal fibrous proliferation by mononuclear cells (T cells and macrophages).
Capillaritis. Neutrophil and mononuclear cell margination in dilated interacinar and islet capillaries
C4d semiquantitative grading. Diffuse positive, ≥50% of interacinar capillaries; focal positive, 5–50% of interacinar capillaries; minimal positive/negative, <5% of interacinar capillaries
Ductitis. Infiltration of ductal epithelium by mononuclear and/or eosinophillic inflammatory infiltrates and ductal epithelial cell damage. May lead to epithelial denudation
Focal acinar inflammation. ≤2 inflammatory foci per lobule with no evidence of acinar cell injury
Minimal intimal arteritis. Rare, occasional, clearly defined subendothelial (intimal) inflammatory infiltration by mononuclear cells
Moderate–severe intimal arteritis: Easily identifiable (more than six to eight) lymphocytes within the intima of an involved muscular artery with some evidence of intimal injury (i.e. endothelial cell hypertrophy, fibrin leakage, coating neutrophils and/or macrophages, activation of intimal myofibroblasts)
Multicellular/confluent acinar cell injury-necrosis: Acinar cell damage/apoptosis involving multiple acinar cells (clusters)
Multifocal acinar inflammation: ≥3 foci of inflammation per lobule with single/isolated acinar cell injury/necrosis. Intervening uninflamed acinar areas
Necrotizing arteritis: Focal or circumferential fibrinoid necrosis of the arterial wall with or without transmural inflammation
Neural and perineural inflammation: Septal inflammatory infiltrates in and around nerve branches (rare finding in needle biopsies)
Septal inflammatory infiltrates: Predominantly mononuclear, including "blastic" (activated) lymphocytes and variable numbers of eosinophils. Eosinophils may be the predominant cell type
Severe/extensive acinar inflammation: Confluent diffuse (widespread) acinar inflammation with focal or diffuse multicellular/confluent acinar cell injury-necrosis. None or very rare uninflamed acinar areas
Single cell/spotty acinar cell injury-necrosis: Only isolated cells are affected, with the vast majority of cells appearing preserved
Transplant arteriopathy: Fibrointimal arterial thickening with narrowing of the lumen. Grading is carried out in the most affected artery as mild, up to 25% of luminal area; moderate, 26–50% of luminal area and severe, >50% of luminal area
Venulitis: Circumferential cuffing of septal veins with subendothelial accumulation of inflammatory cells and endothelial damage/lifting

Adapted from [14] Drachenberg et al. *American Journal of Transplant*. 2008;8:1237 with permission from Wiley.

Acute T-cell-mediated rejection

ACMR is graded as mild, moderate, or severe (Grades I, II and III, respectively), based on the identification of lesions that have been shown to prognosticate progressively worse outcomes [5,24,32,33,36–40,131]. Diagnosis of acute ACMR presupposes the concurrent evaluation of C4d stain to rule out a component of AMR [13,14].

Mild, ACMR Grade I

This grade is defined by the presence of septal inflammatory infiltrates that have not only features of activation ("blastic" lymphocytes, variable numbers of eosinophils), but also involve septal structures (veins, ducts) ± focal acinar inflammation. These findings may vary from septal area to area; however, any degree of venulitis (subendothelial accumulation of inflammatory cells and endothelial damage in septal veins) or ductitis (epithelial inflammation and damage of pancreatic ducts) is sufficient for the diagnosis of mild Grade I T-cell-mediated rejection (Figure 85.13). Inflammation of peripheral nerve branches coursing through the parenchyma is also a feature of rejection.

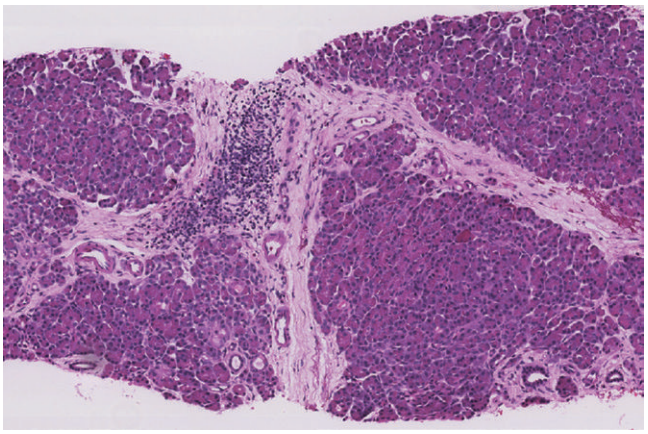

Figure 85.12. Banff grade indeterminate for rejection. The image demonstrates a single focus of mononuclear septal inflammation which does not involve acini, arteries, or ducts.

Focal acinar inflammation in biopsies with the features described above (mild, Grade I), is not uncommon, and is typically seen in the interface between the septal connective tissue and the acinar lobules (e.g. periphery of the exocrine areas).

The mild cell-mediated rejection, Grade I, also includes cases in which due to sampling, septal involvement is not present and only focal acinar inflammation is appreciated.

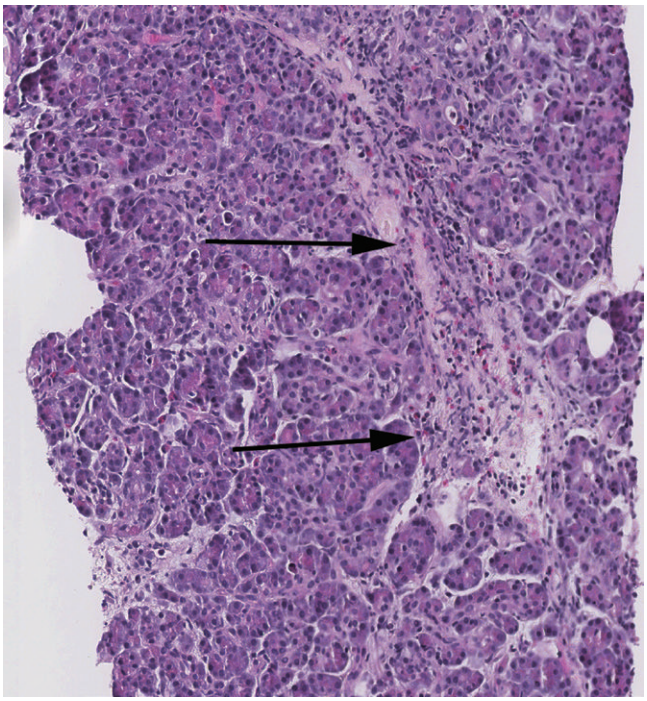
In any case, in mild, Grade I rejection, the acinar inflammation should be clearly focal (i.e. no more than two inflammatory foci per lobule and should be lacking evidence of acinar cell injury – apoptosis, necrosis). The composition of the acinar inflammation is typically similar to that of the septal infiltrates.

Biopsies with the features defining this rejection grade are occasionally found in patients with well-functioning grafts [130] but are more commonly seen in biopsies performed for graft dysfunction (typically, increase in amylase/lipase in serum, or decrease in urinary amylase in bladder-drained grafts) [12,36,65].

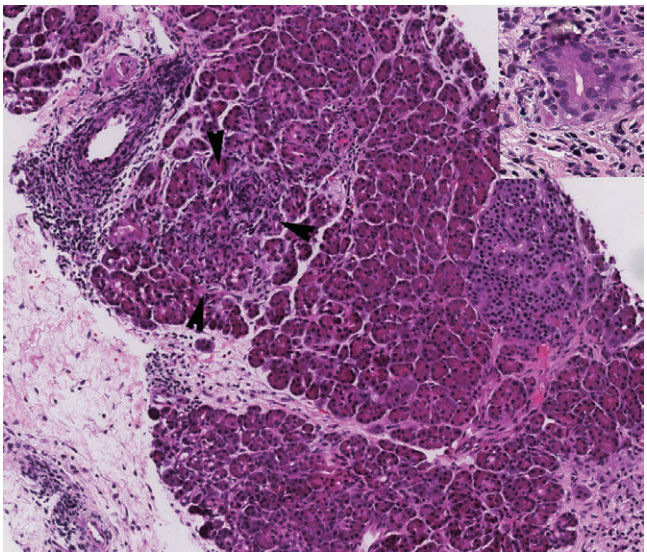
Moderate, ACMR Grade II

Typically found in association with the septal infiltrates described above, this grade is defined by two additional histological features which may be identified either in isolation or concurrently.

Multifocal acinar inflammation. The most common presentation of this grade consists of multiple foci (≥3 foci per lobule) of acinar inflammation and associated spotty (individual) acinar cell injury and dropout. The acinar inflammatory involvement in this grade is identified with ease; however, the involvement should not be confluent or diffuse. From a practical point of view, completely uninflamed acinar or exocrine areas are easily identified between the inflamed foci. Absence of confluent inflammation will differentiate this grade from the next higher category (see later). Significant

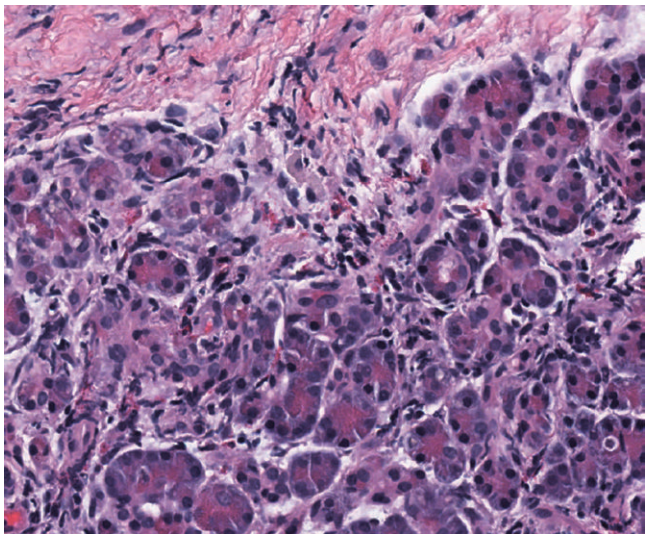


(A)

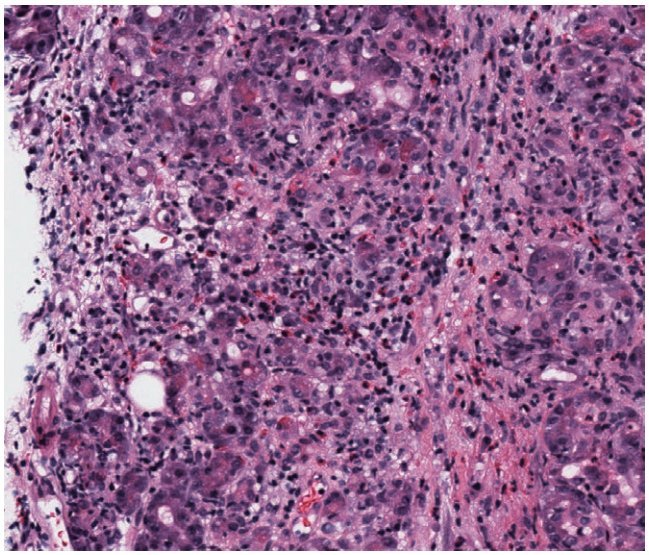


(B)

Figure 85.13. (A,B) Mild ACMR (Banff Grade I). Septal inflammation and edema (long arrows), with venulitis and acinar inflammation (arrowheads) characterize ACMR. The insert demonstrates ductitis, also a common feature of ACMR.



(A)



(B)

Figure 85.14. (A) Acinar inflammation (acinitis) and acinar cell injury. (A) demonstrates the edge of an exocrine lobule with acinar inflammation. Although distortion of the acinar arrangement by the inflammatory infiltrates can be appreciated, there is only minimal acinar cell injury. (B) demonstrates extensive diffuse acinar inflammation associated with multifocal areas of acinar injury and loss (cytoplasmic swelling and clearing, spotty cellular dropout appearing as empty spaces).

acinar inflammation is always associated with evidence of acinar cell injury, but in this grade the latter should be spotty (isolated) (Figure 85.14). Specifically, acinar cell injury may appear as any of the following: cellular dropout (empty spaces equaling the size of individual cells), cytoplasmic swelling and vacuolization, nuclear pyknosis, apoptotic bodies, or single cell lytic necrosis.

Minimal intimal arteritis. Alternatively, depending on sampling variations, the category of moderate, ACMR Grade II, can be defined by the sole presence of mild focal intimal arteritis consisting of rare, occasional but clearly identifiable subendothelial (intimal) mononuclear cells (Figure 85.15). The latter changes may or may not be accompanied by the complete constellation of inflammatory changes described earlier in the septa and lobules.

From a clinical point of view, biopsies with features of moderate ACMR Grade II are typically found in patients with graft dysfunction (usually increase in amylase or lipase in serum or decrease in urinary amylase in bladder-drained grafts) [12,36,65].

Severe, ACMR Grade III

This grade can be defined by three histological features which may be identified ether in isolation or concurrently. These morphologi-

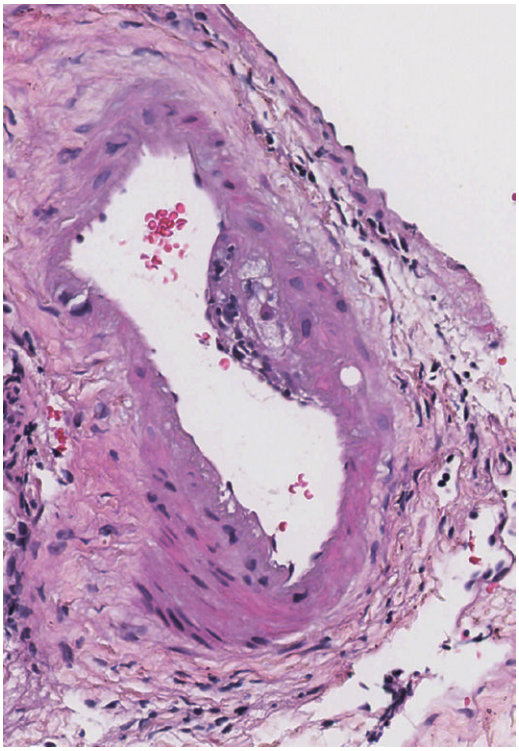


Figure 85.15. A small focus of intimal arteritis (endarteritis) can define moderate ACMR (Banff Grade II, see Banff grading schema). A focal accumulation of foamy macrophages beneath the focus of endarteritis signal the likely development of transplant arteriopathy, particularly if there is persistent vascular inflammation.

cal features also require differentiation from cases of moderate and severe AMR. The latter typically presents with more pronounced interstitial hemorrhage and focal or widespread vascular thrombosis.

Severe acinar inflammation and acinar cell damage. This entity is characterized by confluent or diffuse (widespread, extensive) acinar inflammation with associated focal or diffuse multicellular or confluent acinar cell necrosis (Figure 85.14B). The inflammation may be predominantly lymphoid or may contain abundant eosinophils or variable amounts of neutrophils. By definition, there should be none or only rare focal areas of completely uninflamed acinar or exocrine parenchyma, and C4d staining should be negative.

Moderate or severe intimal arteritis. This feature, defined as easily identifiable (e.g. more than six to eight) lymphocytes within the intima of an involved muscular artery, is by itself sufficient to justify a diagnosis of severe, ACMR Grade III. Moderate or severe intimal arteritis is usually associated with some evidence of intimal injury (i.e. endothelial cell hypertrophy, fibrin leakage, coating neutrophils and/or macrophages, activation of intimal myofibroblasts).

Necrotizing arteritis. Transmural arterial inflammation leading to complete or partial circumferential necrosis also defines severe ACMR (Figure 85.9B). Transmural fibrinoid arterial necrosis is, however, more often associated with AMR. C4d staining and search for DSA is therefore necessary to rule out AMR if necrotizing arteritis is identified.

Each of the three lesions used to define severe ACMR portend poor outcome to the graft, because they are associated with, or lead to, irreversible parenchymal damage. The short- and long-term impact to the organ will depend on the extent of acinar damage and the size and number of arteries affected by intimal arteritis or necrosis. Similar to other solid organ transplants, intimal arteritis is associated with an increased risk of immediate or delayed thrombosis (Figure 85.9B). This lesion is also a precursor of transplant arteriopathy [42,132].

Biopsies with histological findings corresponding to this category are characteristically associated with graft dysfunction and failure, often including hyperglycemia [37,65,90].

Acute antibody-mediated rejection

In recent years, awareness of the possibility of AMR in the pancreas has led to better recognition of this process [56,133–135]. Based on our current knowledge of AMR, the diagnostic criteria defined by the Banff schema rely on the combination of three elements as described in Box 85.2: confirmed circulating DSA, morphological evidence of tissue injury, and C4d positivity in interacinar capillaries (IAC). It is worth noting that a significant proportion of cases of AMR may present with an incomplete constellation of findings. This may relate to our inability to demonstrate DSA (i.e. non-HLA antibodies) or to the lack of sufficient microvascular complement deposition in the graft (i.e. C4d-negative AMR).

Therefore, the presence of two of the three diagnostic elements leads to a diagnosis of "suspicious" for acute AMR, and prompt initiation of treatment for acute AMR is the rule, particularly if the patient has graft dysfunction.

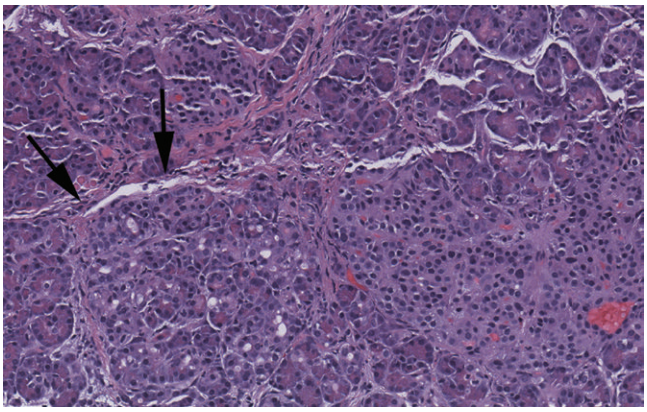
The morphological findings in acute AMR consist of various degrees of inflammation and tissue injury as detailed below.

Acinar or interacinar inflammation is inconspicuous in the milder forms of acute AMR and is accompanied by subtle spotty acinar cell dropout or apoptosis (Figure 85.16).

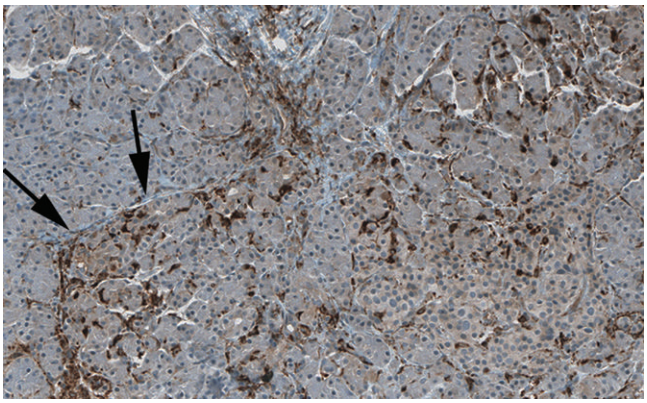
The identification of acinar cell injury in an otherwise bland-appearing biopsy should alert the pathologist to the possibility of subtle interacinar inflammation or capillaritis, and warrants correlation with the C4d staining and DSA studies. More pronounced inflammation leads to the recognition of *interacinar capillaritis* consisting of marginating and intraluminal inflammatory infiltrates in dilated and congested IAC (Figure 85.17). Interacinar capillaritis is morphologically and, presumably, pathogenetically similar to peritubular capillaritis in renal allografts, but in comparison to the renal peritubular capillaries, the pancreatic IACs have a less predictable distribution and are relatively sparse. In fully developed acute AMR there is extensive microvascular injury leading to focal or confluent interstitial hemorrhage, edema, and multicellular cell necrosis of interstitial and acinar cells making the identification of interacinar capillaritis more difficult. Identification of interacinar infiltrates with associated interacinar capillaritis has been found to be strongly associated with C4d positivity and detection of DSA [11,56].

Very severe or advanced forms of acute AMR have morphological features approaching those found in hyperacute rejection. These findings consist of widespread vascular necrosis and thrombosis in small or larger vessels and small or confluent foci of parenchymal necrosis (Figure 85.18).

Acute AMR is graded histologically (mild, moderate, or severe) based on the extent of the interacinar infiltrates or capillaritis and tissue damage (Box 85.1).



(A)



(B)

Figure 85.16. Mild acute AMR. (A) On hematoxylin and eosin stain there is only mild acinar inflammation; however, acinar cell injury is prominent focally (arrows). (B) CD68 stain demonstrates significant increase in macrophages in multiple areas of the biopsy with more pronounced accumulation in the area with acinar cell injury (arrows).

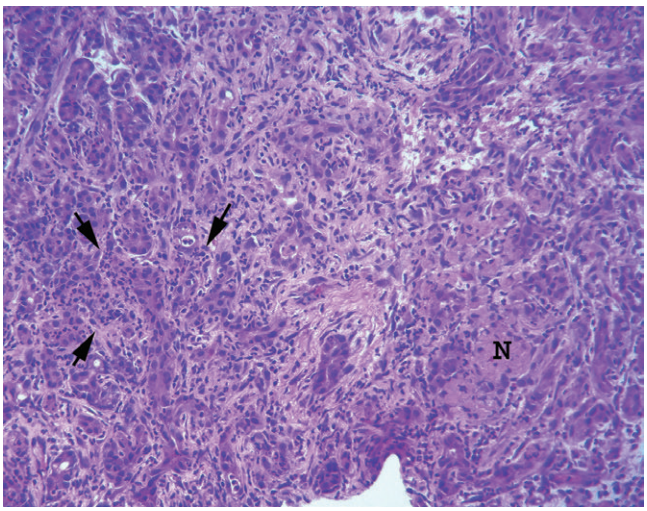


Figure 85.17. A case of moderate acute AMR shows abundant interacinar inflammatory infiltrates including neutrophils (arrows). There is a focus of necrosis (N).

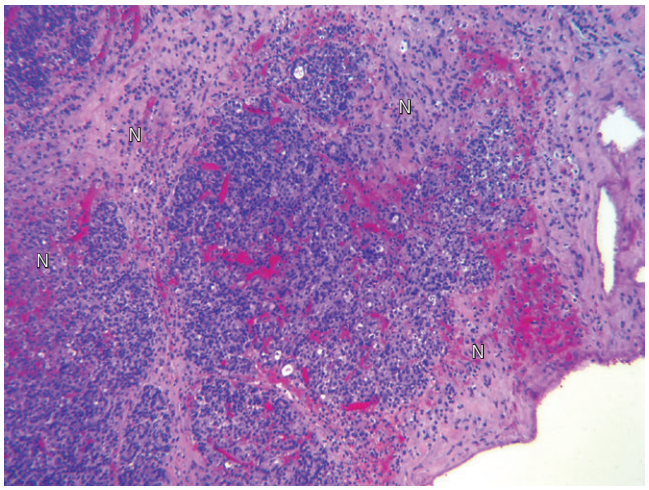
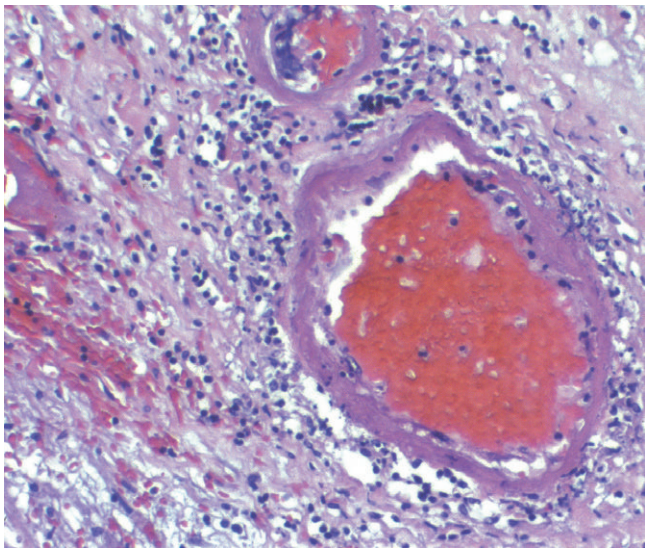


(A)



(B)

Figure 85.18. (A) Moderate to severe acute AMR is defined by more pronounced tissue damage secondary to microvascular injury. In addition to patchy areas of severe congestion and extravasation of red blood cells, there are geographic areas of parenchymal necrosis (N). (B) Severe fulminant acute AMR has features overlapping with hyperacute rejection. The image demonstrates fibrinoid necrosis of all vascular walls.

Chronic active AMR

The histological diagnosis of chronic active AMR is based on the following triad:

1 Features of acute AMR as described in the previous section (also see Box 85.2 AMR diagnostic components);
2 Absence of features of ACMR; and
3 Underlying graft fibrosis (Banff diagnostic categories 5 and/or 6).

The utilization of this diagnostic category presupposes that the main cause of graft fibrosis is ongoing AMR, and therefore requires that other causes of graft fibrosis or sclerosis are ruled out, such as previous episodes of ACMR. In clinical practice this conclusion would be most accurate when serial biopsies are available for evaluation.

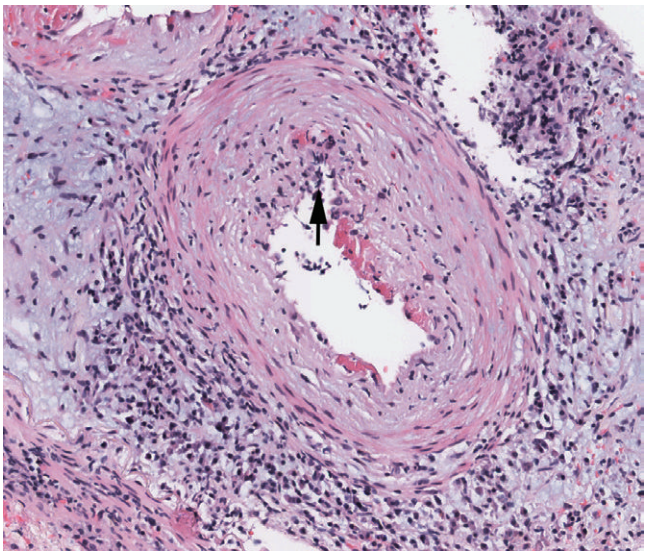


Figure 85.19. Active transplant arteriopathy characterized by a narrowed arterial lumen due to subendothelial proliferation of spindle cells (fibrosis and sclerosis). In addition, the area of fibrosis is infiltrated by mononuclear inflammatory cells (and occasional eosinophils). There is a focus of endarteritis (arrow) and small thrombi adhering to the right and lower left areas of endothelium.

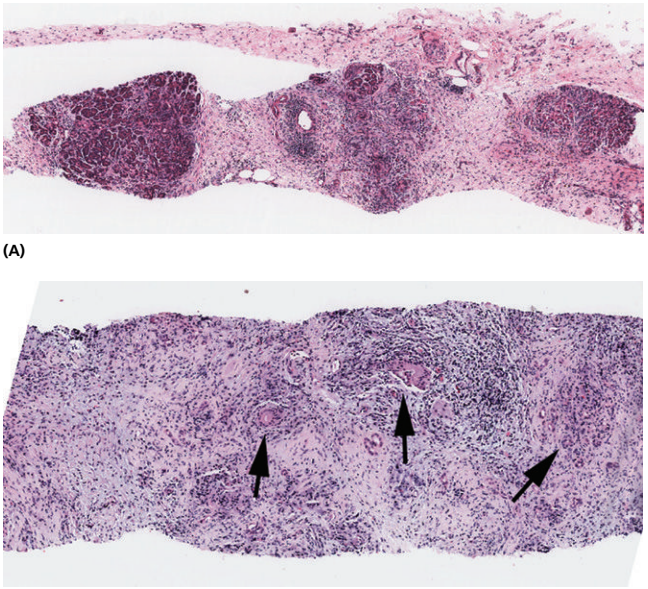

(A)

(B)

Figure 85.20. Chronic allograft rejection and graft fibrosis. There is pronounced architectural distortion due to marked increase in connective tissue and corresponding loss of exocrine (acinar) parenchyma. (A) Three atrophic lobules are recognized, separated by markedly expanded fibrous septa. (B) The parenchyma has been completely replaced by connective tissue. Rare ductal and acinar structures can be recognized (arrows). Note that in both images prominent inflammatory infiltrates remain in the connective tissue indicating ongoing rejection (acute on chronic T-cell-mediated rejection).

Chronic allograft arteriopathy

This diagnosis is defined by the presence of active transplant arteriopathy, which consists of narrowing of the arterial lumen by a subendothelial proliferation of fibroblasts, myofibroblasts, and smooth muscle cells with superimposed evidence of ongoing inflammatory activity (typically T cells and macrophages) (Figure 85.19). Chronic allograft arteriopathy was initially considered to be an expression of T-cell-mediated allograft rejection [14,22,23,45], but recent studies have shown that acute and chronic arterial lesions can also be associated with DSA and AMR [48,109,110]. Accordingly, this lesion is listed as a separate morphological category (independent from ACMR and AMR).

Although rarely seen in needle biopsies due to sampling issues, this lesion is consistently present in pancreatectomies from failed grafts due to chronic rejection [14,41,42].

Recognition of chronic allograft arteriopathy in biopsy samples is clinically important because it indicates ongoing (chronic) alloimmune injury and for its association with late graft thrombosis [42].

Chronic allograft rejection and graft fibrosis

Graft fibrosis is staged in pancreas biopsies according to the proportion of fibrosis replacing the lobular component as mild stage I, moderate stage II, and severe stage III ($\leq$30%, $\geq$30% but $<$60%, and $>$60%, respectively) (Box 85.2; Figure 85.20) [14,41].

Islet pathology

As a result of the increasing acknowledgment of the importance of islet integrity for long-term graft outcome, a separate category has been created in the 2011 Banff schema update for lesions specifically involving these structures [13]. The main purpose of this category is the recognition of recurrent autoimmune diabetes mellitus (characterized by insulitis (isletitis) and/or selective β-cell loss), deposition of islet amyloid (amylin) and islet cell drug toxicity (see discussion later).

The impact of AMR in pancreatic islets remains unclear. Whereas hyperglycemia was documented in early reports of AMR [51], this was a rare indication for biopsy in subsequent larger studies [11,47,55,56]. C4d staining in islet capillary endothelium was found in one fifth of samples from patients with DSA but this did not correlate with hyperglycemia [11]. Hyperglycemia typically develops in severe necrotizing AMR (as well as severe ACMR), correlating with the extent of parenchymal necrosis.

Other histological diagnosis

Acute rejection episodes have become less common under current immunosuppressive protocols and a variety of other pathological processes can be encountered in pancreas biopsies from patients with graft dysfunction. These entities can be identified in isolation or concurrently with other diagnostic categories in the schema (Table 85.3).

Histopathological syndromes of islet dysfunction

Non-specific islet pathology in whole pancreas allografts

The vast majority of pancreas allograft biopsies contain one or more islets of Langerhans (95%) [136], even if these structures are distributed unevenly throughout the normal pancreas parenchyma.

Table 85.3. Other histologic diagnosis: Banff diagnostic category 8.

Diagnosis presentation	Main histological findings	Clinical
Post-transplant ischemic pancreatitis	Inflammation: neutrophils, foamy macrophages Location: septal if mild or diffuse if severe Other features: fat necrosis, edema and interstitial hemorrhage. Patchy coagulation necrosis of clusters of acinar cells may be present. No fibrosis, the septa may be expanded due to edema/fat necrosis	Increase in amylase and lipase in serum Decrease in urinary amylase* Hyperglycemia if there is extensive necrosis
Peripancreatitis/ peripancreatic fluid collection	Inflammation: mixed (lymphocytes, plasma cells, eosinophils, neutrophils) Location: septa and periphery of lobules Other features: dissecting bundles of active fibroblastic proliferation with obliteration of septal structures, relative preservation of the center of lobules ("cirrhotic appearance")	Local or systemic infectious symptoms, abdominal pain, peritonitis. Peripancreatic fluid accumulation.Increase in amylase and lipase in serum
Cytomegalovirus pancreatitis	Inflammation: mostly mononuclear Location: septal and acinar, patchy Other features: cytomegalovirus cytopathic changes in acinar, endothelial, or stromal cells	Increase in serum amylase and lipase Decrease in urinary amylase* Systemic symptoms if generalized disease Other: duodenal cuff perforation
Post-transplant lymphoproliferative disorder	Inflammation: ranging from polymorphic with lymphoblasts, plasma cells, eosinophils in low grade disease, to monomorphic, predominantly lymphoid in high grade disease (lymphoma). Other features: lymphoid proliferation is nodular, expansive. Necrosis may be present	Asymptomatic, or increase in serum amylase and lipase. Lymphadenopathy Tumor mass May co-exist with acute rejection
Bacterial or fungal infection	Inflammation: variable; acute, chronic, purulent, necrotizing (abscess), granulomatous Location: random Other features: same as bacterial and fungal infections in other organs	Systemic and/or localized infectious symptoms. Peritonitis, duodenal cuff perforation. Increase in serum amylase and lipase

* In bladder-drained grafts.

There is no experimental or clinical evidence that in WPnTx the endocrine islets are specifically targeted in alloimmune rejection reactions. It appears that islet pathology in acute and chronic allograft rejection is in essence non-specific, secondary to the overall degree of acute parenchymal injury and ensuing fibrosis or sclerosis. In these entities, the pathological findings consist of islet inflammation and occasional necrosis that involve the islets at a degree proportional to the severity of acute rejection. The inflammation is therefore random and the cells infiltrating the islets are similar to the surrounding inflammatory infiltrates, more or less representing a "spillover" phenomenon [5,33,37,39,136,137].

In long-term pancreas allografts, islet distribution and morphology to a large extent reflects ongoing injury and repair. Extensive collagenization in chronic rejection leads to fragmentation of exocrine lobules, as well as of islets that acquire irregular shapes and may consist of only a few cell clusters with irregular distribution, but still containing a mixture of both insulin and glucagon-producing cells. Conversely, in some grafts, aggregates of large but otherwise normal-appearing islets may reflect compensatory hyperplasia [136,137]. Islet cell atypia, hyperchromasia, is seen in less than 5% of cases independently of the cause of the biopsy and is of unknown etiology or significance [136].

Nesidioblastosis, defined by the identification of insulin-producing cells in adult pancreatic ductal epithelium, appears to represent aberrant differentiation and is most likely regenerative in nature. Nesidioblastosis was demonstrated in an animal model of pancreas transplantation [138] and was found in approximately 4% of samples, with or without evidence of graft rejection in needle biopsies. The process had no discernible clinical significance [136,137]. Marked nesidioblastosis in a pancreas allograft was associated with hypoglycemia in one patient [139].

Histological studies in islet transplantation

Obtaining diagnostic graft samples has proven to be difficult in the case of IT because the infused donor islets (typically weighing 5–10 g in aggregate) are distributed throughout the recipient's whole liver, which has an average weight of 1.5 kg. Toso et al. [140] studied morphological changes in islets and adjacent liver tissue in percutaneous liver core biopsies and autopsy samples from 16 and 2 patients, respectively. Islets were present in 31% of liver core biopsies, with the likelihood of their identification being in direct relationship to the size of the biopsy. As expected, multiple foci of graft islets were visualized in liver tissue collected at the time of autopsy. The adjacent liver parenchyma often showed localized steatosis [140]. Overall, the transplanted islets had similar cellular composition to native pancreatic islets and only minimal inflammation (insulitis) was seen in a few cases independently of the clinical presentation at the time of the biopsy [140]. Similar lack of immunological damage (either allo- or autoimmune) and normal islets of insulin-producing cells were found in liver tissue obtained at the time of autopsy from one patient with two IT, each of which failed 6 months after transplantation [141]. C4d staining has been consistently negative in the samples evaluated histologically [21], although a significant proportion of IT recipients develop DSA [140,141].

The scarcity of available morphological studies highlights the limited scope of our understanding of the causes of IT failure. It is speculated that islet loss may result from metabolic or microenvironmental stresses that may be related to localized islet ischemia, toxic injuries, failure of islets to regenerate, etc. A concurrent low-grade immunologic rejection reaction is likely, but its true impact is unclear [140–142]. Non-invasive techniques to monitor IT are currently being developed [143,144].

Post-transplant diabetes mellitus

Post-transplant diabetes mellitus (PTDM) can develop after an otherwise functional and technically successful pancreas transplantation, presumably resulting from excessive insulin requirements that are beyond what is produced by even a perfectly functioning WPnTx [145]. Although PTDM is more commonly found in patients with solitary pancreas and has also been associated with higher rates of rejection, systematic clinicopathological studies are not available and the understanding of the mechanisms leading to PTDM remains poor [145,146].

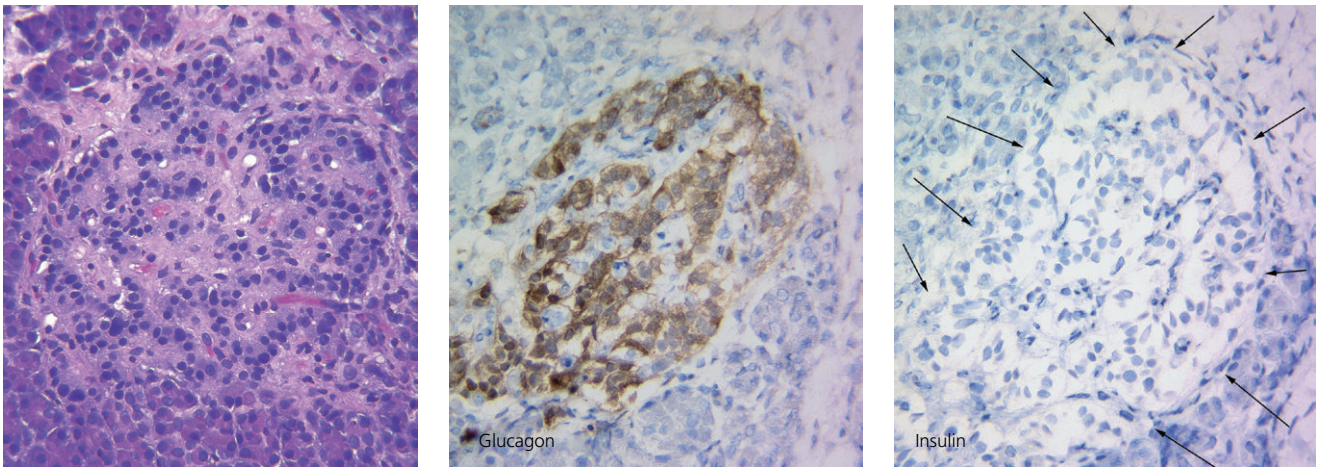

Figure 85.21. Recurrence of type 1 diabetes mellitus. (A) Hematoxylin and eosin image demonstrating an islet of Langerhans from a failed whole pancreas transplant. On this stain the islet lacks any specific pathological features and although minimally represented, the adjacent exocrine parenchyma is within normal limits (i.e. lacks features of chronic rejection and/or graft fibrosis that could explain the graft failure). (B) Glucagon stain demonstrates numerous glucagon-roducing cells (α cells). (C) Insulin stain demonstrates complete absence of β cells.

In a study of a large cohort of pancreas transplant recipients, the incidence of PTDM was 14%, 17%, and 25% at 3, 5, and 10 years post-transplantation, respectively [146]. Factors associated with increased risk for developing PTDM were older donor age, a solitary pancreas transplant ($P = 0.01$), higher recipient body mass index (BMI), donor-positive recipient-negative CMV status, post-transplant weight gain, higher 6-month fasting glucose, HBA_{1C} and triglyceride to high-density lipoprotein ratio, and higher pretransplant BMI and high pretransplant insulin needs [145,146].

Recurrence of autoimmune type 1 diabetes mellitus

This process is defined by the development of autoimmunity with destruction of β cells, loss of insulin secretion, and return to insulin dependence after a period of insulin independence had been achieved with a successful WPntx or an IT. Recurrence of type 1 diabetes occurs despite immunosuppression and regardless of HLA matching [77,111].

Fundamental clinical and pathological features required for the diagnosis of recurrent type 1 diabetes include: selective loss of insulin secretion in the absence of clinical or pathological features of rejection, histological evidence of insulitis and/or selective loss of β cells; and persistence or reappearance of autoantibodies (i.e. glutamic acid decarboxylase (GAD)) prior to the recurrence [77]. Vendrame et al. [147] showed clear evidence of recurrent autoimmune diabetes mellitus in three patients by demonstrating reappearance of autoreactive T cells, associated with documented insulitis and destruction of the β-cell population [147].

It is estimated that at least 5% of WPnTx recipients develop recurrent type 1 diabetes; however, accurate diagnosis of type 1 diabetes recurrence requires exhaustive prospective follow-up, which is not done routinely, certainly leading to under-recognition of this process [77,137].

The cardinal histological features of recurrent type 1 diabetes are insulitis (or isletitis) and selective β-cell loss (Figure 85.21). These two processes occur sequentially in individual islets but are not temporally uniform throughout the pancreatic parenchyma. Insulitis is characterized by selective peri-islet and intra-islet lymphocytic infiltrates that conspicuously do not involve other areas of the parenchyma (Figure 85.22). The distribution of the inflammatory involvement is opposite to that characterizing ACMR. Progression of recurrence of type 1 diabetes leads to selective destruction of the β cells, with eventual clearing of the inflammation in the affected islet when complete disappearance of β cells has occurred. If only evaluated with routine stains, macroscopic and microscopic examination of failed grafts lost to recurrence of type 1 diabetes are remarkably normal architecturally, both with respect to the exocrine and the endocrine components. Immunohistochemical stains

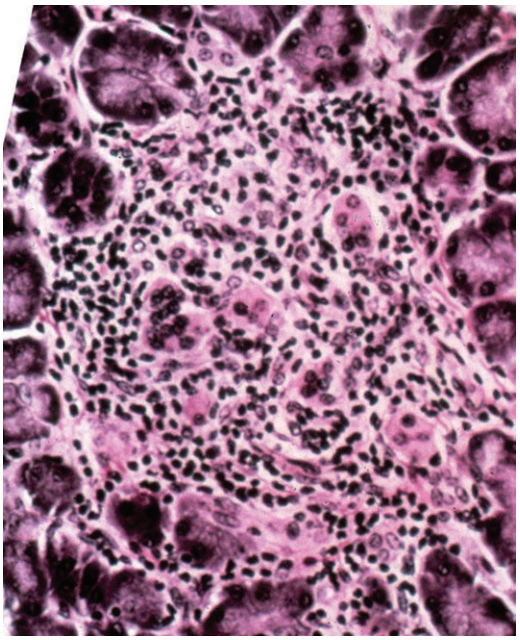

Figure 85.22. Early stages of recurrent type 1 diabetes mellitus is characterized by selective islet and peri-islet lymphocytic inflammation (insulitis).

for insulin and glucagon, however, demonstrate the characteristic selective loss of β cells [77,111,147,148]. Because the insulitis lesions are transient, actual documentation of the inflammatory stage is rare. Such a case was reported by Ishida-Oku et al. [149], who described a patient with documented seroconversion to positive anti-GAD antibody concurrent with abrupt development of hyperglycemia 48 months after transplantation. On tissue samples, loss of β cells was noted with associated insulitis and peri-insulitis. The inflammatory cells consisted predominantly of T lymphocytes and macrophages [149].

Islet amyloid

Islet deposition of amylin (also known as islet amyloid polypeptide (IAPP)) appearing as amorphous Congo red positive material, is increasingly recognized as a pathological process involving transplanted islets. Amyloid deposition in the native islets of a large proportion of patients with type 2 diabetes has been known to occur for many decades, but its role in the development of the disease is unknown [82].

In normal circumstances, IAPP, a protein normally co-secreted with insulin by β cells, is present in the halo region of the β-cell secretory granules together with C peptide and other substances [82]. Under pathological circumstances, and particularly in hyperglycemic states (e.g. type 2 diabetes mellitus), excessive or abnormal IAPP forms insoluble aggregates with the conformational characteristics of amyloid. Accumulation of IAPP amyloid results in islet cell injury and decreased numbers of insulin-producing cells. The mechanisms leading to IAPP aggregation are unknown, but it is possible that abnormalities in the molar ratio between IAPP and other secretory products contribute to the amyloidogenic condition. Deposition of amylin in otherwise normal islets of pancreas allografts is usually associated with loss of glycemic control (hyperglycemia) [19,82,150,151].

Widespread deposition of IAPP was found in the islets of a patient who died of myocardial infarction 5 years after the first of three intraportal islet infusions [150]. Exhaustive studies of liver samples from the autopsies of patients who had previously received IT showed amyloid deposition in the islets of three of four patients, further indicating the possibility that amyloid deposition has a role in the long-term fate of transplanted islets [19]. In rare instances, amyloid deposition has also been seen in the islets of WPnTx (Figure 85.23).

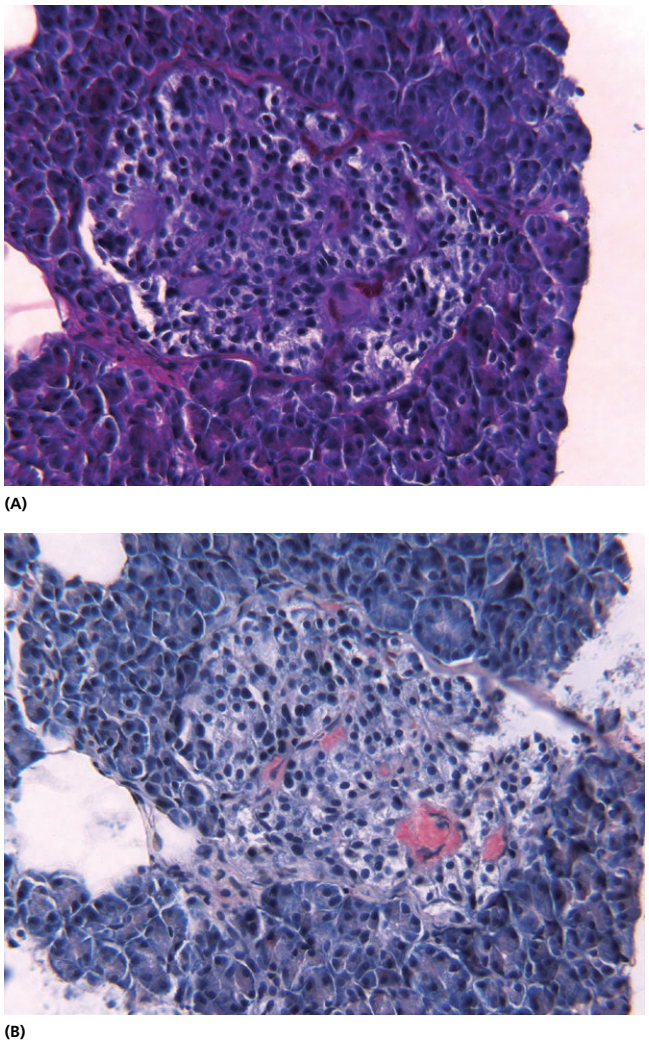

Figure 85.23. Deposition of islet amyloid in a whole pancreas transplant demonstrated by hematoxylin and eosin stain (A) and confirmed by positive staining of the extracellular accumulation with the Congo red stain (B).

Islet cell drug toxicity

In animal studies, cyclosporine administration has been associated with reduction in insulin secretion, diminished β-cell density, decreased insulin synthesis, and defective insulin secretion. Similar morphological findings have been seen also with tacrolimus [152].

The morphological findings in pancreas biopsies from patients with clinical evidence of calcineurin inhibitor drug toxicity consist of cytoplasmic swelling and vacuolization of islet cells. The islets appear optically clear and stand out from the more eosinophilic acinar parenchyma. In more severe cases, islet cell dropout with formation of empty spaces (lacunae) can be seen if there is confluent islet cell dropout. Rarely, intra-islet apoptotic cell fragments can be identified [83].

Immunoperoxidase stains for insulin and glucagon show diminished staining for insulin in β cells in comparison with controls. This is the light microscopic counterpart of the marked loss of insulin-dense core granules seen in β cells by electron microscopy. The histological changes as well as the clinical findings are reversible with reduction or discontinuation of the drug. Hyperglycemia and the histological evidence of drug toxicity are worsened with the concurrent use of pulse steroids to treat acute rejection [83].

Viral infections and pancreatic islets

The role of CMV infection in the development of PTDM and recurrence of type 1 diabetes is unclear but a statistical association between PTDM donor-positive recipient-negative CMV status has been described [146]. Additional discussions of CMV and other viral infections can be found in Chapter 94. There is clear evidence from a rodent model that β cells are susceptible to CMV infection and can sustain ongoing low levels of viral gene expression [153]. After the infection, β-cell immunogenicity is markedly enhanced and there is increased cellular expression of immune cell-activating ligands [20,153,154].

Thus, it is possible that CMV infection can induce changes that may impact β-cell survival as well as development of rejection or recurrent diabetes in WPnTx or IT. From the clinical point of view, it has been observed that recurrent CMV infections were associated

with recurrence of humoral and cellular autoimmunity to islet autoantigens in one pancreas transplant recipient [155].

Recent studies have demonstrated that rotavirus, through molecular mimicry between viral epitopes and pancreatic islet autoantigens, may induce islet cell destruction by autoreactive T cells. Thus, this virus is being implicated as a potential cause of type 1 diabetes [156]. The potential relationship between viral infections and shortened survival of transplanted islets in WPnTx and IT should be better investigated.

Conclusions

Pancreas and islet allografts are subject to numerous alloimmune, autoimmune, inflammatory, metabolic, and technical maladies, and accurate systematic histopathological diagnosis is important in aiding the clinician in determining the proper course of action. Numerous approaches to obtaining tissue have been developed although, in general, tissue acquisition is more difficult in pancreas (and particularly in islet) transplantation than other forms of allotransplantation. Nevertheless, the clinician should seek definitive diagnosis and partner with the pathologist in the care of patients following these forms of β-cell replacement.

CHAPTER 86

Histopathological Syndromes of Intestinal Allograft Rejection and Recurrent Disease

Phillip Ruiz,[1] Jennifer Garcia,[1] Akin Tekin,[1] Seigo Nishida,[1] and Andreas Tzakis[2]

[1] University of Miami Miller School of Medicine, Miami, FL, USA
[2] Cleveland Clinic Florida, Weston, FL, USA

Introduction

Maturation of the field of intestinal (ITx) and multivisceral transplantation (MVTx) has been a welcome advance in the treatment of short gut syndrome (SGS) and intractable gastrointestinal compromise secondary to catastrophic abdominal compartment injury, medical disease, and certain tumors [1–4]. The core failure for ITx and MVTx recipients is a loss of the absorptive function of the intestines, ultimately resulting in malnourishment of the patient. Some of these conditions are listed in Table 86.1 and covered in more detail in Chapters 33 and 117. Although there are special considerations beforehand, both pediatric and adult patients can receive alimentary tract grafts [5], and the disorders compromising gut function are often noticeably different according to the age group of the patient (Table 86.1). The majority of these patients are maintained by parenteral feeding prior to transplantation. Medical management of SGS has had an enhancement comparable to the option of allograft transplantation [6], although chronic parenteral feeding can encumber the patient with life-threatening complications, high costs, and altered quality-of-life issues. In contrast, the successful implementation of an ITx or MVTx allows the recipient to regain a functioning gastrointestinal tract devoid of, or with minimal, dietary restrictions, enhanced growth and development, and the prospect of an improved and independent lifestyle [7].

The surgical procedure of an intestinal allograft varies according to the underlying conditions compromising gut function and presented by the transplant candidate. The intestinal allograft can be provided as an isolated graft (ITx) or as part of an MVTx; the latter is an abdominal organ bloc that can include stomach, small and large intestine, liver, pancreas, and spleen [8,9]. (Note: the omission of liver transplant is known as a modified multivisceral transplant.) Technical details of the procedures can be found in Chapters 62 and 117. The implementation of an isolated intestine or multivisceral graft depends upon the underlying pathological conditions in the recipient. In recent years, the use of MVTx has increased, with graft and patient survival being comparable to isolated ITx [9].

The experience of experimental large and small animal models utilizing orthotopic and heterotopic gut transplantation has contributed to the advancement of procedures and therapies in human grafts [10,11]. As such, multiple issues with ITx and MVTx have notably improved including the pretransplant evaluation and selection of appropriate donors and recipients, surgical mechanics and techniques, exponential growth of our knowledge regarding gut physiology and mucosal immunology, and overall post-transplant maintenance, thus contributing to an observed improvement in graft and recipient survival. A critical member of the monitoring team is the transplant pathologist, a recognized subspecialist who optimally should incorporate anatomic pathology, clinical laboratory, and basic scientific aspects to the solid organ transplant or bone marrow transplant program that he/she is supporting. Thus, the transplant pathologist in gastrointestinal transplantation is a vital component of the clinical team's vigilance of post-transplant complications via coordination of biopsy evaluation, general and specialized clinical laboratory analysis, and comprehension of pathophysiological mechanisms associated with allograft intestine or the other transplanted abdominal viscera [12].

In spite of these advancements, the intestinal graft introduces a massive alloantigenic hematolymphoid and parenchymal cellular mass to the recipient that typically initiates a vigorous host-effector immune response, requiring continuous modulation and interruption by powerful and sustained immunosuppressive reagents. While induction and maintenance immunosuppressive regimens evolve and novel targeted pharmaceutical compounds and antibody-based immunosuppressive reagents are being developed [13], the host-derived immune response [14], and sometimes the graft immune response to the host (i.e. graft-versus-host disease (GVHD) [15], remain significant complications of ITx and MVTx recipients. The level and type of immunosuppression is not the only variable impairing the deleterious effects of the host alloimmune response, because a quiescent immune system (under "appropriate" immunosuppression coverage) can also be the result of many variables such as the type of host innate genetic polymorphisms present that may influence the level of host responsiveness [16], the ratio of effector to regulatory cell populations [17], and the degree and type of genetic disparity between the host and donor. Regardless, intestinal and multivisceral graft recipients more often than not demonstrate immune-based acute rejection episodes that are clinically demonstrable or that may be "subclinical" in severity [18,19]. This is supported by data showing that unlike the present state of other solid organ transplants, in ITx and MVTx acute rejection remains the principal complication in the post-transplant period.

As with other patients undergoing vigorous immunosuppression, the introduction of unrelenting modulation of the immune response places the ITx or MVTx transplant recipient at elevated

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Table 86.1. Anatomic and functional causes of intestinal failure in patients receiving intestinal or multivisceral transplants

Pediatric	Adult
Gastroschisis	Ischemia (venous or arterial infarction)
Midgut volvulus	Crohn's disease
Necrotizing enterocolitis	Trauma
Pseudo-obstruction	Volvulus
Intestinal atresia	Motility disorders
Aganglionosis/Hirschsprung	Desmoids
Retransplant	Retransplant
Microvillous inclusion disease	Radiation enteritis
Malabsorption	Other tumors
	Gardner's syndrome

Box 86.1. Complications and pathological processes in intestinal and multivisceral transplant patients

1 Donor organ pathology and preservation injury
2 Acute rejection
  a. Antibody-mediated rejection (AMR)
    i. Hyperacute and accelerated acute rejection
    ii. Acute antibody-mediated rejection (AAMR)
  b. Acute T-cell-mediated (cellular) rejection (ACR)*
    i. No evidence of acute rejection, Grade 0
    ii. Indeterminate for acute rejection, Grade IND
    iii. Acute T-cell-mediated acute rejection (ACR), mild, Grade 1
    iv. Acute T-cell-mediated acute rejection (ACR), moderate, Grade 2
    v. Acute T-cell-mediated acute rejection (ACR), severe, Grade 3

risk for the development of infections and malignancies [20]. Moreover, the drugs themselves often impart direct toxicities on several organ systems (e.g. renal, neurological) (see Chapters 94 and 95) [21,22]. Aside from complications associable with immune system perturbation, ITx and MVTx recipients are also susceptible to other complications that may be related to pre- and post-transplant alimentation protocols, former surgeries to the abdominal region, or co-morbidities associated with the underlying disease(s) of the host. A list of the complications in the post-transplant period is present in Box 86.1.

The continuous post-transplant scrutinizing of early and late intestinal graft function and patient status by the ITx and MVTx surgical and medical teams has been transformed and enhanced over the past quarter century. An evaluation of MVTx requires that the transplant pathologist understand histopathological changes of native organs and surgical allografts not typically encountered (e.g. stomach, colon) and an awareness of the likelihood of pathological changes depending upon which area is sampled (e.g. duodenal versus ileal). For example, monitoring of an MVTx patient could involve simultaneous procurement of biopsies from native tissues such as esophagus, rectum, skin, as well as biopsies from transplanted stomach, small intestine, large intestine, and liver. A comparison of native versus allograft tissues is a worthwhile tool in many circumstances such as trying to discern whether changes are unique to alloimmune responses (e.g. rejection), generalized pathologies (e.g. infection, post-transplant lymphoproliferative disease (PTLD), or graft-derived changes (GVHD, preservation injury).

Histopathological evaluation

Pathological evaluation of allografts by routine histology involves all stages of ITx and MVTx pretransplant phases and continues through the evaluation of long-term surviving grafts. Histological assessment by biopsies remains the gold standard for evaluating pathological processes in allografts; however, ancillary testing of tissue and concomitant systemic biomarker evaluation is the norm in evaluating these complex processes. ITx and MVTx biopsies must be correlated with concurrent recipient medical laboratory values. The transplant pathologist requires the clinical history of the recipient (e.g. date of transplant, native disease or condition that necessitated the transplantation, current clinical symptoms), previous biopsy results, and the endoscopic results. A description of where the biopsies were procured (e.g. lesional, perilesional, or non-involved areas) is critical. A preponderance of ITx and MVTx allograft tissue samples are endoscopically visualized and superficial mucosal biopsies are obtained. Typically, tissue obtained from an exteriorized ostomy (e.g. ileostomy or colostomy) stoma is discouraged because there may be ongoing inflammatory responses related to surgical wound healing, etc. reflected by histological inflammatory processes, fibrosis, and distorted architecture [23].

As the level of changes provided to the pathologist is typically limited to the mucosa and submucosal layers of the gastrointestinal site, it is critical that the endoscopist have some experience with gastrointestinal transplants in order to determine areas of interest and which regions to biopsy. The endoscopist and pathologist should have ongoing communication regarding the endoscopic changes seen in the mucosa, including normal versus abnormal; if abnormal, the lesion(s) should be characterized as to the graft location and distribution, its limitation to the graft or involvement of native tissue, and its characteristics (e.g. erythematous mucosa, ulcers). Full-thickness evaluations of the gastrointestinal allograft are not the norm and tend to occur when there is surgical revision of problematic areas or when grafts are explanted.

Most of the complications affecting gastrointestinal transplants demonstrate clinical urgency and could rapidly lead to allograft dysfunction and potential graft loss. Hence, the histology laboratory and pathology service providing transplant pathology support must operate to provide particularly rapid turnaround time 7 days a week, with the capacity to incorporate specialized immunohistochemical (IHC), immunofluorescence (IF), and in situ hybridization (ISH) techniques. Moreover, the modern laboratory should also serve as a launching point for initiation of (or performance of) graft tissue-derived molecular assays such as quantitative infectious agent evaluations and specific gene arrays.

One or two gastrointestinal transplant tissue fragments per area should be placed immediately in an appropriate fixative (typically,

buffered formalin) for at least 1 hour. Multiple sections are typically cut at 0.5 cm, and hematoxylin and eosin (H&E) stains are used for the initial evaluation. ITx or MVTx biopsies typically require a variety of special stains; the following should be available: IHC (e.g. for infectious agents such as cytomegalovirus (CMV), adenovirus); ISH for viruses such as Epstein–Barr virus (EBV); viral load measurements (e.g. of EBV), and other molecular assays such as measurement of antigen receptor rearrangement studies for T and B cells (when evaluating the possibility of PTLD). Finally, the transplant pathologist should also have access to, and ideally be involved in, the interpretation of other critical laboratory tests for ITx and MVTx patients such as citrulline levels, immune function assays (e.g. Cylex, Elispot, cytokines), human leukocyte antigen (HLA) typing of donor and recipient, and alloantibody measurements. Because of the evolving nature of MVTx and ITx management, specialized gene testing (e.g. *MBL-2* or *NOD* polymorphisms) and other assays of certain potential biomarkers are currently being evaluated and appear to hold promise as useful adjuncts to the histopathological and clinical presentation of the patient.

Pathological processes

A variety of complications associated with the process of transplantation can befall the ITx or MVTx recipient. As listed in Box 86.1, many of these complications can occur concomitantly, thus requiring their specific identification as therapies may differ or have a negative impact on resolving the principal issue (e.g. therapy for PTLD or infection versus acute rejection differ dramatically).

Donor organ pathology and preservation injury

Successful modern-day procurement of intestinal or multivisceral organs for use as transplants relies on a sophisticated, highly coordinated system whereby potential donors are identified based on an algorithm that incorporates various factors including size (e.g. size of the recipient abdominal cavity; pediatric age), donor clinical history suitability, and an elimination of most transmissible risk factors [24]. The testing laboratory must rapidly provide a comprehensive battery of tests for measuring potential infectious pathogens in the proposed donor, and the clinical team must try to identify the status of the donor organs for issues such as ischemic injury, possible tumors, and ongoing medical conditions that could compromise gut function. Typically, gross inspection of the donor organs by the surgeon retrieving the organs suffices to assess any possible lesions; rarely, frozen section evaluation by a pathologist is needed for ITx or MVTx. Therefore, unlike other allografts such as kidney and liver in which pretransplant biopsies are obtained when there is a questionable clinical history or the organ appears grossly suspicious, it is not usual for the pathologist to be asked to evaluate a donor bowel or stomach prior to being transplanted. Pathological evaluation of residual donor tissue has typically not shown any significant pathological changes aside from minimal ischemic injury, as would be expected from graft preservation.

The majority of transplanted organs undergo varying periods of preservation at cold temperature (depending upon the organ transplant) in solutions followed by warm reperfusion of the grafts upon vascular anastomosis with the recipient blood supply. Gastrointestinal grafts tend not to have much "cold ischemic" time. Regardless, some degree of preservation-associated or ischemia–reperfusion (IR) injury to the allograft often results from this revascularization [25]. IR injury can occur in the gut [26] and cause a cascade of physiological changes that may influence function. In the large majority of the cases, these IR changes are mild and have no great consequence to the organ's short-term function, although there may be significant effects on the allograft organ's eventual susceptibility to immune-mediated injury and physiological function. Evidence is mounting that non-inflamed cadaveric organs have remarkable changes in many genes at the transcriptional level, including genes associated with inflammation [27,28]. The implication of these transcriptional changes in donor bowel grafts remains unknown and there can only be speculation as to whether these changes in the procured organs could impact long-term graft function; no pathognomonic changes are yet known in long-standing allografts that had early IR injury. The use of "marginal" donors [29], while not currently a major issue in ITx or MVTx, would be supposed to predispose the recipient to IR injury, primary nonfunction or delayed graft function, and complications such as rejection.

Morphology. The majority of ITx and MVTx transplants have "protocol" biopsies, particularly in the initial weeks post-transplant. As such, it is not unusual for mucosal biopsies obtained in the early post-transplant period to demonstrate preservation injury changes [30]. Small and large intestine grafts experiencing mild preservation injury can demonstrate diffuse edema and swelling of the villi without a significant increase in the inflammatory cell infiltrate, some vascular congestion, and a separation of the surface epithelial lining from the underlying lamina propria (Figure 86.1). As IR injury progresses and becomes more severe, there are additional changes such as epithelial cell necrosis which can extend from the surface of the mucosa to the deep submucosa. These latter changes have been best described in the controlled environment of experimental models of IR injury; for example, several murine models show gradable and progressive changes from the mucosa which eventually progress to transmural necrosis of the intestine [31,32]. These latter changes are not typically apparent microscopically in a clinical situation unless there is severe IR injury along with prolonged vascular compromise, in which case the allograft tissues

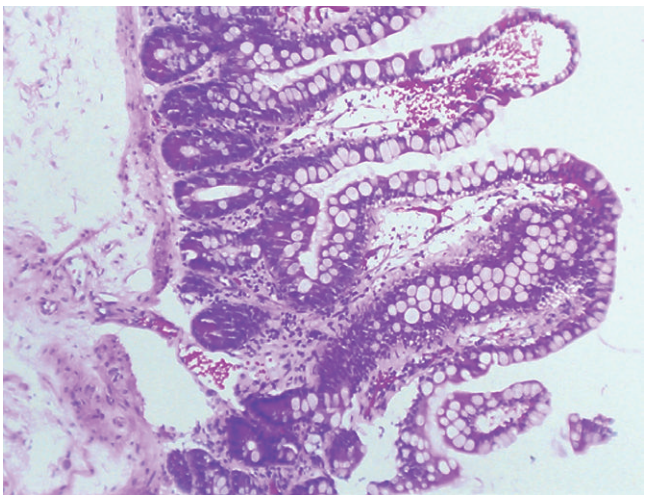

Figure 86.1. Preservation injury. Small intestinal biopsy several days after transplant shows swelling of the villi without a significant increase in the inflammatory cell infiltrate, some vascular congestion, and a separation of the surface epithelial lining from the underlying lamina propria (H&E, original magnification 200×).

show ischemic changes similar to bowel ischemia in native organs. Currently, the morphology of stomach allografts undergoing IR injury is not well described.

Acute rejection

The initiation and propagation of recipient alloimmune effector cell populations (cell-mediated or T-cell rejection), host B-cell-derived alloantibodies (humoral or antibody-mediated rejection), in conjunction with non-specific innate immune mechanisms can constitute an onslaught of anti-graft inflammatory responses that is defined as acute rejection [17]. The fundamental biology of these conditions is described in detail in Chapters 5, 6 and 7. This potent assemblage of immune-based cell populations and soluble molecules can act in concert or individually to manifest different forms of injury that have classically been delineated morphologically and sometimes behaviorally as distinct forms of acute rejection. As a result of the enormous potential for acute rejection to reduce graft function and lead to organ loss, the detection and effective interruption of acute rejection in ITx and MVTx recipients, as with other solid organ transplants, remains a continuous challenge and goal for transplant clinicians. However, in spite of the application of powerful immunosuppressive drugs, allograft acute rejection remains a common complication in gastrointestinal transplantation. The broad mechanisms involved in T-cell-mediated and antibody-based forms of acute rejection are similar to other organ systems and beyond the scope of this chapter. Basically, recipient-derived B and T cells (which represent that adaptive immune response), in a complex interplay with innate immune populations including natural killer cells, dendritic cells, and macrophages, and an assortment of immunomodulatory molecules [33], centrally participate in the genesis and culmination of immunological pathways that recognize the allogeneic gastrointestinal tissue. There are multiple potential stimulatory targets in gastrointestinal tissue for immune effector cells and molecules, including parenchymal or epithelial cells (e.g. enterocytes, Paneth cells), vascular endothelial cells, muscle, endocrine, and neural cells. Acute rejection-mediated injury or death of these various target cell populations in bowel leads to clinical consequences such as fever, malabsorption, dysmotility, and ischemia [7,24,34]. Acute rejection of the bowel can progress rapidly because of the marked antigenicity and huge cellular mass of the bowel and in some circumstances can lead to exfoliation of the mucosa and submucosa [35,36], transmural ischemia, and predisposition to translocation of luminal bacteria [37,38], the latter scenario evolving to sepsis. It is therefore of vital importance to diagnose acute rejection in small bowel and MVTx promptly and precisely in order to avoid the menacing clinical consequences of rejection continuing unabated in the host.

Clinical and endoscopic correlation is critical when considering the potential diagnosis of acute rejection. Bowel acute rejection can be associated with an assemblage of symptoms that include increased fecal output (early on from the patient's stoma), fever, and swelling [9]. These symptoms are not specific and other processes such as infection can also induce similar effects. In this regard, the endoscopically derived gastrointestinal biopsy is often central to distinguishing these processes. Morphologically defined acute rejection in the absence of clinical symptoms is known as **subclinical rejection** (SCR) which has been described in bowel allografts [18], as in other transplants including liver and kidney [19,39,40]. Typically, SCR is detected when biopsies are taken as part of protocol surveillance and the patients are clinically stable. SCR is potentially important because patients have a higher rate of eventual graft loss. Some protocols treat SCR with additional immunosuppression. Adjunctive non-invasive laboratory and biomarker assays, though currently lacking optimal specificity and sensitivity, are growing in use in order to further support a morphological diagnosis of acute rejection on the biopsy [41]. These tests include cytofluorographic analysis of peripheral immune cell populations [42], cytokine profiling, and the quantitation of distinct gene set changes [33]. Serial measurements of peripheral blood levels of the amino acid citrulline, though not specific for rejection, appear to provide a snapshot of viable intestinal mass, and this analyte is routinely measured at our institution in monitoring post-ITx and MVTx patients [43–45].

Morphology. The histopathology associated with acute rejection in biopsies after ITx or MVTx represents a wide range of changes, and differs according to many variables with recipient, graft, and time post-transplant. The categorization of acute rejection in small bowel and MVTx, as with other solid organ allografts, utilizes terms that originate from basic immunology (e.g. hyperacute rejection, accelerated acute rejection, acute vascular rejection); with time these terms have become more standardized. Morphological changes associated with these subtypes of acute rejection also appear to be able to co-exist (e.g. "mixed rejection"). We utilize a general classification, based on the general underlying etiology of the rejection: antibody-mediated or T-cell-mediated (Box 86.1).

Antibody-mediated rejection

Hyperacute and accelerated acute rejection

Hyperacute and accelerated acute rejection are expressions that define the scenario infrequently encountered in which an allograft organ is exposed to extremely high levels of alloantibodies that cross-react with antigens on the organ (i.e. donor-specific antibodies) and is subsequently severely rejected within minutes to hours (**hyperacute rejection**) or a few days (**accelerated acute rejection**) following implantation [46,47]. These potentially devastating forms of acute rejection occur in the presensitized patient (i.e. pre-existing antibodies) and are secondary to a severe antibody-mediated response in which the vasculature endothelium is the principal target; vascular injury, thrombosis, and ischemic lesions characterize it histologically. Experimental evidence of these forms of rejection in bowel allografts exists but documented clinical cases of hyperacute rejection in ITx or MVTx are rarely described [48]. This latter point is a testament to the predictive success of cross-matching of recipient sera by the histocompatibility laboratory with donor cells before gastrointestinal transplantation. Pretransplant cross-matching was historically not the norm, although this is changing since bowel hyperacute rejection episodes associated with the presence of pretransplant donor-specific antibodies have been described [49–51]. Grossly, the donor graft upon anastomosis immediately turns dusky in color and becomes hyperemic, resembling changes seen in other solid organ grafts experiencing hyperacute rejection.

Morphologically, there is extensive mucosal congestion and necrosis with neutrophils and margination around vessels (Figure 86.2). A substantial amount of vascular congestion extends from the mucosa through the entire thickness of the graft (transmural). Native tissue is unremarkable. Curiously, these patients have the capacity to overcome this severe form of antibody-mediated acute rejection with aggressive intervention with plasmapheresis, treatment with anti-CD20 antibody (among other immunosuppressives) and close monitoring [48,50]. One patient we described with

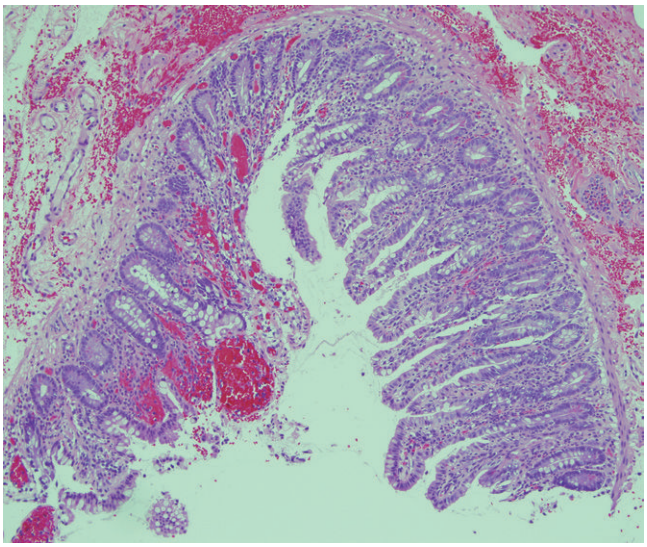

Figure 86.2. Hyperacute rejection. Small intestinal biopsy 1 day after transplant shows severe vascular congestion, neutrophils, early vasculitis, and necrosis (H&E, original magnification 200×).

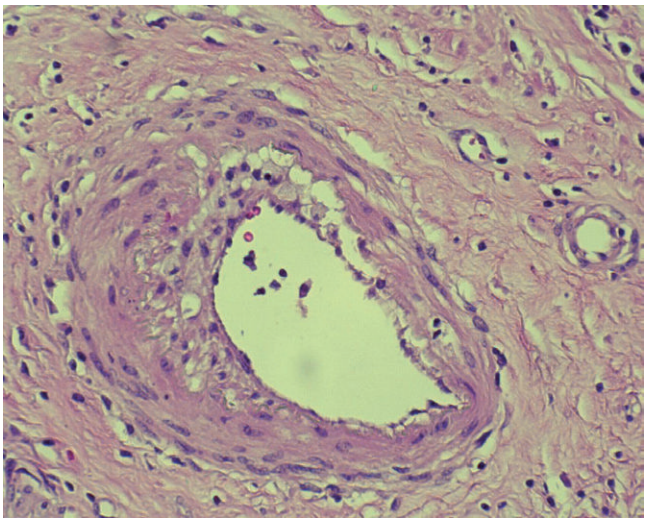

Figure 86.3. Acute antibody-mediated rejection (AAMR). Small intestinal biopsy showing large artery with vasculitis (H&E, original magnification 400×).

hyperacute rejection exhibited a full salvage of bowel graft function (normal graft morphology and asymptomatic), achieved concurrent with a reduction of titers of anti-donor antibodies and the development of normal endoscopic appearance [48]. Crossmatching is routinely performed at our center for all ITx and MVTx recipients.

On occasion, we have also found an accelerated antibody-mediated rejection (AMR) that occurred in the first several days following small bowel of MVTx in which the recipients were sensitized with pre-existing alloantibodies and which morphologically demonstrated features of AMR described below, but not to the degree seen for hyperacute rejection.

Acute antibody-mediated (humoral) rejection

Until recently, acute antibody-mediated rejection (AAMR) in human small bowel and MVTx was an entity whose frequency and severity were not well understood. The pathophysiology of this entity originates with antibodies directed to alloantigens that then initiate a variety of sequelae [49,52]. Accordingly, identification of AAMR cannot be accomplished as a form of rejection without additional techniques and evidence of antibody pre- and/or post-transplant. Vascular inflammation can be one of the histological components of this process; however, this is not specific to antibodies because the cell-mediated arm of the immune response (T-cell-mediated vasculitis) can also be an underlying cause of vasculitis in bowel allograft vessels. **Severe forms** of AAMR in small bowel transplants have been described and are often associated with alloantibody post-transplant sensitization of the recipient to donor antigens and subsequent rises in titers of pretransplant antibodies that were present at very low amounts before the transplant. The graft often demonstrates widespread inflammatory changes, with a critical lesion being vasculitis of large to small arterial branches (Figure 86.3). The vasculitis tends to show an infiltration of acute and chronic inflammatory cells in the intimal layer of the artery, with intimal edema and endothelial cell reactivity. The complement components C4d and C3d are often present in lamina propria and larger vessels; monitoring and grading changes in the immunohistochemical expression of these molecules in sequential lesions is an important requirement to the pathologist. Left unchecked, the vasculitis evolves with transmural inflammation, fibrin deposition, and necrosis of the artery, causing severe ischemic injury to the graft. On occasion, selective arteries in the graft are affected more severely than others by the vasculitis. For example, mesenteric arteries can undergo AAMR and this can lead to sclerosing mesenteritis [53]. This uncommon phenomenon can be associated with increased alloantibodies. Stomach and colon allografts can also demonstrate the severe vasculitis patterns, as seen in the small bowel. When considering a differential diagnosis for this form of severe vasculitis only involving the transplant, other causes such as infectious agents (such as fungal or viral agents) should also be contemplated. Other causes of vasculitis such as neoplasia, drugs, and autoimmune processes are not common causes and would be distributed in native organs as well as the allograft.

Larger vessel vasculitis is typically identified in explants or rejected organs or autopsies. Thus, the diagnosis of AAMR with severe vasculitis lesions in mucosal biopsies can be challenging in small bowel transplants, often only with morphological evidence of extensive necrosis.

However, **less severe forms** of AAMR also occur in small bowel, stomach, and colon transplants and do so at a higher frequency than previously believed. We have described alterations identifying early, mild, or evolving AAMR that can occur isolated or in conjunction with T-cell-mediated acute rejection [52]. These early and/or mild forms of AAMR are represented as mucosal morphological changes and appear associated in many cases with pre-existing or post-transplant alloantibody formation; these changes tend to occur particularly in the early period after transplantation. The microvasculature of the allograft mucosa shows mild to diffuse, significant vascular congestion with erythrocyte extravasation (Figure 86.4). Villous region and lamina propria microvasculature is principally affected and there may be no evidence of any significant vasculitis. Chronic inflammatory cells may or may not be increased and usually there is preservation of epithelial cells. Ancillary tests can be very useful for evaluation of humoral-based forms

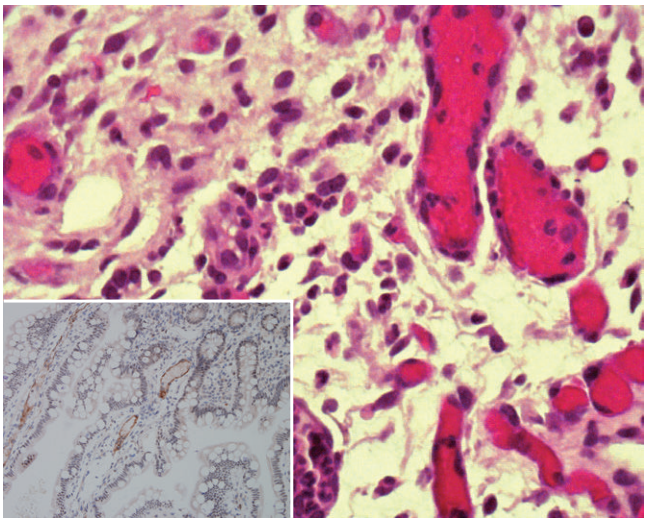

Figure 86.4. AAMR. Small intestinal biopsy with antibody-mediated rejection showing severe vascular congestion of mucosal vessels with neutrophil margination, edematous interstitium, and mixed chronic inflammatory cell infiltrate (H&E, original magnification 400×). (Insert) Lamina propria vasculature with positive C4d staining (C4d immunohistochemistry, original magnification 200×).

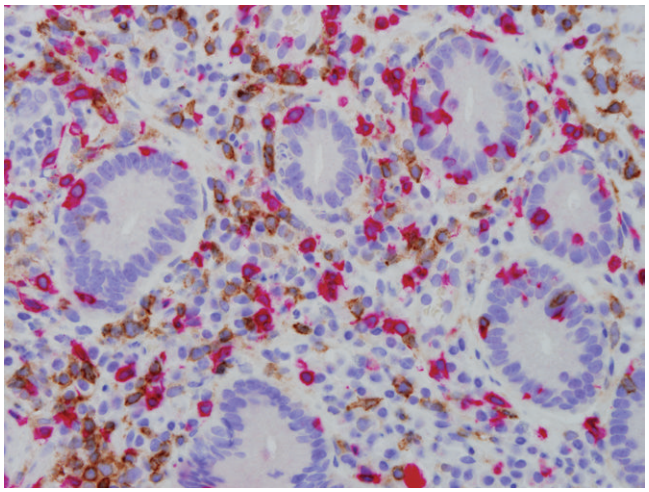

Figure 86.5. Acute T-cell-mediated rejection (ACR) colon allograft undergoing ACR, mild (grade 1) with significant mixed population of $CD4^+$ and $CD8^+$ T cells within interstitium and crypts (two-color immunohistochemistry, original magnification 400×, $CD4^+$ T cells = brown, $CD8^+$ T cells = red).

of acute rejection. For example, in suspected AAMR cases, an immunofluorescence panel is performed to determine the presence of immunoglobulins (IgG, IgA, IgM) and complement components (C3, C4, C1q); fibrinogen, C3d and C4d are performed in our laboratory by IHC optimized for bowel. In AAMR, immunoglobulins can be deposited along vessels and within interstitium along with complement components. As in other transplanted organs and gastrointestinal transplants undergoing severe AMR (mentioned earlier), we have also found C4d, C3d in small arteries and small capillaries in patients with milder or evolving forms of AAMR. These more subtle forms of AAMR do not demonstrate specific histopathological findings, and some of these alterations can be found in ischemia, non-specific enteritis, viral infections, and mechanical vascular problems. Consequently, it is essential to integrate the clinical history and laboratory values (e.g. alloantibody anti-donor titers), lesion distribution (allograft versus native tissue), other morphological findings (e.g. the presence of an acute inflammatory cell infiltrate or superficial epithelial changes with enteritis) and culture results. Moreover, there should be a relationship of symptom and histopathological resolution with augmented immunosuppression concomitant with lessening of alloantibody concentrations.

Acute T-cell-mediated (cellular) rejection

Acute T-cell-mediated rejection (ACR) is the most commonly recognized form of acute rejection in gastrointestinal transplants and can be present concurrently with AAMR, PTLD, infections, or other complications. The primary pathophysiological process operative for this form of rejection is the recipient's T-cell-mediated response to donor alloantigens. Histologically, this is represented by a heterogeneous lymphocyte-rich chronic inflammatory cell infiltrate that is primarily dispersed within the interstitial regions of organs with infiltration and damage of specific tissue parenchyma components [54]. These gastrointestinal elements are principally cells within crypts, glandular structures, and lining of the surface epithelium; however, muscle, endothelial and nerve cells may also be affected. There are several functional and structural sequelae of this injury to the parenchyma, such as metaplasia, apoptosis, and altered regulation of cell pathways.

Vascular compromise from the alloimmune effector cell-based injury to the vessels can be particularly devastating (as with AAMR) because the vascular compromise subsequently leads to extensive necrosis. ACR in gastrointestinal allografts is a complex, multifactorial process in which both $CD4^+$ and $CD8^+$ T cells are involved (Figure 86.5), analogous to other forms of allograft rejection. Crypt epithelial cell apoptosis is one of the chief features associated with ACR in intestinal allografts [55], appearing due to $CD8^+$ cytotoxic T cells' induction of target cell apoptosis via the granzyme B–perforin-dependent granule-exocytosis pathway and Fas and Fas ligand-mediated cytotoxicity [33]. Interestingly, non-$CD8^+$ T cells also appear to contribute to crypt epithelial cell apoptosis and acute allograft rejection in experimental animal models [56,57].

Several classification systems for grading acute rejection in small bowel and colon transplants have been described [54,58], as well as a classification system for stomach [59]. A unified grading scheme for ACR in small bowel allografts was developed in 2003 at the Eighth International Small Bowel Transplant Symposium by an international group of pathologists and clinicians experienced in small bowel transplant morphology (Box 86.1) [60]. This scheme is now widely used and has been employed at our institution for more than 4000 biopsies [61]. To date, there appears to be good correlation between the morphological grading system and the clinical symptoms displayed by the recipient as well as with inter-observer studies between different institutions (unpublished data).

No evidence of acute rejection, Grade 0

The changes associated with this grade are essentially minimal or none (i.e. histomorphology is indistinguishable from normal bowel) in regards to acute rejection; however, other concurrent conditions (non-rejection) may be present.

Indeterminate for acute rejection, Grade IND

The morphological changes seen in biopsies with this grade can be seen at any stage including the early or resolving stages of ACR when there is a minor amount of epithelial cell injury or destruction but nevertheless there is an increased inflammatory infiltrate within the parenchyma. The inflammation is composed of lymphocytes, eosinophils, immunoblasts, some plasma cells, and occasional neutrophils, varying in proportion, but with diffuse or localized intensity visibly increased above normal. Often also present are villous blunting, edema, and vascular congestion, but these features are not necessary for the diagnosis. Cryptitis with lymphocytes or eosinophils and epithelial apoptotic bodies are present. However, the number of apoptotic bodies does not reach the level designated for Grade 1 (mild) ACR.

T-cell-mediated acute rejection, mild, Grade 1

Mild ACR utilizes six apoptotic bodies or more per 10 crypts as the minimal cutoff, as designated in the International Grading Scheme [60]; other features typically include edema, congestion, and altered architecture such as villous blunting. The crypt cell injury, inflammation, and all the other changes listed above for the indeterminate category (Grade IND) are also present in ACR, mild (Grade 1), but at higher levels, including the level of apoptosis. The mild to moderate-intensity mixed chronic inflammatory cell infiltrate tends to be diffusely distributed (Figure 86.6), often with deeper extension to the submucosa, and can involve muscle. All of these morphological features, particularly the character and intensity of the infiltrate, can fluctuate according to the time after transplantation. Regenerative features such as mucin loss, epithelial cell nuclear enlargement, and hyperchromasia may also be present, depending on the duration of the rejection. Vascular congestion and endothelialitis can be present concomitantly with this and higher forms of ACR.

Acute T-cell-mediated acute rejection, moderate, Grade 2

In ACR, moderate (Grade 2), there are the features of mild ACR but with intensified crypt cell injury containing multiple, sometimes confluent apoptotic bodies in single crypts. There may be whole gland necrosis and crypt abscesses. The inflammatory infiltrate in the lamina propria and submucosa is stereotypically more intense than with mild ACR with the nature of the infiltrate being typically mixed but predominantly a mononuclear inflammatory cell population, including blastic or activated lymphocytes and mucosal architectural alteration that tends to be significant. The moderate to severe-intensity infiltrate is less affected by the time after transplantation, and villous blunting, edema, and vascular congestion are inclined to be more widespread with this higher degree than with Grade 1 rejection.

Acute T-cell mediated acute rejection, severe, Grade 3

ACR, severe (Grade 3) is a clinically and morphologically striking form of ACR. This is often also a "mixed" acute rejection (ACR plus AAMR) such that alloantibodies can be present. Crypt cell injury and apoptosis, gland destruction, and related mucosal ulceration are ubiquitous features. The level of crypt epithelial apoptosis is variable; in fact, there may be a normal level of apoptosis among the surviving crypts. There is a marked diffuse inflammatory infiltrate with blastic or activated lymphocytes, eosinophils, and neutrophils. The endoscopist often finds the tissue friable and thus fragments of tissue with significant architectural alterations are obtained. Protracted severe rejection typically results in complete loss of the bowel histological architecture, and there may be predominantly granulation tissue and/or fibrinopurulent (pseudomembranous) exudate, with mucosal sloughing (Figure 86.7). Mucosal ulceration in the absence of active crypt cell injury should not be classified as Grade 3 ACR but rather "consistent with ACR, severe" because ischemic and infectious processes can also lead to mucosal necrosis. The culmination of extended and extensive severe rejection – effectively with only necrotic tissue – has also

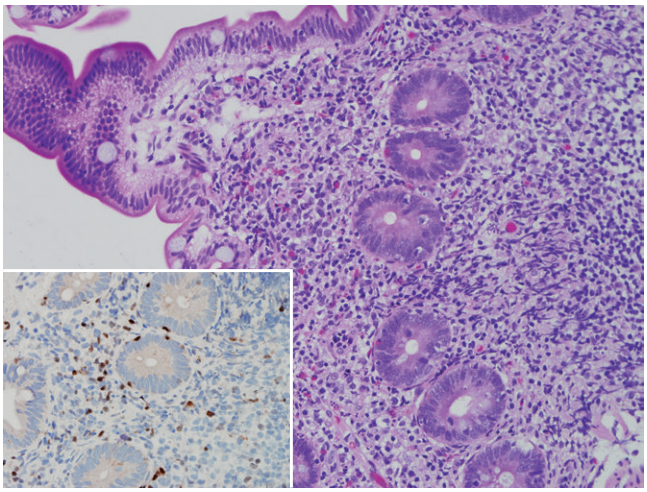

Figure 86.6. ACR, mild. Mixed inflammatory infiltrate and several apoptotic bodies are seen in crypts (more than six apoptotic bodies in 10 crypts) (H&E, original magnification 200×). (Insert) Tbet+ T cells (Th1 type cells) increased with ACR (Tbet immunohistochemistry, original magnification 400×).

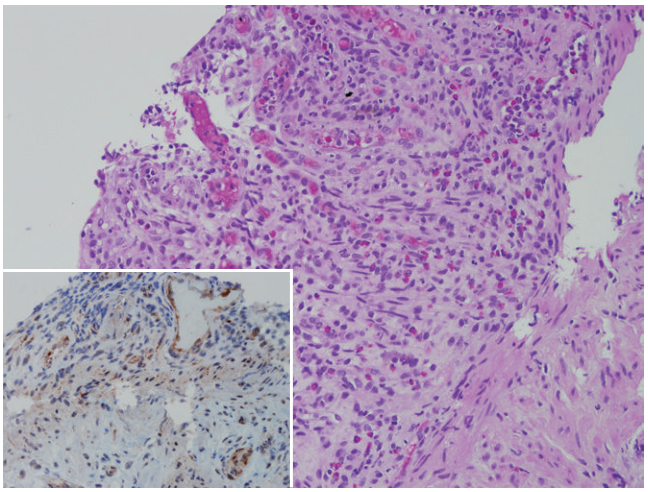

Figure 86.7. ACR/AAMR ("mixed rejection"), severe. Small intestinal allograft architecture mucosal architecture is extensively distorted and replaced by granulation tissue. The evaluation of crypt epithelial cell apoptosis is difficult to assess because of complete loss of crypts. Dense inflammatory infiltrate is seen which consists of mixed but predominantly mononuclear cell population with blastic and activated lymphocytes, eosinophils, and neutrophils (H&E, original magnification 200×). (Insert) Positive C4d within the vasculature. The patient also had donor-specific alloantibodies (C4d immunohistochemistry, original magnification 400×).

been called **exfoliative rejection** [35,36,62]. Therefore, it is very useful to obtain tissue obtained from areas that grossly appear less involved. Severe ACR can lead to intestinal graft loss.

In general, particular regions within the small intestine appear to be more susceptible to ACR; for example, the ileum displays ACR more commonly and often more severely than duodenum or jejunum [63]. There may be severe infectious complications as a consequence of the heavy immunosuppression to treat ACR and alloimmune-mediated injury and impairment of mucosal barrier function (intestinal epithelial cells, intercellular tight junctions, and basement membranes) can result in bacterial translocation into the peritoneal space [38,64].

ACR in colon and stomach

In MVTx patients, segments of the grafted alimentary tract aside from the small intestine can also be involved by acute and chronic rejection. ACR in colon allografts shows similar changes as seen with small intestine, and our experience with biopsies from this organ allograft is increasing as colon segments are included more often now with MVTx [65]. The pattern and composition of the inflammatory cell infiltrate ongoing in colon ACR displays the same pattern as small bowel, as well as the epithelial cell injury in crypts. There can also be architectural distortion, goblet cell loss, and attenuation of the thickness of the surface epithelial cells. We employ the same criteria and grading system for colon as we use in small intestine [60,61,66]. There is often contemporaneous native colon in MVTx patients; thus, obtaining tissue from native and allograft simultaneously can be useful to the pathologist in distinguishing alloreactive versus other inflammatory processes.

Stomach allografts can display ACR in all regions of this organ, exclusively or in combination with other inflammatory processes such as various forms of chronic gastritis and infectious processes. There is epithelial injury in the form of apoptosis and reactive changes, similar to small bowel and colon allografts. The degree of inflammation during acute rejection in the stomach is reduced compared to intestine such that corresponding grades of acute rejection in stomach do not demonstrate the same level of inflammation and epithelial injury as in small bowel or colon. However, we have seen many situations where there is isolated gastric rejection or the grades of gastric rejection exceed other regions of the small bowel or colon. A grading scheme that generates a numerical score to provide different levels of ACR can be a useful approach to evaluating stomach allograft pathology [59].

Chronic rejection

Chronic allograft enteropathy (CAE) or chronic rejection of small bowel allografts is growing in incidence and recognition as graft survival steadily improves in ITx and MVTx [2,34]. Actually, it is becoming one of the principal causes of late graft loss in gastrointestinal transplantation. The pathophysiology of chronic rejection of the bowel, as with other organ systems, appears influenced by an interaction of several non-immune [67] and immune factors [68–71]. The clinical symptoms for CAE tend to be non-specific (e.g. protein-losing enteropathy) and endoscopic information can include loss of villous structure with flattening; these findings can be very beneficial in correlating the pathological findings of the mucosal biopsies. Bowels that are removed with severe chronic rejection grossly show a matted organ bloc due to abundant serosal adhesions, with transmural thickening, an irregular flattened mucosal surface, and intermittent ulcerations.

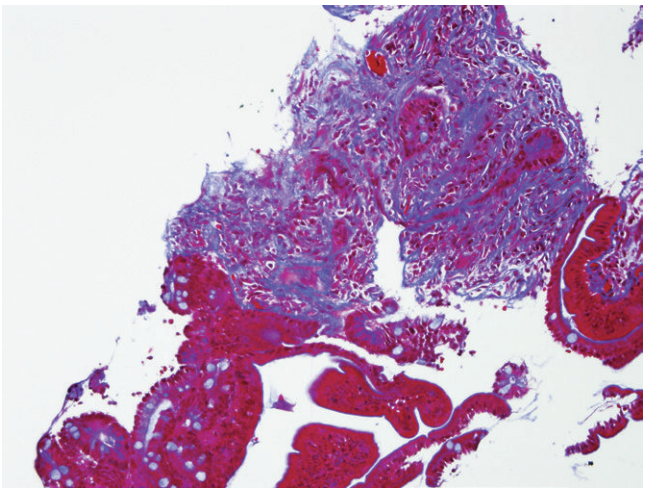

Figure 86.8. Chronic rejection. Trichrome stain shows marked fibrosis in submucosa and lamina propria (trichrome stain, original magnification 200×).

The pathognomonic lesion of bowel chronic rejection is arterial concentric intimal thickening with fibrous changes, medial hypertrophy of smooth muscle cells interspersed with foam cells, and adventitial fibrosis. As such, mucosal biopsies of small bowel are typically limited from being able to demonstrate the large vessel changes of chronic rejection [72,73] because these arteries are not usually present in endoscopic biopsies. Occasional thrombi in arterial branches at various stages can sometimes be seen along with occasional chronic inflammatory cells within the intimal space, the latter identical to "active" chronic allograft arteriopathy described in kidney allografts. There is mucosal, submucosal, and muscular layer fibrosis with crypt loss, crypt separation, villous blunting, mucosal atrophy, and small arterial branches with evidence of transplant arteriopathy. There can be ganglion cell destruction and hyperplasia and there may be fibrinous serositis. Chronic inflammatory cell infiltrates are typically present and there may be ulceration and superimposed acute rejection.

Mucosal biopsies from gastrointestinal allografts with CAE can be very useful in identifying the chronic injury (e.g. fibrosis, crypt loss and distortion, altered architecture) and consequently, with the clinical and endoscopic history provide a practical suspicion for chronic rejection (Figure 86.8). Comparison with adjacent native tissue is very useful because the native tissue is typically unremarkable. A semiquantitative scoring system for the mucosal biopsy evaluation of chronic rejection along with immunohistochemical characterization of lymphoid and macrophage cell populations is also useful in the identification and prognostication of CAE [73].

Infections

Among the serious adverse effects associated with ITx and MVTx immunosuppression is the appearance of opportunistic infections and complications [74–76]. These infections can manifest themselves systemically and/or locally in the graft and adjacent native tissue (e.g. infectious gastritis, enteritis, or colitis). The infectious pathogens can compromise graft function and place the host at risk of death without identification and therapy. Since gastrointestinal graft infections with clinical symptoms can sometimes mimic acute rejection (e.g. diarrhea, fever), these diagnoses must be

differentiated by culture and/or biopsy appearance because treatment often includes reduction in immunosuppression.

This brief overview describes a number of viruses that can involve the bowel allograft and are recognizable by characteristic morphological changes and confirmed by immunohistochemical or molecular techniques or culture. Among these viruses are rotavirus, adenovirus, calicivirus (human calicivirus (HuCV)), CMV, herpes simplex virus (HSV), and EBV. The presence of these viruses in gastrointestinal tissue is accompanied by an interstitial inflammation (e.g. gastritis, enteritis) that is composed of a mixed acute and chronic inflammatory cell infiltrate with focal or diffuse epithelial damage, altered cell proliferation, and cytological changes [77]. Necrosis may be focally present in more severe cases. Concomitant acute rejection may be present; thus, it remains important that the transplant pathologist consider the patient's clinical history and culture and molecular test results when evaluating the histology.

Adenovirus infection can be a perplexing and dangerous infection for gastrointestinal transplant patients, with spotty reports of cases in ITx and MVTx [78,79]. There is crypt cell apoptosis and a mixed chronic inflammatory cell infiltrate with disarray of the surface epithelial cells associated with the presence of enlarged, often hyperchromatic cells; there can be eosinophilic nuclear inclusions as well as "smudge cells" with enlarged basophilic nuclei and proliferation of surface enterocytes [80]. Immunostains, electron microscopy, and viral polymerase chain reaction (PCR) assays (of tissue) for this virus are very useful to help identify the presence of this pathogen. Some of the histopathological changes associated with adenovirus infection can also be evident in acute rejection; therefore it is important to use all tools necessary to distinguish the processes. Rapid diagnosis of adenovirus enteritis is essential because without proper treatment the clinical condition of patients tends to quickly deteriorate.

The general pediatric population commonly experiences *Rotavirus* and it can likewise complicate ITx and MVTx patients. The histopathological alterations associated with this virus are obscure and biopsies are not commonly procured to identify this pathogen. There may be superficial hyperplastic changes in the epithelium, a mixed mucosal surface inflammatory infiltrate with occasional neutrophils and cell debris. Deeper crypts tend not to be affected by the epithelial injury. Co-existence of acute rejection and rotaviral infections is possible [81,82].

Calicivirus (HuCV) is composed of two pathogenic strains: Norwalk-like virus and Sapporo virus. HuCV is a common cause of mild gastroenteritis and/or prolonged high-volume diarrhea in the general population and is usually detected by reverse transcriptase-PCR (RT-PCR) in fecal specimens. Histopathological alterations that have been reported include blunting and flattening of villi, mixed lymphoplasmacytic infiltrate with a small number of neutrophils in lamina propria, disarray and reactive changes of the superficial epithelium with loss of cellular polarity, increased apoptosis in the superficial epithelium and in the crypts, as well as in macrophages in the superficial portion of the lamina propria [83].

Cytomegalovirus (CMV) infection is common in gastrointestinal transplant recipients [84–87] and can be systemic or localized in its distribution. CMV enteritis can present as diarrhea, epigastric pain, and abdominal discomfort. Mucosal erosions and ulcers are frequently found endoscopically in stomach and in small intestine. There can be characteristic large CMV-infected cells that exhibit eosinophilic intranuclear inclusions surrounded by a clear halo and thickened nuclear membrane. Intranuclear inclusions are seen in endothelial, stromal, smooth muscle, and, less often, epithelial cells. These cells are present within a chronic inflammatory infiltrate, composed of lymphocytes and histiocytes, with neutrophils at times observed in the lamina propria. Isolated intranuclear inclusions are sometimes hidden in dense chronic inflammatory infiltrates and hard to identify. Immunohistochemical staining for CMV, and PCR-based assessment of tissues for CMV are helpful to confirm the diagnosis of CMV enteritis, which sometimes is obscured by severe inflammatory cell infiltrates.

Herpes simplex virus (HSV) infection in transplant patients is most frequently found in the oral cavity, esophagus, perianal area, and rectum, whereas HSV enteritis is relatively uncommon [88]. In endoscopic examination, HSV enteritis shows aphthous and necrotic ulcers, mucosal erythema and friability, and inflammatory pseudopolypoid lesions. Microscopically, there are lymphoplasmacytic inflammatory changes with scattered eosinophils. Virally infected cells can demonstrate eosinophilic intranuclear inclusions and multinucleation. Culturing of the biopsy sample and immunohistochemistry is useful to confirm the diagnosis of HSV enteritis.

Epstein–Barr virus (EBV) acute infection is low in the ITx and MVTx population but chronic infection is commonly associable with the development of PTLD (see below).

Bacterial overgrowth in bowel allografts (compared with the density of the normal flora) can be seen and the pathologist should communicate this information. Among potentially important bacterial infections in bowel allografts are **atypical mycobacteria** that can cause significant graft dysfunction [89]. Also, several fungal and parasitic pathogens, including *Candida* and *cryptosporidium* [90], are in the gastrointestinal tract and can involve the allograft.

Recurrent disease and other entities

There is a small proportion of ITx or MVTx patients whose original systemic or intestinal disease has the potential to recur in the bowel allograft. In general, disease recurrence with gastrointestinal transplants is not as frequent a complication as with other solid organ allografts (e.g. liver, kidney). Patients with inflammatory bowel disease (IBD) (e.g. Crohn's) [91,92] may show re-involvement of the bowel and this may be evident in the mucosal biopsies. There may also be IBD involvement of gastrointestinal allografts with certain systemic diseases such as primary sclerosing cholangitis [93]. MVTx patients whose original disease is among certain intra-abdominal neoplastic disorders (e.g. desmoid tumors) [94,95] may show tumor recurrence after transplantation. The recurrences of those neoplasms can be intra-abdominal but also occur outside the gastrointestinal tract or extraperitoneal space.

Gastrointestinal transplants can have inflammatory lesions and processes that have an ambiguous or unexplained origin. Later in the course of treatment, some ITx and MVTx patients may develop **persistent ulcers** that can involve graft, native gastrointestinal tissue, or both [96,97]. These ulcers can originate from several causes, including EBV-positive PTLD (the most common cause), smoldering acute rejection, infections, and some cases that remain of undetermined etiology.

Aside from alloimmune reactions, there are also other miscellaneous inflammatory conditions that can affect the small intestinal allograft and native small intestine [98,99]. **Active enteritis of undetermined etiology** is characterized by acute inflammation (e.g. polymorphic neutrophil infiltration) in lamina propria and/or surface epithelium with focal ulceration and crypt abscess, occurring on a background of chronic inflammation. Several potential

pathogenic mechanisms of this entity have been proposed, including stasis, altered bacterial flora, ischemia, prolapse, and mucolysis. **Eosinophil-rich enteritis and colitis** is an inflammatory condition sometimes associated with allergic sensitization. Some *NOD2* gene polymorphisms are associated with altered bacterial clearance and increased inflammatory infiltrate [16,91,100,101].

Regenerative changes can occur due to healing after acute rejection, infectious enteritis, or after ischemic injury.

Graft-versus-host disease (GVHD) can occur in ITx or MVTx patients with involvement of skin, native alimentary tract, and other systems [15,102–104]. The histopathological features of GVHD in native gastrointestinal tissue can resemble ACR, with increased crypt epithelial cell apoptosis and inflammatory infiltrate. Thus, it is critical to know the clinical history and origin of the tissue sample (whether from allograft or native) in order to diagnose GVHD. PTLD has a high incidence in ITx and MVTx patients Because of their prolonged immunosuppression [20,87,105,106]. This common complication increases in frequency as the time post-transplant increases and often *does* demonstrate involvement of the allograft. EBV infection is often associated with PTLD, although EBV-negative PTLD can occur [107,108]. The histopathology of PTLD in the bowel includes a progression from plasmacytic hyperplasia (an early lesion), polymorphic PTLD, monomorphic PTLD, and frank lymphoma. Lymphoplasmacytic infiltrates (i.e. plasmacytic hyperplasia), the suspected precursor lesions of PTLD, are commonly seen in bowel allograft biopsies as the time from transplant extends and epithelial structures may be effaced by the infiltrate (Figure 86.9). EBV staining by Epstein–Barr Early Region (EBER) gene products and immunostaining for the presence and relative composition of B and T cells within the infiltrate is useful in evaluating possible PTLD [109]. Antigen receptor gene rearrangement studies for T- and B-cell-antigen receptors from the paraffin block are helpful for an assessment of potential monoclonality [107,108]. Monomorphic PTLD can be of T- or B-cell origin [110,111], and are recognized as neoplastic. PTLD lymphomas are classified according to their architectural and cytological features in fashion identical to lymphomas occurring in native tissue [109].

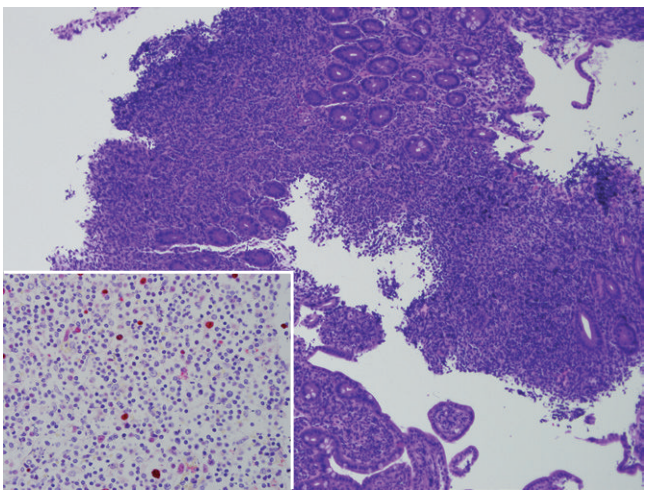

Figure 86.9. Post-transplant lymphoproliferative disease (PTLD). Expansile mild lymphoplasmacytic infiltrate with focal atypia, also indeterminate for acute rejection (H&E, original magnification 40×). (Insert) Epstein–Barr virus (Epstein–Barr Early Region) in situ hybridization. EBV-positive cells within the infiltrate (original magnification 400×).

Conclusions

The success of ITx and MVTx over the past two decades has been multifactorial, with the development of pathological assessment of the transplanted viscera an area of particularly notable improvement. There has been precise delineation of multiple pathological entities affecting these particular organ allografts, development of grading schemes for several conditions, and acceptance that multiple conditions often co-exist in the graft. Moreover, additional biomarker tools are increasingly available for intragraft and systemic tissue evaluation that help refine the morphological impression from the biopsy. The prospect is good that future clinical and basic science findings will further enhance the central diagnostic capacity of the allograft biopsy.

CHAPTER 87

Histopathological Syndromes of Vascularized Composite Allograft Rejection and Recurrent Disease

Introduction

Vascularized composite allotransplantation (VCA) refers to the non-autologous transfer of tissues from diverse embryological origins as a functional unit, with a common example being a hand transplant. VCA is performed to reconstruct tissue defects that are otherwise non-reconstructable. It differs from other vascularized allografts in the diversity of tissues comprising the graft, and in the common inclusion of donor skin. To date, over 90 patients have received VCAs as reported to the International Registry on Hand and Composite Tissue Transplantation: 51 limbs, 7 faces, 9 abdominal walls, 6 knees, 3 femoral diaphyses, 2 digits, 1 lower limb, and 1 larynx [1].

Essentially, all VCA recipients have experienced episodes of rejection. At the time this chapter was written, acute rejection episodes had been observed in up to 85% of VCA recipients within the first year [2]. As noted in Chapter 110, the high incidence is likely multifactorial; one factor being the presence of highly antigenic skin, which could condition a robust alloimmune response. As an external organ exposed to the environment, the skin also allows for visualization of changes not necessarily secondary to alloimmunity, but considered alloimmune in nature and treated as rejection. This adds a unique nuance to the role of histopathological diagnosis not evident in other types of transplanted organs.

Although VCA rejection has been presumed to be mediated by mechanisms similar to those in other organs, it has not been determined whether VCA tissues have a hierarchical predilection for the development of an allospecific infiltrate, or if some elements are spared rejection. Studies in preclinical models have shown different infiltrates between tissues and different survival times when multiple tissues are transplanted rather than one vascularized tissue [3]. Because of the infrequent application of VCA, no single group has accumulated sufficient experience to determine histologic patterns of rejection. As such, this single chapter focuses on the histopathological aspects of graft rejection within the context of the early stage of VCA development. We also provide a historic perspective of the study of VCA histopathology primed by the Banff Working Group [4] and considerations on non-alloimmune pathology.

Background

The first mention of a VCA dates back to the year AD 348, when twin brothers from Arabia, Saints Cosmas and Damian, posthumously transplanted a lower extremity (Figure 87.1). Throughout the years, advances in surgery, immunology, and transplantation have made possible the emerging field of VCA. Soon after Joseph Murray performed the first successful kidney transplantation in identical twins, the first hand transplant was performed in Ecuador in 1964. The graft was rejected after 2 weeks as a result of deficiency of immunosuppressive therapy [5]. Large animal models of VCA emerged shortly thereafter. These models relied on manipulations of the immune system that were not translatable to humans [6]. With the advent of cyclosporine in the early 1980s, interest in VCA was renewed. Large animal models in primates and miniature swine showed improved allograft survival with the use of calcineurin inhibitors. These models also showed the skin as a principal site of rejection [7]. Some consider that the modern era of VCA began after the introduction of cyclosporine with a unilateral hand transplant performed in Lyon, France, in 1998 [8].

Large animal models of VCA have yielded important insights into the tempo and character of immunological rejection in this setting which have been important for the classification of human VCA rejection. Early studies in swine models assessed rejection based on cellular infiltrates involving vessels: dermal connective tissue, skin appendages, and epithelium. Studies in outbred swine correlated visual and histologic findings after forelimb osteomyocutaneous free flaps. The visual scale ranged 0–4 based on skin color, bleeding from biopsy site, and blister formation. Histologic grades were assigned based on the degree of vasculitis, folliculitis, dermal inflammation, and epidermal degeneration [9]. Interestingly, their findings included the presence a visual Grade I rejection with no evidence of rejection histologically, and specimens demonstrating +/– 1 histologic grade on pathologic examination compared to the visual scale. Studies in major histocompatibility complex (MHC) matched miniature swine described acute rejection after heterotopic transplant of hind legs. The animals received a 12-day course of cyclosporine immediately postoperatively. Acute rejection was described as an erythematous indurated appearance of the skin with correlating histologic epidermal cellular infiltrate. Complete sloughing of the epidermal layer followed these incidents. Despite rejection and loss of the epidermis, the dermis, muscle, and bone showed no sign of histologic rejection. Re-epithelialization of the dermis occurred subsequent to these episodes [3].

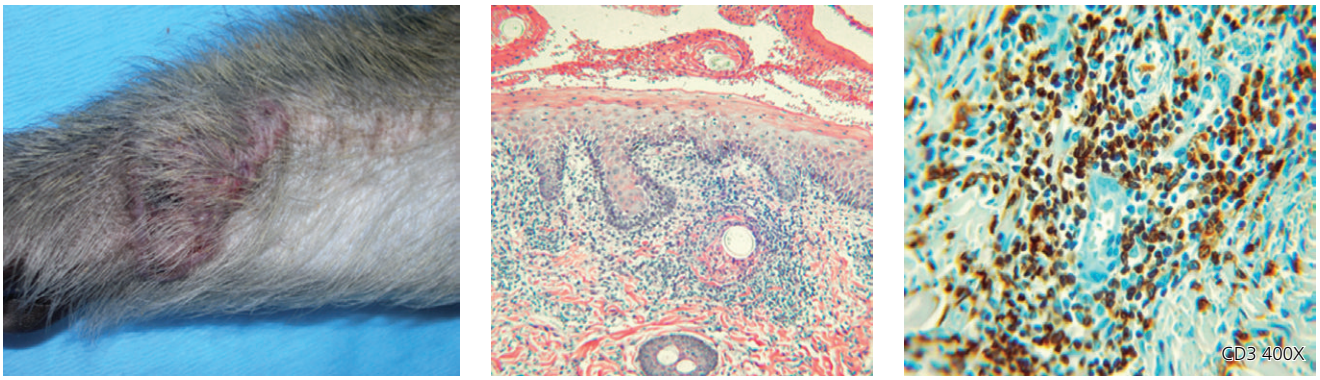
(Reproduced from [10] Barth R, Nam AJ, Stanwix MG, et al. Prolonged survival of composite facial allografts in non-human primates associated with posttransplant lymphoproliferative disorder. Transplantation. 2009;88:1242–1250, from Wolters Kluwer Health.)

Studies in non-human primates include a model of facial VCA containing components of bone, muscle, and skin [10], and a model using a sensate osteomyocutaneous radial forearm flap [11]. Compete rejection of the dermis in the facial VCA model was demonstrated by eschar formation but revealed viable underlying muscle and bone (Figure 87.2) [10]. Immunosuppressed animals in the sensate osteomyocutaneous radial forearm flap experiencing acute rejection developed skin changes such as a patchy erythematous rash without blanching, at times preceded by vesicle formation. Biopsies showed a lymphocytic perivascular and perifollicular dermal infiltrate, as well as a lymphocytic infiltrate at the dermal–epidermal junction. Skeletal muscle had multifocal areas of necrosis and perivascular lymphoid infiltrate. Sections of nerve, arteries, and veins demonstrated moderate lymphoid infiltrates. The histologic pattern of rejection was similar to that described in episodes of rejection in human VCA recipients (Figure 87.3) [11].

As is the case for all transplanted organs, histopathology has a key role for VCA in diagnosing rejection, understanding the pathophysiology of rejection, and facilitating management. Standardization is necessary for reporting clinical results and establishing objective end points for clinical trials. In 2005 a collaborative relationship was established between investigators with experience in clinical VCA worldwide to initiate the groundwork for a universally accepted histological classification. In 2007 the first working classification of VCA rejection was published after the first international consensus meeting at the ninth Banff Conference on Allograft Pathology [4]. The participation of the VCA group at the Banff Conference of Allograft Pathology was the first time the field was recognized as a partner in transplantation. The VCA conference reviewed the four published grading systems on human VCA rejection and noted their similarities: the progressive severity of perivascular lymphocytic infiltrates, which parallels the severity of rejection; moderate rejection marked by inflammation extending to the dermal stroma, epidermis, and adnexa; and severe rejection comprising epidermal apoptosis and necrosis. One system scored rejection based on the extent of vessels infiltrated, with $<10\%$ signifying mild rejection and $>50\%$ signifying severe rejection [12].

The Banff conference sought to answer several questions regarding the diagnosis of acute rejection in VCA recipients: (1) specimen adequacy and biopsy preparation; (2) features required for the diagnosis of acute rejection; (3) grading severity of acute rejection;



(A) (B) (C)

Figure 87.3. Skin rejection in a vascularized composite allograft (VCA) in a non-human primate on immunosuppression. (A) Rash circumscribed to the allograft. (B) Parakeratotic hyperkeratosis with a serocellular crust is evident. A moderate dermal, perifollicular, and perivascular mononuclear cell infiltrate is present (hemtoxylin and eosin, original magnification 100×). (C) Lymphocytic infiltrates are positive for CD3 immunostaining (original magnification 400×). (Reproduced from [11] Cendales L, Xu H, Bacher J, et al. Composite tissue allotransplantation: development of a preclinical model in nonhuman primates. Transplantation. 2005;80:1447–1454, from Wolters Kluwer Health.)

(4) features required for the diagnosis of chronic rejection; and (5) diagnosis of humoral rejection. Currently, the treatment of rejection in VCA parallels the treatment of rejection in other solid organs.

Specimen adequacy

Allografts that contain skin are unique in that rejection can be appreciated by visual inspection and appreciation of lesions that are palpable to the clinician. The tempo by which the visual features of rejection appear in the graft is undefined. Efforts have been made to incorporate this unique feature of VCA into the scoring system and to evaluate its role in distinguishing VCA from solid organ allografts. The area of clinical involvement should be documented at the time of rejection as <10%, 10–50%, >50%, or no visible changes (Figure 87.4). Gross features of rejection include ulceration, rash, edema, erythema, vesiculation, desquamation, and necrosis. Biopsies are directed toward the area of the graft with the most severe skin changes that is still viable. In contrast to other organs such as kidney, and considering that rejection may be visible, at this time, one 4-mm punch biopsy is recommended for diagnosis. Although the site of the biopsy is visible, sampling bias is still to be determined. Some centers have transplanted a vascularized sentinel skin graft (consisting of donor forearm) with face transplants and hand transplants as a site to obtain biopsies in an effort to avoid disfiguring the allograft [13]. This is not a universal approach and validation studies have not been reported.

The biopsy should contain the epidermis and its adnexal structures, dermis, subcutaneous tissue, and vasculature. Slides should be prepared with hematoxylin and eosin (H&E) and periodic acid–Schiff (PAS) stains. Immunohistochemical stains may be performed depending on H&E findings or for research purposes: CD3, CD4, CD8, CD19, CD20, CD68, HLA-DR, and C4d. Trichrome staining is also performed on an as needed basis but is not currently required for diagnosis.

Acute cell-mediated rejection: VCA Banff scoring system

The histopathological diagnosis of acute rejection is recognized by predominantly lymphocytic inflammatory infiltrates progressively involving small dermal vessels, skin adnexa, and the epidermis. The infiltrate includes several cell types, including lymphocytes and neutrophils, and both the cellular density as well as location is noted. Similar to the Banff classification for acute renal allograft rejection, the degree of perivascular infiltrate parallels the extent of rejection.

The Banff 2007 working classification for VCA pathology grades rejection 0–IV in order of increasing severity. Grade 0 comprises no infiltrate or rare inflammatory infiltrate. Grade I, or mild rejection, is described as mild perivascular infiltrate without involvement of the overlying epidermis. Grade II, moderate rejection, includes moderate to severe perivascular involvement with or without mild epidermal or adnexal involvement. Grade III, or severe rejection, is described as a dense inflammatory infiltrate with epidermal involvement including epithelial apoptosis, dyskeratosis, or keratinolysis. Grade IV, necrotizing acute rejection, consists of necrosis of the epidermis or adnexa (Figure 87.5) [4].

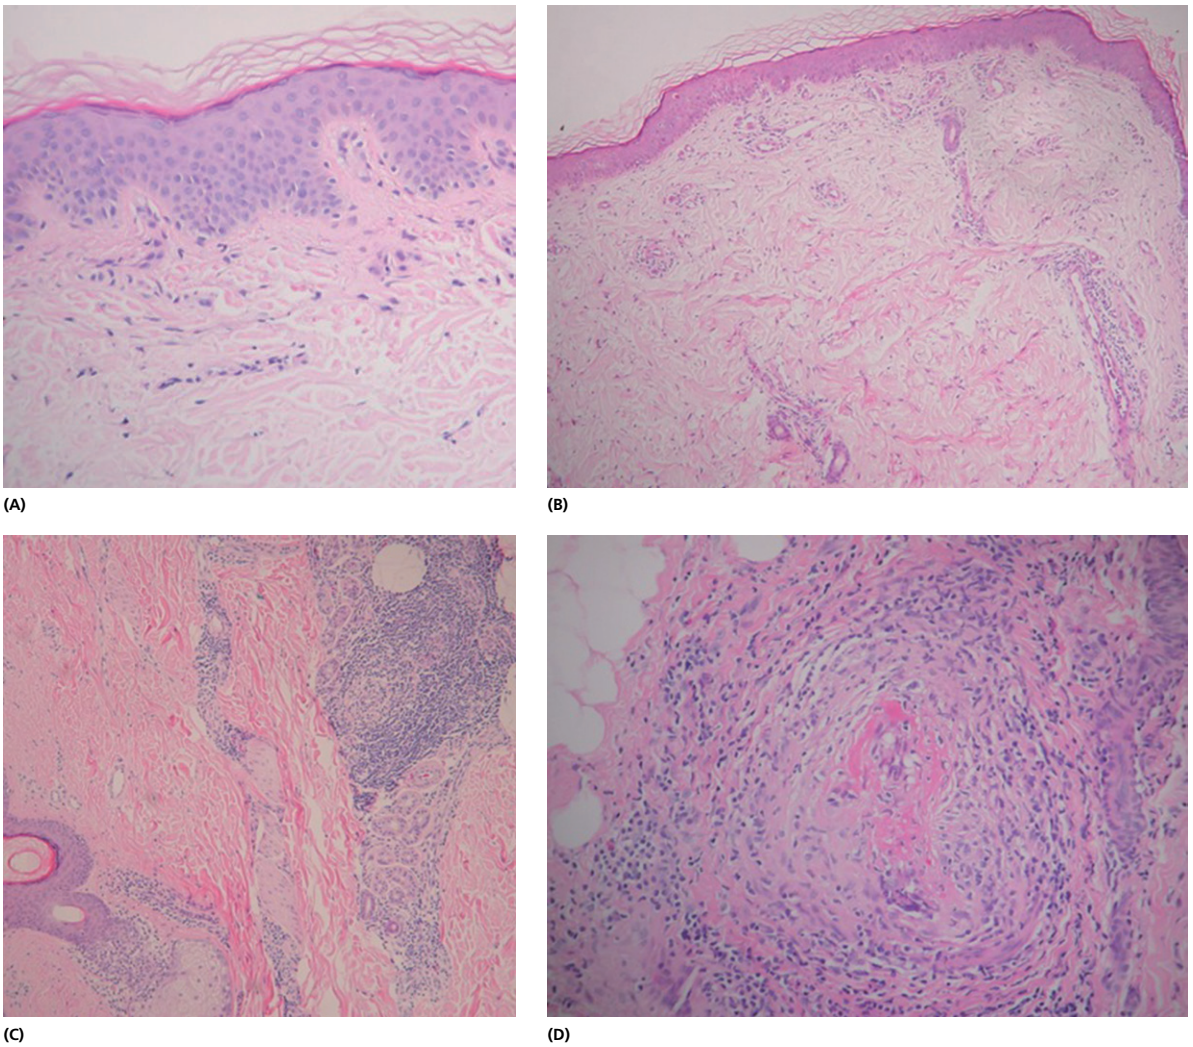

Figure 87.5. Banff classification system for skin containing vascularized composite allografts. (A) Banff Grade 0. No or rare inflammatory infiltrates. (B) Banff Grade I. Mild perivascular infiltration. No involvement of the overlying epidermis. (C) Banff Grade II. Moderate to severe perivascular inflammation with or without mild epidermal and/or adnexal involvement. No epidermal dyskeratosis or apoptosis. (D) Banff Grade III. Severe rejection with fibrinoid degeneration. (Reproduced with permission from [30] Liapis H, Wang HL (eds.) Pathology of Solid Organ Transplantation. Springer, 2011, pp.393–399.)

Vasculitis may be present in other pathologic processes besides rejection, particularly if ulceration or necrosis is involved. Rejection-mediated vasculitis is distinguished by involvement of multiple vessels within the biopsy, especially involvement of multiple sizes of vessels at different depths within the dermis; multifocal involvement of a single vessel; involvement of vessels distant from ulceration; and vasculitis without a history of trauma. Similar to the diagnosis of acute rejection in solid organs, the histopathology of rejection and other pathologic processes may overlap, and these should be considered in the differential diagnosis [4].

Non-alloimmune pathology

Skin-containing VCAs are in constant contact with the environment and the skin can undergo changes unrelated to alloimmune processes. When biopsied, skin changes may exhibit lymphocytic infiltrate not necessarily specific for rejection; thus, a broad differential diagnosis must be considered: infections, drug toxicity, lymphoproliferative diseases, insect bites, graft-versus-host disease (GVHD), and allergic or irritant contact dermatitis [4].

Rejection can be manifested clinically by erythematous macules, which progress to confluent areas of violaceous lichenoid papules if left untreated [14]. Grade I rejection presents clinically as faintly erythematous macules scattered over the allograft or as a generalized rash in the allograft. The clinical appearance at this stage may be similar to viral infections. The histology of Grade I rejection similarly overlaps with viral infection; a lymphocytic perivascular infiltrate concentrated in the upper dermis. Grade II rejection has been clinically observed as erythematous macules which may be scaly. Histologically, the perivascular infiltrate is denser and extends to the mid-dermis; epidermal exocytosis and spongiosis with vesicular changes may be present. The differential diagnosis is broader at this stage and includes viral and drug-related reactions, contact dermatitis, dermatophyte infections, and insect bites.

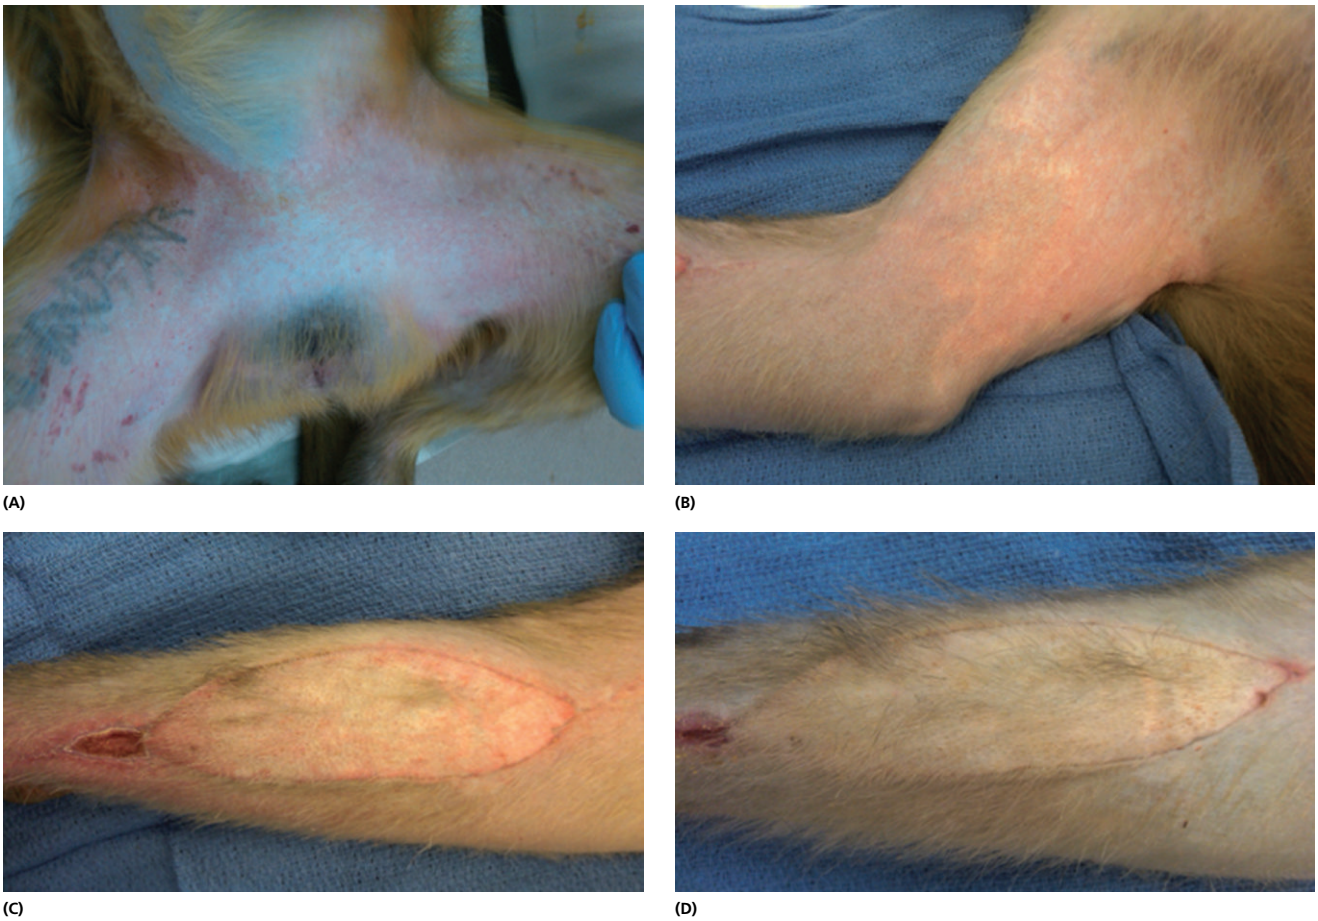

Figure 87.6. Non-specific dermatitis in a non-human primate after a vascularized composite allograft: (A) native skin of groin; (B) native skin of axilla; (C) coinciding rash on allograft skin; and (D) resolution of allograft rash without treatment. (Source: Emory Transplant Center.)

Differentiating between rejection and other causes of inflammation requires a detailed history, physical and pathologic examination. Viral infection and drug reactions are not generally limited to the allograft. Histologically, and different from an alloimmune reaction, samples may contain extravasated erythrocytes in the dermis. Contact dermatitis may have a similar clinical and histologic appearance as rejection and requires history and clinical examination of the native skin to differentiate the two. Dermatophyte infections are characterized clinically by eczematiform skin changes and pathologically by a perivascular dermal infiltrate. Additional cultures and staining such as PAS may be helpful in the differential diagnosis. Insect bites have a high density of eosinophils in the dermis generally not seen with early grades of VCA rejection [15].

More severe rejection can include lichenoid-like plaques and papules. Pathologically, the dermal infiltrate is denser still, extending to the epidermis and surrounding blood vessels and adnexa. The differential diagnosis includes cutaneous lymphomas, pseudolymphomas, lichenoid dermatoses such as GVHD and erythema multiforme. Cutaneous B-cell lymphomas are distinguished by a predominance of B cells in the dermis, epidermal sparing, and presence of Epstein–Barr virus (EBV). Cutaneous pseudolymphomas are characterized by a mixed lymphocytic infiltrate of T and B cells as well as eosinophils. Drug rash with eosinophilia and systemic symptoms syndrome is also part of the differential diagnosis. Lichenoid dermatoses such as erythema multiforme, lichen planus, lichenoid lupus erythematosus, and GVHD are distinguished pathologically by melanin incontinence, a feature not seen with rejection.

The most severe grade of rejection encompasses a dense dermal–epidermal lymphocytic infiltrate similar to Grade III but with the addition of epidermal necrosis and necrosis of the epidermal adnexal structures. Clinically, the appearance may mimic toxic epidermal necrolysis [14,15]. An important visual clue in differential diagnosis is the limitation of the lesions to the allograft. Current research in animal models of VCA include differentiating between rejection and non-rejection-associated inflammation by distinct cytokine signatures [16].

Observations by our group in a non-human primate model of VCA include lacy flat pink rashes noted both on the allograft and in the native intertriginous areas (Figure 87.6). The rash was not treated as rejection and it cleared from both the native and allograft skin. Other lesions included areas of erythema on the allograft that progressed to a thickened scab. A total body skin examination revealed several similar scabs on the native skin which upon investigation were determined to be local reactions to medication injection sites. What was initially thought to be a harbinger of rejection was a misplaced injection into the allograft skin (Figure 87.7).

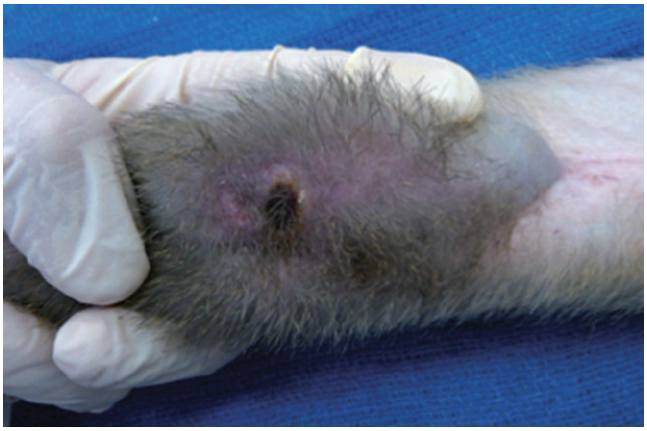

Figure 87.7. Injection site reaction on allograft skin in a non-human primate. (Source: Emory Transplant Center.)

Chronic rejection

As anticipated, chronic rejection has been reported after limb transplantation and the numbers will certainly increase as longer follow-up data are gathered. Chronic rejection in solid organ transplantation is characterized by a gradual loss of graft function, accompanied by transplant vasculopathy, or intimal hyperplasia, often with evidence of C4d deposition and circulating donor-specific antibody [17,18]. Chronic injury to an allograft may be caused by non-immune mechanisms, and its common phenotype belies multiple etiologies. Chronic allograft pathology in VCA is described as vascular narrowing, skin and muscle atrophy, loss of adnexal structures, deep tissue fibrosis, myointimal proliferation, and nail changes [4]. Data are limited regarding the prognosis of composite allografts because of the limited number of transplants that have been performed, as well as the relatively short follow-up when compared with visceral organ transplants, which have been performed for over half a century. None the less, it is anticipated that fibrotic changes and atrophy will decrease range of motion and strength, and long-standing neuritis may translate into sensory changes.

Graft vasculopathy is primarily caused by intimal hyperplasia of vessels and has been observed in a number of human and animal composite allograft models [19–22] . The findings have been likened to myointimal proliferative changes seen in other allograft organs, including cardiac allograft vasculopathy [21]. Based on data from a center with experience in six hand recipients, it appears that vessels, both the arteries and veins, are targets of rejection [19]. Graft vasculopathy should be distinguished from donor arteriosclerosis. If arteriosclerosis is detected on early biopsies, then pre-existing donor arteriosclerosis can be suspected as a contributing culprit of the vascular changes.

Changes in other tissue types have been described in addition to changes that have been seen in vessels. The muscles and tendons can have mild chronic inflammation [23]. Muscular hypotrophy has been described as primarily affecting the intrinsic muscles [24]. This finding could be secondary to slow nerve regeneration. Fatty degeneration may accompany the muscular hypotrophy [24]. Some investigators have reported bone marrow and joints to be spared from chronic changes [25]. However, synovial tissue has been shown to experience rejection. Animal models have demonstrated that the donor bone marrow is replaced with recipient marrow based on short-tandem repeated genotypic analysis [20]. Bone union is observed between the donor and recipient tissue [20]; however, the bone trabecular density decreases in allografts [24]. This particularly occurs in recipient tibia and hand-grafted graft radius. Graft radius changes can also affect the cortices [24].

A series of 15 hand transplants in China with 1–9 year follow-up described the clinical phenotype of chronic rejection as skin erythema, uneven nails, allograft stiffness, muscle atrophy and loss of function, cold intolerance, and pain. These symptoms occurred in most patients over time, according to the authors. Histologically, chronic rejection in this series of patients was described as stromal edema of the epidermis and superficial dermis as well as the vascular endothelium. Perivascular lymphocytic infiltrate and vascular narrowing was also described [26]. Several patients in their series received graft irradiation prior to transplant to reduce donor-derived lymphocytes in the bone marrow. Certain pathologic features of radiation injury overlap with chronic rejection, such as stromal fibrosis, epithelial atrophy, and arteritis, which makes the diagnosis of chronic rejection difficult to differentiate definitively from radiation damage in this patient cohort [26].

Imaging and other ancillary technique findings

Radiologic methods have been proposed to assess chronic changes in VCA. Ultrasound biomicroscopy has been used to assess graft vasculopathy in which vessel wall thickness increases [19]. Magnetic resonance imaging [24], biomechanical analysis, angiography [20], and high-resolution ultrasonography [24,31] may also be useful. Although helpful, it is likely that once the changes detected by imaging are observed, they may be irreversible.

Antibody-mediated rejection

Antibody-mediated rejection (AMR) has been established in multiple organs in both acute and chronic forms. Specifically, donor-specific human leukocyte antigen (HLA) antibodies are risk factors for organ transplant recipients if present at the time of transplantation or produced de novo following transplantation. Thus, monitoring of antibodies directed against antigens is crucial to maximize allograft survival [27,28]. Staining for C4d has been as a marker for antibody-mediated rejection using both immunofluorescence and immunohistochemistry. However, examination of C4d staining in VCA has not yielded a characteristic staining pattern with the current limited data available [11,29]. The development of donor-specific antibodies in combination with vasculopathy has been reported in VCA recipients after hand allograft loss [19]. Although, to date, there is not enough information to draw conclusions on AMR in VCA recipients, it is prudent to assume that several clinical and histological data points should be gathered to help define AMR in VCA. These include C4d deposition on VCA biopsies along with presence or absence of serum donor-specific (anti-HLA) antibody. Additionally, the presence of pathologic markers of chronic injury such as vasculitis, thrombus formation, neutrophilic margination, and necrosis should be noted. A history of patient sensitization is performed before transplantation, including PRA (panel reactive antibody), pregnancy, transfusion, and previous allograft. Additionally a T-cell and B-cell cross-match is performed pretransplant.

Conclusions

The fundamental biology of VCA is sufficiently similar to that of other solid organs that additional phenotypes will surface as clinical experience grows. VCA candidates of a skin-containing transplant should undergo a detailed dermatological examination, including a history of pre-existing dermatosis and a detailed family history, as some dermatoses and malignancies will become evident or develop after transplantation. As a field in development, many questions remain unanswered in VCA. The VCA Banff classification is an international effort that lays the groundwork to advance the understanding and the study of VCA pathology. Similar to other Banff classifications, the VCA scoring system is a living document that changes as more data become available. Further refining of the diagnostic criteria through the analysis of systematic data and clinical trials is needed.

Introduction

Cardiovascular disease (CVD), including myocardial infarction (MI), heart failure, stroke, and peripheral vascular disease, accounts for a significant portion of global morbidity and mortality in the general population [1–3]. As patients survive longer with improvements in immunosuppressive therapy, surgical technique, and a better understanding of infection management, CVD has become a leading cause of morbidity and mortality in solid organ transplant (SOT) recipients [4–6]. CVD is much more prevalent after SOT than in age-matched controls, as shown in Figure 88.1 for kidney transplant patients [7,8]. Although all of the factors contributing to this increase in CVD prevalence are not clear, the side-effects of immunosuppressive therapy are believed to play a substantial role in increasing cardiac risk, in part through the augmentation of traditional risk factors [5,6,9]. This chapter will review CVD in SOT patients. The identification and management of risk factors in the general population, as well as factors specific to transplant recipients will also be discussed. This discussion will complement the organ-specific discussions of waitlist management in Chapters 37–42.

Solid organ transplant recipients and independent risk factors

CVD is the leading cause of mortality among kidney and heart transplant recipients, and one of the main causes of death among liver and pancreatic transplant patients after the first year [4,5,10–13]. Lung transplant recipients have a higher graft failure and mortality rate compared to other SOT patients [13,14]; this shorter life span is associated with lower CVD mortality [5,14,15].

Many independent risk factors for CVD are present in patients prior to transplantation, or are induced or exacerbated by immunosuppression, including hypertension, dyslipidemia, diabetes mellitus, obesity, and the metabolic syndrome [3,13]. Compared to the general population, these risk factors are seen with a higher prevalence in SOT candidates and recipients alike, and have a higher associated CVD mortality [12,16]. In an effort to decrease post-transplant CVD, thorough pretransplant evaluation with imaging (nuclear or echocardiogram), stress testing (exercise and chemical), and cardiac catheterization have been employed [12,16].

Hypertension

Hypertension in a transplant recipient is often defined as a blood pressure of >140/90 mmHg or an increase in blood pressure requiring use of antihypertensive medications [3,17]. A known correlation between hypertension and cardiovascular events exists in the general population [18]; it is stated to be the most common, identifiable, and reversible risk factor for CVD [18]. In transplant patients, hypertension is not only associated with an increase in CVD morbidity and mortality, but has also been correlated with decreased graft function and survival [3,19].

Although this risk factor is often present prior to transplantation, immunosuppressive medications, particularly calcineurin inhibitors (CNIs) and corticosteroids, increase the prevalence of hypertension [3,4,20]. Neither sirolimus nor mycophenolate mofetil (MMF) appears to elevate blood pressure [3]. Use of antihypertensive medications is appropriate to maintain a blood pressure of <140/90 mmHg. Calcium channel blockers are commonly prescribed [20]; their benefits extend beyond optimizing blood pressure as they may decrease CNI-associated renal vasoconstriction [3]. Angiotensin-converting enzyme (ACE) inhibitors and beta-blockers play a significant role in blood pressure management in the general population and have an added morbidity and mortality benefit in post-MI patients. Their benefit in the SOT population is still under debate. In experimental models, ACE inhibitors and angiotensin receptor blockers (ARBs) attenuate the development of transplant arteriosclerosis and chronic rejection [3,21]; in patients they have the added benefit of reducing proteinuria. However, ACE inhibitors and ARBs decrease glomerular filtration rate (GFR), a concern for patients already taking immunosuppressive therapy as this can impair renal function [3,22]. For patients with known coronary atherosclerosis, some have suggested the use of a beta-blocker as the first line in the management of post-transplant hypertension [23]. However, the associated hypertriglyceridemia

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

and lowering of high-density lipoprotein (HDL) with beta–blocker therapy may not make it an optimal choice [3,21,24]. The management of hypertension in specific organ transplant populations is discussed in the sections that follow.

Dyslipidemia/hyperlipidemia

Dyslipidemia has been strongly implicated in the occurrence of CVD in the general population, as well as in SOT recipients [3]. Post-transplant dyslipidemia can be seen in approximately 25–50% of patients [25]. Immunosuppressive therapy has been implicated as an etiology for the occurrence and exacerbation of dyslipidemia/hyperlipidemia [3,25]. The use of cyclosporine A (CyA) in transplant and non-transplant patients alike has been proven to increase lipid and lipoprotein levels (see below) [3,26–28]. Concomitant use of corticosteroids with CyA augments this hyperlipidemic effect [3,29]. Patients taking tacrolimus have an improved lipid profile when compared to CyA, and MMF does not adversely affect plasma lipids [3,30,31]. Sirolimus use often leads to the greatest increases in cholesterol and triglyceride levels [3,32,33].

Treatment of dyslipidemia in the post-transplant population usually requires medication [3]; specific recommendations, when available, will be discussed in the sections that follow. Given the effect of certain immunosuppressive agents on lipid levels, changing immunosuppressive therapy to medications with reduced hyperlipidemic effects may also prove beneficial [3]. In cardiac transplant patients specifically, early introduction of lipid lowering agents not only improves lipid levels, but results in decreased cardiac allograft vasculopathy, decreased rejection, decreased maximal intimal thickening, and increased overall graft survival [34–36].

Diabetes mellitus

A significant increase in CVD-related morbidity and mortality has been associated with post-transplant diabetes mellitus (DM) [37,38]. Post-transplant DM has been reported in 3–19% of transplant patients, with an incidence as high as 25% in renal transplant recipients [39–41]. Immunosuppression plays a large role in the development of post-transplant DM. The CNIs, CyA and tacrolimus induce DM by diminishing insulin synthesis and secretion [39,42]. Corticosteroids are also known to cause or exacerbate DM in both transplant and non-transplant patients via induction of insulin resistance [39,42]. However, this effect is dose related and diminishes with decreasing corticosteroid dosing [3,43,44]. When corticosteroids are used in combination with CNIs, the diabetogenic effects are typically additive. Sirolimus use has also been associated with diabetes [45]; MMF has not been found to elevate blood glucose.

The treatment of post-transplant DM is discussed further in the sections that follow, but is similar to the treatment of diabetes in the general population. Dietary modification according to the American Diabetes Association (ADA), with restrictions on the consumption of carbohydrates, is recommended, as well as the use of oral hypoglycemics and/or insulin. Reduction in diabetogenic immunosuppressive medications can be considered in some SOT patients; however, this must be carefully balanced against the risk of rejection.

Obesity

Post-transplant improvements in nutrition, along with immunosuppression with steroids and CNIs, are associated with increased body weight [46–48]. Recipients of renal transplants have been noted to be overweight or obese prior to transplant more often than their heart, liver, and lung counterparts [49]. Up to 50% of renal transplant recipients have been reported to be obese, gaining an average of 10 kg in their first year post transplant [50]. Studies of liver transplant recipients have found a significant increase in body mass index (BMI) within the first year; 20–40% actually become obese (BMI $>30\,kg/m^2$) several years after transplant [46,51–53]. Of interest, BMI alone does not appear to be a risk factor for cardiovascular events in liver transplant patients [46,51–53].

A well-accepted association between obesity and several risk factors for CVD exists in the general population. Hypertension, DM, and hyperlipidemia are exacerbated by weight gain and improve with weight loss. Interestingly, obesity is also associated with increased inflammation, the newest identified risk factor for CVD (see Chronic inflammation section below) [54]. We can extrapolate that a similar relationship exists between obesity and cardiovascular risk in transplant recipients. Measures to optimize nutrition with attenuated caloric intake and increased physical activity are needed to decrease the influence of obesity on CVD [50,55].

Chronic inflammation

Atherosclerosis is a known chronic inflammatory process. C-reactive protein (CRP) levels predict cardiovascular events, CVD mortality, and cerebrovascular events in the general population [54,56]. These findings, along with increased mortality, extend to the SOT population, particularly to renal and heart transplant recipients [5,57]. Evidence of increased inflammation is present early post transplant, but appears to resolve in most patients over time [9]; liver transplant recipients have the lowest levels of inflammatory markers [9]. Smoking and obesity can both increase inflammation in transplanted and non-transplanted patients alike; however, other etiologies for increased inflammation exist for transplanted individuals [58]. Although it is debatable whether evidence of cytomegalovirus (CMV) infection is associated with CVD in the general population, elevated CMV antibody titers are highly associated with CVD in heart transplant patients [57]. Rejection also appears to play a key role in increased systemic inflammation, and can increase the risk of CVD in the heart transplant population [5,57]. Reducing the occurrence of rejection, and prophylaxis against and treatment of CMV may reduce chronic systemic inflammation and potentially reduce the risk of CVD (see Heart transplant section below).

Mechanisms of the adverse cardiovascular effects of immunosuppressive medications

Modern immunosuppressive therapy has made transplantation a practical treatment for organ failure. However, immunosuppressive medications come at a cost, resulting in an increased risk of infection, malignancy, and CVD. This section will review our understanding of the mechanism of this increase in cardiovascular risk; the clinical manifestations of this risk pertaining to different transplanted organs will be discussed in subsequent sections. Detailed discussions of the targeted mechanism of immunosuppressive drugs are found in Chapter 17.

Calcineurin inhibitors

The CNIs, CyA and tacrolimus, are chemically different but both exert their immunosuppressive effects by inhibiting the phosphatase activity of calcineurin, preventing the passage of nuclear factor of activated T cells (NF-AT) into the nucleus and thereby preventing the transcription of interleukin (IL)-2; this results in the suppression of T-cell activation, prevents the formation of cytotoxic T cells, and inhibits T-helper cell-dependent proliferation of B cells, effectively blocking the immune response [59]. However, the effects of these medications are not limited to the immune system; they are known to adversely affect cardiac risk by raising blood pressure, elevating plasma lipids, and impairing glucose metabolism. It is presumed that these adverse effects are the result of calcineurin inhibition beyond calcineurin's effects on T cells [60,61] as calcineurin is expressed in many tissues throughout the body [61].

Although incompletely understood, CNIs are known to have multiple effects that raise blood pressure [62,63]; CyA appears to have more potent vascular effects than tacrolimus. The primary mechanism of CNI-induced hypertension is through widespread arterial vasoconstriction that results in increased systemic vascular resistance [64]. The effect of vasoconstriction on the kidney is to promote sodium reabsorption and volume expansion. CyA potently activates the renin–angiotensin system (RAS) both by directly affecting juxtaglomerular cells, as well as secondarily activating the RAS through vasoconstriction of the renal vascular bed [65]; CyA also augments the vasconstrictive effects of angiotensin II [64]. CyA affects the balance between vasoconstrictor and vasodilatory metabolites of arachadonic acid, which results in net renal vasoconstriction [60]; it increases local release of the vasoconstrictor thromboxane and decreases the production of the vasodilator prostacylin from vascular endothelial cells [66]. Wadei et al. studied patients after liver transplantation [64] and reported that CyA and tacrolimus both suppressed the vasodilator prostacyclin for up to 2 years post transplant. They also reported marked elevations of urinary endothelin over this period, which was associated with decreases in renal blood flow and GFR, supporting an important role of both CNIs in causing renal vasoconstriction. Further, endothelin receptor antagonists improve renal blood flow and blood pressure in animal models of CyA toxicity [64]. Both CyA and tacrolimus have also been reported to inhibit the production of nitrous oxide [60].

Increased sympathetic nerve activity has been postulated as an important contributing mechanism to CNI-related hypertension, but this is not clear. Studies in renal transplant recipients [67] have demonstrated elevated sympathetic nerve activity, but this effect did not appear to be related to CyA use. However, more recent studies of sympathetic nerve activity in normal volunteers show that CyA, but not tacrolimus, does result in an acute rise in blood pressure and sympathetic tone [62]. Mechanisms of CNI-induced hypertension are listed in Table 88.1.

Table 88.1. Reported mechanisms of calcineurin inhibitor-induced hypertension

- Activation of renin–angiotensin system
- Augmentation of angiotensin II-induced vasoconstriction
- Renal vasoconstriction, sodium reabsorption, and volume expansion
- Increased thromboxane production
- Decreased prostacyclin production
- Increased endothelin production
- Increased sympathetic nerve activity

CNIs are also known to be important contributing factors to the marked lipid abnormalities that occur in kidney transplant patients, including elevations in total and low-density lipoprotein (LDL) cholesterol, lowering of HDL cholesterol, and hypertriglyceridemia, although the pattern of hyperlipidemia may vary markedly between patients. Radioactive tracer studies in rats demonstrate a reduction in the fractional clearance of LDL cholesterol, as well as an increase in the rate of cholesterol production [68]. The latter has been suggested to be related to reduced clearance of very low-density lipoprotein (VLDL) by the liver, resulting in increased conversion to LDL [69,70]. Studies by Rayyes et al. [71] demonstrate that CyA reduces LDL uptake and degradation into hepatic cells by 25%, which appears to be due to decreases in synthesis of the LDL receptor; CyA decreased LDL mRNA by about 40%. CyA has also been found to impair the internalization of LDL particles into human skin fibroblasts [72]. These observation imply that diminished cellular uptake of LDL may lead to elevated plasma levels. In addition, studies by Vaziri et al. in rats have found that CyA reduces the activity of cholesterol 7 alpha-hydroxylase, the rate-limiting step in the conversion of cholesterol to bile acids; reduction of the production of bile acids may contribute to the elevation of total cholesterol levels [73]. Other enzymes involved in bile acid synthesis, such as the 27-hydroxylase, may also be inhibited by CyA, leading to elevated intracellular cholesterol and effecting a reduction in the synthesis of the LDL receptor through negative feedback [69,74]. Studies in CyA-treated patients have demonstrated elevated cholesteryl esther transfer protein (CETP) levels, a protein that circulates bound to HDL and facilitates the exchange of cholesteryl ester from HDL to apolipoprotein B (apoB)-containing lipoproteins (VLDL and LDL) with reciprocal transfer of triglycerides [74]. This enrichment of VLDL and LDL with cholesteryl esters could contribute to their atherogenicity and to the atherosclerotic risk of CNIs in general. Tory et al. confirmed this elevation of CETP by CyA by in-vitro studies of human plasma, but tacrolimus did not cause this change [75]. However, both CyA and tacrolimus did markedly suppress lipoprotein lipase (LPL) activity and could account for the elevation in triglyceride levels seen in some transplant patients treated with CNIs. Follow-up studies confirmed the correlation of reduced LPL and elevated triglyceride levels in renal transplant recipients treated with tacrolimus. Total, HDL, and LDL cholesterol levels were unchanged, as were plasma CETP levels. Indeed changes in cholesterol are known to be less prominent in patients treated with tacrolimus than with CyA (see Renal transplant section below). Animal studies have consistently shown a reduction in LPL activity by CNIs [73] (see above).

Le Goff et al. [76] reported that CyA inhibits the ATP-binding cassette transporter ABCA1 in mice; ABCA1 plays a key role in removing cholesterol from macrophages in the arterial wall by mediating cholesterol and phospholipid transport to lipid-poor

HDL [77]. This effect is a possible mechanism that contributes to the low HDL cholesterol that may be seen in some renal transplant patients, and to increased atherosclerotic risk. Kockx et al. reported that CyA inhibits secretion of apoE from human macrophages via a calcineurin-dependent mechanism, but which was not dependent on ABCA1 [77]. ApoE directs movement of lipids from the periphery to the liver; binding of apoE to the LDL receptor facilitates uptake of lipoprotein particles by the liver and protects against atherosclerosis. These studies notwithstanding, the mechanisms by which CNIs affect lipid metabolism and cardiac risk are still only partly understood.

CNIs have long been known to result in impaired glucose metabolism, and to contribute to the development of new-onset diabetes after transplant (NODAT) [78,79]. CNIs impair insulin secretion [80]; tacrolimus has been found to impair insulin secretion to a greater extent than CyA, and is associated with a higher incidence of NODAT [81]. Studies by Heit et al. have demonstrated that calcineurin/NF-AT signaling is important for pancreatic beta-cell proliferation and functioning [82]; CNIs may block this signaling pathway in the beta-cell [83]. Tacrolimus has also been shown to have a direct effect to reversibly inhibit insulin gene transcription, which leads to a decline in insulin mRNA levels, resulting in decreased insulin synthesis and release [84]. A randomized study comparing tacrolimus and CyA in renal transplant recipients demonstrated reduced insulin secretion in patients who developed NODAT compared to those who remained normoglycemic; the reduction was greater in patients taking tacrolimus [81]. Further, biopsies of pancreas allografts reveal islet cell damage to be more frequent and more severe in patients taking tacrolimus compared with those taking CyA [85].

Corticosteroids

Steroid medications have long been a mainstay of immunosuppressive therapy for transplantation. However, the significant side-effects associated with this class of medications are well recognized, in particular their effects on elevating blood pressure and blood sugar, and in causing abnormalities of lipid metabolism which contribute to increased cardiovascular risk.

The primary mechanism by which steroids cause hypertension has been reported to be through promiscuous activation of the mineralocorticoid receptor [86], resulting in renal sodium and water retention with resulting volume expansion. While this may occur with the chronic use of steroids such as prednisone and methylprednisolone, which have mixed mineralocorticoid and glucocorticoid activity, the rapidity of onset of steroid-induced hypertension cannot be accounted for by an increase in renal sodium reabsorption [86,87], and spironolactone does not prevent the hypertensive response to glucocorticoid administration [87]. Peripheral vasoconstriction, causing an increase in peripheral vascular resistance, has long been recognized as a mechanism of glucocorticoid-induced blood pressure elevation [86–88]. Studies have shown that vascular endothelial and smooth muscle cells possess glucocorticoid receptors, which mediate cellular sodium and calcium uptake [89]. Glucocorticoids also up-regulate angiotensin II receptors [90]. Mangos et al. demonstrated that cholinergic vasodilation of forearm blood flow was inhibited by glucocorticoid administration, implying an impairment of the endothelial nitrous oxide system [91]. Studies by Goodwin et al. in mice, in which the glucocorticoid receptor was knocked out of vascular smooth muscle cells, revealed a marked diminution of the acute hypertensive response to glucocorticoids [86]. Taken together, these findings reveal multiple mechanisms by which glucocorticoids cause vasoconstriction that may result in hypertension.

Corticosteroids have also been associated with plasma lipid abnormalities in patients with and without organ transplants. Elevation in total cholesterol, LDL cholesterol, and triglyceride levels may be seen [92], along with decreases in HDL cholesterol [93]. Steroid-related weight gain, hyperinsulinemia, and insulin resistance are important mechanism that result in alterations in lipid metabolism [94]. Studies in animals have revealed elevations in LDL cholesterol and triglycerides resulting from increased hepatic synthesis of VLDL [95]. Insulin resistance also results in increased uptake of free fatty acids by the liver, contributing to VLDL production [92]. Inhibition of LPL activity increases plasma triglycerides. Other studies have found decreased LDL receptor and increased hydroxyl-3-methylglutaryl co-enzyme A (HMG-CoA) reductase activity [93], which results in increases in plasma LDL.

Glucocorticoids are known to play a role in worsening the blood sugar in diabetic patients and in the development of NODAT. They exert their effects through two mechanisms. First, they have been long known to produce insulin resistance that results in a decrease in peripheral glucose utilization, as well as in increase in production of glucose by the liver [96]. Glucose uptake and glycogen synthesis by muscle tissue are thereby both reduced. Insulin resistance also causes an increase in insulin secretion with fasting hyperinsulinemia. Second, glucocorticoids impair beta-cell function [96].

Sirolimus

Sirolimus causes hyperlipidemia in about 40–60% of liver and kidney transplant patients [97,98]. Hypertriglyceridemia and/or hypercholesterolemia with elevated LDL levels commonly occur. Kinetic studies by Hoogeveen et al. in renal transplant recipients demonstrated that sirolimus significantly decreases catabolism of apoB 100-containing lipoproteins [99]. The decrease in the fractional clearance of LDL apoB 100 resulted in hypercholesterolemia with elevated LDL levels. Hypertriglyceridemia was not related to changes in baseline LPL activity, but was related to a significantly reduced fractional clearance of VLDL apoB 100, resulting in decreased VLDL clearance. In vitro, sirolimus has also been demonstrated to down-regulate LDL receptor gene transcription, leading to a decrease in LDL cellular uptake [97,100]. This finding may in part explain the observed decrease in lipoprotein catabolism [98]. Further studies of sirolimus-treated renal transplant recipients by Morrisett et al. demonstrated an expanded free fatty acid pool [101]. Decreases in [$^{13}C_4$]palmitate incorporation into triglyceride suggested that sirolimus may interfere with insulin's stimulation of adipocyte triglyceride storage, resulting in an increase in hepatic fatty acid uptake and hepatic triglyceride synthesis, and contributing to hypertriglyceridemia. Recent studies in rats have found coordinated down-regulation of multiple genes involved in lipid clearance, fatty acid transport, and adipose tissue triglyceride synthesis and deposition [102], which may underlie the clinically observed elevations in plasma lipids. The pathogenesis of sirolimus-induced hyperlipidemia is only partially understood.

Sirolimus was initially thought not to adversely impact glucose metabolism [103]; however, more recent studies have clearly demonstrated the association of sirolimus with NODAT in patients after renal transplantation [45]. Johnston et al. studied over 20 000 patients from the United States Renal Data System (USRDS) and found an approximately 60% increase in the risk of NODAT when sirolimus was combined with a CNI (CyA or tacrolimus) and an almost 40% increase in risk when combined with an antimetabolite

(MMF or azathioprine) [45]. Other studies have also demonstrated the diabetogenic effect of sirolimus [104,105]. The mechanisms by which sirolimus impairs glucose metabolism are not clearly understood [45]. Proposed mechanisms include impaired insulin receptor substrate signaling [106], insulin resistance resulting from ectopic triglyceride deposition [45,107], and a toxic effect of sirolimus on pancreatic beta-cells [45,108]. A recent study in rats found that sirolimus directly induced transcriptional activation of gluconeogenic genes, resulting in severe glucose intolerance [102].

Cardiovascular disease in cardiac transplant patients

The average life span of a heart transplant recipient is approximately 10 years [5]. CVD, particularly ischemic heart disease, has a much higher prevalence among heart transplant recipients when compared to age-matched individuals in the general population, with an associated increase in morbidity and mortality [109]. Cardiovascular death is one of the top three causes of mortality among heart transplant recipients; some studies report it to be the leading cause of death during the first post-transplant year [5,110]. Given the small patient population, data regarding the benefits of risk factor modification are limited, and much of the data with regards to prevention and treatment of traditional CVD risk factors has been extrapolated from studies involving the general population.

Dyslipidemia

Dyslipidemia is one of the few risk factors that has consistently been proven to be associated with increased risk for cardiac allograft vasculopathy (CAV) [109–111]. The prevalence of this CVD risk factor is as high as 57.6% at the first year post transplant and increases to 93.3% 10 years post transplant [5]. Sanchez Lazaro et al. found dyslipidemia to be present in 68.3% of patients with CAV [110]. Pretransplant dyslipidemia has no bearing on the occurrence of CAV; however, post-transplant increase in total cholesterol, LDL, and triglycerides, as well as a low level of HDL, all have a significant association with CAV [111]. The increased incidence and prevalence of dyslipidemia post transplant is due to the use of steroids, CNIs, and/or sirolimus as a part of the immunosuppressive regimen (see above).

Treatment for dyslipidemia requires a multifactorial approach. Dietary modification in the form of reduced intake of saturated fats and cholesterol has been recommended by the American Heart Association (AHA) for the general population [25]. Omega-3 fatty acids, such as fish oils, have also proven to be beneficial in SOT recipients; this recommendation can be extrapolated to heart transplant recipients [25]. HMG-CoA reductase inhibitors are the most potent agents for treating dyslipidemia [25]. In cases of severe lipid abnormalities, dual therapy with a fenofibrate is recommended [25]. Care must be taken to assess for possible rhabdomyolysis or myopathy when using HMG-CoA reductase inhibitors in patients taking CNIs and/or fenofibrates [25]. Initiation of statin therapy, particularly pravastatin and simvastatin, early post transplant has been shown to improve survival and prevent CAV [35,36,109].

Hypertension

Hypertension is one of the most common traditional CVD risk factors among heart transplant recipients. According to the most recent International Heart Lung Transplant Registry, approximately 73.3% of patients have hypertension 1 year post transplant, which increases to 97.4% at 10 years [5]. Although there is a clear correlation between hypertension and CVD among the general population, the data regarding the association of hypertension with the occurrence of CAV are mixed. Some studies find a clear connection between hypertension and CAV, while other studies have not shown a significant association [109–113]. The increased incidence of hypertension seen after heart transplant is similar to that noted in other SOT recipients; this is due in part to the side-effects of immunosuppressive therapy. However, denervation of cardiac volume loop receptors also appears to play a role in the higher prevalence noted among heart transplant recipients [109].

Treatment of hypertension in heart transplant recipients may require more than one antihypertensive agent [109]. ACE inhibitors and calcium channel blockers have been proven to have significant benefit in this population [109]. Not only do these agents help to lower blood pressure by counteracting the renin–angiotensin–aldosterone system, and reducing renal afferent arteriolar vasoconstriction, respectively, but in small studies both have been shown to reduce coronary intimal thickening in heart transplant recipients, thereby reducing the severity of CAV [3,109,112,113]. In effect, both of these agents work to improve graft and patient survival after heart transplantation.

Diabetes mellitus

Approximately 15–27% of heart transplant recipients develop diabetes after the first postoperative year [5,109]. This value increases to almost 40% 10 years after heart transplantation [5]. The use of steroids and CNIs is strongly associated with the development of this traditional CVD risk factor, along with elevated pretransplant blood glucose, pretransplant metabolic syndrome, a family history of diabetes, and the need for insulin on the second postoperative day [109,114]. The impact of diabetes as a CVD risk factor is still debated in these patients. Some studies have reported diabetes to be a significant risk factor for CAV, while other studies have shown it to be an independent risk factor leading to increased infection and rejection, with hemodynamic compromise and decreased survival [111,115–117]. Still other studies have found diabetes to have little significance with respect to patient outcomes [118]. A report by Czerny et al. showed an 18% decreased 10-year survival in heart transplant patients with diabetes when compared to those without diabetes [116]. Interestingly, the same study also demonstrated no difference in the incidence of CAV between the two groups [116]. In contrast, Valantine et al. found elevated glucose levels to be associated with a significant increase in intimal thickness, decreased freedom from CAV (56% vs. 81%; $P < 0.01$), and decreased actuarial survival (60% vs. 92%; $P < 0.005$) when compared to those with normal glucose levels [117].

Treatment of diabetes in heart transplant recipients is similar to that in the general population. A diet low in carbohydrates, as well as the use of insulin and/or oral hypoglycemics as needed, can aid in maintaining euglycemia [109]. Reduction in the use of corticosteroids and CNIs can help decrease hyperglycemia. However, the risk of rejection with decreased immunosuppressive doses early on must be balanced against the benefit of lower glucose levels [3]. Although it appears there is a correlation between diabetes and decreased survival, increased infection, and increased CAV, it is unclear if treatment of diabetes will actually lead to improved morbidity and/or mortality [109].

Metabolic syndrome

Metabolic syndrome (MS) is defined by the AHA as central obesity, elevated triglycerides, low HDL, elevated blood pressure,

Table 88.2. Adult treatment panel III criteria for metabolic syndrome from the National Cholesterol Education Program

Abdominal obesity	Waist circumference >102 cm (40 in) for men and >88 cm (35 in) for women
Impaired glucose tolerance	Fasting plasma glucose level ≥100 mg/dL (5.6 mmol/L) or drug treatment for hyperglycemia
Hypertriglyceridemia	Triglyceride level ≥150 mg/dL (1.7 mmol/L) or drug treatment for high triglyceride levels
Low HDL levels	HDL level <40 mg/dL (1 mmol/L) for men and <50 mg/dL (1.3 mmol/L) for women or drug treatment for low HDL level
High blood pressure	Blood pressure ≥130/85 mmHg or drug treatment for hypertension

Note: The patient must have three or more of the listed criteria. The International Diabetes Federation uses the same criteria but expands the waist circumference criteria according to ethnicity (South Asians, Chinese, and South/Central Americans, 90 cm for men and 80 cm for women; Japanese, 85 cm for men and 90 cm for women; and all others, 94 cm for men and 80 cm for women). According to the International Diabetes Federation criteria, if the body mass index is >30 kg/m^2, central obesity can be assumed, and the waist circumference does not need to be measured.
Data from Watt et al. [365].

and elevated fasting glucose (Table 88.2) [119]. MS is thought to cause vascular dysfunction via a proinflammatory, prothrombotic state and is associated with increased CVD-related morbidity and mortality in the general population [120,121]. Studies have shown an association between MS and the occurrence of CAV [117,121,122]. Prevalence of MS is 18–39% in the general population; however, due in large part to immunosuppressive therapy, the prevalence of MS is approximately 43% in the heart transplant population [121,123]. Sanchez-Gomez et al. have shown that with increasing numbers of MS components, there is an increased incidence of CAV (Figure 88.2) [121]. When the coronaries were evaluated using intravascular ultrasound (IVUS), approximately 67% of heart transplant patients with MS were found to have CAV at 1 year post transplant [121,123].

Cardiac allograft vasculopathy

CVD in heart transplant patients is typically due to CAV or to rejection, and is one of the leading causes of death in this population. CAV is the leading cause of mortality after the first postoperative year, and accounts for 7% of deaths or retransplantation 5 years post transplant [5,57,109]. Typical symptoms of angina are unlikely to exist as these patients have denervated hearts (reinnervation rarely occurs). Both CAV and rejection can present as fatigue and shortness of breath due to heart failure, with ventricular arrhythmia and/or sudden cardiac death being the other possible manifestations. Given the difficulty of symptomatic recognition of either, scheduled evaluation is needed with right heart catheterization to assess hemodynamics, left heart catheterization to evaluate coronary anatomy, and endomyocardial biopsy to evaluate for rejection.

Table 88.3. Patient characteristics with regards to development of chronic allograft vasculopathy

CAV is an accelerated form of coronary artery disease (CAD). It afflicts approximately 50% of heart transplant recipients over a lifetime and diffusely affects the arteries, capillaries, and veins of the coronary tree [111,124,125]. One-year after transplant, approximately 5.5–7.8% of these patients are diagnosed with CAV [121,126]. Independent risk factors range from those typical for CAD (hyperlipidemia, DM, hypertension, etc.) to more atypical factors such as CMV serology and episodes of rejection (Table 88.3 and see below) [121]. Several retrospective analyses of heart transplant patients have been performed looking at the association of various CAD- and non–CAD-associated risk factors in the development of CAV [110,111]. Donor age of >50 years has been proven in several studies to be an independent risk factor for CAV [121,127]. CMV seropositivity, a non-traditional risk factor for vasculopathy, has also been associated with an increased occurrence of CAV [128,129]. A decreased incidence of CAV can be seen with the use of CMV prophylaxis in heart transplant recipients who are CMV positive or receive a heart from a CMV-positive donor [128]. Dyslipidemia, diabetes, and smoking are the traditional CAD risk factors that have the highest correlation with occurrence of CAV in heart transplant recipients [110,111,121]. Statins have shown not only to be beneficial in treating dyslipidemia, but also in decreasing immunoglobulin G (IgG) autoantibody levels and reducing the incidence of CAV [111]. Detailed consideration of CAV following heart transplantation can be found in Chapter 79.

Allograft rejection

Rejection rates are highest during the first year after transplant, and rejection is one of the leading causes of post-transplant mortality. Frequent evaluation with endomyocardial biopsies and blood sample testing for donor specific antibodies (DSA) aid in screening for both cellular- and antibody-mediated rejection. Allograft rejection can present as heart failure with decreased systolic function and changes on the electrocardiogram (ECG), with increased conduction time or a supraventricular arrhythmia (atrial fibrillation, atrial flutter, atrioventricular (AV) nodal re-entry tachycardia, etc.),

ventricular arrhythmia, or sudden cardiac death [130,131]. The gravity of this diagnosis requires immediate attention with appropriate immunosuppressive treatment, which can range from high-dose corticosteroids to treatment with plasmapheresis and intravenous immunoglobulin (IVIG) or thymoglobulin. The approach taken is based on the hemodynamic compromise noted and the protocols at each individual institution. A single episode of hemodynamically significant cellular- and/or antibody-mediated rejection decreases overall actuarial survival by 8–15%, freedom from CAV by 9–15%, and freedom from non-fatal major cardiovascular adverse events by 2–18% at 5 years post transplant [132].

Conduction abnormalities and atrial arrhythmias

Conduction abnormalities are common after heart transplantation; however, the cause of post-transplant rhythm disturbances cannot always be determined. Approximately 70% of initial ECGs after heart transplantation are noted to be abnormal; right bundle branch block is the most commonly found abnormality [133,134]. Leonelli et al. noted donor heart ischemic time and severity of early post-transplant in-hospital rejection to be associated with evolution of the initial ECG [133]. Patients whose ECGs demonstrated progressive conduction system damage over time, or were initially abnormal and remained abnormal, were noted to have an increased incidence of deterioration of left ventricular function and a higher mortality rate [135]. Patients with progressive conduction abnormality had higher rates of sudden cardiac death due to complete heart block or ventricular arrhythmias [135]. Over time, heart transplant recipients with normal ECGs that remained normal had the best outcome [135].

A study of over 1000 heart transplant recipients by Cui et al. demonstrated that approximately 11% of transplanted patients demonstrate some form of AV block on initial ECG [131]. At times this AV block was associated with atrial tachyarrhythmias [131]. Approximately 88% of the time, rejection was the etiology leading to these dysrhythmias. When the AV block was not associated with atrial tachyarrhythmias, the rate of associated rejection was only 36%, and was less severe [131]. Second-degree block, both Mobitz I and II, and complete heart block were much less common (2%); when they did occur, this was often during coronary interventions or endomyocardial biopsy [131]. Sinus node dysfunction has also been reported. A case series by DiBiase et al. found the incidence of sinus node dysfunction to be about 7%; rejection and sinus node artery vasculopathy were the most common causes of this dysrhythmia [136]. Permanent pacemakers should be implanted when sinus node dysfunction, symptomatic heart block, or concerning asymptomatic heart block (Mobitz type II or complete heart block) are present. If rejection is the underlying etiology, aggressive immunosuppressive therapy is required.

Cerebrovascular events

Neurologic events have been documented in 18% of heart transplant recipients, according to a review by the Mayo Clinic [137]. Eighty percent of ischemic strokes occur in the first 60 days post transplant, and account for 11% of diagnosed neurologic events; however, it is only perioperative stroke that carries a 1-year mortality with a hazard ratio of 4.17 ($P = 0.04$) [137,138]. After the perioperative period when stroke risk is highest, heart transplant recipients have a 4.1% 5-year stroke risk [138]. Approximately 40% of patients who suffer from an ischemic stroke were transplanted for a diagnosis of idiopathic dilated cardiomyopathy, compared to 12% who were transplanted for other indications [137]. These rates are noted to be approximately ten times those seen in heart transplant recipients prior to 1993 [137,139]. In the 1980s, ischemic events had a high association with hypoperfusion or atrial fibrillation [139]. In the current era, increased occurrence of ischemic events has been coupled with the selection of higher risk patients for transplant, such as those with worse cardiomyopathies. Emboli originate from the native heart, or may be released during manipulation and/or cross-clamping of an atherosclerotic aorta [137]. Prior history of stroke, hemodynamic instability, extracorporeal circulation for >2 h, cardiac arrest, and carotid stenosis of >50% have been noted as risk factors for perioperative neurologic events [138]. When looking at risk factors for the occurrence of strokes outside of the perioperative window, history of stroke, both ischemic and hemorrhagic, had the highest associated risk [138]. In a review by the Mayo Clinic, all heart transplant recipients who suffered neurologic events made complete or near-complete recoveries with an "excellent quality of life and outcomes" [137].

Cardiovascular disease in lung transplant patients

The mortality rate after lung transplant is highest during the first year, with a recipient survival of 84%, falling to 49% 5 years post transplant. The graft failure, infection, and mortality rates of lung transplant patients are higher than those of other solid organ recipients [13,14,140], but are continuing to improve. Several factors account for this relatively high mortality (Table 88.4). CVD-related

mortality is highest within the first 30 days post transplant and then decreases markedly (Table 88.4) [141]. However, CVD is not the leading cause of mortality among lung transplant recipients. Of interest, the use of modern immunosuppressive therapy has led to an increase in the occurrence of CVD risk factors (hypertension, DM, and hyperlipidemia) earlier and more frequently in lung transplant recipients compared to other SOT patients [13,142].

Cardiovascular mortality versus other causes

Unlike other SOT patients, lung transplant recipients have a much lower occurrence of CVD events (approximately 30%) and CVD mortality (approximately 10%) [5,14,15,142,143]. Christie et al. noted the increased 5-year mortality in lung transplant recipients to be due to a history of diabetes, human leukocyte antigen (HLA) match level, donor cause of death, and several post-transplant outcomes (Table 88.4) [140,141]. Plantier et al. noted these post-transplant outcomes to be the most significant over the lifetime of a lung transplant recipient, with sepsis the leading cause of death (34.6%), followed by bronchiolitis obliterans syndrome (18.5%), primary graft dysfunction (11.7%), and hemorrhagic complications (8.6%) [143]. Vadnerkar et al. found similar results even among recipients >60 years of age [144]. Interestingly, in a study of 73 patients requiring bilateral sequential lung transplants, Aratari et al. found bronchiolitis obliterans, not sepsis, to be the leading cause of long-term death, with three of these patients requiring retransplantation [145]. In an effort to decrease bronchiolitis obliterans occurrence, improvements in immunosuppression have been adopted with good results [141,144,145]. Cardiovascular events noted to occur most often after lung transplant include vascular events (8.9%), heart failure (7.4%), and atrial fibrillation (4.7%) [141,143]. Vascular events typically had a longer median time to event dates; 1227 days for acute coronary syndrome and 1490 days for severe symptomatic peripheral arterial disease (stage 2+), both with a lifetime occurrence rate of 2% [143]. Strokes, also a vascular event, occurred earliest post transplant at a median time to event of 191 days, with the highest rate of occurrence among the vascular events (5%) [143]. Pretransplant variables of diabetes, carotid atherosclerosis, and history of atherothrombosis events had the highest correlation with increased risk of post-transplant vascular events, with statistically significant hazard ratios (HRs) of 4.06, 3.05, and 7.7 respectively [143]. Heart failure had an incidence rate of 2.08 per 100-patient years in a study by Plantier et al. of lung transplant patients over a lifetime [143]. This is much higher than that seen in non-transplant patients aged 50–59 years [143].

Risk factors after lung transplant

Improvement in immunosuppression has caused an increased prevalence of new-onset hypertension, diabetes, and hyperlipidemia within the first year after lung transplant [13,141,142,146]. Each is an independent risk factor for CVD in non-transplant and transplant populations across the board. Approximately 90% of patients post lung transplant have developed one traditional CVD risk factor and approximately 40% have developed two or more traditional CVD risk factors by 3 years post transplant [146]. However, to date, no clear association between hyperlipidemia or hypertension and increased CVD events or mortality in lung transplant recipients has been documented [13,141–143]. A history of pretransplant diabetes does have a significant bearing on post-transplant CVD-related mortality [143]. Low cardiac index, atrial fibrillation, and elevated systolic pulmonary artery pressures prior to transplant are also related to increased CVD mortality [143].

Diabetes

Approximately 6–32% of lung transplant recipients develop new-onset diabetes in the first year after lung transplant [13,141,146]. The prevalence continues to increase with time; Christie et al. documented a prevalence of 26% at 1 year and 36% 5 years post lung transplant [141,146]. Of the typical CVD risk factors, diabetes has the strongest correlation with CVD events and mortality in lung transplant recipients. Post-transplant diabetes has an associated 5-year relative risk of mortality of 1.24 ($P < 0.05$) in patients who have survived for >1 year [141]. Silverborn et al. reported the risk factors most associated with the development of diabetes post lung transplant to be a higher mean CyA dose (7.2 ± 3.9 vs. 5.2 ± 2.0 mg/kg/day; $P = 0.006$) regardless of serum level, a diagnosis of cystic fibrosis ($P = 0.01$), and an elevated pretransplant blood glucose level ($P = 0.02$) [146].

A history of diabetes prior to transplant also confers an increased risk of both early postoperative (HR 2.3; CI 1.2–4.4) and later 5-year (RR 1.15; $P < 0.05$) mortality [141,143]. Survival is significantly decreased compared to that in non-diabetic lung transplant patients, with a decrease in 5-year survival from approximately 50% to 10% [143]. Pretransplant diabetes has also been associated with increased risk of atherothrombotic events (HR 4.06; $P < 0.05$) and CVD mortality [143]. Interestingly, the negative impact of diabetes on overall survival in lung transplant recipients may be due not only to its affect as a CVD risk factor, but also the role it plays in provoking and exacerbating infection.

There are currently no data demonstrating improvement in morbidity and/or mortality associated with optimal management of blood glucose in lung transplant recipients. Nevertheless, similar to other SOT recipients, the management of diabetes with diet and exercise, as well as the use of oral hypoglycemic agents and insulin as necessary, is recommended to decrease diabetes-associated morbidity, as well as to decrease the effects of diabetes on CVD and all-cause mortality.

Hypertension

Of the three traditional CVD risk factors discussed, hypertension has the highest prevalence among lung transplant recipients (Figure 88.3) [146]. Between 50% and 60% of these patients develop new-onset hypertension within the first year after transplant, with Silverborn et al. noting 69% having developed hypertension with a mean time to onset of 16 ± 13 months [13,141,146]. By 7 years post transplant, 75–85% of surviving patients have developed hypertension [13,141,147,148]. The mechanism of hypertension in this patient population is similar to that in other SOT recipients: vasoconstriction, chronic vascular structural changes, and sodium and water retention secondary to CNI and steroid use [13,148]. Interestingly, although the prevalence of hypertension is similar to that seen in other SOT recipients, in comparison the time to onset appears to be delayed, despite similar co-morbid conditions [148]. An abnormal circadian blood pressure profile noted by a lack of nocturnal drop in blood pressure, or nocturnal hypertension, has been documented in SOT recipients [13,149]. Vandergheynst et al. studied this phenomenon specifically in lung transplant recipients and noted that this phenomenon remains consistent over prolonged periods of time [149]. When compared to control subjects, a lack of reduction in both systolic and diastolic blood nocturnal pressure among lung transplant recipients was noted ($P < 0.01$ and $P < 0.001$, respectively) [149].

Silverborn et al. reported risk factors for developing post-transplant hypertension to be pretransplant diastolic blood pressure

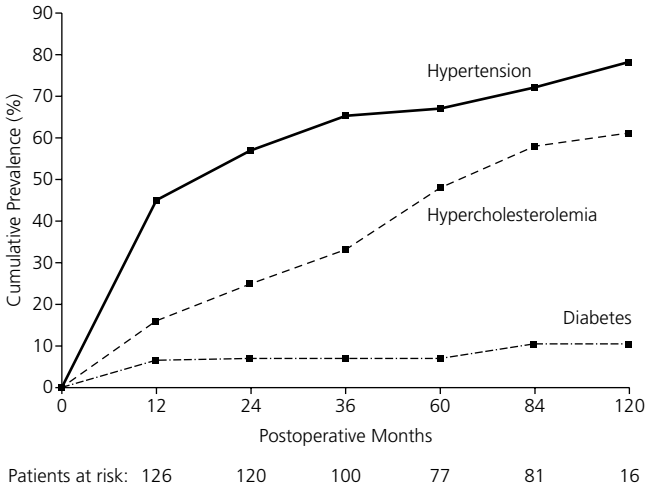

Figure 88.3. Cumulative prevalence of cardiovascular disease risk factors (hypertension, hypercholesterolemia, and diabetes) in post lung transplant patients. (Reproduced from Silverborn et al. [146], with permission from Elsevier. Copyright ©2005, Elsevier.)

and pretransplant blood glucose level on univariate testing ($P < 0.05$); only diastolic blood pressure proved to be significant on multivariate analysis ($P = 0.005$) [146]. Interestingly, no correlation could be identified between dose or serum level of CyA or prednisone and the incidence of hypertension [146]. This study found that patients with hypertension were noted to have significantly lower mean (41 ± 15 mL/min/1.73^2 vs. 47 ± 13 mL/min/1.73^2; $P < 0.05$) and minimum GFRs (33 ± 14 mL/min/1.73^2 vs. 38 ± 15 mL/min/1.73^2; $P < 0.05$) when compared to patient with normal blood pressure [146]. Surprisingly, Silverborn et al. also found that episodes of acute rejection were lower in patients with than without hypertension (0.6 ± 0.6 vs. 1.0 ± 0.8 per year of follow-up; $P = 0.002$) [146].

There are no current studies that demonstrate a correlation between hypertension in lung transplant recipients and the incidence of CVD [143]. However, based on our understanding of the progression of CVD in other SOT patients as well as the general population, standard guidelines for the treatment of hypertension should be followed in lung transplant recipients. Of note, this patient population very often requires more than one antihypertensive agent [13,148].

Hyperlipidemia

Hyperlipidemia is a well-known CVD risk factor in the general population. Goal-directed therapy based on co-existing CVD risk factors has been proven to reduce the incidence of CVD-related morbidity and mortality [150]. Due to the hyperlipidemic effects of immunosuppressive therapy, particularly sirolimus and prednisone, approximately 20% of lung transplant recipients will develop de-novo hyperlipidemia within the first year after lung transplant, almost 50% at 5 years, and 62% at 10 years, with a mean time to onset of 27 ± 21 months after transplant (Figure 88.3) [3,13,146]. Although an association of hyperlipidemia with the use of CyA has been noted, one study failed to correlate a difference in the serum concentration of CyA or prednisone with the occurrence of hyperlipidemia [146,151]. Silverborn et al. reported increased age, systolic blood pressure, BMI, and pretransplant serum triglyceride levels and serum cholesterol levels to be predictive of post-transplant hyperlipidemia on univariate analysis; however, in multivariate analysis only serum cholesterol was predictive [146]. They also observed decreased episodes of rejection among patients with higher lipid levels [146]. Interestingly, cystic fibrosis as the etiology of lung transplant has also been associated with post-transplant hyperlipidemia [146,151].

Although there is an increased prevalence and incidence of hyperlipidemia after lung transplant, no study to date has shown any increase in the occurrence of CVD-related events or mortality associated with hyperlipidemia in this population [141,146,151,152]. There is also no correlation between pretransplant hyperlipidemia and post-transplant CVD [143]. Similarly, treatment of post-transplant hyperlipidemia has not been shown to decrease the incidence of CVD-related events or mortality in this population. A relation between hyperlipidemia and the accelerated progression of chronic kidney disease (CKD) has been reported in lung transplant recipients [153]. Use of statins in this population has been shown to decrease the risk of CKD compared with patients who do not utilize statin therapy [153]. Despite the lack of a CVD-related survival benefit, an overall mortality benefit has been seen with the use of statin drugs after lung transplantation [153].

Management of hyperlipidemia and hypertriglyceridemia is based on similar strategies to those employed in the general population. Medications such as statins, niacin, omega-3 fatty acids, and fenofibrates can be prescribed to improve lipid levels. Care must be taken in the selection and combination of these medications due to drug interactions, which may occur due to the hepatic metabolism of some lipid-lowering and immunosuppressive agents.

Preoperative evaluation of cardiovascular disease

It is standard among lung transplant centers to evaluate recipients >60 years of age for CVD [141]. Some conflicting data exist regarding the correlation between pretransplant coronary disease and post-transplant outcomes. Vadnerkar et al. noted that in patients >60 years of age, pretransplant coronary disease is a risk factor for post-transplant mortality with a HR of 2.43 over a 5-year study period [144]. Sherman et al., however, noted no difference in incidence of CVD (including cerebrovascular events and MI) or survival rates among lung transplant recipients who were noted to have pretransplant coronary disease versus the control group over the same time period [154]. However, an increased risk of thromboembolic events has been associated with lung transplantation in recipients >60 years of age [144].

Post-lung transplant atrial fibrillation

Atrial fibrillation confers an increased risk of mortality in the general population, with an HR of 1.5–1.9, regardless of age [155]. This HR increases to 3.1 among lung transplant recipients with a pretransplant history of atrial fibrillation, with most events occurring in the early postoperative period [143]. In a study looking at 137 lung transplant recipients by Isiadinso et al., mortality rates as high as 43.5% were associated with post-transplant atrial fibrillation within 200 days of transplant [156]. De-novo atrial fibrillation was noted to occur in approximately 20% of lung transplant recipients, with a history of atrial fibrillation carrying an HR of 12.2 with regards to postsurgical atrial fibrillation [157]. In the study by Plantier et al., massive hemoptysis, likely due to anticoagulation for the arrhythmia, was one of the leading causes of mortality seen in lung transplant patients with a history of atrial fibrillation [143].

Although atrial fibrillation is the supraventricular tachycardia that most commonly occurs early after transplant, an increased

incidence of atrial tachycardia is noted >12 months after receiving a new lung [158]. Older age, primary pulmonary hypertension, and either obesity or being very thin increase the likelihood of developing atrial fibrillation [157]. In a study by Mason et al., peak occurrence of atrial fibrillation was seen 2 days after transplant with occurrence at a mean of 11 ± 9 days, and atrial tachycardia occurred at a mean of 1486 ± 2462 days [157]. Since atrial fibrillation originates as aberrant electrical activity around the pulmonary veins and can be induced by increased pulmonary pressures, the lower pulmonary pressures associated with double lung transplant provides protection from post-lung transplant atrial fibrillation [159].

Different strategies can be employed to treat atrial fibrillation after lung transplantation, including the use of pharmacologic agents and cardioversion. Cardioversion can be used to quickly return a patient to sinus rhythm [157]. Amiodarone is often used to control the heart rate and may result in chemical cardioversion. Interestingly, the use of amiodarone has been shown to be associated with an increased risk of mortality [156]. Isiadinso et al. observed that the increase in mortality among patients with atrial fibrillation was only seen in those who were treated with amiodarone [156]; patients who did not receive amiodarone had a mortality rate similar to that for those without atrial fibrillation [156]. This increase in mortality has been attributed to the pulmonary toxicity that is commonly associated with amiodarone use in lung transplant recipients [156]. Consideration should be given to performing prophylactic ablation to reduce the burden of atrial arrhythmias and improve post-lung transplant survival [159].

Other complications

Pericardial constriction

Pericardial constriction is extremely rare in the general population, with an occurrence of 0.1% [160]. Interestingly, it is even less common among lung transplant recipients. It is noted by a thickening of the pericardial sac, leading to limited cardiac filling, decreased end-diastolic volume, decreased stroke volume, and decreased cardiac output, or constrictive physiology. Equalization of diastolic pressures in the left and right ventricles is consistent with this diagnosis. Also, ventricular interdependence and deep "x" and "y" descents of the venous wave forms are appreciated. One may consider manipulation of the pericardium to place double lung transplant recipients at decreased risk for pericardial constriction [160]. Sever et al. performed a retrospective study of renal transplant recipients and noted the incidence of pericardial constriction to be 2.4% among this patient population, which is much higher than that documented among lung transplant recipients [161]. In an effort to prevent rejection, higher levels of immunosuppression are often maintained in the lung transplant population. It is very likely that this level of immunosuppression aids in preventing the inflammation needed to cause pericardial constriction, thereby making this an extremely rare complication in the post-lung transplant population [160].

Bronchial fistula to the pulmonary vein causing air embolism

The formation of post-surgical adhesions is a common occurrence after any surgery. After lung transplant, infectious and anastomotic complications can be the source of fistula formation between the bronchi and adjacent vasculature [162]. This fistula formation can occur as an early or late complication of transplant and can lead to air emboli being the etiology of ischemia. Although it is thought to be an extremely rare occurrence, bronchial–pulmonary vein fistulas likely occur more often than is noted [162]. This possibility should always be considered when evaluating a lung transplant recipient who presents with MI or peripheral ischemia. Prompt evaluation and diagnosis of this problem is necessary to provide a meaningful outcome for the patient [162]. Bronchoscopy, transesophageal echocardiogram, and/or cardiac computed tomography (CT) can be used to establish this diagnosis [162].

Compromise of the right coronary artery

Patients who undergo single lung transplant have been known to undergo a mediastinal shift;. this may occur immediately or late after transplant. A reported case of acute mediastinal shift was reported to have an associated "accordion" effect of the right coronary artery. Although there was good flow within the coronary artery, the kinking at the proximal portion of the right coronary artery led to positional changes in the inferior leads of the ECG [163]. Given these findings, percutaneous intervention was employed to successfully return adequate blood flow through the right coronary artery [163].

Cardiovascular disease in kidney transplant patients

Patients usually come to kidney transplant after a long period of CKD or ESRD requiring renal replacement therapy with dialysis. Hypertension and diabetes are the leading causes of ESRD and are also common in patients with other causes of renal failure. Hyperlipidemia and obesity are also frequently found in this population. These and other associated factors result in accelerated atherosclerotic CVD as well as myocardial dysfunction. The result is a 30–120% increase in the mortality of patients with CKD [164,165] and a staggering ten-fold increase in the risk of cardiovascular death in dialysis patients [166]. Although overall life expectancy is almost doubled by renal transplantation, CVD remains the leading cause of mortality in kidney transplant patients (Figure 88.4) [166]. It is fortunate that the rate of cardiovascular mortality after renal transplantation appears to be decreasing [167]; however, the risk is still three to five times that of the general population [7] and has played a major role in limiting the long-term survival of kidney transplant recipients [168]. This section will review known factors that contribute to cardiovascular risk after kidney transplantation, and review guidelines for managing these risks.

Congestive heart failure

Transplantation has been called a "state of accelerated heart failure" [168,169]. Congestive heart failure (CHF) and MI are the most common cardiovascular complications occurring in kidney transplant patients; among patients covered by Medicare, the rate of hospitalization due to cardiovascular causes in the first year post transplant was almost 15 admissions per 100 patient years at risk [166]. CHF was the most common primary cause, accounting for almost 25% of cardiovascular hospitalizations in the first 2 years, followed by approximately 17% related to coronary atherosclerosis or acute MI. A recent study by Lentine et al. of over 67 000 patients waitlisted for kidney transplant from 1995–2004, showed a more than doubling in the risk of CHF in the early post-transplant period (<90 days) compared with patients remaining on the waitlist; fortunately that risk quickly drops [170]. Rigatto et al. [169] studied 638 patients transplanted between 1969 and 1999 who were free from CVD 1 year post transplant; over 7 years of follow-up, de-novo

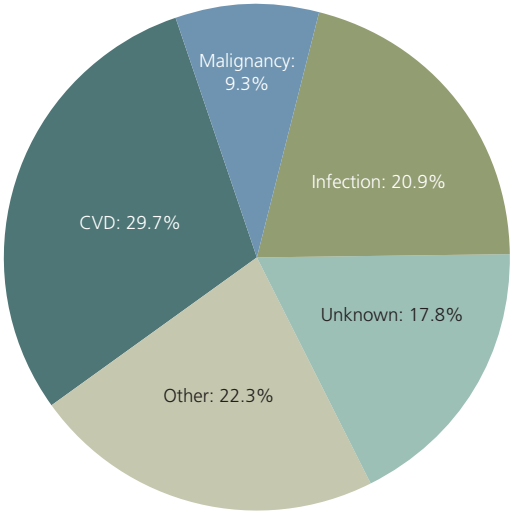

Figure 88.4. Causes of death with a functioning kidney transplant in first-time kidney-only transplant recipients aged 18 years and older, from 2005 to 2009. (Reproduced from United States Renal Data System (USRDS) [256].

CVD, cardiovascular disease.

CHF occurred as frequently as de-novo ischemic heart disease (IHD) and carried a similarly high risk for mortality; this pattern is distinctly different from that of a Framingham cohort that had a similar incidence of IHD but a much lower rate of CHF. In this study hypertension and anemia were two factors associated with the risk of developing CHF. In a subsequent study, Rigatto et al. found a strong correlation between the development of new ECG evidence of left ventricular hypertrophy (LVH) 5 years post transplant and the risk of CHF or death [171]; hypertension was the major predictor of the occurrence of LVH. Although the risk of CHF persists post transplant, the Lentine et al. study found that renal transplantation reduced the risk of CHF long term, compared with the risk in patients who remain on the waitlist; patients with living related donor transplants and those who were not obese experienced the maximum risk reduction [170]. Transplant can be expected to improve factors that contribute to the "uremic milieu," such as intradialytic weight gain, volume overload, hypertension, hyperphosphatemia, and anemia, which are associated with cardiovascular mortality [172], LVH, and "uremic cardiomyopathy" [173,174]. Further, most studies reveal an improvement in left ventricular systolic function [175] and in LVH in patients after renal transplantation [176–178]. A randomized study comparing lisinopril and nifedipine found a similar degree of regression of LVH in patients with well-controlled hypertension in the first year post transplant [178]. Of note, a small study by Patel et al. employing cardiac magnetic resonance, which may be more sensitive than echocardiography, did not document regression of LVH in 25 patients 2.5 years post transplant, compared with controls who remained on dialysis; these findings remain to be confirmed [179]. It is recommended that careful attention be paid to controlling blood pressure and volume status in renal transplant recipients; normalization of these factors is expected to help improve left ventricular function, and may reduce the occurrence of episodes of CHF [176].

Coronary heart disease

IHD is a common source of morbidity and mortality in renal transplant patients. Although less common than CHF, acute MI (AMI) is a complication that may occur in the early postoperative period or late post transplant [168]. Kasiske et al. [180] studied over 53 000 Medicare patients listed for transplant from 1995 to 2002. Cumulative incidence of AMI 3 years post transplant in patients receiving a deceased donor transplant was 6.1% and 4.2% in those receiving a living donor transplant; overall, transplant patients experienced a 17% reduction in AMI compared with patients remaining on the list. Of interest, the incidence of AMI was highest in the early post-transplant period, even in the face of the screening and coronary revascularization that usually occurs during the transplant evaluation. The next section will discuss the risk factors for coronary heart disease (CHD) that are of importance in renal transplant recipients.

Non-traditional risk factors

Hypertension, hyperlipidemia, and diabetes, which may be pre-existing, are common among renal transplant recipients and are important contributors to the risk of CVD. These conventional risk factors will be discussed in detail later. However, it has long been recognized that these risk factors do not by themselves adequately predict cardiac risk in renal transplant patients [38,181]. This point was made in 1996 by Kasiske et al., who studied 1000 kidney transplant recipients from Hennepin County Medical Center [38,181]. They found that pre-existing cerebrovascular, peripheral vascular, and CHD were associated with up to a nine times increase in cardiovascular events, while smoking, hypertension, and hyperlipidemia were not predictive of this composite endpoint (CHD, MI, and cardiac death or coronary intervention). They later reported that the use of the Framingham equation underestimated the risk of IHD after renal transplantation, particularly underestimating the risk in patients with diabetes [181].

Subsequent studies have found that non-conventional risk factors were strongly associated with cardiac events in kidney transplant recipients (Table 88.5) [169,182–184]. Recently, the Patient Outcomes in Renal Transplantation (PORT) study comprehensively evaluated non-traditional risk factors. PORT analyzed data from almost 24 000 patients from 14 transplant centers worldwide [185]. The conventional Framingham Heart Study variables cholesterol, hypertension, and the use of antihypertensive medications were individually correlated with CHD beyond the first year post transplant, but they did not improve the ability of their model to predict CHD events (Table 88.5). This study confirmed the association of pretransplant co-morbid cardiac conditions with post-transplant CHD events. Non-traditional risk factors that were also verified included obesity [183], duration of dialysis [184], diabetes, and hypertension as the cause of ESRD [182], as well as risk factors associated with poor allograft function such as deceased versus living donor transplant [169], episodes of acute rejection [169], and delayed graft function [182]. CKD stage is well recognized as a risk factor for CVD in the CKD population (see below) [186]. The up to 70% increase in cardiovascular events previously reported in patients with NODAT [187] was confirmed in the PORT study, although patients with diabetes pretransplant were at even higher risk, presumably due to longer diabetic exposure.

Table 88.5. Non-traditional risk factors for coronary heart disease post transplant

- Recipient age
- Male gender
- White race
- Body mass index >35 kg/m^2
- Panel reactive antibody (PRA) >10%
- Time on dialysis prior to transplant
- Deceased donor transplants
- Delayed graft function
- Acute rejection
- History of cancer pretransplant
- Post-transplant lymphoproliferative disorder
- New-onset diabetes post transplant
- Decreasing renal function
- Number of pretransplant cardiovascular comorbid conditions*

* Includes acute myocardial infarction, congestive heart failure, coronary revascularization, cerebrovascular accident, and revascularization procedures for peripheral arterial disease.
Data from Israni et al. [185].

It is likely that the predominance of non-traditional causes of cardiac disease is a reflection of years of damage to the cardiovascular system associated with progressive CKD and dialysis. It is well known that duration of dialysis has a major association with poor transplant outcomes. Of interest, cardiovascular mortality rates have been found to fall over time in patients transplanted before the age of 21 years while infection-related mortality rates remain stable [188]. This may imply a continuing positive influence of the transplant milieu, as opposed to the uremic milieu, on the cardiovascular system in this younger population with a shorter exposure to uremia-related cardiac risk factors. This finding is in direct contrast to that of the PORT study, as well as other studies of adults [189], which report high rates of CVD and mortality in long-term survivors of renal transplantation.

The PORT investigators point out that many of these non-conventional risks are potentially modifiable, including BMI, duration of dialysis, acute rejection, post-transplant lymphoproliferative disorder (PTLD), new-onset diabetes post transplant, and post-transplant renal dysfunction. It is also important to recognize that retrospective studies in no way imply that traditional risk factors should not be identified and treated [185].

Other non-traditional risk factors that have been identified as associated with CVD in the kidney transplant population include anemia [184], elevated CRP reflecting systemic inflammation [190], and homocysteine elevations [191]. Unfortunately, the Folic Acid for Vascular Outcome Reduction in Transplantation (FAVORIT) trial [192] found that folic acid did not reduce cardiovascular events in over 4000 kidney transplant patients randomized to folic acid or placebo, despite significant reductions in homocysteine levels in the treatment group. Studies reporting the cardiovascular effects of raising the hemoglobin concentration have shown mixed results. Heinze et al. [193] retrospectively studied almost 1800 renal transplant patients and found a decreased survival in those patients treated with erythopoietins and in those with higher hemoglobin values. On the other hand [194], a recent small study of 128 kidney transplant recipients randomized to treatment with β-erythropoeitin to normal hemoglobin values of 13–15 g/dL versus partial correction to 10.5–11.5 g/dL, showed the normalization group had significant slowing of CKD progression with improved quality of life; cardiovascular events were low in both groups. Although small, this study did not find the high rates of cardiovascular events previously reported to be associated with erythropoietin therapy [193] or in CKD patients, as previously reported in the Correction of Hemoglobin Outcomes in Renal Insufficiency (CHOIR), Cardiovascular Reduction Early Anemia Treatment Epoetin beta (CREATE), and Trial to Reduce Cardiovascular Events with Aranesp Therapy (TREAT) trials [195–198]. There may be a fundamental difference in the response to erythropoietin between patients with chronic allograft dysfunction and those with CKD of their native kidneys.

In the general population, CKD with reduced GFR is associated with a high prevalence of cardiac risk factors, as well as with an increased risk of cardiac events and of all-cause mortality [186,199,200]. Similar findings have also been demonstrated in the kidney transplant population; transplant patients with elevated creatinine levels and decreased estimated GFR have been shown to be at increased risk for cardiac death and for all-cause mortality [201,202]. Thus, cardiac risk may potentially be reduced through efforts to preserve renal function, such as avoiding episodes of rejection, reducing exposure to nephrotoxic medications, and controlling hypertension.

Hyperlipidemia

Hyperlipidemia is common among renal transplant recipients. Hypercholesterolemia occurs with a prevalence of approximately 40%, and hypertriglyceridemia in about 60% of patients [203]; HDL levels are usually normal, but low HDL levels may also be observed. Not only are these abnormalities of serum lipids strongly associated with an increase in cardiovascular risk, but elevations of both cholesterol and of triglycerides have each been associated with a decrease in renal allograft survival [204,205]. In the setting of hyperlipidemia, patients should be evaluated for contributing factors that may be amenable to medical therapy, including the nephrotic syndrome, hypothyroidism, excessive alcohol use, and liver disease [206]. Obesity, and diabetes are also frequently present, but immunosuppressive medications are the major contributors to lipid abnormalities. The adverse effects of CNIs, mTor inhibitors, and corticosteroids on plasma lipids are discussed in detail above. Of note, CyA has a greater adverse effect on the lipid profile than tacrolimus, although sirolimus is most likely to result in an extreme elevation of total cholesterol and triglycerides [207]. It has been theorized that the antiproliferative effects of sirolimus may mitigate some of the damage it could potentially cause to the vascular endothelium [203,208]; indeed, patients on sirolimus-containing regimens do not seem to have a noticeably higher incidence of cardiovascular events on short-term follow-up compared to CyA-treated patients [207]. Other drugs that are well known to contribute to hyperlipidemia include diuretics, beta-blockers, oral contraceptives, and highly active antiretroviral agents [206].

Drug therapy and lifestyle modification

The Assessment of LEscol in Renal Transplantation (ALERT) trial [209] published in 2003 is the only large randomized controlled trial of statin therapy in renal transplant patients, and continues to influence the use of lipid-lowering treatment in this population. In this trial, 2102 renal transplant recipients with total cholesterol of 4.0–9.0 mmol/L (150–350 mg/dL) were randomly assigned to fluvastatin or placebo and followed for up to 6 years. A significant decrease in both total and LDL cholesterol (32% reduction) was achieved. Despite a 17% reduction in the primary endpoint of major adverse cardiac events, defined as cardiac death, non-fatal MI, or coronary revascularization, the study did not reach statistical significance (odds ratio 0.83; 95% CI 0.64–1.06; $P = 0.139$). This was due in part to a lower than expected event rate; in retrospect, a study of 6800 patients would have been required to be

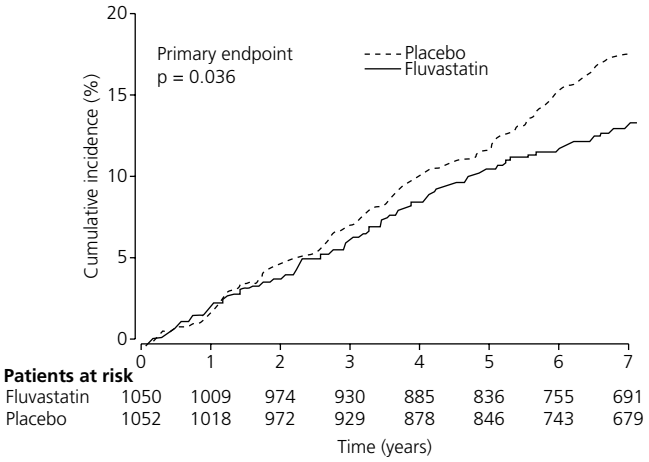

Figure 88.5. Cumulative incidence of major adverse cardiac events by original treatment group based on intention to treat (Kaplan–Meier estimates). (Reproduced with from Holdaas et al. [210], with permission from John Wiley & Sons.)

adequately powered to meet the primary endpoint. However, fluvastatin did significantly reduce the predefined secondary endpoints of cardiac death by 38% and of non-fatal MI by 32%. Further, a 2-year extension of ALERT also showed a significant 21% reduction in the primary endpoint of major adverse cardiac events (P = 0.036) (Figure 88.5) [210]. Set in the context of the many studies that have shown clear reductions in cardiovascular and cerebrovascular death and morbidity in patients without CKD [211], as well as the Study of Heart and Renal Protection (SHARP) trail [212], which demonstrated the efficacy of the combination of simvastatin and ezetimibe in reducing major atherosclerotic events in patients with advanced CKD, the ALERT trial offers strong evidence for aggressive treatment of hyperlipidemia in kidney transplant patients [203].

Although most statin drugs are generally safe and effective in lowering cholesterol [213], it is important to recognize that many statins, including simvastatin, atorvastatin, and lovastatin, are extensively metabolized through the same cytochrome P450 isoenzyme as CyA (CP3A4), resulting in elevation of plasma statin levels and a greater risk of rhabdomyolysis [214]. Simvastatin's package insert states that it is contraindicated in patients taking CyA, and although rosuvatatin clearance is not dependent on the 3A4 pathway, the manufacturer recommends that the dose be limited to 5 mg once daily in patients taking CyA to avoid increased drug exposure. Pravastatin and fluvastatin are metabolized differently and appear to be safe at their usual dosages. Significant interactions between tacrolimus and statin drugs may also occur, as well as interactions with fibrates and nicotinic acid derivatives that may increase the risk of muscle breakdown [214,215]. Most statins are metabolized in the liver, with the exception of pravastatin and lovastatin that have significant renal excretion. Although most statin drugs are not renally excreted, it is generally recommended that this class of medication be started at low doses in patients with CKD [216]. A high index of suspicion for rhabdomyolysis should be maintained for all kidney transplant patients taking statins, and CPK levels should be measured at baseline and in the presence of any muscle-related symptoms.

The 2003 Kidney Disease Outcomes Quality Initiative (KDOQI) dyslipidemia guidelines, updated in the 2009 Kidney Disease: Improving Global Outcomes (KDIGO) transplant guideline report, represent the most current assessment of the literature pertaining to the evaluation and treatment of lipid abnormalities in renal transplant recipients [206,213]. These guidelines differ in their recommendations from those for the general adult population as described in the National Cholesterol Education Program [217], although the association of lipid abnormalities and CVD is often extrapolated from that population. The general approach to detecting and managing lipid abnormalities in kidney transplant patients, as in CKD patients in general, considers these patients to be in the highest cardiovascular risk category. The KDIGO guidelines recommend that lipids should be measured before transplant, 2–3 months post transplant, and at least yearly thereafter. Drug therapy with a statin should be initiated for patients with a LDL cholesterol of 100–129 mg/dL who do not respond to 3 months of therapeutic lifestyle modification; lipids should be rechecked 2–3 months after a change in lipid-lowering therapy.

Despite the high prevalence of CVD among renal transplant patients, statin drugs appear to be underused. Pilmore et al. reported that only 62% of the PORT cohort with previous MI was treated with a statin [218], and Gaston et al. found only 59% of patients in the Long-Term Deterioration of Kidney Allograft Function Study with a history of CVD had received a statin 6 months post transplant [219]. Aspirin was also only prescribed in 75% and 59% of these two patient groups, respectively. These findings suggest that there is an opportunity to improve the management of transplant patients with and at risk for CVD through the appropriate use of lipid-lowering as well as other cardiovascular medications.

Change in immunosuppression

Withdrawal or avoidance of steroids may result in improvements of plasma lipids. A recent study by Vincenti et al. [220] found a reduction in weight gain, lipid-lowering medication use, and triglycerides in patients in whom steroids were avoided, or withdrawn early post transplant. A Cochrane review of 30 randomized controlled trials of steroid-sparing strategies found that steroid avoidance was associated with lower cholesterol levels in patients taking both CyA and tacrolimus, although a reduced need for lipid-lowering medication was only observed in the tacrolimus patients [221].

Hypertension

Hypertension is nearly ubiquitous in kidney transplant patients; 50–90% have blood pressure above 140/90 mmHg or are taking antihypertensive medications [10,64]. Ambulatory blood pressure studies of untreated patients have confirmed that 95% have BP readings over 130/80 mmHg [222]. As discussed previously, hypertension is an important risk factor for CVD in renal transplant recipients [223]. Reports, such as the Collaborative Transplant Study of over 24 000 deceased donor transplant patients, have also shown the degree of blood pressure elevation to be a major determinant of the rate of graft failure (Figure 88.6) [19].

Subsequent studies of this population showed that in patients with systolic blood pressure above 140 mmHg 1 year post transplant, who subsequently had their blood pressure lowered to below 140 mmHg, graft survival was improved compared with patients who remained hypertensive; for patients under the age of 50 years, cardiovascular deaths were also reduced [224].

In the immediate post-transplant period, CNIs and steroids are well known to cause or exacerbate hypertension. However, many

other factors contribute to the high prevalence of hypertension currently seen in renal transplant patients (Table 88.6) [225]. Important donor factors that can result in hypertension include the background of the deceased donor; in the pre-CyA era, studies by Guidi et al. suggested that patients receiving kidneys derived from donors with a family history of hypertension were more likely to develop hypertension themselves [226]. Recipients of kidneys from older donors are also more likely to develop hypertension [227,228]. Recipients who receive a transplant that is relatively small in relation to their body size have been found to require more antihypertensive medication [229]. Recipient factors are important as well: up to 90% of renal transplant candidates are hypertensive pretransplant [164]. These patients have evidence of vascular calcification and arterial stiffness, factors that contribute to blood pressure elevation and persist post transplant [230,231]. Obesity is also prevalent in this population. Transplant dysfunction with CKD can result from episodes of acute rejection, or can occur in the setting of chronic allograft dysfunction or recurrent renal disease. Occasionally, specific anatomic abnormalities, such as transplant renal artery stenosis, or obstruction related to ureteral stenosis or extrinsic compression, may be identified through appropriate diagnostic studies (see below). Specific factors that are important contributors to hypertension in kidney transplant patients will be discussed further below.

Calcineurin inhibitors

Hypertension was appreciably less of a problem in the era prior to the widespread use of CNIs in renal transplant patients [168,232], pointing to the central role current immunosuppressive medications play as a cause of elevated BP. The widespread use of CNIs in the setting of bone marrow, liver, and cardiac transplantation has also been associated with a marked increase in the incidence of hypertension [225], as well as in patients with autoimmune diseases. It has been noted that tacrolimus-treated patients have a lower incidence of hypertension than those treated with CyA [233]. Normal volunteers treated with usual doses of CyA, but not tacrolimus, exhibit raised blood pressure and reduced GFR and renal blood flow [234]. Cross-over studies have demonstrated that patients switched from CyA to tacrolimus have significant improvement in hypertension, but this reverses when CyA is reinstituted [235].

Although incompletely understood, CNIs are known to have multiple effects that raise blood pressure [62,63]. The mechanisms by which CNIs cause blood pressure elevation are discussed above.

Corticosteroids

Steroids have long been known to contribute to hypertension. The mechanisms by which steroids elevate blood pressure are discussed above; this occurs principally through vasoconstriction that results in an increase in peripheral vascular resistance. Although a randomized trial did not demonstrate a significant difference in blood pressure among CyA-treated patients who received prednisone, or underwent steroid withdrawal or steroid-free renal transplantation [220], a systematic review of 30 randomized controlled studies concluded that steroid-sparing and steroid withdrawal strategies reduced the need for antihypertensive medication [221]. Steroid use has dropped significantly over the past two decades; over 90% of kidney transplant patients received them in 1995 but this had decreased to approximately 60% in 2007 [236].

Transplant renal vascular disease

Hypertension resulting from decreased renal perfusion may come from obstruction of the main renal artery, or from disease of the renal microvasculature. Transplant renal artery stenosis (TRAS) is estimated to occur in up to 12% of hypertensive renal transplant patients [225], usually presenting as hypertension with varying degrees of renal failure. Trauma to the vessels, occurring during organ procurement or during the transplant procedure, and malpositioning of the allograft may be causes of TRAS that presents early post transplant. Suggested risk factors contributing to TRAS that occur late post transplant include CMV infection, rejection, and long cold ischemic time [237]. Doppler ultrasound is a good screening test for TRAS, but may overestimate the incidence of hemodynamically significant arterial obstruction. In one study [238], only about 25% of patients with elevated transplant artery peak systolic velocity had angiographically confirmed stenosis. Magnetic resonance angiography (MRA) using modern techniques may be also used to identify anatomic abnormalities of the transplant renal artery [239,240]. Arteriography remains the gold

standard for diagnosis, and angioplasty is usually technically successful; even so, blood pressure may not improve in all patients [241,242]. The presence of TRAS appears to negatively affect transplant outcome [237].

Thrombotic microangiopathy may complicate CNI therapy, malignant hypertension, or transplant glomerulopathy, or result from disorders of the coagulation system such as antiphospholipid antibody syndrome [243], or recurrence of diseases such as hemolytic uremic syndrome or scleroderma [244]. The clinical picture includes one of renal ischemia with resultant hypertension and renal failure, and may include thrombocytopenia and the characteristic hematologic abnormalities of hemolysis. The treatment depends on the underlying pathophysiology, but avoidance of CNIs is recommended. Renal prognosis is often poor [245]. Dragun et al. described a syndrome of malignant hypertension in kidney transplant patients with refractory vascular rejection, but without anti-HLA antibody, associated with the presence of antibodies to angiotensin II type 1 receptors [246]. These patients responded to treatment with plasmapheresis and the ARB losartan, with prolongation of graft survival. Infusion of these antibodies into rats resulted in hypertension with lesions of endarteritis. Subsequent studies confirmed a strong association of high-affinity antibodies to the angiotensin II type 1 receptor in patients with clinically diagnosed antibody-mediated rejection, also in the absence of anti-HLA antibodies [247], although malignant hypertension was not prevalent in this study. These antibodies can be identified in 3–4% of transplant candidates; whether this class of receptor-activating autoantibodies will be further borne out as clinically significant is currently unknown [248].

Treatment post transplant

There are no large randomized studies to guide treatment of hypertension in renal transplant recipients. The KDIGO practice guidelines recommend a target blood pressure of 130/80 mmHg or less based on practice guidelines in other populations at high risk for CVD, such as patients with hypertension and diabetes or CKD [213]. This appears to be a reasonable treatment goal; it is consistent with the recommendations of the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) [249]. Controlling blood pressure can be expected to reduce cardiovascular events and to prevent accelerated loss of allograft function [225].

Lifestyle modifications such as diet, exercise, and reduction of the consumption of sodium and alcohol are recommended first steps in the treatment of hypertension, and may result in an improvement in blood pressure control [250]; however, the institution of antihypertensive medication is usually required. Although there are small trials comparing antihypertensive medications [251], there are no large studies that clearly indicate the superiority of any particular class of drug. The choice of antihypertensive agent is often dictated by the patient's co-morbidities and the experience of the transplant center. No agent is contraindicated in renal transplant patients [213], except for endothelin receptor blockers; CyA decreases their hepatic metabolism and can result in elevated blood levels [64]. Dihydropyridine calcium channel blockers are often prescribed due to their efficacy, safety, and the theoretical advantage that they counteract the vasoconstriction caused by CNIs (see above) [64]. Caution should be exercised when prescribing the non-dihydropyridine calcium blockers verapamil and diltiazem as they potently inhibit the cytochrome P450 3A4 isoenzyme, and result in elevation of tacrolimus and CyA levels. Calcium channel blockers may also potentiate CNI-induced gingival hyperplasia [64]. Beta-blockers are often prescribed in renal transplant recipients, and are particularly beneficial in patients with underlying CVD. Diuretic medications are useful in the post-transplant period where volume overload may be present; however, resulting volume depletion and prerenal azotemia may result in elevation of the serum creatinine level. ACE inhibitors and ARB blockers are also effective antihypertensive agents and have been demonstrated to reduce post-transplant proteinuria [252]; their use has been advocated as cardioprotective agents [219]. There are currently no clear data to recommend blockers of the renin–angiotensin system over other classes of antihypertensive medication; adverse effects of ACE inhibitors and ARBs in the transplant population include anemia and hyperkalemia. Recent reviews of the management of hypertension in renal transplant recipients are available [63,64,225].

Diabetes

Diabetes is the leading cause of ESRD in the US; it is listed as the cause of ESRD in 46% of patients initiating dialysis [253] and also occurs in patients with other causes of ESRD. Almost 24% of transplant patients have diabetes as their primary renal diagnosis [254]. Diabetes has long been recognized as a risk factor for CVD, and many transplant programs subject prospective diabetic kidney transplant recipients to extra scrutiny for evidence of pre-existing CVD prior to listing. For instance, Cosio et al. reported on 933 first transplant recipients at the Mayo Clinic from 1998 to 2006 [187]. Patients who were diabetic at the time of transplant had a higher rate of cardiovascular events (25%), cardiovascular mortality (12%), and all-cause mortality (19.3%) over the 46 months of follow-up, compared with patients without diabetes (7.4%, 1.1%, and 6.1%, respectively; $P < 0.0001$); not surprisingly, diabetic patients also had a much higher incidence of prior CVD. Recently, Kuo et al. reported on 37 448 primary transplant recipients from 2004 to 2007 from the Organ Procurement and Transplantation Network/United Network for Organ Sharing (OPTN/UNOS) database who survived for 1 year post transplant [255]. They found that patients with pretransplant diabetes had an adjusted 89% increase in cardiovascular mortality ($P < 0.001$).

NODAT has been increasingly recognized as a serious problem. The most recent USRDS data report shows the cumulative incidence of post-transplant diabetes to be approximately 30% at 1 year and >40% at 3 years post transplant in adults, and >10% 3 years post transplant in pediatric patients younger than 18 years of age [256]. However, the incidence may have been over-reported, as the criteria used for NODAT were not known. Valderhaug et al. [257] studied 1410 consecutive first-time renal transplant recipients without diabetes, and performed oral glucose tolerance testing 10 weeks post transplant on those who had not already developed NODAT. Using the current ADA criteria, they found 17% of patients developed NODAT and 22% had impaired glucose tolerance. This high incidence of NODAT occurs in an era in which almost 90% of patients use tacrolimus as their initial CNI [236]; tacrolimus use has been strongly associated with NODAT (see above) [78]. The current criteria for the diagnosis of diabetes as defined by the ADA and the World Health Organization are listed in Table 88.7.

New-onset diabetes after kidney transplantation has long been recognized as a risk factor for mortality. Kasiske et al. [78] studied

Table 88.7. Current criteria for the diagnosis of diabetes as defined by the American Diabetes Association and the World Health Organization (WHO)

1 Fasting plasma glucose of ≥126 mg/dL (7.0 mmol/L). Fasting is defined as no caloric intake for at least 8 h*
or
2 Symptoms of hyperglycemia and a casual plasma glucose of ≥200 mg/dL (11.1 mmol/L). Casual is defined as any time of day without regard to time since last meal. The classic symptoms of hyperglycemia include polyuria, polydipsia and unexplained weight loss
or
3 2-h plasma glucose of ≥200 mg/dL (11.01 mmol/L) during an oral glucose tolerance test. The test should be performed as described by the WHO, using a glucose load containing the equivalent of 75 g of anhydrous glucose dissolved in water*

*In the absence of unequivocal hyperglycemia, these criteria should be confirmed by repeat testing on a different day.

11 659 patients reported to the USRDS who had received first kidney transplants from 1996 to 2000 and were not diabetic. NODAT developed in 24% of these patients by 36 months, and was associated with a 47% increase in death from CVD ($P = 0.0140$) and an 87% increase in death from all causes ($P < 0.0001$). Cole et al. [258] reported on 27 707 first kidney-only transplants from the USRDS database transplanted from 1995 to 2002. They found that patients with NODAT experienced a relative risk of death with a functioning graft of 1.41 (1.25–1.59), which was presumed to be from CVD. In Valderhaug et al.'s study [257], post-transplant diabetes patients experienced an 80% relative increase in the risk of cardiovascular death ($P < 0.05$) and a 54% relative increase in all-cause mortality ($P < 0.05$). Each 1-mmol/L (18-mg/dL) increase in plasma fasting glucose was associated with a 19% increase in cardiovascular mortality risk ($P < 0.05$). Of interest, in Kuo et al.'s study of over 35 000 patients, those with NODAT had a 15% increase in risk of cardiovascular death, which was not statistically significant [255]. This negative finding may be related to the short 1.5-year follow-up period, or to incompleteness in the reporting of NODAT (only a 6.6% reported incidence at 1 year post transplant). The morbidity and mortality risk associated with NODAT requires further study.

Risk factors for NODAT

Many important risk factors for NODAT in renal transplant recipients are not modifiable and include African–American and Hispanic ethnicity, male gender of either the recipient or the donor, increasing number of HLA mismatches, and a family history of diabetes in a first-degree relative; infection with hepatitis C virus (HCV) or CMV also confers increased risk [78,103,142,259]. Increasing age is an important risk factor; patients who are over age 45 years have over twice the risk of NODAT compared with younger patients [78]. Autosomal dominant polycystic kidney disease has been reported to be associated with an increased risk for NODAT [260]; however, more recent studies have not confirmed that finding [261,262]. Potentially modifiable risk factors include obesity, which is increasingly common; up to 60% of renal transplant recipients have been reported to be overweight or obese [263]. In a report by Shah et al., patients who were overweight (BMI 25–30 kg/m^2) have a 1.5-fold increased risk, and those who were obese (BMI >30 kg/m^2) a 1.8-fold increased risk, of NODAT [261]. Other potentially modifiable risk factors include episodes of acute rejection (which may be related to the resulting steroid treatment) and the use of CNIs, mTOR inhibitors, and corticosteroids [103]. In particular, NODAT occurs more commonly with tacrolimus than with CyA [78,79]. The mechanisms of impaired glucose tolerance relating to immunosuppressive medications are discussed above.

Management post renal transplant

Modification of the immunosuppressive regimen

The mechanisms by which corticosteroids, CNIs, and sirolimus impair glucose tolerance have been reviewed above. Reducing the doses of, or in some cases eliminating, these medications must balance the potential improvement in blood sugar control with the risk of rejection. Studies of steroid withdrawal or avoidance, summarized in the Cochrane review by Pascual et al. [221], indicate a decrease in the rate of NODAT, particularly in patients taking CyA; patients taking tacrolimus did not seem to benefit from steroid withdrawal. Confirming these observations, two recent randomized studies of steroid avoidance, or early withdrawal, did not find a reduction in NODAT in patients taking tacrolimus and low-dose prednisone [220,264]; however, the steroid-free groups did require less antidiabetic medication. In patients at high risk for NODAT, a strategy of rapid steroid tapering, or steroid withdrawal, should be considered if a steroid-free regimen is not the standard of care. Similarly, selected patients may benefit from a change from tacrolimus to CyA, although the potential exists for worsening of hypertension and hyperlipidemia, and the resulting overall change in cardiovascular risk is unknown [263]. High tacrolimus levels above 15 ng/mL in the early post-transplant period seem to convey an increased risk for persistent impairment of glucose control and should be avoided [265].

Lifestyle changes and medical therapy

Changes in lifestyle aimed at improving diet and increasing exercise are important ingredients for controlling diabetes in transplant and non-transplant patients alike. If adhered to, active lifestyle modification has been shown to improve glucose control in patients with and at risk for NODAT [266]. However, many patients will go on to require treatment with hypoglycemic medications. There are currently no randomized studies on which to base drug selection in the management of diabetic patients after renal transplant; practice guidelines such as KDIGO offer only general advice [213]. A stepped approach, starting with monotherapy with an oral agent, and escalating through combination therapy with the eventual institution of insulin, is in keeping with consensus guidelines for the management of diabetes in the overall population [263,267]. A recent review by Yates et al. suggests institution of hypoglycemic therapy if the hemoglobin $A1_c$ ($HbA1_c$) remains above 7.0% despite lifestyle measures [263]. The KDIGO guidelines suggest considering a target $HbA1_c$ of 7.0–7.5% to avoid severe hypoglycemic reactions, which have been shown to be more common in kidney transplant patients treated with an intensive glucose control regimens [268]. All classes of hypoglycemic agents have been prescribed to this patient population. Considerations in transplant patients include the fact that many sulfonylureas raise CyA levels, which should be carefully monitored; this effect does not occur with glipizide, which may be preferred [263,269]. Gastrointestinal upset can occur with metformin use, and particularly may be problematic in patients taking mycophenolic acid; swelling and a possible increase in cardiovascular events may have been reported with thiazolidinediones

[263]. If insulin therapy is required, many endocrinologists recommend the use of morning NPH insulin, as its duration of action matches the pharmacokinetic profile of oral glucocorticoids. Recent reviews of the management of diabetes in renal transplant recipients are available, and international consensus guidelines were published in 2003 [103,142,263].

New immunosuppressive agents

Belatacept is a member of a new class of immunosuppressive agents that work by blocking costimulation signals (signal 2) between T cells and antigen presenting cells, thereby preventing T-cell activation [270]. Belatacept is a fusion protein that is intravenously administered monthly in place of a CNI. In the Belatacept Evaluation of Nephroprotection and Efficacy as First-line Immunosuppression Trial (BENEFIT), in which belatacept was randomly compared to CyA in 1209 patients who also received MMF and prednisone, the absence of a CNI resulted in lower systolic and diastolic blood pressure, non-HDL cholesterol, and triglycerides [271]. Further, the patients treated with a belatacept-based regimen had an estimated GFR that was 21 mL/min/1.73 m^2 higher than in the CyA group after 3 years of study [272]. Although graft and patient survival have not yet proven to be superior in patients who receive belatacept, the markedly reduced cardiovascular risk profile and improvement in renal function associated with this class of medication offers promise for decreased CVD and increased patient and allograft longevity in the future. It is not known whether existing renal transplant patients with, or at high risk for, CVD would benefit from conversion to a belatacept-based regimen.

Tofacitinib is an inhibitor of Janus kinase (JAK), a tyrosine kinase that participates in signaling from multiple cytokine cell surface receptors essential for T-cell, B-cell, and natural killer cell function [273,274]. A preliminary study compared tofacitinib with CyA in renal transplant recipients. Tofacitinib-treated patients showed improved renal function and a lower incidence of NODAT; however, there was a higher incidence of serious infections, hematologic abnormalities, and PTLD in the tofacitinib group [274]. In the future this class of medications may provide an alternative to current agents, but with a lower profile of cardiac risk.

Cardiovascular disease in pancreas transplant patients

Pancreas transplantation is a successful method for treating diabetes; simultaneous kidney and pancreas transplantation (SPK) accounts for over 70% of pancreas transplant procedures [275]. Although type 1 diabetics have traditionally been considered the only candidates for pancreas transplantation, type 2 diabetics have increasingly benefited from this operation [276].

Compared to patients who undergo deceased donor kidney transplant alone, patients with a successful SPK transplant have a significantly improved survival. Of note, SPK and living donor transplant recipients with type 1 diabetes have similar excellent patient and graft outcomes [277]. Because living donor and SPK recipients have different characteristics, it is hard to compare these two groups precisely; living donor patients are older, have higher rates of co-morbid cardiac disease, receive kidneys from older recipients who are less likely to be African–American, may receive a pre-emptive transplant, and have better HLA matching compared with SPK patients [277]. Recent multivariate analyses have tried to take these differences into account, and have come to different conclusions. Young et al. analyzed the UNOS database and found living donor transplant recipients have superior outcomes [278]. However, Weiss et al. examined Scientific Registry of Transplant Recipients (SRTR) data and reported the outcome advantage of living donor recipients to be concentrated in the first year post transplant; SPK patients with pancreatic allografts functioning >1 year had the best long-term patient and graft survival rates [277]. Patients receiving a pancreas after a living kidney transplant also have good long-term results [279]. The improved outcomes of pancreas recipients are likely due to the long-term salutary effects of euglycemia.

Restoration of euglycemia after pancreas transplantation has been shown to slow and eventually halt the progression of diabetic retinopathy [280] and neuropathy [281,282], as well as to prevent the recurrence of diabetic nephropathy in the simultaneously transplanted kidney [282]. Changes of diabetic nephropathy have been found to pathologically reverse in patients who undergo pancreas transplant alone [282].

Pancreas transplant patients have often been reported to experience an improvement in cardiac risk factors that includes a reduction in total cholesterol and serum triglycerides, as well as lowering of both systolic and diastolic blood pressure [283,284]; but not all studies have consistently found these improvements. Pancreas transplantation has also been seen to have an effect on improving macrovascular disease. Larsen et al. studied patients before and approximately 2 years after pancreas transplant; they reported improvement on ultrasound in carotid intima-media thickness (IMT), which has been correlated with the risk of cardiac events [285]. In a cross-sectional study, Fiorina et al. also found the improvement in IMT, and further reported an improvement in endothelial function; endothelial-dependent dilation of the brachial artery was found to normalize in SPK patients but not in patients with kidney transplants alone [286]. Jukema et al. performed quantitative coronary arteriography on 26 SPK patients with functioning pancreatic grafts and on six patients who had lost their grafts [287]. After a mean of 3.9 years, progression of coronary atherosclerosis was markedly slowed in patients with functioning allografts; lesion regressed in 38% of these patients compared with 0% of patients in whom the pancreatic graft was lost. Left ventricular systolic and diastolic function has been shown to improve to a greater extent in SPK patients as well [288,289]. Rates of acute MI [288,290] and congestive heart failure [288] have also been reported to be lower in patients with combined pancreas and kidney transplants, compared with patients receiving a kidney transplant alone.

Taken together these data provide strong evidence that pancreas transplantation improves both microvascular and macrovascular disease, and provides a benefit in cardiovascular morbidity and mortality. Nevertheless, CVD is still a leading cause of morbidity and death in this patient population [288,291].

Cardiovascular disease in liver transplant patients

Improvements in orthotopic liver transplantation (OLT) have resulted in patients living longer than ever before. Current 1- and 5-year survival rates are 85% and 67%, with a 10-year survival of over 50% [292]. Steadily improving patient survival rates are related to improvements in surgical technique, and in the medical management of these patients both pre- and post-operatively. Although patients with significant underlying CVD are not considered candidates for liver transplantation, now that patients are surviving

longer CVD is becoming an important cause of morbidity and mortality in this patient population [293]. Further, risk factors for CVDs, such as hypertension, hyperlipidemia, diabetes, and the metabolic syndrome are becoming increasingly prevalent post OLT. Cardiac complications are also a common cause of death in the immediate postoperative period [294]. Liver transplant patients have been reported to have higher cardiovascular death rates compared to the general population [295]. Of note, liver transplant recipients are becoming older every year, with the most recently available data showing that the average age has increased from 46 years in 2000 to almost 50 in 2009 [292]; patients over the age of 65 years are the most rapidly growing group, increasing from 7% of OLT patients in 2000 to over 11% in 2009. Along with this increase in age comes an increase in cardiac risk factors. Although less prevalent than in kidney or cardiac transplant, patients coming to liver transplant often have underlying CVD, which may be unrecognized. This section will review the factors that contribute to cardiovascular risk after liver transplantation, and discuss management guidelines.

Postoperative cardiovascular complications

Patients undergoing liver transplant are at high risk of cardiovascular complications in the days and weeks following transplant surgery; cardiac complications are a leading cause of perioperative death [294].

Although a relatively small number of patients have underlying CHD (see below), cirrhotic cardiomyopathy is a common occurrence [296]. The identification of abnormal cardiac function in cirrhotic patients is attributed to Kowalski and Abelmann [297]; later classic studies by Regan et al. [298] and by Gould et al. [299] uncovered an abnormal increase in left ventricular end-diastolic pressure, and a notable decrease in cardiac contractility in cirrhotic patients, under the stress of angiotensin administration or exercise. It is now accepted that cirrhotic cardiomyopathy occurs in alcoholic and non-alcoholic patients alike [296]. Clinically, patients exhibit abnormalities in systolic and diastolic function when challenged by stress; however, the peripheral vasodilation and reduced afterload that occurs in patients with liver disease may prevent clinically apparent CHF.

These underlying cardiac abnormalities leave patients at risk for adverse cardiac events during and after liver transplant surgery. During the operation, bleeding, third space fluid shifts, and ongoing production of ascites may result in marked drops in preload, while overly aggressive volume replacement with fluids or blood products may result in postoperative volume overload [296]. Underlying impairment of myocardial diastolic and systolic function increases the risk of reduced cardiac output and hypotension, and of pulmonary edema. Pulmonary edema is common; it has been reported to occur in 22–56% of OLT recipients in the first postoperative month [294]. The rapid increase in blood pressure and systemic vascular resistance that occurs post transplant places a stress on the heart and, in the setting of fluid administration, may account for the common occurrence of pulmonary edema; most clinical episodes resolve with appropriate medical therapy [296,300]. Even in the absence of evidence of, or risk factors for, underlying heart disease, Eimer et al. reported 7% of 86 patients with normal heart catheterizations and normal echocardiograms developed severe heart failure after liver transplantation [301]. It is critical that careful monitoring of hemodynamic status is done in the intraoperative and perioperative periods, with meticulous attention to fluid balance and electrolytes, to minimize acute cardiovascular complications.

Sampathkumar et al. reported the rare development of dilated cardiomyopathy in the early post-transplant period (seven of 754 patients); cardiac function subsequently improved [302]. Studies by Torregrosa et al. have shown that the structural and functional abnormalities of cirrhotic cardiomyopathy typically resolve by 9–12 months post OLT [300,303].

Post-reperfusion syndrome (PRS) is another complication that can occur in the immediate postoperative period. It was initially described by Aggarwal et al. in 1987 [304], and is defined as a decrease in mean arterial pressure of at least 30% and a decrease in heart rate for 1 min within the first 5 min after reperfusion. Associated hemodynamic findings include elevation of pulmonary artery, central venous, and pulmonary capillary wedge pressure, and a decrease in systemic vascular resistance [305]. This syndrome is incompletely understood, and is attributed to postoperative metabolic abnormalities, such as metabolic acidosis and hyperkalemia, and to vasoactive substances released from the allograft. PRS occurs in approximately 30% of liver transplant recipients [306]. A review by Hilmi et al. of 338 patients transplanted at the University of Pittsburg from 2002 to 2003 found that patients with more severe PRS were sicker, required longer intensive care unit and hospital stays, and were more likely to be retransplanted. However, these patients did not have a decrease in 5-year survival [307].

Other cardiac complications that can occur postoperatively include atrial and ventricular arrhythmias, MI, air embolism [308], intracardiac and pulmonary embolism [309], and cardiac arrest [294,310]. Fouad et al. reported on 324 OLT patients over 40 years of age who were transplanted between 2002 and 2007. Twenty-three patients suffered an intraoperative cardiovascular event, including two patients who died of PRS. Of twenty-one patients who died in the first 6 months, five (23%) deaths resulted from direct cardiac causes, making CVD the leading cause of death after surgery in this study [294]. Other studies have estimated cardiovascular complications to account for 7–15% of deaths post transplant [296,311].

Long-term cardiovascular death and coronary heart disease

It is now common for patients to die of CVD after liver transplantation [294]. Although early reports found CVDs to be an unusual cause of death [312–314], recent data have demonstrated cardiovascular deaths to be an increasingly important problem. Abbasoglu et al. prospectively collected data on 1174 OLT patients transplanted from 1985 to 1995, and found that 17% of patients who had survived for $>$ 1 year died of CVD or stroke at a mean of almost 5 years post transplant [315]. CVD was reported to cause death in 8.3% of 4000 consecutive patients reported by Kashyap et al. from the University of Pittsburg, with a mean follow-up of 9.4 years [316]. Pruthi et al. reported CVD as the cause of death in 21% of 299 adult patients transplanted between 1984 and 1977 who survived for at least 3 years post liver transplant; most had previously recognized coronary disease or known cardiac risk factors [317]. Rabkin et al. reported that 13% of late mortality unrelated to recurrent liver disease resulted from cardiovascular causes among 459 patients transplanted between 1991 and 2000 [318]. Johnston et al. studied 110 consecutive OLT patients and found a 2.56 relative risk for cardiovascular death compared to an age-matched population; 16% of the patients died of CVD over the 3.9-year median follow-up period [295]. Albeldawi et al. reported cardiovascular events in 775 patients transplanted at the Cleveland Clinic from 1996 to 2008; 83 patients (10.7%) died from cardiovascular-related causes over the 40-month mean follow-up period, the third most

common cause of death after liver failure and infection [319]. Watt et al. have recently published a detailed study of 798 patients from the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) database transplanted at multiple centers between 1990 and 1994, and followed for a median of 10 years [320]; almost 20% of deaths not related to hepatic disease were due to cardiovascular causes [320]. Diabetes, hypertension, renal insufficiency, and patient age were important factors associated with death beyond 1 and 5 years post transplant [320]. A review of these studies reveals that, along with hepatic disease, infection, and malignancy, CVD causes a significant proportion of deaths after liver transplantation, and is an increasingly important problem.

Coronary artery disease (CAD) has been reported to have a high prevalence in patients referred for liver transplant, but is often unrecognized. Carey et al. studied 37 consecutive patients over 50 years of age who were referred for OLT and underwent coronary arteriography at the Cleveland Clinic [321]. Although 30 patients had no history of heart disease, 10 patients (27%) had moderate or severe CAD and six patients (16.2%) severe CAD; diabetes was found to be the most significant risk factor. More recently, Tiukinhoy-Laing et al. reported cardiac catheterization results from 174 consecutive end-stage liver disease (ESLD) patients over the age of 45 years who were referred for OLT between 2000 and 2003 [322]. Risk factors were common in this patient group; half of patients had hypertension or diabetes and one-third were current or previous smokers. Sixty percent of patients had angiographic coronary lesions; 26% had previously unknown coronary disease that was moderate or severe. Patients with known CHD have significantly increased morbidity and mortality after OLT [323,324]. The increase in mortality is well demonstrated by Yoo and Thuluvath's analysis of 18 044 patients recorded in the UNOS database undergoing OLT between 1988 and 2001, in whom the absence or presence of CAD and diabetes was recorded prior to transplant (Figure 88.7). A history of CAD or diabetes were both independent risk factors for an approximately 40% lower 5-year survival; patients with both conditions demonstrated a 60% survival decrease [324].

Cardiac events post transplant

Despite routine screening of transplant candidates for CVD, cardiovascular events after liver transplantation are common [319].

In Johnston et al.'s study [295] of 110 patients assessed at a median of 3.9 years post OLT, 25 ischemic and 32 non-ischemic cardiovascular events occurred (early postoperative events were excluded). The relative risk of ischemic cardiac events was 3.07 compared with the expected risk in a matched population. Mazuelos et al. found 9.4% of 170 OLT patients experienced cardiovascular complications after 5 years of follow-up [53]. In the Albeldawi et al. study, 83 patients experienced one or more cardiovascular events over the 40-month follow-up, with a calculated cumulative event rate of 13.5% over 5 years. Multivariate analysis identified independent risk factors that included post-transplant metabolic syndrome (PTMS), age, male gender, and post-transplant diabetes and hypertension. MMF was also found to be a risk factor, but was felt to be a surrogate for renal failure as it was used when CNIs resulted in side -effects requiring a significant reduction in dose [319]. Laryea et al. reported on 118 patients in the Canadian Transplant Atlantic Registry receiving liver transplants between 1998 and 2004 [325]. Over 58 months of follow-up, 25 major vascular events occurred, including acute coronary syndrome, MI, transient ischemic attack (TIA), and stroke. Significantly more events (21 vs. 4; $P = 0.003$) occurred in patients with PTMS. Laish et al. reviewed the files of 248 patients undergoing liver transplant from 1991 to 2007, and reported similar results. Twenty-three patients experienced major vascular events over the 6.2 years of follow-up; these were significantly more common in patients with PTMS (17 vs. 6, $P = 0.027$) [326]. A recent report from the Mayo Clinic sought to define cardiac risk in 230 adults receiving transplants between 1998 and 2001 and followed for a median of 8.2 years; 59 cardiac events occurred, including clinically documented CAD (angina or angiographically significant stenosis), CHF, CVA, peripheral vascular disease, or cardiovascular death [293]. Although multiple risk factors were prevalent among this population, multivariate analysis confirmed pretransplant diabetes, prior smoking history, and prior cardiac disease as independent risk factors. In addition, elevated troponin I levels predicted the observed cardiovascular events, possibly reflecting underlying cardiac microvascular disease or unrecognized left ventricular dysfunction.

Cardiovascular risk factors

Cardiac risk factors are common in patients after OLT. Single center observational studies of relatively small numbers of patients, as reviewed above, may be too underpowered to confirm factors in liver transplant patients that are known to be associated with cardiac risk in the general population. The Framingham risk factors of hypertension and hyperlipidemia, in addition to diabetes and obesity, may be present before transplant, but are increasingly common after OLT. It can be presumed that they play an important role in causing cardiovascular morbidity and mortality in liver transplant recipients.

The high prevalence of cardiac risk factors in this population is in large part due to exposure to immunosuppressive medications. CNIs and corticosteroids play important roles in increasing blood pressure and blood glucose, as well as resulting in dyslipidemia (see above section on Mechanisms of the adverse cardiovascular effects of immunosuppressive medications); sirolimus may also contribute

Table 88.8. Risk factors for cardiovascular disease in liver transplant patients

- Patient age
- Male gender
- Diabetes pre or post transplant
- Hypertension pre or post transplant
- Dyslipidemia
- Obesity
- Post-transplant metabolic syndrome
- Non-alcoholic fatty liver disease
- Smoking
- Pretransplant cardiovascular disease
- Chronic kidney disease
- Troponin I

to cardiac risk. Cigarette smoking at the time of listing increases cardiac mortality [327]. Other contributors to the risk of CVD include patient age, a history of pre-existing cardiac disease prior to transplant, CKD, and non-alcoholic fatty liver disease (NAFLD) (Table 88.8) [328]. A significant number of patients with multiple risk factors exhibit the metabolic syndrome, which is becoming increasingly common after liver transplantation [329]. The next section will expand on the role of selected important risk factors in liver transplant patients.

Hypertension

Hypertension is common in liver transplant recipients; estimates of the incidence range from about 30% to 80% of patients [330]. The use of CNIs appears to play an important role in de-novo hypertension; this incidence is demonstrably higher in patients treated with CyA than with tacrolimus (Figure 88.8) [331,332]. The use of corticosteroids also contributes to hypertension. Studies of OLT without steroids, and of late steroid withdrawal, demonstrate improved blood pressure [333,334].

Other factors contributing to the high incidence of hypertension include obesity (see below) and the development of CKD, which is common after liver transplantation, attaining a cumulative incidence of approximately 20% after 5 years [335].

There are no specific evidence-based practice guidelines for the management of hypertension in liver transplant recipients. A target blood pressure of 130/80 mmHg has been suggested by recent reviews [330,336,337]. As with hypertension in the general population, changes in lifestyle, including weight reduction, exercise, and decreased dietary sodium, are recommended, but if not successful institution of antihypertensive medication is required. Liver transplant recipients may be successfully treated with a variety of agents; there are no large studies in this population on which to base therapy, although recommendations for treating hypertension in the general population and in renal transplant recipients may be used as a guide [213,249]. Calcium channel blockers are recommended based on their excellent safety profile and on the theoretical advantage that they may counteract the vasoconstriction that occurs with CNIs [338,339]. It is recommended that the non-dihydropyridine calcium channel blockers, diltiazem and verapamil, be used with caution, as they raise CNI levels by competing with cytochrome P450 3A4. Beta-blockers are preferred for patients with CHD, and are also well tolerated by most patients. ACE inhibitors and ARBs have been recommended for patients with CKD and with proteinuria. A small randomized study of nifedipine versus carvedilol in patients with de-novo hypertension after OLT found that carvedilol was better tolerated; both drugs lowered blood pressure to target levels by themselves in only a minority of patients [340]. Indeed, many patients will require a combination of blood pressure medications. Consideration may be given to changing immunosuppressive medication in selected patients. Corticosteroids can be reduced or eliminated. Patients on CyA can change to tacrolimus, or a regimen can be instituted based on MMF or sirolimus.

Hyperlipidemia

Although ESLD patients often have low serum cholesterol, due to impaired hepatic cholesterol synthesis and esterification, hyperlipidemia commonly occurs after liver transplantation [341]. About half of OLT recipients have hyperlipidemia, although this fraction may be decreasing over time [342]. For instance, Laryea et al. studied 118 liver transplant patients who had been followed for at least 18 months; 46% developed dyslipidemia with 45% having abnormal triglycerides [325]. In Johnston et al.'s report of 110 patients studied in 1999, and followed for a median of 3.9 years, 44% had raised serum cholesterol, 52% a low HDL, and 8% elevated triglycerides [295]. Neal et al. reviewed 181 patients receiving OLT from 1994 to 1999 with a median follow-up of 54 months [343]. Hypercholesterolemia was present in 16% of patients prior to and 60% after transplant, and the percentage of patients with elevated triglycerides increased from 10% to 40%. Mixed hyperlipidemia is most commonly seen post transplant, but isolated elevation of cholesterol or triglycerides may also be seen.

As with hypertension, immunosuppressive medications play a major role in abnormal lipid metabolism. CNIs, sirolimus, and corticosteroids all result in dyslipidemia; the mechanisms by which this occurs are discussed in detail above. Diet, obesity, and diabetes also contribute to lipid abnormalities (see below). CyA has been stated to cause more dyslipidemia than tacrolimus after OLT, and switching from CyA to tacrolimus has resulted in decreases in cholesterol [344]. However, recent studies reported different findings; one study comparing these two drugs found similar levels of total cholesterol and triglycerides 1 year post transplant in patients without baseline lipid abnormalities [345]; this observation has been confirmed [346].

Dietary modification is not usually sufficient to normalize plasma lipids, and lipid-lowering medication is usually required. Statin

drugs are safe and effective agents after OLT, and are well tolerated with a low incidence of adverse effects [347]. A variety of statins have been used safely in transplant patients. It is probably wise to start with a reduced dose, such as atorvastatin 20 mg/day or pravastatin 20 mg/day, both of which have been studied in liver transplant patients [348,349]. The drug interaction between statins and CNIs is discussed above. There are no evidence-based guidelines to provide guidance on choosing a threshold cholesterol level for treatment. We recommend that liver transplant patients be considered at high risk for CVD, and that LDL cholesterol be kept below 100 mg/dL (2.6 mmol/L). Ezetimibe may be added safely if the LDL target is not achieved with a statin or statin drugs are not tolerated [350]. Fish oil and fibric acid derivatives can be used to treat triglyceride elevations and are generally safe.

Of interest, liver transplantation has been used to treat homozygous familial hypercholesterolemia, including preemptively before the development of severe CVD [204].

Diabetes

Diabetes is becoming increasingly common after liver transplant. The prevalence is about 15% prior to and 30–40% post transplant [351]. Earlier studies reported a prevalence of 13–27% [352], but more recent studies have found a much higher prevalence. For instance, Larea et al. reported an increase in diabetes from 13% to 61%, and Laish et al. an increase from 14.4% before to 39.6% after liver transplantation [325,326]. This increase in prevalence may be explained in part by the use of a lower cut-off fasting blood sugar of 126 mg/dL to define diabetes established by the ADA (Table 88.7) [325,352,353]. Risk factors for developing NODAT in liver transplant patients include patient age over 50 years, male gender [354], BMI over 30 kg/m^2 [355], use of tacrolimus as compared to CyA [355], and infection with CMV [356]. HCV infection plays an important role as a risk factor for developing NODAT in liver and kidney transplant recipients [259,355], and has also been linked to type 2 diabetes in non-transplant patients [355,357]. Hepatic infection with HCV leads to insulin resistance [358,359]; the virus can also infect pancreatic β-cells that could potentially lead to a decrease in insulin production [360]. In both liver and kidney transplant patients, HCV seems to cause NODAT most commonly in patients taking tacrolimus compared with CyA [259,355]. Denervation of the transplanted liver itself may result in insulin resistance and contribute to NODAT [361]. As reviewed above, the occurrence of diabetes in liver transplant patients is strongly associated with CHD, cardiovascular events, and cardiac death [293,319–321].

As with other transplant patients, treatment of diabetes after liver transplant is similar to that in the general population [351]. It should be noted that the liver metabolizes most sulfonylurea and thiazolidinedione drugs; these agents should be used carefully and preferably in patients with normal and stable graft function [362]. Steroid dosage should be minimized [330]; in selected patients, conversion from tacrolimus to CyA or to a CNI-free regimen may be considered to improve glucose tolerance [363,364].

Obesity and the metabolic syndrome

PTMS is becoming an increasing problem among liver transplant recipients. We have already discussed many of the individual components of the MS, including hypertriglyceridemia, low LDL, hypertension, and impaired glucose tolerance above (Table 88.2) [351]. Abdominal obesity is also prevalent among adults in general and liver transplant patients in particular. The presence of ascites can make the assessment of central obesity difficult [351], thus some programs use a BMI above 30 kg/m^2 as an additional criterion for MS [325]. Obesity occurs in over one-third of ESLD patients and non-alcoholic steatohepatitis (NASH) is continuing to increase as a cause of ESLD requiring liver transplant. Overall the MS has been reported to occur in 5–29% of patients prior to liver transplantation, and has a prevalence of 43–58% in liver transplant recipients [365]. PTMS has been demonstrated to be an important risk factor for major vascular and cardiac events after liver transplantation, although an increase in cardiac mortality has not yet been shown [319,325,326]. PTMS is managed by addressing the individual components that contribute to cardiac risk. In addition to diet and exercise, the use of orlistat has been found to be a safe adjunct for weight loss in liver transplant patients [366].

Summary

Transplant patients suffer the same cardiovascular ills as the general population, but are encumbered by the augmentation of these conditions by their primary diseases and the acquired effects of their immunosuppressive drug regimens. As general transplant outcomes have improved and patients have enjoyed longer post-transplant lives, cardiovascular-related conditions now represent the most significant threat to long-term outcome. As such, all transplant physicians should diligently address modifiable risk factors and seek to mitigate acquired risks to avoid premature morbidity and mortality due to CVD. This should go hand in hand with the more recognized plans for immunosuppressive drug management.

CHAPTER 89

Monitoring for HLA Antibody after Organ Transplantation

Robert A. Bray and Howard M. Gebel
Histocompatibility and Molecular Immunogenetics Laboratory, Department of Pathology, Emory University Hospital, Atlanta, GA, USA

Introduction

A peripheral biomarker capable of informing the state of an allograft, particularly as it relates to the adequacy of immunosuppression, is much needed for all organ transplants, particularly those like the heart for which a useful functional surrogate is not available. Although many biomarkers exist and some have been tested to a degree, the presence of donor specific antibody (DSA) is the most widely published and best validated. Indeed, DSA monitoring is increasingly recognized as a critical part of the postoperative management of all allograft recipients. While DSA monitoring is known to relate well to clinical outcome, it nevertheless has substantial nuances that the clinician should be aware of in order to follow a transplant recipient with appropriate rigor. This chapter will examine the existing strategies for following DSA post transplant, and outline their interpretation and ability to yield useful information about the post-transplant immune status of a solid organ recipient. Specific information about the tests used for DSA detection and operation of a histocompatibility lab are covered in Chapter 36.

Rationale

There are many reasons to identify clinically informative biomarkers of rejection; they include detection of subclinical rejection, differentiating rejection from conditions resulting from over immunosuppression, and identifying patients whose immune suppression can be minimized or eliminated. There is little doubt that the presence of DSA post transplant is a harbinger of an inferior outcome compared to individuals devoid of DSA. This holds true for renal, cardiac, lung, and possibly liver allografts, as will be discussed below [1–4]. If monitoring for HLA DSA is to be performed, there are several questions that must be addressed:

- When and how often is monitoring needed?
- What method of monitoring DSA is most informative?
- How can it be determined when and if the presence of DSA predicts poor outcome and conversely, when and if the absence of DSA indicates an immune tolerant state?
- What should be done with the information obtained?

DSA and transplant outcomes

Renal transplants

In a multicenter retrospective study involving 1329 recipients of deceased donor renal transplants, Terasaki et al. reported that the 4-year graft survival was only 58% among recipients with de-novo HLA antibody but 81% among recipients without HLA antibody [5]. The hazard ratio for graft loss in recipients with HLA antibody was 3.3. While these results were intriguing, there were several limitations to this study, including incomplete classification of rejection and reasons for graft loss, which included death with a functioning graft. Nonetheless, these data supported the earlier speculation that there was a significant association between HLA DSA and graft rejection [6], and suggested the clinical relevance of de-novo HLA antibody even though its incidence was <20% on average. Subsequently, Lee et al. [7] showed that de-novo DSA detected within the first year after transplantation was more deleterious than DSA detected after the first post-transplant year. Similar findings were described by Li et al. [8] who reported a 5-year graft survival rate of 96% among HLA antibody-negative recipients of living donor transplants compared to a 69% 5-year graft survival rate in recipients who developed de-novo HLA DSA. In a subsequent and longer term study by Lee et al. [9] of renal transplant recipients, the 5-, 10-, and 15-year graft survival rates for those in whom de-novo DSA was never detected were 85%, 75%, and 56%, respectively, and in recipients who developed de-novo HLA DSA, were 65%, 53%, and 28%, respectively. These differences were highly significant. Lachmann et al. [1] went on to show that even late producers of de-novo DSA, i.e. >5 years post transplant, had decreased long-term graft survival (49% vs. 83% in DSA-negative patients; $P < .0001$). In addition to DSA alone, Lachmann et al.'s data also indicated that a combination of DSA and graft function, as measured by glomerular filtration rate (GFR), could better identify patients with decreased long-term allograft survival. DSA alone, although associated with decreased long-term survival, was not as significant as DSA in conjunction with a decreasing GFR. Interestingly, Lachmann et al. also showed a small decrease in graft survival among individuals who developed non-DSA HLA antibodies. This is an interesting observation and may have several explanations. Since these individuals were only assessed at a single time point post transplant, it is possible that DSA could have been adsorbed to the graft and not yet detected in the serum of the recipient. The HLA antibody that was detected may be part of a broader immune response to related HLA specificities; i.e. cross-reactive groups. Lastly, non-DSA HLA antibodies could be a surrogate marker for other, non-HLA DSAs. There is a growing body of literature that indicates other non-HLA DSAs may play a role in graft failure in the absence of HLA DSA [10,11]. Future

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

strategies for post-transplant monitoring will most likely need to include such assays.

In earlier studies by Terasaki and Ozawa [12], an association between serum creatinine, HLA DSA, and outcome was established. For recipients with de-novo DSA and a serum creatinine of <2.0 mg/dL, the 2-year graft survival was not significantly different from that in individuals with no DSA. However, for DSA-positive recipients whose creatinine values were >2.0 mg/dL or >3.0 mg/dL, the graft failure rate rose significantly to 17.9% and 16.3%, respectively.

Thus, the combined data of Terasaki and Lachmann shows that DSA alone is important, but not as significant as the combination of DSA plus a functional parameter, e.g. serum creatinine or GFR. These data also suggest that not all DSAs are immediately deleterious. It is well known that some patients with DSA maintain good long-term allograft function. The challenge, then, is for investigators to understand the mechanisms that lead to early graft failure in one DSA-positive group yet appear to be innocuous in another.

To address some of these issues, investigators have also used additional parameters such as C4d deposition [13], soluble CD30 [14], and the extent of transplant glomerulopathy (TG) to supplement HLA DSA detection [15]. For example, Sis et al. [15] showed that 73% of patients with TG exhibited evidence of antibody-mediated damage to their renal allograft. Similarly, Eng et al. [16] reported that, among 61 post-transplant cases with biopsy-proven TG, >50% had evidence of class I and/or class II HLA DSA. In that study, TG with DSA was associated with significantly decreased graft survival, but TG in the absence of DSA was not associated with decreased graft survival. Clearly, multiple mechanisms are in play and the association between TG and DSA requires further study.

Other studies have focused on the fine specificity of the DSA as an additional biomarker. In a series of 586 renal transplant recipients with a median post-transplant follow-up of 5.9 years, Kobayashi et al. [17] observed that antibodies against HLA-DRB1* were most closely associated with chronic antibody-mediated rejection (CAMR), at least when they were present in moderate to high concentrations. In contrast, antibodies to HLA-DQB1* were not as tightly associated with CAMR as antibodies against DRB. These intriguing data suggest there may be some importance to the immune target of the DSA response. For example, certain targets may not be expressed on the vascular endothelium or be expressed at a significantly lower concentration than other targets. Hence, binding of antibody may not occur or may not be of sufficient density to result in significant pathology. In a contrasting study by Wiebe et al. [18], patients with antibody-mediated acute renal allograft dysfunction (DSA positive with rapid rise in serum creatinine) or antibody-mediated indolent graft dysfunction (DSA positive with slow rise in serum creatinine) showed a wide distribution of different HLA antibody specificities, e.g. both class I and class II. While there was a greater percentage of class II antibodies (DRB and DQB) than class I antibodies, the latter were clearly associated with dysfunction. The contrast to the findings of Kobayashi et al.'s study [17] was that Wiebe found a greater number of affected patients with HLA-DQB1* antibody although antibodies against DRB1, DRB3, 4, 5, and DPB1 were also observed. The presence of de-novo DSA was also associated with decreased HLA-DRB matching, non-compliance, and the presence of an earlier acute rejection episode. The median 10-year survival between de-novo DSA-positive versus DSA-negative groups was 57% versus 96% ($P < .0001$). Interestingly, there was a similar distribution of HLA specificities among DSA-positive patients with stable graft function, reiterating the notion that the detection of de-novo DSA alone may be incomplete.

As previously mentioned, DSA alone may not be a robust predictor of imminent graft deterioration. Yet, it is striking that in virtually every study listed above, independent and statistically significant associations with poor graft survival were seen when de-novo HLA DSA was present post transplant. Such data suggest that the clinical manifestations of rejection result from a multi-hit pathological process. HLA DSA is clearly an important component but not necessarily a stand-alone biomarker. Future studies will need to focus on the clinical, immunological, and/or physiological factors that lead to graft dysfunction in the presence of DSA [18,19].

Cardiac transplants

In studies by Smith et al., 224 cardiac transplant recipients were followed for up to 13 years for the production of de-novo DSA [20]. Compared to recipients who did not make DSA, those with either transient DSA or persistent DSA had significantly reduced survival (hazard ratio 4.351; $P < 0.001$;). In that study, the investigators also looked at the impact of complement fixing antibodies. To their admitted surprise, the ability of the DSA to fix complement was not associated with an increased risk compared to the presence of DSA alone. However, there was a trend, although not a statistically significant one, for patients with complement fixing antibodies to have a greater risk for developing coronary artery disease. In similar studies in cardiac transplant recipients by Nath et al., the presence of de-novo DSA was associated with both AMR and coronary artery disease [21]. Smith et al.'s study also implicated antibodies against MHC class I-related chain A (MICA) antibodies along with HLA DSA. In most instances, HLA DSA preceded the appearance of MICA. Whether MICA alone is an independent biomarker of poor outcome in cardiac or renal transplantation is controversial [22–25].

Lung transplants

The importance of monitoring for DSA in lung transplant recipients has also been studied, albeit not to the same extent as in renal or cardiac transplantation [26]. This is in part because the mechanisms of antibody-mediated damage to the lung are less well understood and there is no clear histological picture that is diagnostic for antibody-mediated allograft rejection [27,28]. Rather, AMR tends to present as broncheolitis obliterans syndrome (BOS), a progressive airway obstructing process and a major cause of death following lung transplantation. Staining of biopsies for C4d or C3d has been reported as a marker for AMR in lung transplantation [29]; however, the staining process is challenging [27] and not routinely performed by all transplant centers. Nonetheless, there are studies that have identified post-transplant HLA DSA, with or without complement deposition, as a risk factor for BOS [26]. In earlier work by Girnita et al. [30], it was suggested that the combination of DSA, vascular C4d deposition, and the presence of soluble C4d in bronchoalveolar lavage fluids along with lung dysfunction, constituted a diagnostic set consistent with AMR in lung transplant recipients. Hachem et al. [31], reported that HLA DSA in the post-transplant period was quite common. Among 116 lung transplant recipients with a mean follow-up of 1.67 years, 65 recipients (56%) developed de-novo HLA DSA. In that study, some recipients were

treated in an attempt to reduce the quantity of DSA. The incidence of BOS in patients whose DSA was reduced following treatment was similar to that in patients without DSA and statistically lower than in non-treated DSA-positive individuals. In short, these data suggest the early and frequent monitoring for DSA combined with aggressive therapies to reduce DSA can reduce the incidence of BOS and, at least theoretically, increase graft and patient survival. In a retrospective study by Saini et al. of 42 lung transplant recipients [32], the relationship between alloimmunity and autoimmunity was investigated. A clear association between the appearance of HLA DSA, autoantibodies, and BOS was observed. Similar to previous studies, the incidence of HLA DSA was 42.7%. Among the HLA DSA-positive recipients, approximately 30% developed antibodies to K-α1 tubulin and collagen V self-antigens. Based on these findings, the authors proposed that the production of HLA DSA led to vascular damage that permitted the production of autoantibodies ultimately contributing to the pathology of BOS. Since HLA DSA preceded the development of autoantibodies and BOS, strategies to monitor for and reduce HLA DSA may be effective in reducing the incidence of BOS.

Liver transplants

A new and growing concern has been the role of post-transplant DSA in liver transplantation [33,34]. Once believed to be of little clinical importance [35,36], HLA DSA in liver recipients has now become a topic of extreme interest. Post-transplant DSA monitoring in association with C4d deposition is being used to help differentiate between rejection and recurrent hepatitis C. More importantly, two studies have shown that post-transplant production of DSA is associated with poor outcomes in ABO identical/compatible liver transplants [4,37]. In a study by Musat et al. [4], 17 of 43 (40%) liver transplant recipients produced DSA post transplant in association with diffuse portal C4d deposition. This group had a statistically higher incidence of acute cellular rejection and steroid-resistant rejection. Three of these patients required therapeutic DSA reduction therapy to salvage graft function. As was the case in renal transplantation, AMR in liver transplantation may be fully reversible with appropriate therapy [4,38]. Thus, for liver transplantation, the production of DSA post transplant appears to be significant and can be associated with poor outcomes.

Biological properties of DSA

One aspect of DSA that is beginning to be studied in detail is whether the intrinsic biological properties of the antibody make a difference to transplant outcomes. Deleterious effects of post-transplant DSA can be observed in renal, cardiac, lung, and most recently, liver transplantation. Several studies have evaluated the pretransplant immunoglobulin isotype and complement fixing capability of DSA and their relationship to graft allograft outcome. However, the results to date are divided, with some studies showing an association with rejection/graft loss and others showing no clinical effect [39–42]. In a recent study of 1016 patients, the presence of C1q-positive DSA in the post-transplant period was associated with an increased incidence of antibody-mediated rejection and renal allograft loss. Although C1q positivity was correlated with post-transplant outcomes, as a pre-transplant predictor of outcome is was not informative. Hence, the enthusiasm for this specific assay should be tempered [43,44]. Nonetheless, it is intriguing to speculate on the importance of the functional properties of DSA related to clinical outcomes. Clearly, more work is needed in this area.

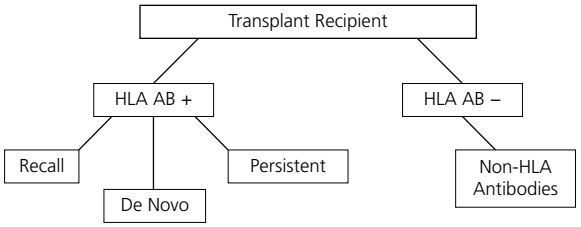

Figure 89.1. Potential classification of patients in the postoperative period. Post-transplant patients can be classified as having a donor specific antibody (HLA Ab positive) or not (HLA Ab negative). For individuals classified as HLA Ab positive, there are at least three subcategories. *Recall*, patients who are DSA negative at the time of transplant but have a significant history of sensitizing events, e.g. pregnancy or prior transplant; *persistent*, patients with DSA at the time of transplant; *de novo*, DSA-negative patients without a history of significant sensitizing events. For patients initially classified as DSA negative and who do not produce HLA antibodies post transplant, there is still the possibility for the production of non-HLA DSAs.

Strategies for post-transplant DSA monitoring

Before embarking on a strategy for post-transplant monitoring, it is important to understand and classify the types of patients who will be transplanted [45]. Depending upon the patients' histories at the time of transplant, the approach to monitoring may vary considerably. Figure 89.1 outlines some of the potentially divergent patient populations that could be encountered. While the majority of patients will be low risk (i.e. no DSA) at the time of transplant, changes in clinical practice at many centers have resulted in the transplantation of higher risk patients, with high risk defined as the presence of DSA at the time of transplant. These are patients who either underwent desensitization protocols to reduce/remove DSA just prior to transplant or were transplanted across a positive cross-match or transplanted with a DSA but a negative cross-match. Therefore, post-transplant DSA-positive patients can be divided into three groups:

- Group 1 patients have DSA prior to transplant, and were either desensitized to a negative cross-match or transplanted across a positive cross-match. Such patients could be classified as "persistent" antibody.
- Group 2 patients are DSA and cross-match negative at the time of transplant yet have a known history of DSA. For this group, the appearance of post-transplant DSA may be considered a recall or anamnestic response rather than true de-novo antibody production.
- Group 3 patients are those who truly lack DSA, both historically and at the time of transplant, yet make DSA after transplantation. This group could be considered true *de-novo* DSA.

Importantly, monitoring strategies for each of these groups may differ significantly. Presensitized and/or DSA-positive patients are at increased risk for early AMR and may benefit from early and more frequent monitoring after transplantation. Alternatively, patients in group 3 who have a low likelihood of developing a DSA post transplant may only require infrequent monitoring via a simple HLA antibody screening method. If screening results become positive, subsequent testing can be performed to confirm the presence of DSA.

Once DSA is confirmed several important questions then arise:

- Is there a benefit to more frequent DSA monitoring?
- If signs of dysfunction are present, is treatment helpful?
- If there is no graft dysfunction, is treatment warranted?

These questions await a definitive answer.

Patients with DSA at the time of transplantation

Compared to group 3 patients, groups 1 and 2 patients present a greater challenge and may require unique and individualized approaches [2,46,47]. For patients with DSA at the time of transplant (groups 1 and 2), sensitive testing should be performed that clearly identifies the DSA and perhaps attempts to quantify how much antibody is present as well as assessing the DSA response after the transplant [48]. Both of these aspects may be beneficial in planning initial therapies as well as monitoring patient progress post transplant. Identification of the DSA can be challenging since most of these recipients will possess antibody to non–donor-specific HLA antigens. First, one must ensure that the antigens of interest (DSAs) are present on the bead panel. This assessment must be made at the antigen level, but increasingly allele-specific HLA antibodies are being recognized [49]. Failure to make this distinction may result in either a false-positive or false-negative assessment of DSA. Next, one should consider if there are any factors that inhibit the detection of DSA. Immunoglobulin M (IgM) and complement components have been shown to interfere with the detection of immunoglobulin G (IgG) HLA antibodies in the single antigen bead assay [50–52]. It may be advantageous to remove these factors prior to testing. Specific treatments such at dithiothreitol (DTT), heat inactivation, or hypotonic treatments have been shown to be quite successful in removing the interfering factors and permitting the detection of HLA antibody [50–52]. Lastly, the frequency of testing must be taken into consideration. For high-risk patients, frequent monitoring soon after transplant may be useful in signaling the onset of a recall response. For low-risk patients, the frequency may be higher in the early years post transplant and then becomes significantly less in subsequent years. Importantly, frequency of monitoring is crucial when antirejection therapies are utilized. Some antirejection therapies can interfere with the detection of HLA antibody, even when solid-phase assays are used. For example, high-dose intravenous immunoglobulin (IVIG; 2 g/kg) can significantly interfere with the ability to detect an HLA antibody. Therefore, it is recommended that approximately 30 days pass between the administration of high-dose IVIG and solid phase testing. Rabbit antithymocyte globulin and other polyclonal antibody preparations are other therapeutic agents that can interfere with the detection of HLA antibody. These agents contain many different antibody specificities, including anti-HLA and anti-beta2 microglobulin [53]. As such, when present at high blood levels they can interfere with the solid phase assays. It is critical that the testing laboratory be aware of the post-transplant therapies administered to each patient.

In addition to clearly identifying the presence of a DSA, quantification of HLA DSA is highly desirable. Unfortunately, as recently reported following a Food and Drug Administration (FDA) workshop on antibody-mediated rejection [54], the current assays are not designed for quantification, and determining antibody amounts by median fluorescence intensity (MFI) levels is not reliable. A number of factors can influence the apparent quantity of antibody present. First, a patient's HLA antibodies represent a polyclonal response. This means that the observed HLA specificity is a culmination of the overall binding of many different immunoglobulin molecules. For most patients, it is not known how many different HLA epitopes are recognized by a single polyclonal serum or how many unique antibodies may be present in that serum. What is recorded is the "big picture" of the immune response to HLA. Such differences can clearly alter how a test "measures" the amount of DSA present. For example, in the current configuration of one manufacturer's class I single antigen, HLA antibody detection product, there are 31 individual beads that express the Bw4 epitope, yet only one bead for antigens such as HLA-B7 or HLA-B8. If one individual possesses a specified quantity of a Bw6 antibody and a second patient the exact same quantity of a B7 antibody, the profiles observed in the solid phase testing would be quite different. For the second patient, all of the B7 antibody would be deposited onto a single bead. In contrast, for the Bw6-bearing individual, the antibody would be divided among the 31 distinct beads. Hence, the measured fluorescence intensity, on a per bead basis, would be ~3% of the fluorescence measured on the B7 bead.

Second, if a patient has made antibodies against more than one distinct donor-specific HLA antigen, the cumulative fluorescence value for all DSAs may be more informative than the fluorescence values of the individual bead/DSA.

The above are just two examples of how challenging the interpretation of a DSA may be. It also highlights the importance of the technical aspects of the testing and how they can affect the perception of antibody quantity and strength.

Methods to detect HLA DSA

A more detailed discussion of the methods for detecting HLA alloantibodies is provided in Chapter 36. Current state-of-the-art approaches now utilize solid phase methods to identify the presence of HLA antibodies as well as determine the fine specificity of the antibody. In combination with molecular methods for HLA typing, the ability to unambiguously confirm or refute the presence of a DSA is better than in any past era. Personalized approaches to DSA assessments that utilize the HLA antigens isolated directly from the specific donor as targets for the assay [55–58] are under development and there utility awaits further studies.

Summary

The development of post-transplant HLA DSA is an important biomarker that is closely aligned with graft injury, graft dysfunction, and accelerated graft loss. Although monitoring for DSA is not uniformly predictive of impending graft failure, the presence of DSA clearly portends a worse outcome compared to that in individuals without DSA. When combined with other biomarkers (invasive and/or non-invasive), the clinical correlation with graft failure increases significantly. The observation that many recipients exhibit normal graft function in the face of demonstrable DSA suggest that there are DSAs that are not deleterious or that all of pieces of the puzzle have not yet been identified. Additional studies delineating differences in the biological activity of DSA combined with information obtained from other "-omic" evaluations may ultimately provide the complete picture. Lastly, it is unknown whether early identification of DSA or other biomarkers of rejection will translate into effective therapeutic interventions. Some groups have shown that successful reduction in DSA after transplant can lead to improved allograft survival [59–62], but the numbers are small and there has been no long-term follow-up.

However, under any circumstances, post-transplant monitoring for HLA DSA is an important tool for the transplant clinician.

Introduction

Infections, malignancies, and cardiovascular and metabolic complications constitute major causes of death after organ transplantation. These complications are caused and/or negatively influenced by chronic exposure to immunosuppressive agents. Given the narrow therapeutic window of immunosuppressive drugs and the marked interindividual variability of transplant recipients, the search for tools to tailor immunosuppressive therapy to the individual needs of transplant recipients has been an ongoing research priority in transplantation. Despite the interest and clinical relevance of this topic, monitoring of immunosuppressive therapies in the clinic continues to be performed almost exclusively by employing pharmacokinetic markers. This practice persists even though currently employed pharmacokinetic guidelines have never been properly validated in long-term clinical trials. Furthermore, pharmacokinetic characteristics of immunosuppressive drugs do not accurately reflect their biological (or pharmacodynamic) effects [1,2] and cannot be employed to estimate the real need for immunosuppression in a given individual recipient.

The recipient's immune status and donor-specific immune reactivity have a large impact on transplantation outcomes. The use of immune monitoring tools to assess the optimal level of immunosuppression for a transplant recipient is therefore intuitively appealing. Recent advances in cellular and molecular analytical technologies have allowed the identification of many biomarkers with potential relevance to applied immunology and transplantation. The development of these markers holds promise to improve patient care by facilitating personalized medicine in transplantation. Furthermore, measuring biomarkers within clinical trials can provide valuable mechanistic insight into the cellular and molecular basis of clinical responses. Unfortunately, the implementation of these biomarkers in clinical transplantation is not straightforward and faces various scientific, technological, financial, and regulatory challenges (Figure 90.1). As a consequence, although a plethora of biomarker studies have been performed and many articles have been published in the field of organ transplantation, their validation and standardization is still in its infancy. Thus, to date only two biomarker-based diagnostic tests have gained regulatory approval and have reached the market [3–6]. Even in these two cases, the two commercialized tests have not yet greatly influenced routine clinical practice. Clearly, the promise of biomarker-based diagnostics and personalized medicine in organ transplantation is still far from being a reality in clinical practice. It is important to note that the detection of donor-specific alloantibody is a clear indicator of uncontrolled alloimmunity and can be considered a biomarker of sorts. It is covered separately in Chapter 89.

Identification and evaluation of biomarkers relevant to transplantation

A *biomarker* is defined by the Biomarkers Definitions Working Group as "a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacological responses to a therapeutic intervention" [7]. In transplantation, biomarkers have been developed to monitor therapeutic interventions and as diagnostic and prognostic tools. A biomarker that can be employed as a substitute for a clinical endpoint is known as a *surrogate endpoint*. Characterization of a biomarker as a surrogate endpoint requires demonstration within clinical trials and/or epidemiological studies that the biomarker is capable of predicting clinical benefit with accuracy and reproducibility [7]. General considerations in biomarker discovery are covered here. A more in-depth coverage of statistical and trial design issues relevant to this discussion is given in Chapter 134.

The first step in the biomarker development process is the definition of the clinical question to be addressed and the population to be targeted (Figure 90.1) [8–10]. The technology to be employed, the sample type (blood, allograft tissue, urine, etc.), and the most appropriate gold standard against which the test will be compared also need to be selected. A biomarker discovery phase followed by one or more validation phases are then conducted. In the discovery phase a high-throughput "-omics" technology is often employed in order to simultaneously evaluate a large panel of potential biomarker candidates. During the discovery phase, the diagnostic/prognostic performance of candidate biomarkers needs to be assessed. The minimum performance threshold depends on the nature of the available gold standard and on the intended use of the test. The sample size estimation for subsequent validation studies in independent cohorts of patients can be established based on these assessments. Often the initial validation is conducted on

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

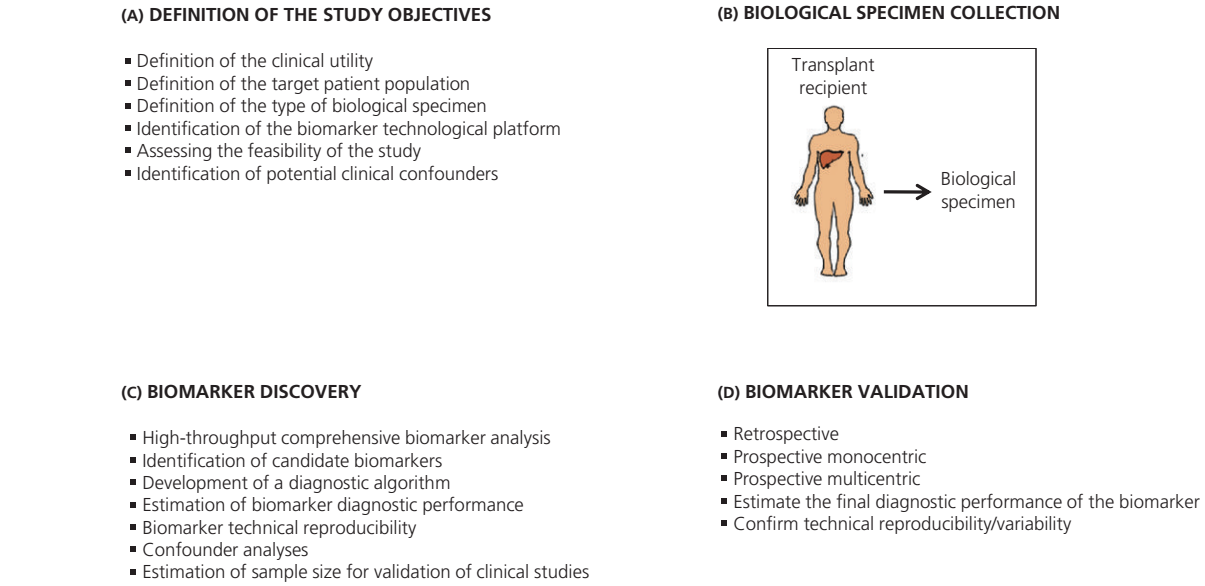

Figure 90.1. Strategy for the development of biomarkers in transplantation. The first step includes a careful definition of the clinical question to be addressed, the target population, type of sample and analytical platform, and overall study design. The key aspects are then the discovery of candidate biomarkers and their validation.

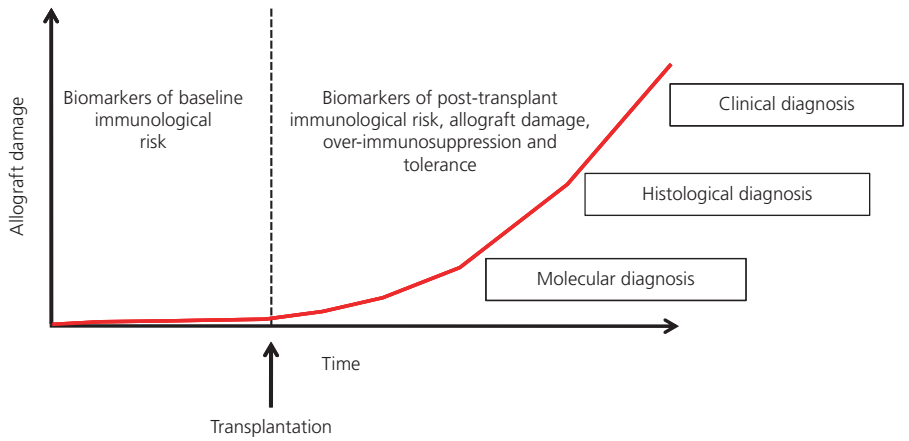

Figure 90.2. Application of immunomonitoring biomarkers in transplantation. The way biomarkers are employed in transplantation evolves with time. Before transplantation the emphasis is on assessing the baseline immunological risk of transplant recipients. After transplantation the goals are to determine the risk of graft rejection and/or graft damage and to detect graft damage as early as possible. The assumption here is that molecular markers of graft damage precede histological changes and clinical manifestations. (Adapted from Anglicheau et al. [210] and Roedder et al. [9].)

retrospective samples. This should be followed by prospective validation studies, ideally within a multicenter setting. It is important to make sure that the cohorts of patients employed for biomarker validation faithfully represent the target population on which the test will be employed. The influence of clinical and technical confounders needs to be carefully investigated. If a high-throughput platform is employed in the discovery phase, a technological transfer into a platform more amenable to widespread clinical application needs to be implemented within the validation phase.

In interventional clinical trials involving transplant recipients, the use of endpoints such as recipient survival and/or irreversible graft failure has become impractical. Given the good short-term results achieved in clinical organ transplantation, the use of these endpoints results in the need to enroll unrealistically large sample sizes and to conduct very long-term recipient follow-up. The identification of adequate surrogate endpoints is therefore of paramount importance in transplantation in order to expedite the evaluation of novel therapies. The main surrogate endpoints currently employed in routine clinical practice are either conventional markers of allograft dysfunction (e.g. serum creatinine, glomerular filtration rate, liver function tests) or pathological changes derived from allograft biopsies. These markers fail to anticipate the initiation of allograft tissue destruction and therefore provide little predictive information [11] (Figure 90.2).

Furthermore, they are not always linked to long-term outcomes and do not offer information on the recipient's overall immune status. Given the clinical complexity of transplant recipients, a combination of different biomarkers derived from a variety of different platforms is likely to be required to capture the full effect of medical interventions.

In transplantation, immune-related biomarkers have been developed in an attempt to address four major aspects relevant to transplant patients:

- to identify whether the recipient is presensitized to the donor before transplantation and therefore likely to develop rejection;
- to detect inflammatory changes related to rejection before clinically apparent graft damage has taken place;
- to predict the success of immunosuppressive drug minimization or withdrawal strategies;
- to assess the net state of immunosuppression in order to identify over-immunosuppressed recipients likely to develop opportunistic infections or malignancies.

Principles of cellular alloimmune monitoring

Recipient-to-donor sensitization has been recognized as an immunological barrier to successful transplant outcomes since the initial stages of transplantation medicine. Despite the well-established central role of T cells in allograft rejection, only the assessment of humoral sensitization by means of alloantibody measurement is currently employed in routine clinical practice. This is covered in detail in Chapter 89. In contrast to alloantibody measurements, which are currently a fundamental decision-making tool in clinical transplantation, none of the tests assessing cellular alloimmune effector mechanisms has been widely implemented in the clinic. This is attributable to the heterogeneity of T-cell subsets and the complexity of their immune responses (see Chapter 5 for detailed information relevant to the discussion of T-cell mediated immunity). The T-cell receptor complex recognizes donor antigens by two distinct pathways: (1) the direct pathway, where donor peptides bound to donor major histocompatibility complexes (MHCs) on the surface of donor antigen-presenting cells (APCs) are recognized by recipient T cells; and (2) the indirect pathway, where donor peptides bound to recipient MHCs on recipient APCs are recognized by recipient T cells. Extensive studies [12–15] revealed a dominance of the direct pathway during the first months after transplantation, when professional donor APCs are still present, whereas the indirect pathway has been associated with chronic immune-mediated graft injury [16–18]. More recently, a novel pathway, called the third or semi-direct antigen presentation pathway, has been identified in experimental animal models, in which recipient APCs acquire donor MHC–peptide complexes and thus are capable of simultaneously priming recipient T cells via direct and indirect allorecognition pathways [19].

Upon MHC–peptide–T-cell receptor complex binding and appropriate costimulation, naïve T cells become activated. This results in intracellular production of adenosine triphosphate (ATP), calcium influx, and protein phosphorylation, all of which have been used as biomarkers to quantify T-cell activation. Primed naïve T cells subsequently proliferate, synthesize cytokines, and differentiate into effector T cells, a process that takes several days. Some effector T cells eventually differentiate into memory T cells. In contrast to naïve T cells, rechallenged memory T cells have a lower activation threshold, need less costimulation, and produce effector cytokines within hours instead of days. It is now well understood that donor reactive $CD4^+$ T cells take important cues from the fine texture of inflammation in which they recognize donor antigens. Depending on the local cytokine milieu in which lymphocyte antigen activation takes place, naïve $CD4^+$ T-helper cells can commit to a variety of cytopathic and/or immunoregulatory phenotypes [20]. Thus, when activation occurs in a microenvironment rich in interleukin (IL)-12 (usually produced by activated mature dendritic cells), $CD4^+$ T cells commit to a tissue-destructive interferon (IFN)-γ-producing Th1 program. In contrast, $CD4^+$ T cells activated in an IL-4 rich milieu differentiate into the IL-4- and IL-5-producing Th2 cells. In the absence of proinflammatory cytokines, tumor growth factor (TGF)-β directs $CD4^+$ T-cell commitment into the $Foxp3^+$-induced regulatory T-cell phenotype. In direct contrast, TGF-β expression accompanied by IL-6 and/or IL-21 expression precludes commitment into the transplant-protective regulatory T-cell phenotype. Instead, such antigen-reactive $CD4^+$ T cells commit to the highly cytopathic IL-17-producing (Th17) T-cell phenotype [20–23].

Until recently, it was thought that antigen-activated T-helper cells became either Th1 or Th2 terminally differentiated cells and that these T-cell subsets caused opposing Th1-dependent cytopathic rejection or Th2-dependent cytoprotective effects. The Th1/Th2 paradigm is incorrect insofar as both Th1 and Th2 can orchestrate graft rejection [24,25], and that regulatory T cells, and not Th2 cells, are crucial to inhibition of cytopathic allospecific immune responses [26–28]. Recent discoveries have also revealed that neither Th17 nor regulatory T cells are terminally differentiated phenotypes and that these two cell subtypes are in fact closely interlinked and exhibit remarkable plasticity [29]. The current paradigm is that the clinical outcome of the allograft response following withdrawal of therapy, rejection or tolerance, is determined by the relative balance between cytopathic Th1 and Th17 $CD4^+$ T cells versus rejection blocking cytoprotective regulatory T cells, and that this balance is critically dependent on the fine texture of inflammation within the microenvironment in which T-cell activation takes place.

Cellular assays developed to assess alloimmune responses rely on the characterization of lymphocyte subpopulations and/or their repertoire, the measurement of events related to T-cell activation (e.g. intracellular markers of activation, proliferation, cytokine production, cytotoxicity), or the detection of markers of allograft damage. Furthermore, with the advent of high-throughput "multi-omics" technologies (transcriptomics, proteomics, metabolomics, etc.), systems biology approaches have been undertaken in an attempt to capture within a single read-out both the effects of immune cells and the response of the allograft to them.

Alloantigen-specific assays

In contrast to chronic immune-mediated conditions in which the identity of the causal antigens is unknown, in transplantation access to donor material allows for the assessment of *alloantigen-specific cellular immune responses*. These assays should, in principle, provide a more accurate individualized estimate of the actual risk of graft rejection. Furthermore, they might be capable of identifying patients who have developed allograft tolerance. On the other hand, these techniques are expensive, labor-intensive, and difficult to standardize. Classic alloantigen-specific cellular assays assess proliferation, cytotoxicity, and/or cytokine production, and include mixed leukocyte reaction (MLR) assays, cytotoxic T-lymphocyte precursor (CTLp) determination, and limiting dilution analyses

(LDAs). While MLR assays have been shown to have little predictive value in transplantation [30], CTLp determination and LDAs are more informative and reproducible as measurements of effector T-cell functions, such as proliferation and cytokine production, that correlate with alloreactivity [31–33]. The utility of these measurements, however, has been mostly shown in the context of bone marrow transplantation, where CTLp frequency is a good predictor of graft-versus-host disease [34,35]. In contrast, in solid organ transplantation, contradictory data have been reported and the clinical utility of these tests is less clear [36–38]. A more recent alloantigen-specific assay that is more amenable to routine clinical use is the enzyme-linked immunosorbent spot (ELISPOT) assay [32,36,39,40]. In this assay, frequencies of cytokine-secreting naïve or effector/memory recipient T cells are quantified after in -vitro stimulation with donor antigens, usually blood, spleen, or lymph node mononuclear leukocytes. If analyzed after a short stimulation period of <24 h, only memory/effector T cells are detected, thus providing an estimate of antidonor T-cell sensitization. The assay has been used to quantify IL-2, IFN-γ, IL-10, or granzyme B-producing T cells. Limitations are the impossibility to simultaneously analyze different lymphocyte subsets and/or cytokines, although new two-color assays are in development. Recent research efforts have focused on the standardization of this technique in order to increase its reliability [41–44].

Multiparameter flow cytometry has the advantage of allowing simultaneous analysis of multiple cell phenotypic markers. Furthermore, with recent technological refinements, it can also provide information about intracellular signaling pathways, cytokine release, and antigen specificity. Flow cytometric analysis of T-cell cytokine production by combined intracellular and cell surface marker staining has been developed as an alternative technique to assess donor-specific T-cell responses [45,46]. However, this assay has a lower sensitivity for the enumeration of cytokine-producing lymphocytes than ELISPOT [39]. Flow cytometry can also be employed to assess T-cell mitotic activity after donor antigen stimulation on the basis of carboxyfluorescein succinimidyl ester (CFSE) labeling, but this has shown little predictive value in kidney transplantation [36].

Non–alloantigen-specific assays

These do not require the availability of donor material, which might be problematic, particularly in the case of deceased donors. Furthermore, these techniques are often easier to standardize and/or commercialize for routine clinical application than functional antigen-specific assays. In addition, by providing information on the net state of immunosuppression (i.e. general immune competence), they may serve to predict not only graft immunological outcomes but also complications related to over-immunosuppression.

The immunophenotypic characterization of circulating lymphocytes by flow cytometry has been widely employed in an attempt to identify biomarkers relevant to transplantation. Numerous observations employing flow cytometry have shown that patients undergoing acute rejection display increased levels of circulating activated and/or effector memory T-cell subsets (as assessed by cell surface markers such as CD45RA, CCR7, CD62L, CD69, or CD38) [47–52]. The problem with these assays has been their lack of specificity, given that similar levels of cell surface activation marker expression are observed in other inflammatory conditions. As an example, renal transplant patients with cytomegalovirus (CMV) infection showed increased levels of activation markers on $CD8^+$ T cells, correlating with CMV viremia but not with acute rejection [40,53,54]. The quantification of graft- or leukocyte-derived gene transcripts in biological specimens of transplant recipients using quantitative polymerase chain reaction (qPCR) [55,56] has been one of the most informative non–antigen-specific approaches. Changes in transcript levels reflecting activation of leukocytes and/or non-immune cells can be used to analyze the quality and magnitude of the immune response in all possible compartments such as peripheral blood, graft tissue, and fluids draining the graft.

The recent discovery of small regulatory RNA molecules (microRNAs; miRNAs) has resulted in the availability of a new set of potential diagnostic and prognostic biomarkers relevant to transplantation. The activation of immune cells can also be estimated by analyzing immune cell-derived soluble products such as CD30, CXC-ligands, and receptor chemokines [57–62]. A different approach has been the analysis of the specific patterns of T-cell receptor repertoire usage associated with the development of tolerance and/or graft rejection [63–65]. Another interesting non–antigen-specific approach for measuring the overall T-cell functional capacity consists of the quantification of whole blood $CD4^+$ T-cell intracellular adenosine triphosphate (iATP) content after phytohemaglutinin (PHA) stimulation. This assay has been approved by the Food and Drug Administration (FDA) for the determination of ATP content and is available commercially (ImmuKnow® assay; Cylex Inc., Columbia, MD, USA). However, it has yet to be validated as a useful guide for clinical practice.

Given the relevance of regulatory $CD4^+CD25^+Foxp3^+$ T cells (Tregs) in the prevention and/or development of human autoimmune diseases and their critical role in many experimental animal models of transplantation [66,67], the quantification of this T-cell subset in blood and/or allograft infiltrates has gained substantial attention. In contrast to rodents, however, activated human T cells can also transiently express the intracellular transcription factor Foxp3 [68–70]. For this reason, the use in flow cytometry analysis of cell surface CD25 and intracellular Foxp3 labeling is not an accurate method to quantify Tregs in humans. The addition of the CD127 marker can partially address this limitation, given that Tregs are typically CD127low while CD127high T cells tend to be activated lymphocytes [71,72]. However, the most reliable method of identifying human Tregs is to assess the methylation state of a conserved region in the first intron of the *Foxp3* gene, known as the Treg-specific demethylated region (TSDR). This can be quantitatively assessed in sorted T cells, whole blood, and even paraffin-embedded graft biopsies [73–75]. Differences in circulating Tregs between transplant recipients exhibiting chronic graft damage and allograft tolerance, or between recipients receiving different immunosuppressive regimens, have been noted [76–81]. Furthermore, high levels of Foxp3 transcripts both in urine and within the graft have been reported in kidney patients undergoing acute allograft rejection [56,82–85]. The clinical relevance of these observations and their unambiguous association with clinical outcomes are, however, still unclear.

Pretransplantation biomarkers: assessment of the baseline immunological risk of transplant recipients

Detection of donor HLA-specific antibodies in the recipient's serum is a widely employed strategy to identify sensitized transplant recipients at risk of humoral rejection, and is extensively covered in

Chapter 89. We will focus here on novel technologies that allow the measurement of T-cell sensitization and/or activation, and that have shown potential clinical relevance.

IFN-γ ELISPOT assay

Heeger et al. [32,36,39,40] were the first to describe IFN-γ production by recipient T cells in response to donor cells in a 24-h ELISPOT assay as constituting a measurement of primed donor-specific immunity, correlating with the risk of acute cellular rejection after kidney transplantation. Thereafter, additional studies by different groups confirmed the relevant association between heightened pretransplant IFN-γ-producing donor-reactive T cells and early kidney allograft acute rejection [43,44,86,87]. Importantly, these studies recognized that a significant proportion of patients who exhibited pretransplant cellular sensitization had low panel reactive antibody (PRA) scores. Early severe rejection and graft loss were observed in several of these patients, even those under potent immunosuppression with calcineurin inhibitor (CNI) drugs [86,87]. Another study revealed that pretransplant IFN-γ ELISPOT reactivity correlated with cumulative duration of dialysis treatment [88], suggesting that increased cellular sensitization could contribute to the lower graft survival rates observed in long-term dialysis patients.

The panel reactive T-cell (PRT) assay was developed in order to evaluate cellular sensitization before transplantation when donor cells are not available [89,90]. The PRT assay measures IFN-γ ELISPOT responses against a panel of stimulator cells with the most common HLA antigens. Notably, PRT responses were shown to be independent of PRA scores [91]. Furthermore, PRT reactivity correlated with previous transplants, HLA mismatches, and female gender, and was able to predict post-transplant acute rejection and 6-month renal function better than PRA [91]. To provide a renewable source of donor stimulator cells for ELISPOT and PRT experiments, Zand et al. [92] described the use of CD40L-stimulated $CD19^+$ donor-type B cells. Thus, the IFN-γ ELISPOT assay constitutes one of the most promising tests available to assess the pretransplant immunological risk of an individual kidney recipient. The usefulness of the test in transplant recipients grafted with other organs remains to be explored.

Soluble CD30

The CD30 molecule belongs to the tumor necrosis factor receptor (TNF-R) superfamily. In activated T cells the membrane-bound CD30 molecule is proteolytically cleaved, thereby generating a soluble form (sCD30), which can be measured in serum [93,94]. Healthy humans tend to exhibit low CD30 serum levels, whereas increased sCD30 serum concentrations are detected in several inflammatory situations [95]. In transplantation it was hypothesized that sCD30 could reflect the pretransplant activation status of the T cells and thereby allow identification of high immunological risk recipients [93,96]. Indeed, several studies showed that either pre- or post-transplantation sCD30 levels predicted the development of acute kidney allograft rejection independently of PRA [57–59]. However, Altermann et al. detected a high interindividual variability in serum sCD30 levels of potential kidney recipients. Thus, when analyzed over time in kidney patients awaiting transplantation, substantial fluctuations were noted [95], hampering its implementation as a pretransplant risk-stratification marker. Furthermore, additional studies revealed that although low sCD30 pretransplant levels identified patients at low risk of developing acute cellular or humoral rejection, accurate identification of high-risk patients was not possible [97,98]. The accuracy of sCD30 as a predictive transplantation biomarker was shown to be further diminished in patients receiving induction therapy [58,99] or in those undergoing acute viral or bacterial infection [100].

Chemokine and chemokine receptor serum levels

IFN-γ-induced CXC chemokine ligands 9 (CXCL9; Mig) and 10 (CXCL10; interferon γ-inducible protein-10) attract CXC chemokine receptor 3 (CXCR3)-positive T cells into the graft. Some studies suggested that high pretransplant serum CXCL10 and CXCL9 levels were predictive of renal graft loss and early acute rejection of cardiac and renal allografts [60,61]. However, these observations were not corroborated in a subsequent study [62] in which pretransplant CXCL9 and CXCL10 serum levels had suboptimal prognostic value in recipients treated with either alemtuzumab or basiliximab induction treatment, likely due to depletion or inactivation of $CXCR3^+$ T cells.

ImmuKnow® assay

The goal of this assay, which measures whole blood $CD4^+$ T-cell iATP content after phytohemaglutinin stimulation, is to provide a reflection of the recipient's general immune status rather than a measurement of allograft-specific T-cell reactivity. The assay has been used to quantify immune responses before and after lung, small bowel, liver, and kidney transplantation [101]. Uncontrolled data have been employed to correlate iATP levels with infectious risk, with exceptionally low iATP levels having loose correlation with adverse outcomes [102,103]. However, at present, there are no prospectively controlled data supporting the use of this tool for immunosuppressive management.

Post-transplantation biomarkers: acute allograft rejection and chronic allograft injury

IFN-γ ELISPOT assay

In kidney transplantation a number of studies have employed IFN-γ ELISPOT monitoring to investigate the influence on clinical outcomes of blood alloreactive T-cell numbers [42–44,86,88,104–106]. Hricik et al. [86] first described that post-transplant directly-primed antidonor and third party responses positively correlated with 6- and 12-month serum creatinine levels. Because of its high sensitivity, the IFN-γ ELISPOT assay has also been used to measure alloreactive memory/effector T-cell responses primed by the indirect allorecognition pathway. Kidney recipients with indirect alloreactivity showed poorer graft function than those without [104–106]. Nonetheless, directly primed memory/effector T cells had superior long-term prognostic value, at least when assessed by IFN-γ ELISPOT [106]. ELISPOT and/or flow cytometry/intracellular staining technologies have also been employed to quantify frequencies of antiviral T-cell responses after transplantation. High frequencies of viral-specific T cells directed against overlapping peptide pools covering LT and VP1 BK virus (BKV) antigens correlated with control of BKV replication [107–109]. Similarly, the number of IFN-γ-producing T cells reacting against overlapping peptide pools covering CMV IE-1 protein positively correlated with protection from CMV disease and improved graft function in heart–lung and kidney transplant patients [110,111].

Chemokine and chemokine receptor serum levels

In liver transplantation CXCL10 serum levels were correlated with early liver graft fibrosis due to hepatitis C virus recurrence [112]. In addition, different reports have shown an association between high post-transplant urinary levels of CXCL10 and increased incidence of acute rejection, subclinical rejection and even BKV infection in kidney transplantation [113–115].

mRNA and miRNA expression in graft tissue samples

Studies aimed at the use of gene expression markers to identify acute rejection episodes were first undertaken in the context of kidney transplantation in the early 1990s. The group of T.B. Strom first demonstrated that during acute kidney graft rejection there was a marked increase in intragraft expression of cytotoxic T lymphocyte (CTL) transcripts such as granzyme B and perforin [116–120]. In subsequent studies, differences in CTL transcript composition were shown to discriminate between therapy-resistant and -sensitive acute rejection episodes [121], and between clinical and subclinical rejection [122]. A more comprehensive transcriptional profiling approach employing microarrays revealed different immunological and histological subgroups of rejection with different clinical outcomes [123–127]. Similar studies conducted in liver, heart, and pancreas allografts identified specific mRNA expression signatures associated with acute rejection and with histological and clinical outcomes [128–130]. The quantification of miRNAs in graft tissue samples has also been shown to be useful in discriminating between stable patients and patients with variable degrees of intragraft inflammation [131–133]. Anglicheau et al. [134] were the first to report on miRNA profiling as a tool to predict the status of human renal allografts. Expression of a set of miRNAs, including miR-142-5p, miR-155, and miR-223, was significantly altered in biopsies of patients with acute rejection [134]. Additional studies from other groups identified miRNA signatures associated with renal or intestinal acute cellular rejection [135,136] or with outcome after liver transplantation for hepatocellular carcinoma [137,138].

mRNA and miRNA expression in peripheral blood

In order to avoid invasive monitoring of immune responses following transplantation, researchers have studied the diagnostic potential of mRNA expression in other compartments such as peripheral blood [139]. The first studies conducted on peripheral blood mononuclear cells isolated from rejecting and non-rejecting kidney recipients reported that rejection was also associated with an increase in CTL transcripts such as perforin and granzyme B [140–142]. These transcripts were detected at the time of and even prior to clinically apparent acute rejection [140–142]. With the development of whole blood stabilizing reagents, such analysis was performed in a more standardized manner, which resulted in the identification of additional transcriptional markers of rejection, such as the costimulatory genes *CD154* and *ICOS* [143]. Toag-1 expression, originally identified as a rejection-related biomarker in experimental animal models of kidney, heart, and liver transplantation [139], also correlated with graft function and acute/chronic rejection when measured in whole blood from human transplant recipients before and after kidney transplantation [144,145]. In heart transplantation the analysis in peripheral blood mononuclear cells of an 11-transcript set has been commercialized as a diagnostic test to non-invasively identify heart recipients with a high likelihood of exhibiting moderate-to-severe rejection [3,4,146]. This FDA-approved test (Allomap, XDx) was designed to reduce the need to conduct surveillance endomyocardial biopsies. Accordingly, it exhibits a very high negative predictive value but very low positive predictive value. As described in detail below, analysis of peripheral blood mRNA expression can also be used to identify "operationally" tolerant transplant patients, who have stable graft function despite being off all immunosuppressive drugs. The use of blood as the source for mRNA, while highly desirable due to its accessibility, might be associated with technical problems. When peripheral blood mononuclear cells are employed, Ficoll isolation may cause significant interlaboratory variability. Although whole blood mRNA stabilization associated with globin mRNA reduction and strict sample handling protocols can address this problem, the differences in transcript levels observed when comparing different groups of transplant recipients tend to be weaker than those observed at the graft itself [139,147]. This could compromise the reproducibility of predictive expression models. The influence of blood cell subset heterogeneity [148], still not well studied in the context of transplantation, can also be a source of variability. Clearly the use of "deconvoluting" bioinformatic algorithms needs to be further pursued [149]. Alternatively, transcriptional analyses of isolated peripheral blood mononuclear cell subsets, a strategy that has proven useful in autoimmune diseases [150], should also be explored as a way to generate robust predictive signatures. Interestingly, miRNAs are very stable in serum, which makes serum analyses of miRNA levels a suitable diagnostic tool for monitoring immune responses in transplant patients. Indeed, Farid et al. recently showed that hepatocyte-derived miRNAs can serve as serum biomarkers of hepatocyte injury and rejection after liver transplantation [151]. It remains to be shown whether serum miRNA levels are also markers of rejection and/or tolerance in other transplantation settings.

mRNA and miRNA expression in fluids draining the graft

The analysis of fluids draining the graft, such as urine, bronchoalveolar lavage (BAL), and bile for kidney, lung, and liver transplantation, respectively, allow the study of local immune responses. Taking advantage of the direct communication between the kidney allograft epithelium and the outside world via the urine, several investigators have studied urinary chemokines and cytokines to non-invasively detect acute rejection. Given the fundamental relationship between invasion of the renal tubular epithelium by activated lymphocytes and the diagnosis of acute rejection, urinary biomarkers have been conceptually attractive. Suthanthiran et al. were the first to describe the possibility of a non-invasive diagnosis of renal allograft rejection by measurement of messenger RNA for perforin and granzyme B in urine [55].

In keeping with assessment of the interferon-γ axis in serum samples as described above, increased transcript and protein urinary levels of CXCL9 and CXCL10 (IP-10) and their receptors were associated with impaired short- and long-term graft function, and correlated with T-cell mediated inflammatory events in the kidney, including acute rejection and BKV nephropathy [114, 115,155,156]. Many other groups have confirmed the usefulness of these markers not only to diagnose rejection but also to predict long-term graft function [56,152–154]. In lung transplantation,

similar transcriptional analyses have been performed on BAL fluids. In this setting Madsen et al. showed that BAL, but not blood, transcript levels of CTLA-4, Foxp3, and granzymeB were elevated during acute rejection [157].

Urinary miRNA signatures have also been proposed as biomarkers of rejection in kidney transplantation [158]. In this setting, miR-10b and miR-210 were down-regulated and miR-10a up-regulated in urine samples of patients with acute rejection, and expression levels of miR-210 predicted long-term graft function as determined by glomerular filtration rate decline 1 year after transplantation [158].

Biomarkers of over-immunosuppression

Transplant recipients require frequent monitoring of immune responses to avoid both under-immunosuppression resulting in rejection and a state of global non-specific over-immunosuppression that may lead to life-threatening complications [145]. Unfortunately, it is currently not possible to determine the "adequate" level of immunosuppression for an individual transplant recipient. Similarly, no consensus has been reached on the definition of "over-immunosuppression," other than by the development of its most common manifestations, namely opportunistic infections and malignancies [159]. Examples of biomarkers reflecting the general state of adaptive and/or innate immune competence and their relevance for transplantation medicine will be discussed here.

Assessing the functional capacity of T cells

The ImmuKnow® assay was designed as a standardized test to measure lymphocyte reactivity in immune-suppressed patients in order to discriminate between under- and over-immunosuppression [101,160,161]. In several studies, high iATP levels were weakly associated with occurrence of acute rejections [101], whereas patients displaying very low iATP levels had an apparent increased risk of developing post-transplant infectious complications and higher short-term mortality [162,163]. A single time point analysis of iATP levels, however, was subsequently shown to be inaccurate in the prediction of opportunistic infections or acute rejection, indicating that the test should be conducted and interpreted longitudinally with sequential sampling [164–168]. More recent results showed that iATP levels are influenced by patient age and immunosuppressive regimen, with transplant recipients under 12 years old showing lower immune response levels [167,169–171]. A recent study also reported that reduced ImmuKnow® levels are very common during the first 6 months after kidney transplantation and not necessarily associated with dangerous over-immunosuppression [172], whereas low 12-month levels are associated with BKV infection. Overall, when analyzed longitudinally, the ImmuKnow® assay has been envisioned as a useful tool to stratify patients into low- and high-risk groups and to guide the tailoring of immunosuppression. However, a number of critical questions regarding the clinical applicability of the assay remain unanswered (e.g. What is the ideal immune response for recipients of different organs at different time points? What is the influence of HLA mismatch, type of organ, or immunosuppressive therapy?). Thus, published data should be interpreted with caution until large prospective studies demonstrate that adjustment of immunosuppressive therapies on the basis of ImmuKnow® read-outs results in improved clinical outcomes.

Serum levels of complement pathway mediators

Complement is one of the major inflammatory mediators involved in transplantation [173–176]. Apart from the classical and alternative complement pathways, the mannose-binding lectin (MBL) pathway also plays an important role in transplantation; the binding of MBL to injured tissue amplifies the inflammatory response. In some studies, pretransplant MBL plasma levels have been shown to predict graft outcome. Berger et al. showed that low pretransplant MBL serum levels are associated with increased patient and graft survival after kidney [177] or simultaneous pancreas–kidney transplantation [178]. In addition, plasma MBL levels increase after lung transplantation, and in this setting, persistently elevated MBL levels are associated with poor long-term outcomes [179]. Plasma MBL concentration has also been associated with the development of infections. In kidney transplantation, post-transplant plasma MBL deficiency (<500 ng/mL) increases the risk of CMV disease [180,181]. Pretransplant plasma MBL levels, in contrast, do not correlate with CMV disease [182,183], while high levels have been shown to protect against urinary tract infections and urosepsis following simultaneous kidney–pancreas transplantation [183]. Regarding BKV infection in kidney transplantation, post-transplant plasma MBL levels do not appear to influence the development of BKV viremia [184]. Overall, data indicate that measuring plasma MBL concentration may be useful to identify over- or under-immunosuppression, although the capacity of MBL levels to predict clinical outcomes is variable depending on the type of viral infection and on whether this marker is analyzed before or after transplantation.

HLA-DR expression on monocytes

Another approach to assess over- or under-immunosuppression is to evaluate the expression level of the MHC class II molecule HLA-DR on circulating monocytes of transplant patients [185,186]. MHC class II expression on APCs such as monocytes is tightly regulated. Inflammatory mediators such as IFN-γ and granulocyte macrophage-colony stimulating factor (GM-CSF) increase MHC class II monocyte expression [187–189], whereas anti-inflammatory mediators such as IL-10, TGF-ß, stress hormones, immunosuppressive drugs such as steroids, and regulatory T cells decrease MHC class II levels [190–195]. Thus, studying the HLA-DR expression per circulating monocyte can reveal the individual balance between systemic inflammatory and anti-inflammatory mediators. Upon major surgery, trauma, or systemic infections, circulating monocytes develop a state of functional unresponsiveness or desensitization characterized by low MHC class II expression and impaired antigen presentation capacity [196,197]. Furthermore, low HLA-DR expression on monocytes is associated with increased risk of infection after surgery or trauma [198]. After solid organ transplantation, persistently low HLA-DR expression on circulating monocytes precedes bacterial or fungal sepsis [185,198–200]. Thus, measurement of monocytic HLA-DR levels could be useful to identify severe over-immunosuppression and to assess the risk of infection. This may be especially important in transplantation, now that more T-cell–depleting agents and biologics targeting memory T cells are entering the clinic. Similarly, this parameter could be a useful safety biomarker to identify global immunosuppression in clinical trials incorporating cellular therapies such as adoptively transferred polyclonal regulatory T cells. To determine the clinical utility of these safety biomarkers, they need to be included in future clinical trials. In order to allow patient stratification into low- and high-risk groups, standardized flow cytometric analyses with

acceptable variances (<30%) between different labs or different flow cytometers have to be established. This has been achieved with commercially-developed BD Quantibrite HLA-DR/Monocyte, which allows quantification of HLA-DR molecules per monocyte based on provided standards. Interlaboratory comparisons of this test in multicenter clinical trials have achieved very low co-efficients of variation (4–25%) [201].

Biomarkers of graft accommodation and allograft tolerance

Liver and kidney transplant recipients can occasionally discontinue all immunosuppressive drugs without undergoing rejection. These selected recipients who maintain stable graft function in the absence of clinically significant detrimental immune responses and immune deficits are conventionally known as "operationally" tolerant. Despite being a very small subgroup of transplant recipients, operationally tolerant recipients have received substantial attention from the transplantation research community. Operationally tolerant patients might exhibit a signature of tolerance that could potentially be useful to select recipients amenable to drug minimization or withdrawal. Furthermore, elucidation of the molecular pathways associated with the operational tolerance phenotype could provide novel targets for therapy. These studies have focused mostly on the analysis of peripheral blood samples and employed flow cytometry immunophenotyping and transcriptional profiling technologies. In addition, in liver recipients molecular analyses of graft tissue have also been conducted.

The first studies performed to identify biomarkers of tolerance in liver transplantation employed flow cytometry immunophenotyping and/or gene expression profiling on blood samples [79, 80,202–204]. In these retrospective cross-sectional studies, operationally tolerant recipients (stable graft function off immunosuppression for various periods of time) were compared with recipients under maintenance immunosuppression considered to be non-tolerant (although the absence of tolerance had not been formally demonstrated in all of these cases by a prior attempt at immunosuppression withdrawal). Mazariegos et al. [202] quantified the relative frequency of monocytoid (mDC) and plasmacytoid (pDC) peripheral blood dendritic cell precursors in samples from six operationally tolerant recipients (0.8–7.9 years after complete immunosuppression cessation), 23 recipients undergoing prospective drug weaning (but still on minimal immunosuppression at the time of blood collection), and 11 recipients on conventional maintenance immunosuppression (in whom drug weaning had failed or had never been attempted). In both tolerant recipients and those receiving minimal immunosuppression the pDC/mDC ratio was significantly increased as compared with recipients on maintenance immunosuppression or with healthy individuals. Li et al. [79] assessed the frequency of peripheral blood B cells natural killer (NK) cells, and several T-cell subsets from 12 tolerant (2–6 years after complete immunosuppression cessation) and 19 potentially non-tolerant (receiving maintenance immunosuppression) pediatric living donor liver transplant recipients. Tolerant recipients exhibited: (1) increased numbers of B cells and $CD4^+CD25^+$ T cells; (2) decreased numbers of NK cells; and (3) an alteration in tolerant recipients of the normal distribution of the two major peripheral blood γδ T-cell subsets (namely δ1 and δ2), with an expansion of δ1 T cells and an increase in the δ1/δ2 T-cell ratio. Martínez-Llordella et al. [80] were the first to employ whole-genome Affymetrix microarrays to comprehensively analyze the blood molecular patterns associated with the tolerance phenotype. Blood samples from tolerant recipients were enriched in transcripts related to γδT cells and NK cells. Operationally tolerant and non-tolerant recipients also differed in the distribution of circulating γδ T-cell subsets and in the frequency of $CD4^+CD25^+Foxp3^+$ T cells. This cell subset was increased in tolerant patients, albeit no differences in $Foxp3^+$ transcript levels between tolerant and non-tolerant recipients were noted.

Martínez-Llordella et al. subsequently expanded their initial observations to a larger cohort of patients (28 operationally tolerant and 33 non-tolerant recipients) [203]. The tolerance-related expression dataset was enriched in NK- and γδ T-cell–related transcripts and significantly correlated with the frequency of circulating NK and γδ (but not $CD4^+CD25^+Foxp3^+$) cells [203]. Significant transcriptional differences were also observed in magnetically sorted peripheral blood mononuclear cell (PBMC) subsets from tolerant and non-tolerant recipients. Furthermore, three predictive blood gene expression signatures (containing two to seven genes) were identified.

Böhne et al. recently reported the results of the first prospective immunosuppression withdrawal trial in liver transplant recipients that included blood and liver tissue transcriptional biomarker analyses [147]. In this study 75 of the 98 liver recipients completed the trial, 57 of whom rejected while 41 were successfully weaned. Sequential blood and/or liver tissue samples from 75 recipients were analyzed using whole-genome microarrays and qPCR. The enrichment in PBMC NK-related transcripts described by Martínez-Llordella et al. [203] was already present at enrolment (i.e. before the discontinuation of immunosuppressive drugs was initiated), thus confirming the results of previous retrospective studies. In contrast, no differences in Foxp3 transcript levels or $CD4^+Foxp3^+$ T cells were noted between tolerant and non-tolerant individuals at enrolment. Transcriptional differences between tolerant and non-tolerant recipients were also identified at the graft itself. The intragraft gene expression profile, however, was mainly enriched in genes involved in iron homeostasis, and showed no overlap with the PBMC-derived expression markers. These markers were found to be independent of the type of immunosuppression and all other clinical parameters associated with the success of drug withdrawal. In agreement with the blood results, at enrollment no differences between tolerant and non-tolerant patients in intragraft $CD4^+Foxp3^+$ T cells or Foxp3 mRNA levels were detected. Importantly, in a side-by-side comparison, liver tissue-derived transcriptional signatures were found to be more accurate and reproducible at predicting the success of drug withdrawal than PBMC-derived signatures [147].

Together these studies suggest that operationally tolerant liver recipients have unique blood and liver tissue gene expression patterns that could be useful to discriminate between tolerant and non-tolerant recipients. NK cells and related transcripts appear to be the most robust blood markers of operational tolerance, as they are already present in the blood of tolerant liver recipients before immunosuppressive drugs are discontinued. The role of $CD4^+CD25^+Foxp3^+$ T cells is less clear due to the confounding effects of pharmacological immunosuppression. Importantly, blood cellular and transcriptional markers do not appear to reflect the nature of intragraft immune responses. Furthermore, liver tissue-derived biomarkers are more accurate than blood-related markers at predicting the success of drug withdrawal strategies.

Brouard et al [205] performed the first molecular profiling analysis of operationally tolerant kidney recipients. The study included

17 operationally tolerant recipients (i.e. stable graft function without immunosuppression for at least 2 years), 22 chronic rejectors, 10 patients on corticosteroid monotherapy, 12 stable patients on standard immunosuppressive treatment, and 14 recipients with acute rejection. A custom immunology-focused cDNA microarray (Lymphochip) was employed to analyze blood samples from a training group of five operationally tolerant recipients, 11 chronic rejectors, and eight age-matched healthy subjects. A set of 49 genes was able to differentiate operationally tolerant patients from healthy subjects, and chronic rejectors were identified. On first analysis [205] the tolerance-related expression pattern was found to be enriched in T-cell–related genes and in genes involved in cell cycle regulation, but a subsequent reanalysis of the same dataset revealed a significant enrichment in B-cell–related transcripts [206,207]. Operationally tolerant kidney recipients exhibited an increased frequency and absolute number of circulating B cells with a potentially inhibitory profile [207].

A significant contribution of circulating B cells to the blood gene expression profiles noted in operationally tolerant kidney recipients was also described by the investigators of two large multicenter studies [208,209]. Newell et al. reported the results of the Immune Tolerance Network (ITN) US multicenter study, in which 25 operationally tolerant kidney patients (i.e. stable graft function without immunosuppression for at least 1 year) and 33 stable kidney recipients on triple immunosuppression were analyzed. Whole blood Affymetrix microarray experiments were performed on samples collected from a training set of 19 operationally tolerant recipients, 27 immunosuppressed recipients, and 12 healthy controls. Twenty-two of the 30 genes were differentially expressed by more than two-fold between tolerant and immunosuppressed recipients and were B-cell specific. These differences were not observed when operationally tolerant patients were compared to healthy controls. Clearer evidence of the association between B cells and operational tolerance was provided by the demonstration that CD20 transcript levels were increased in urine samples from tolerant recipients as compared with both immunosuppressed patients and healthy individuals. The Indices of Tolerance/RISET (Reprogramming the Immune System for Establishment of Tolerance) Consortium European multicenter study [209] evaluated whole blood samples from 11 operationally tolerant patients, 11 stable recipients under corticosteroid monotherapy, 10 patients on immunosuppressive treatment without CNIs, 30 patients under CNI-based treatment, nine patients with chronic rejection, and 19 healthy controls. Operationally tolerant patients exhibited a higher number of circulating B and NK cells compared to healthy controls and all other study groups. The expansion in the number of B cells was mainly due to an increase in the number of transitional and naïve B-cell subsets. Operationally tolerant patients expressed a unique set of genes not shared by the remaining comparison groups and enriched in B-cell–related pathways. In this study Foxp3 transcription per se was not significantly increased in tolerant patients, but a combinational analysis calculating the ratio of Foxp3 to MAN1A1 transcription could discriminate between drug-free patients, stable kidney recipients, and recipients undergoing chronic rejection. These results could be also reproduced in patient samples provided by the ITN study.

These studies have a number of methodological limitations. In kidney transplantation the specificity for tolerance of the gene signatures identified in the retrospective cross-sectional studies described above is difficult to establish. The main problem derives from the lack of appropriate comparators. Indeed, there is no such thing as an adequate control group for allograft kidney recipients who exhibit stable graft function despite receiving no immunosuppressive drugs. The absence of biopsies from tolerated organs is another potential problem. First, a "minimal" form of subclinical rejection cannot be excluded. Second, whether analyses on peripheral blood samples constitute a good surrogate of the immune responses taking place within the graft is unclear. The stability and prognostic value of the kidney tolerance-related signatures is also unknown and will need to be determined in long-term longitudinal studies. In liver transplantation the availability of a prospective immunosuppression withdrawal trial [147] incorporating protocol liver biopsies partially addresses some of the methodological limitations of kidney studies. However, the cohort of liver recipients from whom the predictive gene signatures were derived is still relatively small. Therefore, the robustness and stability of these signatures in large independent validation cohorts cannot be taken for granted. Furthermore, the long-term outcome and overall clinical benefit of drug withdrawal in liver transplantation is still unknown.

Summary

There is general consensus that individual patients come to transplantation with widely variable immune competence, and that their needs for immunosuppression, both in terms of amounts and types, are similarly varied. At present, there are no prospectively validated ways to stratify patients based on risk for rejection or immunosuppression-related complications, and only general associations between emerging biomarker assays and patient outcomes exist. As such, immune management remains largely driven by reactions to complications rather than pre-emptive actions. Nevertheless, the marked improvement in the collective mechanistic understanding of the biology of rejection that has characterized the past two decades is now informing the design of mechanistically driven monitoring tools. Their development and validation will play a major role in the improvement of transplantation, and their deployment will undoubtedly be a part of the transplant clinician's future armamentarium for patient care.

CHAPTER 91

Protective Immune Competence after Organ Transplantation

Aneesh K. Mehta
Division of Infectious Diseases, Department of Medicine, Emory University School of Medicine, Atlanta, GA, USA

Introduction

Advances in immunosuppressive regimens and in multidisciplinary clinical care have significantly improved short-term outcomes in transplant recipients. However, improvements in long-term outcomes have plateaued due to complications of immunosuppressive medications, including metabolic dysregulation, infections, and malignancies [1,2]. The types of post-transplant infections and their epidemiology are continuously changing due to newer immunosuppressive regimens, expanding donor and recipient criteria, improved longevity of recipients, and mounting ability to provide prophylaxis, administer vaccinations, and monitor the immune status of transplant patients [3]. Thus, the field of transplant infectious disease continues to evolve along with the shifting patterns of morbidity associated with traditional and novel pathogens. The dynamic nature of transplant infectious diseases is outlined in Chapters 92–94.

Achieving the optimal balance of immune modulation has been constrained by the inability to characterize the net state of immunosuppression for the individual patient. Further complicating the assessment of protective immune competence is the recognition that one's immune system addresses the challenge of every pathogen differently. Therefore, the equilibrium between alloimmunity and protective immunity in a transplant patient is more than a dichotomous balance of simple scale; rather it is more akin to a web of interacting influences.

Ideally, a simple, non-invasively obtained biomarker or set of biomarkers linked to a particular clinical outcome would allow for targeted, individualized treatment plans for transplant recipients. Dinavahi and Heeger have reviewed the diverse methods and early results produced in this promising quest [4]. Much of this work has focused on the characterization of lymphocytes populations and functions relevant to alloimmunity. The methods employed have included ELISPOT, flow cytometry, antibody detection, gene expression, and "omics" assays. These methods and their application are discussed in detail as they relate to alloimmunity in Chapters 13 and 90. More recently, the field has begun to extrapolate these techniques and their data to the assessment of protective immunity. However, the translation of data from these assays to broader clinical contexts has suffered from each assay's variability and lack of standardization. This chapter will introduce methods proposed for the assessment of a patient's protective immune competence, and discuss their translation into broader clinical use.

Protective immunity

Earlier chapters have addressed thoroughly the biology of the immune system (see Chapters 2 and 5–7) as it faces exposure to the allograft and the therapeutic methods used to modulate these responses (notably, see Chapters 17, 98, and 101). However, these largely non-specific immune modulations also significantly thwart the recipient's immune system from appropriately identifying and controlling pathogens. Thus, it is critical to understand, and thus briefly recount here, the interplay between components of protective immunity and alloimmunity [5,6].

Primary immune responses

The innate immune system serves as the first line of defense against primary infection, and subsequently potentiates the adaptive immune system to produce an effective immune response. Natural killer (NK) cells and dendritic cells (DCs) comprise the primary cellular components of the innate immune system. NK cells can have direct cytotoxic effects on infected cells and also secrete cytokines, such as interferon-gamma (IFN-γ), which activate and coordinate the adaptive components. DCs recognize foreign pathogens through pattern recognition receptors (PRRs), including Toll-like receptors (TLRs), mannan binding lectin receptors, integrins, NOD-like receptors, and subsequently present antigens to the adaptive immune system [7]. PRRs are not specific for any particular pathogen but are specifically non-self. Depending on the type of pathogens and the context in which the innate immune system encounters them (e.g. which TLR is activated), these cells express cytokines and costimulatory molecules to induce proinflammatory or tolerogenic immune responses [5,8]. Potentiated by cells of the innate immune system, the antigen-specific T and B cells of the adaptive immune system differentiate into effector cells, disseminate throughout the organism, and eventually contract in number after further differentiation into memory cells. For more in depth discussions of this topic, see Chapter 7.

Immunologic memory

Immunologic memory encompassed memory B cells, antibody secreting plasma cells (ASCs), antibodies, and memory CD4 and CD8 T cells. Antibodies bind directly to pathogens or foreign proteins, and may neutralize or facilitate opsonization of pathogens to aid in controlling an infection. Memory B cells provide the ability to respond to these pathogenic challenges by rapidly differentiating

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

into ASCs upon reactivation to increase antibody titers. The memory T cells provide rapid cellular response by means of rapidly proliferating, secreting cytokines, and expressing cytotoxic enzymes to aid in clearance of the infection.

The mechanisms by which memory responses are maintained are being explored to date. The most effective means to maintain B-cell memory is repeated exposures to the antigen. However, even in the absence of antigenic exposures, memory B cells can persist for decades; vaccine-specific antibodies and memory B cells can be detected over 50 years after vaccination with the smallpox vaccine [9]. For antigen-specific T cells, after the effector response, ~90% are eliminated during the contraction phase. The majority of the remaining cells are converted into long-lived memory T cells [5]. Recent data have demonstrated that memory T cells are actually a heterogeneous set of populations that play distinct roles in future pathogen challenges. The type of infection, the underlying genetics, and the concurrent disease processes may significantly influence the relative frequencies of these pathogen-specific subsets [10]. Importantly, emerging research in cellular effects of immunosuppressive drugs seems to indicate that each agent may inhibit and enhance the development of these memory populations differently [11,12]. A thorough discussion of memory as it relates to the spectrum of alloimmunity is found in Chapter 9.

Immune competence prior to transplantation

Immune deviations prior to transplant

Chronic kidney disease (CKD) creates chronic inflammatory states that contribute to the morbidities faced by patients with end-stage renal diseases [13]. Studies have shown that patients with CKD have increased expression of inflammatory biomarkers, such as C-reactive protein, and increased levels of circulating proinflammatory cytokines [13–15]. Kimmel et al. demonstrated that the increased levels proinflammatory cytokines, such as tumor necrosis factor (TNF) and interleukin (IL)-1 correlated to mortality in dialysis patients, with a likely association with increased infections in these patients [15]. These data would suggest that in certain patients with CKD significant cellular immune dysfunction is involved in the progression of their diseases.

Patients with chronic liver disease develop immunologic impairments related to the hepatic dysfunction and resultant loss of functional mucosal immunity [16]. Patients with cirrhosis develop diminished intestinal barriers, likely due to alterations in intracellular channels and cell integrity, leading to increased translocation of pathogens through the intestinal lining into the mesenteric and lymphatic circulatory systems [17,18]. The resultant bacterial endotoxins and antimicrobial responses lead to systematic increases in inflammatory cytokines [19]. One of the most significant ramifications of bacterial translocation is the increased concentration of TNF, which is a vital component to hepatocyte injury response and usually promotes the proliferation of hepatocytes [20]. However, in the cirrhotic liver, the exaggerated levels of TNF induce increased secretion of IL-1, IL-6, and IL-8, and activation of downstream kinases and proteases, leading to dysregulation of the adaptive immune system [19].

A large proportion of the immune dysfunction in cirrhotic patients occurs within the cellular immune system. In particular, chronic hepatic dysfunction leads to dysfunction of neutrophils, monocytes, and macrophages, and reduced opsonization against pathogens [21–25]. Probably the most significant deficit seen is within the reticuloendothelial system (RES), which constitutes the primary defense system against pathogens in the blood, and approximately 90% of these immune cells are located in the liver [26]. Patients with a decreased RES activity are at higher risk of developing bacterial infections than patients with a normal RES [27]. As the hepatic dysfunction worsens, the RES function continues to be lost, and this is largely responsible for the higher rate of infections experienced in progressive cirrhosis [28].

Thus, the underlying pathology contributing to the patient's need for organ transplantation often leads to significant deficits in protective immune functions, which can contribute to infectious diseases morbidity in the post-transplant period.

Pretransplant assessments of protective immunity

During the evaluation process, potential transplant recipients undergo extensive assessment of infection risks and exposures, which is discussed by organ system in detail in Chapters 28–33. In general, most transplant centers evaluate serologies for previous pathogen exposures, including cytomegalovirus (CMV), Epstein–Barr virus (EBV), human immunodeficiency virus (HIV), and the hepatitis viruses [29]. While positive serologies for a pathogen imply some degree of protective immunity, they do not correlate to adequate protection post transplant [30]. These screening tests also allow for the development of vaccination strategies to boost protective immunity. While most vaccines have not been sufficiently studied in the maintenance of protection post transplant, the limited data and expert opinion indicate increased efficacy of vaccination prior to transplant when possible, and that it may boost immunity sufficiently to expand the donor pool for the recipient, as in the case of hepatitis B [31,32]. Completing these assessments and vaccinations provides a better characterization of protective immune competence and what challenges the net state of immunosuppression will bring for the patient.

Assessment of the "net state" of protective immunity

The concept of a transplant patient's "net state of immunosuppression," which encompasses all the factors that contribute to the risk for infections, is important to understanding the approaches to monitoring and caring for these patients [3,33,34]. Classically, this state has been influenced by the immunosuppressive regimens used, as well as disease-specific immune deficits (as described above), bone marrow function (e.g. ability to maintain appropriate leukocyte counts), perioperative complications, allograft/organ dysfunction, metabolic derangements, exposures to antimicrobials, and concurrent infections [3,34]. This concept has been very useful for ascribing epidemiologic risks for groups of patients with similar combinations of these factors. However, due to the difficulties in quantifying these factors, and thereby an inability to specifically quantify the net state of immunosuppression, clinicians have struggled to provide individual-level risk assessments in a patient. Recently, new monitoring tools have been introduced that are enabling more individualized assessments of post-transplant risks.

Transplantation immune cell function assay

In the last decade, the transplant community has seen great effort, if perhaps not great progress, in the development of biomarkers and immunologic assays to help guide clinical decision-making and aid in individualizing the care of transplant recipients. The first and only commercially available test to directly address the global immune system responsiveness is the ImmuKnow® assay (Cylex Inc., Columbia, MD, USA). This immune function assay, also

known as the Transplantation Immune Cell Function Assay (ICFA), measures the in-vitro production of ATP by $CD4^+$ T cells in response to stimulation by a mitogen [35]. As ATP is the primary energy source for all cells, including lymphocytes, and more immunosuppressant agents modulate T-cell functions, the assay is designed to quantify responses of T-helper cells as a surrogate marker for global cell mediated immune functional capacity [35]. The ICFA is Food and Drug Administration (FDA) cleared for assessing ATP content in cells from populations undergoing immunosuppressive therapy for solid organ transplantation, and thus reports immune responses based on the ATP detected: "low" ($\leq$225 ng/mL), "moderate" (226–524 ng/mL), or "strong" ($\geq$525 ng/mL). The test has not been approved to specifically assess a patient's need for immunosuppression but no validated guidelines exist for its use.

Several studies have examined this test as a predictor of cellular rejection and/or of infection. In general, no prospective randomized data are available for the use of this assay and as such, its utility remains unvalidated. Certainly, no utility has been demonstrated with regard to anticipating rejection in any setting. The data for this assay for assessing risk for infections are, however, more intriguing. Kowalski et al. published a multicenter retrospective analysis of relative risk for rejection in 504 solid organ transplant recipients (heart, kidney, kidney–pancreas, liver, and small bowel), who received prospective observational assessments with the ICFA at various times post transplant [35]. Recipients with immune response values of 25 ng/mL of ATP were 12 times more likely (95% CI, 4–36) to develop infections than recipients with stronger responses. Interestingly, this group's data demonstrated an intersection of the odds ratio curves for rejection and infection at 280 ng/mL of ATP, suggesting this value as the target immunologic zone for solid organ recipients [35]. Several subsequent studies have shown an association of low ICFA values with higher risk of infections in general [36,37], as well specific infections: BK virus (BKV) [38,39], CMV, EBV [40,41], post-transplant hepatitis C virus (HCV) [42–44], and invasive fungal infections [45]. However, the translation of these data to common use has been limited by the small numbers of patients, heterogeneity of immunosuppression, single center enrollment, and importantly, the wide variety of target immunologic zones conveying risk of infections. Two studies have suggested that patient ethnicity may affect the ICFA values when correcting for other clinical and demographic factors [46,47]. Furthermore, many of the studies showing a correlation of the ICFA values with infectious disease risks do not demonstrate a strong association of higher ICFA values with cellular rejection [38,48–50]. Therefore, a single ICFA value for a single patient does not produce high predictive value for risk of either infection or rejection events in the immediate period of time [47,51]. Thus, several targeted studies, and a recent meta-analysis of the studies of ICFA, have not shown clear efficacy of the assay in the general monitoring of transplant recipients [52–54].

An interesting aspect of utilizing the ICFA is to monitor the response after reduction of immunosuppression in order to control infections [55,56] and malignancies [57]. Gautam et al. utilized the ICFA to titrate the reduction of immunosuppression, in addition to antivirals, in 12 patients with a variety of post-transplant viral infections without any associated rejection [55]. However, while the mean ICFA was 56.8 ng/mL of ATP during infection and 194.5 ng/mL after reduction of immunosuppression, the ICFA value ranges overlapped significantly; 3–178 ng/mL and 53–409, respectively [55]. Lee et al. compared EBV viral loads to ICFA values in 18 pediatric liver transplant recipients, and in a subset of three patients with consistently high EBV viral loads, to determine the utility of ICFA values in titrating reductions in immunosuppression [56]. None of these patients developed post-transplant lymphoproliferative diseases (PTLDs); however, while all had increases in ICFA values, only two of three demonstrated reductions in EBV viral loads [56]. These studies are limited by very small numbers, but the approach shows promise in individualizing the reduction of immunosuppression in difficult-to-treat infections where T helper function is critical.

In summary, the role of the ICFA assay in post-transplant patient monitoring remains to be defined. It is conceivable that risk thresholds and appropriate monitoring schemes will vary by patient age and ethnicity, transplanted organ, and immunosuppressive regimen, particularly when lymphocyte counts are altered through depletional induction or rescue strategies. In addition, clinical trials comparing ICFA monitoring to other conventional monitoring are needed to fully understand the utility of this assay for patient risk assessment.

Monitoring immunoglobulins

As the importance of antibody mediated rejection has emerged in the past decade and a half, the study of memory B cells, antibody secreting cells, and antibodies in transplantation has grown concurrently. While checking the titers of pathogen-specific serologies does not predict post-transplant protection, several studies have implied that immunoglobulin levels in general may help predict protective immune competence. The first large study to examine the contribution of net state of protective immunity was that by Goldfarb et al. of 67 lung transplant recipients [58]. This group demonstrated a significant incidence of post-transplant hypogammaglobulinemia (70%) and severe hypogammaglobulinemia (37%), defined as IgG levels of $<$400 mg/dL in these lung transplant patients [58]. Infections, including bacterial, viral, and fungal, were significantly more common in patients with hypogammaglobulinemia ($P = 0.006$ for total infections) [58]. Severe hypogammaglobulinemia was further associated with invasive aspergillosis (incidence of 44%) and with patient mortality [58]. Yamani et al. reported on 111 consecutive heart transplant recipients who had immunoglobulin G (IgG) level monitoring at baseline and 3 and 6 months post transplant, finding that 10% of their cohort developed severe hypogammaglobulinemia, defined as an IgG of $<$350 mg/dL, after transplant [59]. Patients with severe hypogammaglobulinemia were found to be at increased risk of opportunistic infections compared to patients with an IgG of $>$350 mg/dL, with an odds ratio of 22.8 [59]. These patients were diagnosed with a variety of bacterial, viral, and fungal infections, without a dominant syndrome [59]. They also found that post-transplant hypogammaglobulinemia was highly associated with treatment of rejection, adding another mechanism by which rejection can induce risk of infections [59]. Similar conclusions were drawn from a study of 41 heart transplant recipients by Sarmiento et al., with the additional finding of pretransplant IgG, and in particular pretransplant IgG1, being associated with an increased risk of opportunistic infections [60]. This study also showed a preponderance of CMV disease in patients with hypogammaglobulinemia. After adjustment for clinical predictive variables, decreased values of post-transplant IgG remained significant predictors [60]. This same group attempted to extend these data to liver transplantation in a report of 46 consecutive liver transplant recipients from their center [61]. However, contrary to the heart transplant studies, in this study, pretransplant IgG

hypergammaglobulinemia and IgA hypergammaglobulinemia, with relative risks of 2.78 and 2.77, respectively, were associated with post-transplant infections [61]. Post-transplant immunoglobulin levels were no different between patients with or free from infections [61]. These findings were attributed to the immune stimulation of chronic liver disease, as described above, with resultant increasing antibody levels with increased severity of liver disease [61,62]. Recently, Fernández-Ruiz et al. analyzed the impact of hypogammaglobulinemia on infectious disease risk in 226 kidney transplant recipients, in whom serum immunoglobulin levels were prospectively quantified at baseline, 1 month and 6 months. The prevalence of IgG hypogammaglobulinemia in this cohort was 52% and 31% at 1 and 6 months, respectively, and was associated with higher incidences of infections generally, and specifically with bacterial infections [63]. These data did not indicate an association of CMV or other opportunistic viral infections with hypogammaglobulinemia within the first 6 months [63].

These studies provide preliminary evidence that monitoring of pre- and post-transplant immunoglobulin levels may serve a valuable role in predicting a transplant recipient's risk for infection. Alterations in immunoglobulin levels pretransplant seem to be linked with significant voids in protective immunity, while post-transplant hypogammaglobulinemia appears to extend the risk for infections. It is intuitive that alterations of humoral immunity may be linked to bacterial infections, given the dependence on neutralization, opsonization, and complement activation for clearance of these infections [63]. The lack of association CMV disease with hypogammaglobulinemia in many of these studies is not surprising given the primacy of T-cell immunity for the control of most manifestations of this virus. Again, the available data may not be generalizable for global use in transplantation. Most studies were single center and many were retrospective analyses. The definition of hypogammaglobulinemia and assays used to assess it varied across these studies. Also, these groups used different immunosuppressive regimens, infectious diseases diagnostics, and follow-up durations, and monitored for different infections. Given these variations, the association between acquired hypo- or hyper-gammaglobulinemia and risk for infections may not be causal, as many infections induce immune dysregulation leading to altered B-cell functions. However, given the ready availability and low cost of these assays at most transplant hospitals, the serial monitoring of serum immunoglobulin levels in well-designed multicenter studies, in particular in trials of new immunosuppressive agents, should be warranted.

Molecular monitoring of pathogens as surrogates for net state of immunosuppression

Molecular monitoring for pathogens, particularly quantitative polymerase chain reaction (PCR) assays for viral pathogens, has become commonplace in transplant centers. Many experts believe that these pathogen monitoring tools may be used as markers of the net state of protective immune competence [64]. This idea emerged primarily from the experiences in monitoring for polyoma BKV for the prevention of BK nephropathy. After the original descriptions of BKV inciting a significant incidence of tubular nephritis and nephropathy in kidney allografts and that BKV titer correlates with risk of polyoma virus associated nephropathy (PVAN), PCR monitoring for BKV replication in kidney transplant recipients has become increasingly prevalent [65–67]. Much of this experience demonstrated the possible utility of reduction of immunosuppression in response to BKV viremia [68–70]. Ginevri et al. published the first report of specific reductions in immunosuppression in response to BKV viremia as pre-emptive intervention to prevent PVAN in 62 pediatric kidney transplant recipients [71]. This cohort was prospectively monitored with quantitative BKV PCR from blood and urine samples. This group's four stage process for reducing immunosuppression demonstrated clearance of viremia in all patients without any associated incidence of allograft rejection [71]. BKV-specific ELISPOT assays were used to monitor the viral-specific T-cell responses and demonstrated an association of poor responses with risk for BKV viremia. (The ELISPOT assay is described in Chapter 13). Importantly, it was shown that the pre-emptive reduction of immunosuppression improved viral-specific responses, and these improved responses were associated with viral clearance [71]. Several studies have further demonstrated the pre-emptive reductions in immunosuppression in kidney transplant patients with BKV viremia are associated with viral clearance, prevention of PVAN, low incidence of subsequent rejection, and good long-term renal function [67,72–76]. Thus, in renal transplant patients who develop BKV viremia, the BKV PCR assay provides a good assessment of the net state of immunosuppression and can be used to guide the balance of protective immunity and alloimmunity.

More recently, many have speculated that EBV monitoring may inform the assessment of the net state of immunosuppression applicable to all solid organ transplantation groups. To address the utility of EBV PCR in this manner, Ahya et al. conducted a retrospective analysis in 31 lung transplant patients who were followed with serial plasma and whole blood assays for up to 2 years after transplantation [77]. Patients with detectable EBV viral loads had a significantly lower incidence of grade 2 or higher rejection compared to recipients without detectable EBV (45% vs. 83% respectively, with an odds ratio of 0.17) [77]. Importantly, having detectable EBV was not associated with risk of other infections (odds ratio = 1.6) [77]. Doesch et al. published similar data from a study evaluating the utility of EBV PCR as a prognostic tool for detecting the development of PTLD in 172 stable adult heart transplant recipients [78]. Thirty-six (21%) patients had sustained detectable EBV, which did not correlate to the risk of PTLD, but was associated with level of immunosuppression [78]. A study of 41 pediatric heart transplant recipients also found a strong relationship between the type and amount of immunosuppression and increased EBV viral load [79]. Bakker et al. demonstrated the ability to exploit EBV monitoring to guide immunosuppression in a prospective evaluation of 75 lung transplant recipients [80]. Patients at this center received EBV viral load monitoring at least twice a year, and at least monthly after a positive test, and when demonstrating a rising slope, their immunosuppression was reduced [80]. Of the 26 (35%) patients who developed detectable EBV, immunosuppression could be reduced in 19 and led to a rapid and sustained decrease in EBV viral load without associated rejection or bronchiolitis obliterans [80].

These data provide the very real possibility of using the viral PCR testing already employed in monitoring patients for viral activity as a measure of the net state of immunosuppression. One of the current limitations to broadly translating these data is the variety of assays being employed and their broad spectrums of sensitivity and dynamic ranges [81–83]. The variability of some PCR assays is being addressed with the introduction of World Health Organization (WHO) standards for CMV and EBV. However, the highly variable rates of pathogen exposure and the unique biology of each organ transplant type make the application of a single PCR assay difficult. Some experts have suggested that the simultaneous quan-

tification of multiple viruses would improve specificity of viral monitoring as a surrogate for assessing the level of immunosuppression [64]. Given the ready availability of PCR assays, the diminishing costs of the technology, and improved reproducibility with international standards, the utility of viral PCR assays, either in single or multiplex format, for the assessment of immunosuppression should be evaluated further in large clinical studies.

Assessment of pathogen-specific protective immunity

The assessments of immunosuppression and global protective immunity described above provide insights into the individual level of risk for infectious diseases in general and could influence clinical care tremendously. However, it is well observed that select patients have difficulty eliminating specific infections, while successfully controlling other pathogens. Thus, the understanding of the net state of immunosuppression lacks the specificity of informing the clinician on which pathogen the patient is at risk of. There is growing research into assessments of immunity to specific pathogens and evidence that these data can convey specific estimation of risks to those pathogens. In addition, the ability to monitor for parameters of effective immune responses may aid in determining the type and duration of monitoring and treatment of infectious diseases.

Immunologic testing

It has become well understood that monitoring of pathogen-specific antibody titers in immunosuppressed patients does not sufficiently establish a quantitative risk for disease from that pathogen, particularly for pathogens, such as viruses, that require T-cell help and/or cytotoxic activity for control [84,85]. Optimal T-cell activation, which is the primary target of most immunosuppressive drugs, requires a delicate network of signals and eventually results in the formation of immunologic memory [86]. The memory T-cell compartment is comprised of subsets of both CD4 and CD8 T cells that rapidly proliferate, secrete inflammatory cytokines, and kill infected cells upon infection to eliminate the pathogen. Recent technologic developments in measurements pathogen-specific immunity, including pathogen–peptide/major histocompatibility complex (MHC) multimers, peptide proliferation assays, and cellular cytokine assays by ELISPOT and flow cytometry, have allowed quantification, characterization, and monitoring of pathogen-specific T cells [87–90]. MHC multimers, usually tetramers, detect $CD8^+$ or $CD4^+$ T-cell responses to a single HLA-restricted epitope from a viral protein. Several studies in organ transplantation have utilized viral multimers, including those for CMV, EBV, and BKV, to detect and track pathogen-specific T-cell populations post transplant. These assays consistently show that transplant patients on immunosuppression are able to generate and expand viral-specific T cells, and the kinetics often correlate to the viremic course [91–93]. These data, however, indicated that the enumeration of pathogen-specific T cells alone does not predict the level of protection for the patient due in part to the lack of data as to the functional quality and proliferative ability of these cells.

An effective anamnestic T-cell response is marked by rapid cytokine secretion. The mixture of cytokines secreted by T cells influences the character of this pathogen-specific response; for example, Th1 cytokines (TNF, IFN-γ, IL-2) are important for immune responses against intracellular pathogens, such as EBV and CMV, whereas Th2 cytokines (IL-4 and IL-10) are crucial for generating immune responses to extracellular infections. Measures of these characteristic responses are proving useful for predicting protection in transplant recipients, particularly against CMV, which has been well reviewed by Egli et al. [90]. These assays usually involve in-vitro stimulation of lymphocytes from whole blood or from PBMCs with a single or combination of peptides, an overlapping peptide pool, or whole lysate of a particular virus. HLA-specific epitopes stimulate $CD8^+$ and/or $CD4^+$ T cells to produce cytokines, which are then detected by a flow cytometer, ELISPOT, or enzyme-linked immunosorbent assay (ELISA) (Figure 91.1). As would be expected, baseline functional immunity correlates with serostatus [93]. Data from several studies indicated that the ability to produce cytokines, usually IFN-γ, with in-vitro stimulation with viral antigens correlates with protection against viral replication and viral diseases [94–98]. However, these responses may not be predictive in all populations. Transplant recipients at high risk of CMV infection, as defined by CMV donor seropositive–recipient seronegative pairing, seem to be capable of developing a diverse population of CMV-specific T cells, but these responses do not predict freedom from CMV disease [99,100]. The lack of clearance of CMV viremia with antiviral therapy may be associated with deficiencies of a functional specific T-cell response and not antiviral resistance [93]. Another utility of measurements of these responses may be the determination of antiviral treatment [90]. For example, patients who are being treated with antivirals and develop improved viral-specific T-cell function may be able to stop treatment earlier than similar patients without functional responses. The ability of these data to predict risk of infection and ability to control infection are immensely interesting, yet need to be evaluated in larger studies.

These assays for the enumeration and functional characterization of pathogen-specific immunity have tremendous research potential, but the feasibility of moving them into the clinical setting is limited [90]. These assays require specialized equipment, expensive and temperamental reagents, and significant technical expertise and time. Most importantly, these assays lack standardization across laboratories, which in turns inhibits the ability to create reference ranges or categorical values. However, a recently developed assay, QuantiFERON-CMV® (Cellestis Ltd., Valencia, CA, USA), addresses many of these limitations for CMV immune monitoring. For this assay, whole blood is cultured overnight with a combination of 21 CMV peptides from several different CMV proteins and specific for 20 HLA class I haplotypes. Two other tubes of whole blood are simultaneously incubated for 24 h with no antigens (negative control) or with phytohemagglutinin (PHA; positive mitogen control) [101]. IFN-γ production from each tube is quantified by an ELISA. Results are positive when the CMV peptide response minus the negative control response is $\geq$0.2 IU/mL of IFN-γ [101]. The test is very sensitive and specific in detecting CMV immunity in healthy controls [101]. The predictive value of this test for CMV disease has been variable. In a study of 297 samples from 39 lung transplant recipients drawn at the time of a bronchoscopy, QuantiFERON® responses did not predict for episodes of CMV reactivation in lung transplants, but the group did not evaluate viremia [102]. In a study better designed to predict viremia, Kumar et al. evaluated this test at baseline, 1, 2, and 3 months post transplant in 108 lung, kidney, liver, and kidney–pancreas recipients from a single center [103]. CMV immunity was detected in 35.2% of patients, though a lower cut-off of 0.1 IU/mL of IFN-γ was used in this study [103]. CMV disease occurred in 5.3% patients with detectable CMV responses compared to 22.9% of those with a negative response ($P = 0.038$) [103]. Thus, a positive result was highly predictive of freedom from disease, but a negative test was not predictive of developing CMV. Lisboa et al. followed this with a prospective study of QuantiFERON-CMV® values in 37

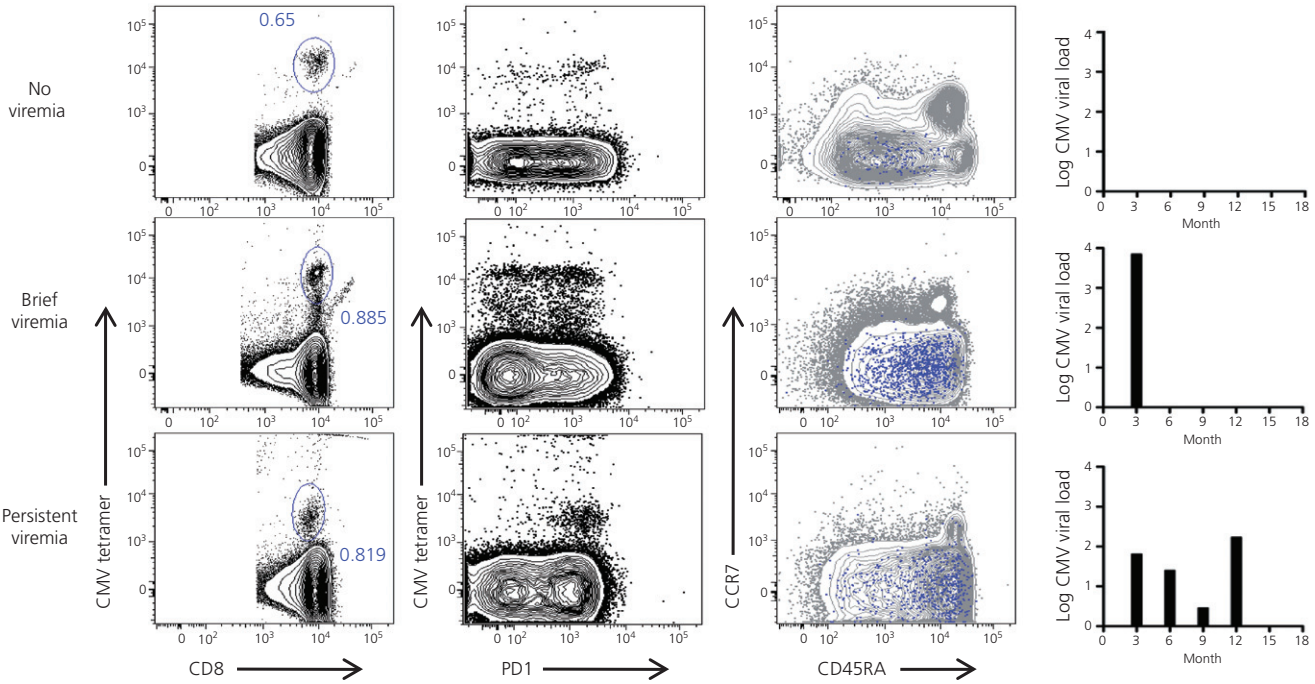

Figure 91.1. Example of integrating cellular phenotyping by flow cytometry, enumeration of viral-specific T cells by MHC tetramers, and virologic monitoring by PCR. Data from three patients are displayed, one health control without viremia and two transplant patients, at month 18. The second column demonstrates duration of cytomegalovirus (CMV) viremia is associated with increased expression of PD-1 on CMV-specific $CD8^+$ T cells. The third column displays CMV tetramer stain cells overlaying bulk $CD8^+$ T cells and demonstrates the skewing of both $CD8^+$ T cells in general and CMV-specific $CD8^+$ T cells with persistent CMV viremia.

transplant recipients who developed low-level viremia [104]. In patients with a positive test at onset, the frequency of spontaneous viral clearance was 92.3% compared to 45.5% in those with a negative test ($P = 0.004$) [104]. These data demonstrate in limited studies that this method may have a clinically useful predictive value in determining the risk of developing CMV viremia and the ability to control low-level viremia without antiviral medications. However, this test is limited by the frequency of indeterminate results, occurring when both the mitogen and the CMV results are <0.2 IU/mL, of up to 30% in transplant patients [102,103]. Furthermore, the positive threshold of 0.2 IU/mL has not been well validated in solid organ transplant recipients [90]. Yet, the ease of performing the assay and a determined interpretation has allowed some centers to utilize this test in clinical monitoring. It is expected more assays of a similar nature will be available for study in transplant patients and these and the ongoing study will inform the transplant center on their utility in the coming years.

Summary

The introduction of newer immunosuppressive regimens and better clinical monitoring tools has improved transplant patient survival steadily over the last three decades. However, the long-term survival of patients is still restricted by the morbidity of infections, which in some patient groups exceeds that of acute rejection [105]. While the models of the net state of immunosuppression and pathogen-specific protective immunity have been understood, the ability to explicitly quantify these concepts and translate them to patient-specific risk is still elusive. It has been understood that every type of allograft conveys unique risks of infectious diseases based on anatomy and level of exposures to external and non-sterile internal environments. More recently, data from clinical trials have indicated that specific immunosuppressive medications incur unique infectious risk. Examples of agent-specific modulation of risk are a proposed association between mTOR inhibition and a decreased risk of CMV infections [106–109], and the emergence of the increased incidence of EBV-related PTLD in clinical studies of costimulation blockade [110] These trials and mechanistic data indicate each agent and regimen specifically modulates generation, maintenance, and quality of protection immunity [11,12]. Therefore, it is highly plausible that the assessments of protective immune competence and the probability of infections will require stratification by age, ethnicity, organ type, and immunosuppressive regimen. Despite the complex nature of the transplant patient's state of protective immunity, if the recent data presented in this chapter are an indication, the field is burgeoning into an era that provides the clinician with the tools for patient-specific predictive assessments of protective immune competence.

CHAPTER 92

Donor-derived Infections after Organ Transplantation

Marissa B. Wilck and Emily A. Blumberg
Perelman School of Medicine, University of Pennsylvania; Hospital of the University of Pennsylvania, Philadelphia, PA, USA

Introduction

Transplant recipients are known to be at risk for numerous infectious diseases (see Chapters 93 and 94). While their immunocompromised state (a result of therapeutic immunosuppression and the influence of their underlying organ failure) clearly contributes to this risk in a manner similar to in other states of immunodeficiency, transplant recipients have unique risks related to the transplanted organ itself. Indeed, transplantation itself breaches the mechanical infectious disease barriers that effectively exclude many pathogens, and in introducing an organ with disparate major histocompatibility molecules, perturbs a major means of immune surveillance. This chapter will provide an overview of donor-derived infections and guidelines for their diagnosis, treatment, and avoidance.

General considerations

Donor-derived infections are a significant source of morbidity and mortality following solid organ transplantation. The actual incidence of these infections is unknown, in part due to the diversity of the infections, the absence of required reporting for anticipated transmissible infections, and the failure to recognize and/or report unanticipated donor-derived events. In data from US surveys of infections reported to the Organ Procurement and Transplantation Network (OPTN), <1% of transplants were associated with donor-derived infection [1,2]. Since most reports stem from deceased donors, it is unknown whether this accurately reflects the incidence of transmissible infections from living donors, which is presumed to be lower. Of note, this estimate does not include common expected potentially transmissible infections such as cytomegalovirus (CMV) or Epstein–Barr virus (EBV); inclusion of these infections would increase the overall incidence of donor-derived infections.

Donor-derived infections are a well-recognized risk of transplantation, and in some cases predonation identification of infection has led to the implementation of prophylactic strategies to mitigate the impact of pathogen transmission. Other infections, including geographically restricted mycoses and tuberculosis, may not be anticipated, and thus available prophylactic strategies are not immediately implemented following transplantation; a result is the development of symptomatic infection. Recent reporting has focused on the occurrence of infections that are more difficult to diagnose and have limited or no treatment or prophylactic options.

Donor-derived infections have been attributed to diverse pathogens, and bacteria, viruses, fungi, protozoa/parasites, and prions have all been transmitted via organ transplantation [1–4]. The etiologies of donor-derived infections vary with donor geography and demographics (Table 92.1). Given the greater geographic diversity of donor populations and the more frequent use of expanded criteria donors (see Chapter 53) in the US, there is increased potential for unexpected infections with geographically restricted organisms related to donor demographics [5].

Although the changing demography of the donor population has had a significant impact on outcomes in patients with donor-derived infection, other factors have also been important. These include the choice of immunosuppressive agents, improved diagnostics both for screening and treatment, and the availability of prophylactic antimicrobials. In many cases, not all recipients may be equally affected by a transmission event [1,3]. This may reflect the specific pathogen, variable infection of different donor organs by a given organism, recipient immunity, and the impact of specific immunosuppressive regimens or antimicrobial interventions.

The timing of donor-derived infections is variable and related to the specific pathogen, the use of antimicrobial prophylaxis, and the choice of immunosuppression (see Chapter 94). Bacterial infections typically occur in the first month after transplant; other pathogens may present later [4]. Prophylaxis may alter the timing of symptomatic infection, e.g. CMV typically presents following suspension of prophylaxis [6].

There are several clues that should alert providers to the possibility of donor-derived infection, especially when considering infections presenting in the first few months after transplant. These include the development of unanticipated infection with unusual or unexpected organisms in a recipient for whom there is no other explanation or the development of the same infection in multiple recipients from the same donor. Additionally, the finding of infection in a donor, either pre- or post-mortem, should alert providers to the potential for transmissible infection to recipients.

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Table 92.1. Major pathogens reported to cause donor-derived infections in transplant recipients*

Organism	Distribution	Comment
Bacteria		
Pyogens (e.g. *Staphylococcus aureus*, *Pseudomonas aeruginosa*, etc.)	Worldwide	
Treponema pallidum	Worldwide	
Mycobacterium tuberculosis	Worldwide	Most common in Africa, South-East Asia, India, Pakistan, Afghanistan, and Russia; also in donors with history of incarceration, homelessness, alcohol abuse, history of untreated tuberculosis or tuberculosis contact
Fungi		
Candida	Worldwide	Perforated abdominal viscus
Histoplasmosis	Ohio and Mississippi river valleys in the US; South America, Asia, and Africa	
Coccidioides	South-western US, northern Mexico, Central and South America	
Aspergillus	Worldwide	Association with immunosuppression in donors
Cryptococcus	Worldwide	Association with immunosuppression in donors, including cirrhosis
Parasites/protozoa		
Toxoplasmosis	Worldwide	More common in Latin America, Sub Saharan Africa, parts of Europe
Trypanosoma cruzi	Latin America	
Strongyloides stercoralis	Worldwide	Most common in tropical, subtropical, and warm temperate regions
Viruses		
Cytomegalovirus	Worldwide	
Epstein–Barr virus	Worldwide	
Hepatitis B virus	Worldwide	Most common in South-East Asia and Africa
Hepatitis C virus	Worldwide	Most common in injection drug users, commercial sex workers and other high-risk sexual behaviors, transfusion prior to 1994
Human immunodeficiency virus (HIV)	Worldwide	
Human T-cell lymphotropic virus 1 (HTLV 1)	Worldwide	Asia, Caribbean, South America, Oceania, and West Africa
West Nile virus	Worldwide	Seasonal with incidence based on prevalence of infection in mosquito vector

*Additional organisms transmitted by organ donors include other bacteria (*Bbrucella*, *Bartonella*, non-tuberculous mycobacteria); fungi (*Scedosporium*, *Prototheca*), parasites/protozoa (*Plasmodium*, *Balamuthia*), viruses (other herpesviruses, parvovirus, rabies, lymphocytic choriomeningitis virus), and prions.

Screening

Optimal screening of donors should begin with obtaining a medical and social history and physical exam, and include laboratory testing for common transmissible infections [7] (Table 92.2). As donor organs are often retrieved from remote hospitals, the recipient clinician should become skilled in eliciting details from the procuring center regarding the history and physical exam relevant to the donor's potential for infectious agent transmission. Since donor transmissions may result from either latent or active infections in the donor, screening should evaluate both. In the US, the OPTN has established a minimum standard for donor screening. This includes serologic testing for human immunodeficiency virus (HIV), hepatitis B and C viruses (HBV and HCV), syphilis, CMV, and EBV, and blood and urine cultures [8]. Additional recommended screening tests include toxoplasmosis antibody (especially for cardiac donors), herpes simplex and varicella antibodies, and human T-cell lymphotropic virus 1 and 2 (HTLV 1 and 2) antibody [7]. Donor medical and social history and geography may be important clues to additional potential donor infections, and dictate the need for additional testing (Table 92.2). In some cases, the results of these assessments will exclude a donor from donation because the risk to the recipient exceeds an acceptable threshold, but in other instances test results may dictate prophylactic interventions for the recipient.

Regardless of the test, it is important to consider the potential limitations of test accuracy due to hemodilution [7,8]. Donors who require massive volume repletion with blood products, colloids, or crystalloids may have false-negative test results; consequently, whenever possible pretransfusion samples should be used for donor screening [7–9]. If the only available specimens are post-transfusion samples, recommendations for calculating the impact of hemodilution are outlined in a guidance document from the Food and Drug Administration (FDA) [10].

Determining the ideal donor testing platforms for specific infections varies with the pathogen and test availability. It is notable that although organ donors are frequently tissue donors, testing recommendations differ for organ and tissue donors, in part due to both the availability of different assays and the impact of false-positive test results on donor utilization. In the US, tests used for routine organ donor screening must be approved by the FDA [8]. Serologic testing is most useful for determining the presence of past infections that may reactivate in the recipient after transplant (e.g. CMV). Nucleic acid amplification testing (NAT) will identify active infections prior to the development of an antibody response and has been most commonly used for the identification of HIV, HCV, and HBV in donors with recent infections. The time between infection and detection of nucleic acid and antibody varies with the pathogen and with the test. One study estimated that time to identification of infection in tissue donors was 7 days by NAT versus 22 and 70 days by antibody testing for HIV and HCV, respectively; thus, infection is identified at a significantly earlier time using NAT [11] (Table 92.3). Newer antigen antibody tests may identify HIV infection within 3–5 days of NAT positivity, and may be another option for earlier identification of infection; currently, these tests are not licensed for organ donor screening in the US [12]. "Window-period" infections (i.e. those that occur prior to the development of a positive laboratory test) remain an uncommon source of donor-derived infection. NAT testing may be most useful for identification of window-period infection for HCV as it increases the test yield ten-fold [13,14]. Whether NAT testing should become the standard for organ donor screening for HIV, HBV, and HCV is controversial; there has been concern regarding the potential for

Table 92.2. Recommended donor testing for major transmissible pathogens

Disease	Primary test*	Additional tests	Deceased donor	Living donor
Cytomegalovirus (CMV)	CMV IgG*		Yes	Yes
Human immunodeficiency virus (HIV)	Anti-HIV 1 and 2*	NAT	Yes.	Yes
		Antigen testing (should not replace serology)	NAT for donors at increased risk for HIV	NAT if new risk factors close to transplant
Hepatitis B virus (HBV)	HBsAg, anti-HBcAb*	HBV DNA (should not replace serology)	Yes	Yes
			NAT for donors at increased risk for HBV	Check NAT if new risk factors close to transplant
Hepatitis C virus (HCV)	Anti-HCV*	NAT (should not replace serology)	Yes	Yes
			NAT for increased risk donors, possibly universal	Check NAT if new risk factors close to transplant
Syphilis	RPR or VDRL*		Yes	Yes
Epstein–Barr virus (EBV)	EBV antibody tests*		Yes	Yes
Bacteria	Blood and urine cultures*	Respiratory cultures	Yes	No
Additional Testing based on risk				
Human T-cell lymphotropic virus 1 and 2 (HTLV 1 and 2)	Serology	NAT		
West Nile virus	Serology	NAT		
Toxoplasma	Serology		Heart donors	
Trypanosoma cruzi	Serology (EIA, IFA)	Peripheral blood smear, NAT		
Strongyloides stercoralis	Serology	Stool ova and parasites		
Leishmania	Serology			
Plasmodium	Peripheral blood smear	Antigen detection		
Schistosomiasis	Urine and stool ova and parasites	Serology	Kidney donors	Kidney donors
Mycobacterium tuberculosis	Skin testing with purified protein derivative (PPD)	Interferon-γ release assay	No	Yes
Coccidioides	Serology (immunodiffusion, complement fixation)	Antigen testing		
Histoplasmosis	Serology (immunodiffusion, complement fixation)	Urine and serum antigen		

*Required by US Organ Procurement and Transplantation Network
NAT, nucleic acid amplification testing; HBsAg, hepatitis B surface antigen; HBcAB, hepatitis B core antibody; HBSAB, hepatitis B surface antibody; EIA, enzyme-linked immunoassay; IFA, indirect immunofluorescence assay; RPR, rapid plasma reagin; VRDL, Viral and Rickettsial Disease Laboratory.

Table 92.3. Impact of window period on detection of human immunodeficiency virus (HIV) and hepatitis C virus (HCV) in potential organ donors*

		Window period* serology	Estimated risk of undetected infection during serology window period*	Window period* nucleic acid test	Estimated risk of undetected infection during nucleic acid test window period*
HIV	Normal risk	22	1.72 (0.63–4.40)	7	0.55 (0.2–1.3
	Increased risk~	22	8.54 (1.52–23.99)	7	2.72 (0.49–7.44)
HCV	Normal risk	70	3.65 (1.69–8.30)	7	1.16 (0.53–2.61)
	Increased risk (as defined in [19])	70	19.91 (10.75–31.93)	7	1.99 (1.09–3.23)

*Window period is defined as the time between when the virus reaches a transmissible level to the time when it is detectable by standard laboratory test (serology or NAT).

organ donor loss due to false-positive NAT and unavailability of testing in a timely and reliable fashion by all Organ Procurement Organizations (OPOs). Consequently, a consensus conference convened in 2009 recommended that NAT be reserved for donors perceived to be at increased risk for infection with HIV, HCV, or HBV [15].

Recipient evaluation

Since infections after transplant may occur due to reactivation of latent recipient infection or to de-novo infection of the recipient from the donor, a key to identification of donor-derived infection is screening of the recipient prior to transplant. Some donors with known infections may be more appropriate for recipients with a prior history of the same infection (e.g. HCV). Pretransplant recipient screening also allows for immunization against potentially transmissible infections, notably HBV, thereby potentially increasing the donor pool. Standard recipient screening for HIV, HBV, and HCV is mandated by OPTN policy in the US [16] Additional studies that should be considered include CMV antibody, HTLV 1 and 2 antibody, VDRL or rapid plasma reagin (RPR) (to screen for syphilis), EBV antibody (either to viral capsid antigen or EBNA), and toxoplasmosis antibody [17]. Recipients with potential geographic exposure to specific parasites/protozoa, such as *Trypanosoma cruzi* and *Strongyloides*, or fungi, including *Coccidioides immitis* and *Histoplasma capsulatum* may benefit from serologic screening for those organisms [17].

Limitations to determining donor-derived infections

Despite increased attention to the identification of donor-derived infections, there are a number of limitations that affect recognition of these infections [18]. Initial donor evaluation includes review of medical and social history, something that may be suboptimal in deceased donation due to its provision by individuals who may not

be fully aware of the donor history. This history may affect the choice of tests that are obtained as part of the donor evaluation. Laboratory screening may also be limited as serologic testing is dependent on adequate time for the development of an antibody response and NAT is not available for all pathogens and at all times. Both serologic and NAT testing have the potential for false positives and negatives; hemodilution may further confound the test accuracy. Moreover, there are some pathogens for which there are no standard screening assays. A particular challenge has been the identification of transmissible infections in donors presenting with altered mental status of unclear etiology; these donors should be carefully evaluated for infection and excluded from donation if there is likelihood that undiagnosed infection may have contributed to the donor's demise (Table 92.4).

Consent Issues

Transmission of infection is a significant potential risk of transplantation and recipients should be aware of this prior to transplant. Consequently, OPTN policy mandates that recipients must be notified if the donor has a medical condition that may be transmissible to them [16]. If the donor has medical or social risk factors that have been associated with increased risk for HIV, HBV, or HCV based on US Public Health System guidelines, or if the testing for these infections was only performed on hemodiluted blood, the recipient must be specifically informed regarding the potential risk for transmission of HIV, HBV, and HCV [19]. Recipients should be notified that donor screening is never comprehensive; some organisms cannot be anticipated and there are limitations to all available tests. In some cases, donor infections may be identified following transplant and recipients should also be informed of this possibility.

Reporting of donor-derived infections

Globally there has been increased attention to the reporting of donor-derived infections. In the US, all unexpected proven or potential transmissions must be reported to the OPTN Patient Safety System. These cases are then reviewed by the Ad Hoc Disease Transmission Advisory Committee, which determines the likelihood of donor transmission, using a set of standardized definitions [2,16]. This reporting allows the notification of centers caring for other potentially infected recipients, thereby permitting interventions for prevention and/or treatment as appropriate. A World Health Organization (WHO) initiative, Project Notify, has developed a similar set of standardized definitions to encourage reporting of donor-derived transmission events with the hope of developing a worldwide database of donor-derived infections to improve the safe use of donors [18].

Pathogen-specific issues

Bacterial infections

Donor-derived bacterial infections are uncommon but can cause significant morbidity and mortality in the organ transplant recipient, particularly when they result in endovascular disease, infection of anastomotic sites, or disseminated infection. Bacterial cultures in donors are routinely obtained and frequently positive, although these often reflect colonization or involvement of sites with minimal risk of transmission to recipients [20]. Bacteria isolated from the bloodstream may have a greater potential for transmission and blood cultures have been noted to be positive in approximately 15% of donors [20,21]. Recipient infection may occur through bloodstream transmission from bacteremic donors, infection or contamination of the donor organs, or contamination of preservation fluids. Deceased donors often have multiple risk factors for bacterial infection or colonization prior to organ donation, including endotracheal intubation, intravascular devices, urinary catheters, and prolonged stays in intensive care units [22–24].

The significance of a positive donor culture depends on the site of the culture, the organ to be transplanted, and the specific organism. At times, differentiation of true infection from contamination or colonization can be difficult. In the case of blood cultures, isolation of organisms such as coagulase-negative staphylococci, *Corynebacterium* spp., *Propionibacterium* spp., and *Bacillus* spp. typically reflect contamination. Isolation of the same organism (even typical contaminants) from multiple blood cultures suggests the presence of donor infection.

Donor-derived bacterial infection usually occurs within the first 7–14 days after transplant, but it may be delayed due to the use of prophylactic antibiotics and partial treatment. Additionally, an infection with a common hospital or community organism may not be recognized as donor derived. Confirmation of donor-derived infection requires molecular typing to prove an infection is caused by the same strain in both the donor and recipient; finding the same organism in multiple recipients from the same donor also suggests donor derivation of infection [2].

A number of retrospective analyses have attempted to quantify the risk to the recipient when organs from infected donors are used [20,25,26]. In a retrospective review of all donor bacterial cultures (including true infections, colonizers, and preservation fluid cultures), 8.8% of 3322 donors were identified as "infected" [20]. The greatest number of positive cultures reflected lung colonization and lung infection, followed by bloodstream, urinary tract, central nervous system, abdomen, wound, and preservation fluid cultures. Despite the high incidence of donor infections, donor-to-recipient transmission was documented in only 1.71% of recipients and the majority of post-transplant bacterial infections occurred in those individuals whose donors had negative cultures [20]. Studies suggest that bacteremic donors do not transmit infection regardless of whether the positive cultures are appreciated prior to transplant, provided recipients receive standard postoperative surgical prophylaxis, and antibiotics are adjusted and treatment extended to cover donor cultures as appropriate [25,26]. Furthermore, overall recipient and graft survival does not appear to be compromised when organs from donors with bacterial infection are used [20,22,23,25–28]. Thus, organs from bacteremic donors with antibiotic-susceptible

organisms may be safely used if the transplanted organ is not involved and antibiotics are tailored to the sensitivity of the organism and administered for 7–14 days postoperatively.

Donors with bacterial meningitis may also be considered acceptable. A number of small studies involving donors with *Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Hemophilus influenzae*, among other organisms, have shown favorable recipient outcomes and no evidence of transmission [28–30].. Whether donors with bacterial meningitis due to bacteria with a higher risk of metastatic seeding, such as listeria, salmonella, tuberculosis, *Staphylococcus aureus*, and *Pseudomonas aeruginosa*, can be used is not known, but it has been postulated that these donors may be at greater risk for pathogen transmission and thus may not be used as safely [31].

Lungs are unique in that they are usually colonized or sometimes infected at the time of procurement [32].. Bacteria have been transmitted from donor lungs to recipients; however, positive donor Gram stains are not predictive of early postoperative pneumonias [33]. In one retrospective analysis, despite the presence of colonization or infection in >50% of donors, transmission only occurred in approximately 15% of recipients of donors with positive cultures [34].

Information regarding outcomes for specific donor-derived bacterial infections is usually limited to case reports. *S. aureus* and *P. aeruginosa* have been more frequently reported to cause anastomotic dehiscence and significant morbidity and mortality in the recently transplanted patient. However, despite multiple reports of *S. aureus* bacteremia in donors, transmissions have been uncommon [20,25]. Transmission events have been more frequently noted with *P. aeruginosa*, and a number of case reports and small series of donor-derived *Pseudomonas* infection have been reported with significant morbidity and mortality related to vascular dehiscence and allograft loss [35–38]. While this high morbidity and mortality likely reflects some reporting bias, particular care must be taken with donors infected with *Pseudomonas*, especially those with bacteremia, and early antimicrobial therapy should be administered to recipients [6]. Donors with multidrug-resistant bacteria may pose a greater risk to recipients due to the failure of standard antimicrobial prophylaxis to cover these organisms. Adverse outcomes have been noted when multidrug-resistant organisms have been transmitted; however, at this time there are no specific recommendations for exclusion of these donors [39–41].

Tuberculosis

Mycobacterium tuberculosis has been increasingly recognized as a cause of donor-derived infection. This infection has been concentrated in areas of the developing world where organ transplant is not often offered. However, changing migration patterns, globalization, and expansion of transplant programs to parts of the world that have higher incidences of tuberculosis (TB) have increased the likelihood that organ donors may be infected with latent TB or undiagnosed active TB. Early studies in the US and Europe estimated that 0.35–6.5% of transplant recipients develop TB and of these 4% are likely donor-derived infections; this is likely an underestimate [42]. Between 2005 and 2009, 22 cases of TB in organ donors were reported to the US OPTN; 10 recipients had confirmed transmissions and there were two related deaths [1,2]. Lung transplant recipients are at highest risk given the predilection of TB for the lungs; however, all organs can be involved in the setting of disseminated TB [43,44].

Donor-derived TB may be difficult to recognize in recipients due to the increased occurrence of disseminated and extrapulmonary disease and the low index of suspicion for both active and latent donor infection [44,45]. Donor risk factors for TB, including residence in areas where TB is endemic, social risk factors (e.g. homelessness and incarceration), and suspicious medical histories (e.g. persistent or recurrent unexplained pneumonias), were often present in reported cases of donor-derived infection and may be clues to which donors require more intensive scrutiny [43,44]. Unexplained meningoencephalitis in a donor has also been related to TB [44]. Even in cases with a high index of suspicion for TB, diagnosing TB in the donor can be difficult. Screening donors for TB relies on donor infection and exposure history and assessment of risk factors; both may be incomplete at the time of organ procurement. Physical examination and imaging [chest radiography or computed tomography (CT) scanning] may be helpful. Acid fast bacilli (AFB) smears of sputum and tissue may identify active disease either premortem or soon after transplant, but must be specifically requested as they are not part of routine donor evaluations. Definitive confirmation requires cultures, which will take longer (up to 6–8 weeks with standard techniques). Molecular methods for mycobacterial culture and identification should be used if possible to reduce the time to diagnosis.

Guidelines for screening for TB have been developed by a consensus conference sponsored by the American Society of Transplantation, the Canadian Society of Transplantation, and the Transplantation Society [46]. These guidelines have recognized the difficulties of standardizing screening on an international scale due to the geographic differences in TB prevalence worldwide. Regardless of geography, these guidelines and others recommend exclusion of donors with active TB due to poor recipient outcomes [17,45]. It is less clear how donors with latent TB should be managed. Currently, there is no automatic exclusion from donation; instead the risks and benefits of the transplant must be weighed [17]. Identifying which donors should be screened for latent TB and how donors with latent TB should be managed, especially in areas where TB is common in both donor and recipient populations, is also controversial. Identification of latent disease is particularly challenging in the deceased donor as there are currently no tests that have been validated in this setting. In low-prevalence areas especially, living donor candidates should be screened for latent TB using history, examination, and either tuberculin skin testing or interferon-γ release assays [17,45]. Chemoprophylaxis should be considered for living donors, assuming this can be completed prior to donation. If donors are found to have untreated latent TB, previously uninfected recipients should be given standard chemoprophylaxis to prevent donor-derived infection, although rifamycins should be avoided due to drug interactions with immunosuppressive medications [47]. Donors with a history of active TB in the preceding 1–2 years are at higher risk for relapse and this increases the risk for transmission of TB to the recipient. Careful consideration must be given to the risks and benefits of transplantation utilizing organs from these donors, and chemoprophylaxis, based on known drug susceptibilities, should be strongly considered [17]. When active TB is discovered in a donor after donation, infectious disease consultation should be sought to determine the optimal management of recipients.

Syphilis

Serologic testing for syphilis is standard practice for all solid organ donors. The results may not be available until after transplantation; nevertheless, positive serologies or a history of prior treatment for syphilis is not a contraindication to donation as treatment is

available. The estimated risk of donor-derived syphilis is 0.15% [48]. Immunosuppressive regimens in the recipient may attenuate and delay the serologic responses and these cannot be relied upon to diagnose recipient disease. Early treatment of recipient and donor if possible has been successful in preventing the development of clinical disease [49–52]. The long-term outcome of untreated donor-derived syphilis is unclear, but potentially could result in accelerated disease. Recipients of organs from donors with active or latent syphilis should be treated according to standard guidelines and then monitored postoperatively for both clinical and serologic signs of response to treatment [7,53].

Viral infections

Viral infections are commonly transmitted from organ donors to recipients. Many infections can be anticipated, such as CMV and EBV, and therefore are not included in most surveys of donor-derived infections. Details regarding these infections are given in Chapter 94 and the focus here is unanticipated donor-derived viral infections.

Donor-derived viral infections present unique challenges, particularly with regard to predonation diagnosis. In some cases, these infections may be asymptomatic or mistaken for other conditions or may stem from blood transfusions administered to the donor in the predonation phase; thus, routine diagnostic assays may be inadequate to identify the infection prior to transplant. Moreover, even when they are identified either prior to or following transplant, therapeutic options are often limited or unavailable.

Donor viral infection should be considered when donors present with fevers without a clear-cut etiology. In particular, donors with unexplained altered mental status should be suspected of having viral meningitis and/or encephalitis. Lymphocytic choriomeningitis virus, West Nile virus (WNV), and rabies have all been transmitted by donors with these presentations [54–56]. A detailed history (including exposure to rodents and insects) should be elicited, physical exam performed, and imaging of the brain either with a contrast CT scan or magnetic resonance imaging (MRI) and lumbar puncture should be considered when the clinical suspicion is high. In the absence of a specific diagnosis of a treatable infection, these donors should be deferred from donation [17].

Because many donor viral infections are latent, standard screening may not detect potentially transmissible infections. Routine donor screening includes testing for HIV, HBV, HCV, and EBV [17]. Whether or not all donors should be screened for either HTLV or WNV is controversial. In some cases, false-positive NAT for WNV may result in unnecessary donor exclusion [57]. Consequently, although tissue banks routinely screen for WNV, this is not part of the standard organ donor evaluation. In the US, testing for HTLV 1 and 2 is no longer a requirement due to the low incidence of HTLV 1, the occurrence of false-positive tests in a low prevalence population, and the discontinuation of the FDA-approved test for this virus [58].

Human immunodeficiency virus

HIV is one of the most feared donor-derived infections, although the actual incidence of donor transmission of HIV is miniscule. In the US, donors with HIV are excluded from donation and donor screening for HIV became a requirement in 1985 [59]. This has greatly reduced the number of donor-transmitted infections; however, sporadic cases of transmission from both deceased and living donors have occurred in the US and in Europe [60–66]. Recipient outcomes have been variable, with the development of acquired immune deficiency syndrome (AIDS), allograft loss, and death in the earlier cases especially. In part, poor outcomes likely reflect the impact of co-morbidities, including HCV, limited antiretroviral options, and immunosuppressive therapies, as carefully selected HIV-infected kidney donors have been successfully used in a population of HIV-infected recipients in South Africa [67].

The more recent unanticipated transmission events have sparked a controversy regarding optimal evaluation of donors for HIV infection. Deceased donor screening should consist of a careful assessment of the donor's risk for HIV infection by reviewing both medical and social histories and laboratory testing for HIV. Mandated screening relies on serologic testing [8]. As previously noted, NAT has the potential to identify donors with more recent infection, by decreasing the window period for infection detection [11] (Table 92.3). Because two recent transmissions were related to window-period infection, greater consideration has been given to mandating NAT testing [63,64]. A 2008 survey of US OPOs revealed that almost half voluntarily use NAT testing for HIV screening in potential donors [68]. NAT testing cannot fully replace serology for HIV; however, as HIV-infected individuals on highly active antiretroviral therapy (HAART) may have undetectable virus, false-negative testing results if serology is not performed.

Screening of live donors enables a more thorough assessment of risk factors, and where potentially risky behavior is present, allows for risk reduction counseling and repeat serologic testing for identification of potential window-period infection. If there is a significant delay between evaluation and donation, repeat assessment of risks and testing should be considered.

It is difficult to estimate the incidence of undetected HIV infection in potential donors. One extrapolation from blood donor data suggests a prevalence of HIV in normal-risk donors of 0.10% and 0.50% for high-risk donors [13] The estimated incidence of undetectable infection by serologic screening was 1 in 50 000 for normal-risk donors and 1 in 11 000 in high-risk donors. Optimal screening for HIV should consider both the risk of donor transmission and the potential for organ donor loss due to false-positive or unavailability of NAT testing. US OPTN policy requires that all potential recipients are informed of and give specific consent for transplantation of organs from donors who are designated at increased risk for HIV [8]. Guidelines suggest that NAT screening be reserved for increased-risk donors and that recipients of these donor organs be tested 1, 3, and 12 months post transplant to exclude donor-derived HIV transmission [15].

Hepatitis B virus

Despite well-documented transmission risks, donors with hepatitis B have been considered an important potential source for expanding the donor pool, especially in areas such as South-East Asia and parts of Europe where the prevalence of HBV exceeds that in the US [7,69,70]. In most cases, the risk of donor-derived infection may be predicted based on the results of serologic testing. The highest risk of transmission is associated with HBV surface antigen- and/or DNA-positive donors who can transmit infections regardless of organ; however, donors with isolated core antibody positivity have also transmitted infection [71,72]. Additional factors affecting transmission and outcomes include the organ transplanted, recipient immunity, prophylaxis, and immunosuppression [7,72–78].

Standard testing for HBV in organ donors generally includes hepatitis B surface antigen, surface antibody, and core antibody [17]. Additional tests may include hepatitis B core IgM and hepatitis B DNA assays, although these are typically reserved for specific

donors considered to be a higher risk for infection and donors with isolated hepatitis B core positivity, as these tests may identify window-period donors, who are at higher risk for HBV transmission [17]. Data specific to the organ donor population regarding the utility of DNA testing is not available. However, blood donor screening suggests that DNA positivity may be found in 1.6% of core antibody-positive individuals and 1 in 410 540 blood donations (the majority of whom had evidence of prior vaccination) [79,80]. Notably, DNA levels were typically low and in at least one study, only 36% of surface antigen-positive individuals had detectable DNA; thus, only screening organ donors with HBV DNA may fail to identify donors with HBV [79–81]. To date, there has been only one case report identifying transmission of HBV from a multiorgan donor with negative serology and low level DNA positivity to three of five non-immune recipients [82]. Testing for HBV delta has not been standard and it is not known whether donors with this virus may pose a greater risk to recipients.

Currently, because of the high risk of transmission, it is recommended that donors with hepatitis B surface antigen, core IgM, and/or DNA positivity be excluded from consideration, although there may be exceptions in life-threatening situations [7]. Donors who are positive for surface and/or core antibody may be considered in certain circumstances, which are outlined below [7].

Liver transplant recipients are at the greatest risk for the development of de-novo hepatitis B from donors who are positive for HBV core antibody, with rates as high as 33–100% in the absence of prophylaxis [72]. Transmission risk is substantially lower for recipients of other core antibody-positive organs and long-term patient and graft survival are comparable for these recipients [70,73,83–88]. One key factor that has been associated with reduced transmission is the presence of pre-existing immunity. Prior infection, as evidenced by the presence of both surface and core antibody in the recipient, conveys greater protection than vaccination [73,76,87]. Nevertheless, pretransplant hepatitis B vaccination has been an important preventive strategy and is recommended to increase the safety of core antibody-positive donors [7]. Because the level of pre-existing antibody may affect transmission, booster dosing may be indicated when levels decline below 200 mIU/mL [75,78].

Antivirals and immunoglobulin also play an important role in preventing transmission from core antibody-positive donors, especially for liver recipients, dramatically reducing the rates of transmission and symptomatic disease [72,74,76,77,89]. The optimal prophylactic strategy for recipients has not been determined; many centers combine early hepatitis B immunoglobulin with prolonged antiviral administration (typically lamivudine) for liver recipients [90]. At this time, there are no specific recommendations for prophylaxis in non-hepatic recipients.

Recognition of donor-derived hepatitis B may be difficult, especially since the onset of infection may be delayed for as long as 60 months [72]. The average time to de-novo infection probably reflects recipient immune status, with an average time to evident infection of 14.7 months in naïve liver recipients and 23.7 months in recipients with both surface antibody and core antibody positivity [76]. Because of this, it is recommended that recipients of potentially infectious organs (especially liver recipients) be screened every 3 months for 5 years with hepatitis B surface antigen, core and surface antibody, and DNA testing [72].

Hepatitis C virus

Transmission of HCV from donor to recipient has been well-recognized for many years [91–93]. In contrast to HBV, HCV is efficiently transmitted regardless of the organ transplanted, with 50–93% of HCV-negative recipients acquiring HCV from their donors [92,94–97]. A number of factors may affect the likelihood of transmission, especially to non-liver recipients. These include the presence or absence and level of donor viremia [97]. Not all antibody-positive donors are viremic, and donors without detectable viremia appear less likely to transmit HCV if the liver is not used [98]. The method of organ preservation may also affect transmission; pulsatile perfusion has been reported to decrease the HCV viral load, thereby reducing the risk of transmission via kidney transplantation [99].

Recipients of HCV-positive organs have had significant complications following transplant; however, outcomes vary based on recipient HCV status and the organ transplanted. The best outcomes have been reported in HCV-infected liver recipients. In these recipients, adjusted short- and long-term patient survival and graft survival have been similar regardless of whether or not the donor was infected with HCV [100–104]. However, organs from HCV-infected donors have been associated with earlier recurrence of HCV, a factor that has been associated with patient death and graft loss [103]. Retrospective analyses of the US Kidney Data System and the OPTN databases noted reduced survival with HCV-positive kidney donors, regardless of recipient age; furthermore, deaths due to liver disease and infection were more common in recipients of HCV-positive grafts [105,106]. When HCV-positive recipients were considered, outcomes with HCV-positive and -negative donors were similar [107,108]. Because using HCV-positive kidneys decreases waiting time on transplant lists, this may improve survival in some dialysis patients [106,109]. Several studies have demonstrated that recipients of HCV-positive cardiac allografts have decreased early and long-term survival when compared with HCV-negative allografts regardless of recipient age or HCV status [110,111]. Recipients of HCV-positive hearts experienced increased vasculopathy and advanced liver disease. Consequently, it is recommended that HCV-positive donor organs (especially kidney and liver grafts) be reserved for HCV-positive recipients or those in life-threatening situations [112].

Routine donor screening for HCV includes antibody testing. NAT significantly increases detection of window-period infections and should be considered for donors at increased risk for HCV [15]. The highest yield for NAT may be in donors with a history of intravenous drug use, commercial sex workers, and others with high-risk sexual behaviors [14]. Donor genotypes are not routinely obtained and there are no specific recommendations regarding matching of donor and recipient HCV genotype. Whether the donor or recipient genotype prevails following transplant may be genotype dependent rather than reflective of the HCV source; genotype 1 has more commonly prevailed [71,90,113].

West Nile virus

In recent years, there has been greater concern regarding donor-derived WNV infection. This reflects the increasing prevalence of WNV in donor communities as well as enhanced recognition of donors as a potential source of infection. Nevertheless, the actual number of reported donor-derived transmissions remains small. Also, the true transmission rate is unknown, since infection is commonly asymptomatic and donor screening is not routinely performed. Moreover, although symptomatic infection has been described in the majority of recipients of infected donor organs, there is the possibility that recipient infection may not be recognized due to asymptomatic or atypical presentations.

Donors may transmit infection regardless of the presence or absence of symptomatic infection in the donor [56,114,115]. Blood products may also be a source of WNV infection and in some cases, donor-derived transmission occurred due to the administration of infected blood products to the donor, further confounding the ability to recognize donor infection [116,117]. The most severe consequences of donor-derived infection are neuroinvasive disease and death; asymptomatic transmission has also been reported [56,114,116,117]. There have also been cases in whom donor infection was identified without evidence of transmission to any recipients. Factors affecting transmission risk are not known. There does not appear to be a propensity for any single donor organ to transmit infection. It is likely that recipient immunosuppression has an impact on outcomes and there are reports of improved outcomes with immunoglobulin administration to at-risk recipients [56,115].

Whether all potential donors should be screened for WNV prior to organ procurement is controversial. Although testing for WNV is routinely performed in blood and tissue donors in the US, screening of organ donors is not required. Some European centers routinely screen for WNV [118]. Screening tests include serology and NAT. A single screening test is probably insufficient, since neither antibody nor NAT alone will identify all potentially affected donors [114]. The geographic and seasonal variability of infection, which can change on a year-to-year basis, further complicate screening. At this time, routine screening has not been demonstrated to be cost-effective and at least one large-scale screening initiative in Alberta, Canada, failed to identify any cases between 2003 and 2005 [119]. Moreover, a medical decision analysis performed based on prevalence data for 2002 demonstrated a potential loss of 452 life years related to false-positive testing [57]. At this time there is insufficient data to recommend routine screening of all donors; however, obtaining NAT and antibody may be warranted if the prevalence of WNV in the community is high. Because WNV may be associated with neuroinvasive disease, donors with undiagnosed febrile illnesses associated with altered mental status and/or new limb weakness should be excluded from donation.

If a donor is found to have infection, based on anecdotal evidence, some investigators advocate administration of hyperimmune globulin to recipients prior to the development of infection [56]. There is insufficient evidence to recommend this routinely at this time. Further investigation regarding optimal donor identification and recipient management is warranted.

Arenaviruses including lymphocytic choriomeningitis virus

Donor-derived arenavirus infection is a rare occurrence following organ transplantation, albeit one associated with a high fatality rate [55,120,121]. Lymphocytic choriomeningitis virus has been most frequently described; in at least one case a novel arenavirus has also been implicated in donor-derived infection. Donor-derived arenaviruses are difficult to recognize prior to donation since the majority of donor infections are asymptomatic; only one donor was reported to have a febrile illness [120–122]. Routine screening of donors for arenaviruses is not indicated.

Recipient infections have been characterized by hepatocellular necrosis, cytopenias, and encephalitis, and may present as early as 3–4 days following transplant, although the majority occur approximately 2–3 weeks postoperatively. Deaths occurred within 2 months of transplant [120–122]. Based on a single case report, ribavirin may improve outcomes when administered early after the onset of symptoms [120]. Currently, there is insufficient evidence to routinely recommend ribavirin for recipients suspected of acquiring donor-derived arenavirus infection.

Human T lymphotropic virus 1 and 2

HTLV 1 and 2 are retroviruses that are routinely considered jointly due to the testing methodology and despite the differences in their epidemiology and disease association. HTLV 1 is endemic in Asia, the Caribbean, parts of South America, West Africa, and Oceania, with lower prevalence in North America and Europe. It has been implicated in the development of acute T-cell leukemia and lymphoma, and HTLV 1-associated myelopathy (HAM) and tropical spastic paraparesis (TSP). In the US, HTLV 2, which is endemic in American Indians and Western and Central Africa, is predominantly seen in intravenous drug users and sexual contacts of infected individuals. It has yet to be associated with a specific disease entity. Confirmed donor-derived transmissions of HTLV 1 and 2 are rare, even in endemic countries, and it is likely that many transmission events are not associated with the development of symptomatic disease or impaired transplant outcomes [58,123–127]. When symptomatic transmissions have occurred, recipients have typically developed neurologic symptoms (TSP/HAM) within 2 years of transplant [125].

Testing donors for the presence of these viruses is controversial and currently a requirement in select geographic locales only [58,128]. In part this reflects the low positive predictive value of the currently available tests [58]. Standard serology for HTLV 1 and 2 involves performance of an enzyme-linked immunosorbent assay (ELISA), which does not distinguish between the two viruses. Although highly sensitive, it is not specific, increasing the potential for false-positive results. Confirmatory testing with Western blot or NAT is not routinely available within the time frame of deceased donor management. There is significant potential for false-positive screening serology with estimates of 167–227 potential organs lost annually [58]. In 2010, the FDA-licensed test for donor screening became unavailable in the US, prompting a reassessment of the requirement for HTLV screening. Based on data demonstrating an extremely low prevalence of confirmed positive screening tests, the absence of significant impairment of recipient outcomes, and the potential for donor loss, the OPTN abandoned the requirement for donor screening in 2010. In Spain, HTLV screening is restricted to donors from endemic areas only [128].

Donor-derived fungal infections

Fungal infections are a significant cause of morbidity and mortality following transplantation; donor-transmitted infections are rare. Nevertheless, there have been significant reports of donor-derived fungal infections with subsequent allograft loss and death [1]. Donor-transmitted infections may result from latent donor infection, donor bloodstream infection at the time of procurement, unrecognized disseminated infection, or through contamination of preservation fluid. Proving donor derivation may be especially challenging for some fungal infections as it can be difficult to exclude the presence of latent endemic mycoses in recipients who may share geographic risk factors with their donors.

Candidiasis

Donor-derived *Candida* infections are an uncommon but important cause of allograft loss and death in transplant recipients. Abdominal organ and kidney recipients are at the highest risk of donor-derived infection, most likely related to bowel colonization with *Candida* and subsequent seeding of the allograft [129]. The

actual incidence of these infections is not known; a multicenter study in France estimated an incidence of one infection per 1000 renal allografts [129].

The sources of *Candida* are diverse and include the bloodstream, urinary tract, and direct contamination of the allograft from preservation fluid contamination or soilage related to abdominal trauma and bowel disruption [20,129–132]. The pancreas is particularly vulnerable to direct infection due to the presence of *Candida* in duodenal contents; in some cases, organ contamination has been attributed to incision of the duodenum during back-bench preparation [133,134]. Donor-derived *Candida* infections are less frequently reported in heart and lung transplantation [135]. *Candida* is a common oropharyngeal tract colonizer; consequently, donor respiratory cultures are often positive but the significance of this is unknown. Infection of the anastomosis is the primary concern; however, in at least one study this did not occur despite positive donor cultures, possibly related to the routine administration of nebulized amphotericin B [34,135]. Donor-derived cardiac infections with *Candida* have not been routinely described.

Determining the significance of *Candida* in preservation fluid culture is a particularly difficult issue and the true incidence of *Candida* infection in this setting is unknown. The risk for infection when the preservation fluid is negative appears to be low, at least in the setting of renal transplantation [136,137]. In kidney recipients, the rates of positive preservation fluid cultures range from 5% to 23%, with 2–10% attributed to fungi [133]. *Candida* has been isolated in approximately 4% of preservation fluid samples from liver recipients [22,138,139].

Donor-derived *Candida* infections have been most clearly characterized in kidney recipients who typically present within the first months after transplantation [129]. Complications of this infection are diverse and include infected perinephric collections, urinomas, and pyelonephritis in renal transplant recipients, and candidemia, surgical site infections, and involvement of vascular structures in all recipients [129–131,140]. The most significant complications in other abdominal organ transplants involve infection of vascular structures resulting in anastomotic rupture, arteritis, and mycotic aneurysm, all of which may lead to catastrophic intraperitoneal hemorrhage with graft loss or death [129,130,134].

To prevent adverse outcomes of donor-derived *Candida* infection, prophylactic strategies for recipients of donors with *Candida* infection and colonization are used and have been most clearly defined for kidney recipients. When *Candida* is detected in preservation fluid or there is evidence of viscous perforation, expert opinion recommends administration of 2 weeks of empirical antifungal therapy combined with imaging of the graft at baseline and at day 7. If no graft site infection is found, antifungal therapy may be discontinued after 2 weeks [141]. Recipients who develop symptoms, signs, or microbiologic evidence of infection should have imaging repeated and antifungal therapy prolonged. Because the liver, pancreas, and small bowel are particularly susceptible to contamination by bowel flora, some centers recommend amphotericin B instillation into the donor duodenum during procurement [134]. Other centers may choose to start prophylactic antifungals irrespective of cultures. Given the concerns for arteritis and graft loss, imaging should be considered when evaluating positive pancreatic donor cultures. There is no evidence-based data for recommending management of positive donor cultures in this setting. In cardiothoracic recipients, evidence for management of positive donor cultures, including preservation fluid, is scant. Lung recipients routinely receive antifungals as part of peritransplant management due to the high rate of fungal infections in these recipients and because donor status is not the only factor considered. When lung donors are colonized with *Candida*, systemic antifungals and nebulized amphotericin have been used alone and in combination by some centers [34,135]. The duration of prophylaxis is not defined but may be prolonged, depending on the appearance of the anastomosis. *Candida* in preservation fluid cultures from heart donors does not appear to be associated with recipient infection and is not an indication for prophylaxis [142].

Although some donors with *Candida* infections have been successfully used, based on the potential for adverse outcomes, donors with untreated candidemia and pyelonephritis should not be routinely used [20,25,143]. The risk of transmission when donors have candiduria is unknown, although transmission to non-renal recipients is unlikely in the setting of isolated candiduria.

If donor-derived *Candida* infection is suspected, therapy should be based on the species and known antifungal sensitivity, when available. Fluconazole is generally the preferred antifungal, as it is well absorbed and attains high levels in the urine; the other azoles do not achieve high levels in the urinary tract and thus should be avoided if the urinary tract is involved. Because of their extensive metabolism and poor penetration into the urinary tract, echinocandins should be reserved for non-albicans infections (which may be resistant to fluconazole) and for extrarenal and renal parenchymal disease [144]. Amphotericin B deoxycholate is active against most forms of *Candida*; however, its use is limited by the potential for renal toxicity and the lipid formulation does not achieve appreciable levels in the renal parenchyma or urine, making it a less preferred option, especially for infections involving renal allografts. Recommendations for surgical management of cases vary from transplant nephrectomies for all to a more conservative approach of immediate antifungal therapy and close monitoring [130,131,145]. In general, drainage of renal abscesses or perinephric collections should be considered and the presence of arteritis or aneurysm should prompt evaluation for possible nephrectomy.

Cryptococcal infections

Cryptococcus is a ubiquitous encapsulated yeast that is a rare cause of donor-derived infection. Infection occurs following inhalation of the organism. It is typically asymptomatic in the normal host and can persist in latent form primarily in the lungs, providing the potential for donor-derived infection in the absence of symptoms [146].

The vast majority of cryptococcal infections in transplant recipients are not donor derived, instead representing reactivation of latent recipient infection [147,148]. Although uncommon, donor-derived cryptococcal disease was reported as early as 1971 and there have been additional reports since then [149,150]. Differentiating donor- from recipient-derived infection can be difficult; however, a donor source should be suspected if the donor presents with an undiagnosed neurologic disorder or meningoencephalitis [150]. Potentially immunosuppressed donors, e.g. those with a history of corticosteroid use, other organ dysfunction such as end-stage renal or liver disease, sarcoidosis, or rheumatologic disorders, are at increased risk for cryptococcal infection and therefore should be more closely scrutinized, especially if they present with undiagnosed neurologic disorders or granulomatous pulmonary disease. Although the majority of the cases are related to deceased donors, living donors have also been reported to transmit *Cryptococcus* [151].

Recognition of cryptococcal infection in donors may be challenging and it is easy to miss the diagnosis prior to donation. In donors with abnormal neurologic findings, sampling serum and cerebrospinal fluid (CSF) for cryptococcal antigen may be informative. Obtaining donor serum for cryptococcal antigen is helpful if positive, but does not exclude the diagnosis if negative, especially if findings are isolated to the lungs. In those cases, sampling of donor tissue or fluid for microbiology and histopathology is required to confirm the diagnosis. Assessment of living donors with evidence of granulomatous disease on lung imaging should include a thorough investigation to exclude *Cryptococcus* prior to donation [151]. Although finding cryptococcal infection in the first month following transplant is a possible sign of donor derivation, it is important to remember that some recipients, especially liver recipients, may have been at increased risk for this infection prior to transplant, which further confounds source attribution.

Donors with suspected or confirmed cryptococcal infection should not be routinely used for donation because of the risk of severe disease in the recipient. However, if the lung is the only donor organ known to be involved, the risk for non-lung recipients is undefined, as pulmonary infection may exist without dissemination. If donor infection is identified after the transplant has occurred, recipients should receive prophylactic fluconazole. Based on a case report of a successful transplant from a donor with asymptomatic pulmonary disease, a 3-month course has been proposed to be effective, although there are no large-scale trials to confirm this recommendation [151]. Treatment of donor-derived cryptococcal disease should follow published guidelines with support from infectious diseases experts [152].

Aspergillosis

Aspergillus is ubiquitous in the environment. It is the second most common fungal infection post transplant, but is an uncommon cause of donor-derived infection [153]. The majority of donor-derived cases occur in lung transplant recipients where the greatest concern is the potential for infection along suture lines and vascular invasion. In one study of lung transplant recipients and their donors, five of 197 donors were found to be colonized with *Aspergillus fumigatus.* Despite nebulized amphotericin B prophylaxis, donor-to-host transmission of infection was documented in three of the five cases, with the development of tracheobronchitis in two recipients and fatal mediastinitis in one [34].

Identification of *Aspergillus* prior to donation may be difficult as it is rarely suspected. Extreme caution should be taken when evaluating donors who are themselves immunocompromised as they are at increased risk for this infection. This is particularly true in cases where potential donors have died of unexplained neurologic disease. Two case reports of donor-derived *Aspergillus* infections have been described where the donors were solid organ transplant recipient themselves whose deaths were attributed to cerebral hemorrhage [154,155]. Because of the potential for adverse outcomes, including allograft loss, donors with confirmed or suspected aspergillosis should be excluded from donation.

When donors are suspected or found to have aspergillosis following donation, optimal preventive measures should include administration of systemic antifungals to the recipients (e.g. azoles such as voriconazole, echinocandins, or amphotericin-based compounds). There are no guidelines to direct either the specific choice of antifungal or the duration of prophylaxis. Many lung transplant centers routinely use prophylactic antifungals against *Aspergillus* in the postoperative period until donor respiratory cultures and/or recipient bronchoscopy show no evidence of infection or colonization. This pre-emptive strategy may avert many potential cases of donor-derived infection.

Coccidioidomycosis

Coccidioidomycosis is endemic in areas of the south-western US, northern Mexico, and parts of Central and South America. Infection is acquired by inhalation and leads to primary pulmonary infection, which is typically asymptomatic; endospores may then spread hematogenously to distant sites [156]. The majority of *Coccidioides* infections are likely due to reactivation of latent disease [157,158]. The incidence of donor-derived infection is unknown but it is thought to be rare, although likely under-recognized. Both living and deceased donors have transmitted infection both in the presence and absence of donor symptoms [159–162]. The incidence of *Coccidioides* infection in donors will depend on donor exposure to locations where this infection is endemic. In one center located in an endemic region, positive serologies for this infection were detected in 2.1% of asymptomatic living donors [163].

Donor-derived *Coccidioides* has resulted in significant morbidity and mortality in transplant recipients, with deaths due to disseminated infection, severe pneumonia, and central nervous system infection in >50% of organ recipients [162]. Although lung recipients may be at greatest risk due to the predominance of infection in the lungs, diverse organ recipients have been affected and it is likely that outcomes are most affected by the degree of T-cell dysfunction and timing of targeted antifungal therapy [161,164]. Presentation of donor-derived infection frequently occurs within the first month following transplantation, especially when donors have unrecognized active infection, although later onset may occur, especially in the setting of reduced immunosuppression and/or prophylactic antifungals. Early intervention with prophylactic antifungals, including fluconazole or itraconazole, may prevent development of recipient infection [163].

Because of the potential impact on recipient outcomes with early antimicrobial intervention, it is imperative that donor infection be identified as early as possible. Donor-derived *Coccidioides* infection should be considered in deceased donors presenting with undiagnosed neurologic syndromes and/or pulmonary infiltrates or nodules, especially if the donor has spent significant time in an endemic area [160,162]. Unfortunately, recognition of *Coccidioides* infection in a donor may be complicated by the absence of symptoms at the time of donation and limited history of residence and/or travel to an endemic area. Diagnosis may be further confounded by the variable availability, sensitivity, and specificity of different serologic tests and the difficulties isolating the organism in culture. There are a number of serologic tests available for detecting antibody responses against specific coccidioidal antigens. These include complement fixation, enzyme-linked immunoassays (EIAs), tube precipitin, and immunodiffusion assays for the detection of antibody. Antigen tests, polymerase chain reaction (PCR), and culture may detect active infection, although these are less likely to be available in the organ donor setting. Donor screening should include multiple assays as the sensitivity and specificity of the available tests may be variable [163]. Serologic tests may be useful for screening both deceased and living donors for past infection, but there is a potential lag in antibody responses following acute illness, especially in the setting of immunosuppressive medications; thus, none of them can be relied upon to make a diagnosis in the acute setting [163,165,166]. Antigen tests may play a role when serologic

testing is negative [165]. In some cases histopathologic examination may be required to diagnose active infection.

Although donors with active *Coccidioides* should be excluded from donation, a history of past infection is not an absolute exclusion and living donors with a history of coccidioidomycosis and no evidence of active infection have been successfully used for kidney and liver donation [163]. Recipients of organs from donors with quiescent infection should receive prophylaxis with fluconazole or itraconazole. Those already on an azole for prophylaxis against other fungi generally do not require the addition of fluconazole [167]. At this time, the optimal dose and duration of antifungal prophylaxis for recipients of donors with quiescent infection is unknown. Regimens as short as 1 month with doses as low as 100 mg of fluconazole have been used, although the majority of experts recommend 6–12 months of prophylaxis with higher doses of fluconazole [157,163]. Because development of disease may be affected by the extent of donor infection, the organ received, and the level of immunosuppression, determination of optimal prophylaxis should be tailored to individual recipient circumstances and infectious diseases experts should be consulted.

Histoplasmosis

Histoplasma capsulatum is ubiquitous in the soil in diverse regions worldwide, including the Americas, Asia, and Africa; in the US, this infection is most commonly observed in the Ohio and Mississippi river valleys. In endemic areas, up to 75% of residents show evidence of prior infection, although the vast majority are asymptomatic [168]. Histoplasmosis occurs in 0.1–0.5% of transplant recipients in endemic areas and the vast majority of these infections are presumed to be due to reactivation of prior disease or acquisition of new infection; infection in the first post-transplant month may be donor derived [168–170]..

The true incidence of donor-derived histoplasmosis is unknown, but is likely extremely low, even in hyperendemic areas [171]. One estimate of donor-derived histoplasmosis in endemic areas is approximately 1 in 10 000 transplants [172]. When a donor is found to have histoplasmosis, not all recipients are equally affected; the majority of reports have involved renal recipients. In a large retrospective study from an endemic area, approximately 0.1% of recipients (all lung) were found to have evidence of histoplasmosis in donor lymph nodes [170]. No cases of donor-derived histoplasmosis were noted, possibly due to the use of routine antifungal prophylaxis.

There are few published cases of donor-derived histoplasmosis [173–177].. Although recipients with donor-derived infection generally present within 2–3 weeks of transplant, presentation as late as 36 weeks has been reported. Non-specific fever and allograft dysfunction are the most common manifestations of infection, followed by pancytopenia and weight loss.

Given the low incidence of donor-derived histoplasmosis and relatively high prevalence of prior exposure in healthy individuals, routine testing of all donors is not warranted; however, it is important to identify donors who are actively infected as they are more likely to transmit infection [141]. Diagnosis of histoplasmosis in donors requires a multifaceted approach, including antigen detection in urine and serum, antibody testing (by immunodiffusion and complement fixation), and culture and histopathologic examination of involved tissues. In order to exclude active histoplasmosis, donors with unexplained pneumonias from endemic areas should undergo specific testing. Because the liver and spleen are common sites of involvement in disseminated infection, these organs should be included in the histopathologic evaluation. Evaluation of living donors from endemic areas should include specific information about past histoplasmosis and unexplained pneumonia, followed by imaging studies and serologic and antigen testing. Expert opinion suggests that active disease in living donors should be treated for at least 6 weeks prior to donation [141]. Because antibody production may be delayed for up to 3 months and reduced in immunosuppressed hosts, antigen detection may be preferable in cases of early infection and immunosuppression [178].

There are no large-scale trials to dictate management of donors with suspected or confirmed infection. Expert opinion recommends that if the donor infection is confirmed by either culture or antigen testing, then 1 year of treatment of the recipient is recommended [141]. If histopathology alone is consistent with infection and/or donor complement fixation titers are $>$1:32 or if H and/or M precipitins are present, these experts recommend a 3–6-month course of itraconazole [141]. In unconfirmed cases with lower titer antibodies, close monitoring with serum and urine antigen may be helpful for detection of early infection in recipients [179].

Parasitic disease

With the exception of toxoplasmosis, most donor-derived parasitic infections are restricted to specific geographic regions and/or donor risk profiles. They are thought to be uncommon even in those regions where the infections are endemic. In many cases, it is especially difficult to attribute post-transplant infection to the donor organ because the recipient and donor may share similar exposure histories. However, given the greater diversity of donors in regions where these infections are not endemic, there have been sporadic case reports of donor-derived parasitic infections involving deceased and living donors. Some examples have included donor-derived trypanosomiasis, strongyloidiasis, schistosomiasis, malaria, filariasis, and clonorchis [180–189]. Because of the predilection for involvement of different organs by the various parasites, transmission risk varies based on the pathogen. For example, donor-derived schistosomiasis and clonorchis infection are both more likely in liver transplantation, whereas *Trypanosoma cruzi* infection is associated with heart transplantation [180,181,188]. In some cases, living donor screening by serology, review of peripheral blood smears, and ova and parasite examination of stool, urine, and tissue has allowed for donor treatment prior to donation to prevent transmission [180,189,190]. Because many of the tests required for diagnosis of parasitic infections are not routinely available within the time frame of deceased donor evaluation, predonation diagnosis is often not possible. Donor travel and residential history should be part of routine donor evaluation and peripheral blood smears and tissue biopsies should be considered for febrile donors from areas where these organisms are endemic. Donor eosinophilia may be an additional clue to the presence of parasitic infections and should prompt serologic evaluation for specific organisms and prophylactic antimicrobials to avert reactivation of donor disease (Table 92.2). In the absence of documented donor organ infection, there are no recommendations for avoidance of deceased donors who are "high risk" based on exposure history alone.

Toxoplasmosis

Toxoplasma gondii, the etiologic agent of toxoplasmosis, is found worldwide. Infection is most common in patients from endemic areas such as the tropical areas of Latin America and sub-Saharan Africa and European countries such as France where prevalence approaches 90% [191]. Rates in the US are lower with estimates of

10–40% [192,193]. Primary sources of infection in the US include ingestion of raw and undercooked meats, and exposure to soil and cat feces [194]. Acute infection after transplant may result from donor-to-recipient transmission, reactivation of quiescent infection, and rarely, newly acquired infection after transplant.

Because of the predilection of the organism for musculoskeletal tissue, cardiac transplantation bears the highest risk for donor transmission, although donor transmission via other organs has been reported [195]. It is estimated that seronegative cardiac transplant recipients have a 50–75% risk of developing symptomatic infection from a seropositive donor without prophylaxis [196,197]. Donor transmission in the seronegative recipient is the most common cause of disease acquisition in all recipients; in cardiac transplant recipients, donor transmission accounts for approximately 60% of disease [198].

Toxoplasmosis after solid organ transplant can result in severe disease, often with a fulminant course. Presentation may be non-specific and in the absence of prophylaxis, usually occurs within the first 3 months after transplant [195,199]. Myocarditis, pneumonitis, cerebral abscesses and meningitis, chorioretinitis, hepatitis, lymphadenitis, and disseminated disease have all been described [195,198,199].

Donor toxoplasmosis is typically latent and easily identified using standard serologic methods; however, this is not currently mandated even for heart recipients in the US where the infection is presumed to be low in prevalence. This practice has been supported by a Canadian study which demonstrated both low seroprevalence in donors and recipients and minimal acquisition of new infection; possibly related to the standard use of prophylaxis [200]. Screening may be more cost-effective in areas of the world with higher prevalence of infection.

Prevention of symptomatic infection can be accomplished by administration of either trimethoprim sulfamethoxazole (TMP-SMX) or pyrimethamine and should be considered, especially for the highest risk recipients (seronegative recipients of seropositive donor organs) [192,199,201]. The optimal dose and duration of TMP-SMX is unknown. Most of the earlier studies used a dose of 160 mg of TMP/800 mg of SMX three times per week [201,202]. Current guidelines support the use of daily single strength TMP-SMX as an acceptable alternative to the three times weekly dosing regimen [192,203]. For patients unable to receive TMP-SMX, alternative regimens may include pyrimethamine, atovaquone, or dapsone. Symptomatic infection has been noted rarely after discontinuation of prophylaxis [199,203].

Serodiagnosis may demonstrate asymptomatic transmission by around 7.5 $\pm$ 2 weeks post transplant, but given the blunted immune responses post transplant, seroconversion alone should not be relied upon to rule out the acquisition of new infection [198].. Active infection often involves the myocardium in heart recipients and ring-enhancing lesions in the brain in any recipient. Diagnosis may be confirmed by either histopathologic examination of involved tissue, detection of anti-*Toxoplasma* antibodies in the CSF, or the presence of DNA on PCR testing of CSF or bronchoalveolar lavage [192]. Pyrimethamine in combination with sulfadiazine is the preferred first-line treatment; alternatively, sulfadiazine may be substituted with clindamycin, clarithromycin, azithromycin, or atovaquone [192].

Trypanosoma cruzi (Chagas disease)

Trypanosoma cruzi, the etiologic agent of Chagas disease, is most commonly found in Latin America and is typically associated with prolonged periods of asymptomatic infection, during which time *T. cruzi* may be transmitted by blood transfusion and solid organ transplantation. In the US over 300 000 persons are thought to be infected with imported *T. cruzi*, with the highest prevalence recorded in Florida and California [204]. Due to immigration from Latin America, it has also been identified as a potential problem in Europe, Japan, and other countries [205]. Because donor epidemiologic information may not be readily available and local prevalence may be low, diagnosis is often delayed in areas of low prevalence.

Donor-derived infection most commonly involves heart transplant recipients, although it has also been reported following kidney transplantation; it often results in significant morbidity and mortality [206–208]. Presentation of donor-derived *T. cruzi* is usually non-specific with fevers and malaise. Acute infection may mimic transplant rejection, especially in the setting of cardiac transplant [206–208].

Donor screening for *T. cruzi* relies on detection of antibody to *T. cruzi* antigens, most commonly by EIA or indirect immunofluorescence antibody testing; radioimmune precipitation assays may also be used [209]. Due to low sensitivity and specificity of any single test, it is recommended that two tests be used for donor screening [209,210]. Screening for *T. cruzi* is routine in solid organ donors in endemic areas, but is not routinely recommended in low prevalence areas [209,211]. However, current US recommendations encourage the screening of donors from Latin America [209].

Because transmission of *T. cruzi* from infected donors is not universal, affected donors of organs other than the heart may be considered for donation [209,211]. When donors with Chagas infection are used, there is no recommendation for routine prophylactic antimicrobials, due to the limited transmission risk, cost, and toxicity of the medications. Instead, close monitoring with both serologic and buffy coat examination with Giemsa staining and PCR is preferred [209]. Cardiac transplantation from affected donors should be avoided due to the higher transmission rates, and extreme caution or avoidance of transplant of other organs is advised where high immunosuppression is required [209]. Suspicion of *T. cruzi* donor-derived infection should prompt immediate contact with the Centers for Disease Control and Prevention (CDC) for confirmatory testing and antiparasitic therapy if indicated [209].

Summary

Although donor-derived infections cannot always be anticipated or avoided, careful attention to donor evaluation with directed prophylactic interventions may avert significant morbidity and mortality from these infections. It is important that centers and OPOs be aware of the potential for this occurrence. If donor-derived infection is suspected, prompt communication to OPOs and the OPTN (or other regulatory bodies as dictated by government authorities) is critical to ensure that those caring for the other recipients of the donor's organs may intervene to prevent further adverse consequences of unintended transmission events.

CHAPTER 93

Perioperative Infections after Organ Transplantation

Daniel Kaul[1] and Michael Green[2]

[1] Division of Infectious Disease, University of Michigan School of Medicine, Ann Arbor, MI, USA
[2] Division of Infectious Diseases, University of Pittsburgh School of Medicine, Children's Hospital of Pittsburgh, Pittsburgh, PA, USA

Introduction

Infectious complications are an important cause of morbidity and mortality in recipients of solid organ transplantation (SOT). The timing of specific infections is generally predictable regardless of the type of organ transplanted, with most clinically important infections occurring within the first 180 days post transplant. Individual pathogens and infectious syndromes tend to present at stereotypical times after transplantation (see Figure 94.1). However, the timing of presentation of certain pathogens, e.g. cytomegalovirus (CMV), can be affected by the use of prophylactic strategies, augmentation in immunosuppression, or need for additional surgery. Over time, we have learned to categorize infectious complications according to which of three major time intervals the patients present in: (1) early (0–30 days after transplantation); (2) intermediate (30–180 days); and (3) late (>180 days). However, some infectious syndromes, e.g. catheter-associated bloodstream infections, can occur throughout the post-transplant course whenever risk factors predisposing to them are present. While some exceptions to these patterns may occur, these divisions provide a useful framework for the approach to a potentially infected patient after SOT and serve as a guide to differential diagnosis. This chapter will focus on postoperative infections occurring within the first 30 days following the organ transplant procedure. We will also address common preventative strategies applied during this period. Additional information on infectious complications is given in Chapters 92 and 94.

We define perioperative infections as those occurring up to day 30 after SOT. Infections developing during this time period are frequently associated with the presence of pre-existing conditions in the recipient or are attributable to complications of the transplant or subsequent surgeries. Additionally, some of these infections may be derived from the organ donor (see Chapter 92). In general, bacteria or yeast are the most frequent pathogens recovered during this time period [1,2]. Fifty percent or more of all bacterial infections that develop after transplantation occur during the early post-transplant period [1,2]. Superficial or deep surgical site infections are the most common infectious syndromes observed during this period. Technical difficulties, particularly those resulting in anastomotic stenosis or leak, are important risk factors for the development of invasive infection in the first month after most types of organ transplantation. Given the relationship between the majority of early infections and the surgical site, it is not surprising that the organ undergoing transplantation is the most important determinant of the location of infection, especially during this time period [3]. The chest, abdomen, and urinary tract are the most common sites of infection after thoracic, liver, and kidney transplantation, respectively. Explanations for these site-specific infections include local ischemic injury and bleeding, as well as potential contamination during the transplant surgical procedure [4].

Predisposing factors

The primary factors predisposing to infection during the early time period after organ transplantation can be categorized into those present in the recipient before transplant and those secondary to intraoperative and post-transplant events.

Pretransplant factors

The underlying illnesses causing organ failure are important risk factors for the development of infection during the early time period after SOT. For example, a history of cystic fibrosis predisposes to early pseudomonal and fungal infections after lung transplantation; colonization with *Clostridium difficile* is also common in this population, predisposing them to disease due to this pathogen after transplantation [5]. Diabetes mellitus is a risk factor for the development of post-transplant urinary tract infection (UTI) [6]. A history of palliative surgery before transplantation increases the technical difficulty of the transplant procedure, enhancing the risk of developing a post-transplant infection [7]. The severity of disease at the time of transplantation tends to correlate with the risk of postoperative morbidity and mortality [8]. For example, liver transplant recipients with higher Model of End-stage Liver Disease (MELD) scores are at increased risk for postoperative infectious complications [9]. Similarly, long-standing malnutrition predisposes to infections before and after transplantation. While correction of nutritional deficits with parenteral alimentation may help to alleviate these risks, its use is associated with the risk of catheter-associated infection, which may present in the perioperative time period. Finally, admission to the intensive care unit (ICU) and requirement for mechanical ventilation while awaiting transplantation increases the risk of colonization and infection with hospital-acquired pathogens, many of which have multidrug resistance and cause disease in the first month but also beyond the early time period.

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Age is an important determinant of both susceptibility to certain pathogens and severity of infection after transplantation. While age-related differences in the type and range of manifestations associated with individual pathogens may be less notable in the first month after SOT, these can still be important for some early infections. Young children undergoing transplantation experience greater disease severity with certain viruses, such as respiratory syncytial virus (RSV) or parainfluenza virus, compared to older children or adult recipients [10,11]. This is particularly true early after transplant when the recipient is more highly immune suppressed and not fully recovered from the transplant surgery [10,11]. Decreased psoas muscle size, a marker of frailty in older adults, is associated with increased mortality in liver transplant recipients, and we have observed an increased incidence of early bacterial and fungal infections in recipients with preoperative markers of frailty [12]. Older recipient age may increase the risk of early infection after heart transplantation [13].

Transplant recipients are at risk for acquiring pathogens from their donors who have active or latent infections at the time of organ harvesting. Many of the donor-derived infections, including bacteria-associated systemic infection in the donor [14], West Nile virus, *Strongyloides*, and *Cryptococcus neoformans* to name a few, tend to present shortly after transplant during the early time period. A more complete discussion of donor-derived infection can be found in Chapter 92.

Intraoperative factors

Intraoperative factors unique to each SOT procedure can predispose to infectious complications. For example, the type of biliary reconstruction used in liver transplantation influences the likelihood of developing an infectious complication [15]. Similarly, the type of drainage chosen after pancreas transplant is also associated with a differential risk of infection [16,17]. Surgical events during the operation also alter the risk of infection. Injury to the phrenic, vagal, or recurrent laryngeal nerves during surgery affect pulmonary toilet, predisposing a lung transplant recipient to pneumonia [18]. Ischemic injury to the allograft during the transplant procedure reduces its viability and increases the risk of infection. Additional factors, including prolonged operative time, contamination of the operative field, and bleeding at or near surgical sites, also increase the risk of postoperative infections. Specific aspects of the surgical procedures are covered by organ type in Chapters 55–64.

Post-transplant factors

Technical problems manifesting after transplantation are amongst the most important risk factors for perioperative infectious complications. Thrombosis of the hepatic artery predisposes to hepatic abscesses, infected biloma, and bloodstream infection (BSI) after liver transplantation [19]; vesicoureteral reflux predisposes to graft pyelonephritis in renal transplant recipients [20,21]; and mediastinal bleeding requiring re-exploration predisposes to mediastinitis and BSI in thoracic transplant recipients [2].

The prolonged use of indwelling cannulas is a significant risk factor for infection after transplantation. Central venous catheters are a risk for BSI, urethral catheters predispose to UTI, the use of a cannula in an obstructed biliary tract predisposes to cholangitis, and prolonged endotracheal intubation is associated with pneumonia. While the presence of an indwelling cannula is associated with infection at any time post transplant, their use typically is greatest during the early post-transplant period. Accordingly, this is a very important cause of perioperative infections.

Nosocomial exposures constitute another important group of post-transplant risk factors. All transplant recipients are at risk for developing infection with transfusion-associated pathogens, though these infections tend to be associated with relatively long incubation periods, leading to clinical presentation beyond the first month post transplant. Children and to a lesser extent adults undergoing transplantation during the winter months may be exposed nosocomially to common community-acquired viruses associated with annual seasonal epidemics, e.g. respiratory syncytial virus (RSV) and influenza. Infection early after transplant has been shown to be associated with an increased risk for morbidity and possibly mortality, especially in young pediatric transplant recipients [10,11]. The presence in the hospital of areas of heavy contamination with pathogenic fungi, such as *Aspergillus* spp., increases the risk of invasive fungal disease in these patients. Finally, nosocomial transmission of multiply resistant bacteria predisposes to infection with these pathogens.

No discussion of postoperative risk factors would be complete without including immunosuppression. While less important in the early post-transplant period, immunosuppression remains the major risk factor for infection following transplantation. Immunosuppressive regimens are continually evolving in an attempt to achieve more specific control of rejection with the least impairment of immune function. However, all immunosuppressive regimens interfere with host defenses. Treatment of episodes of rejection exacerbates this risk. The use of antilymphocyte preparations or other biologic agents is associated with an enhanced risk of infection [15,22,23]. As newer immunosuppressive agents (particularly the increasingly diverse number of new biologic agents) are introduced, clinicians must be aware of and alert for the changes in infectious manifestations and profiles seen in SOT recipients [24,25].

Early postoperative infections

Infectious complications occurring during the early post-transplant period can generally be divided into two major categories: those affecting all SOT recipients and those associated with the individual transplant procedures (Table 93.1).

Infections common to most organ transplants

The vast majority of early postoperative infections are caused by bacterial pathogens, though infections due to *Candida* and some viral pathogens also occur in the early time period [26]. Early postoperative infectious complications may manifest as systemic disease associated with sepsis and bloodstream involvement or may present with localized signs and symptoms with or without fever. Early infections are frequently a direct complication of the surgical procedure and can be categorized as being either "superficial" or "deep." "Superficial" infections that can develop in any SOT recipient affect the skin and/or fascia at the surgical site and are indistinguishable from wound infections occurring after any surgical procedure. Accordingly, their management is similar to that used for surgical site infections in patients undergoing other types of surgeries. "Deep" infections typically occur at or near the site of the transplanted organ and are usually related to anastomotic issues or other technical problems complicating the transplant surgery. Because of the differences in technical aspects and locations associated with each of the organ transplant procedures, infectious syndromes associated with deep infections vary by the type of organ transplantation the patient undergoes (see below). In this section,

Table 93.1. Risk factors and preventative strategies for early infections by organ type

	Predisposing factor	Specific infection	Preventative intervention
Kidney	Urinary catheter/stent	UTI	Decreased duration of catheterization/ stenting
	Diabetes mellitus [6]		
	Vesicoureteral reflux [20,21]		Antibacterial prophylaxis
	Female gender [57]		Ureteroneocystostomy
Pancreas	Duodenal stump	Intra-abdominal infection ± BSI	
	Anastomotic leak	UTI	Enteric drainage
	Bladder drainage [16,17]		
Liver	Anastomotic leak	Infected biloma	T-tube use may increase risk (late infections)
	Hepatic artery thrombosis [19]	Liver abscess/cholangitis	
	Renal failure/prolonged intraoperative time/*Candida* colonization/high transfusion requirement/choledochojejunostomy [74,75]	± BSI Candidemia	Serial ultrasound and early intervention Antifungal prophylaxis
	Above + graft dysfunction/prolonged ICU [15,78,79,112]	Aspergillosis	Mold active prophylaxis
Lung	Cystic fibrosis/operative nerve injury/prolonged mechanical ventilation	Pneumonia	
	Ischemia	Fungal anastomotic site infection	Fungal prophylaxis
	Donor or recipient colonization [112]	Aspergillosis	Mold active prophylaxis
Heart	Prolonged mechanical ventilation	Pneumonia	
	Postoperative circulatory support	BSI

UTI, urinary tract infection; BSI, blood stream infection; VAD, ventricular assist device.

we highlight details of selected perioperative infectious issues occurring regardless of transplant type.

Catheter-related infections

Catheter-related infections are an important cause of bacterial, and to a lesser extent fungal, infections, potentially affecting all SOT recipients in the perioperative period. The use of central venous catheters (CVCs) is associated with the development of central line-associated bloodstream infection (CLABSI). The risk of developing a CLABSI persists as long as the central line is in place. While many SOT recipients may require the presence of a CVC only for the first week or two after transplant, some patients need a CVC for longer periods of time due to requirements for hyperalimentation, ongoing hemodialysis, limited alternative vascular access, and/or ongoing clinical instability. While the use of long-term catheters, e.g. Broviac, or implanted ports may reduce the risk of CLABSI, these patients remain at increased risk for the development of this complication until the line is removed. In general, the management and treatment of CLABSI in SOT recipients is similar to that for other patients developing this complication. Guidelines published by the Infectious Diseases Society of America provide appropriate recommendations (including duration and ability to treat without removal of the affected line) based upon both recovered pathogen and the clinical condition of the patient [27,28].

Clostridium difficile colitis

C.difficile colitis (CDAD) is an important potential complication affecting all SOT recipients. *C. difficile* is the most common infectious cause of diarrhea following SOT in adults. In general, the rate of CDAD in SOT recipients appears to be higher than that observed in other hospitalized patients [29]. Recent studies demonstrate a rate of about 5%, which represents a significant increase in the rate of this complication in the past decade due to the emergence of the NAP1 strain [29–35]. While data are more limited for pediatric SOT recipients, rates of CDAD ranging from 5% to 13% have been reported in children undergoing organ transplantation [5,36]. In many series, the median time to onset of CDAD was <30 days [29,32,34,37], though later cases clearly occur. Particularly during the early post-transplant period, traditional risk factors for CDAD such as antibiotic use, hospitalization, and acid suppression are common. In liver transplant recipients, retransplantation, higher MELD scores, intra-abdominal complications, and other systemic infections have also been associated with the development of CDAD [29]. Higher rates of colonization with *C. difficile* have been documented in patients with cystic fibrosis, predisposing to infection after lung or liver transplantation [5]. Death and severe morbidity due to CDAD are relatively uncommon in SOT recipients, occurring in <5% of CDAD patients [35,37–39]. Early recognition and treatment likely improve outcomes. Diagnostic testing for CDAD is generally indicated for patients with otherwise unexplained diarrhea in the early transplant period both because early treatment of CDAD improves outcome and because findings such as abdominal pain, fever, and leukocytosis may be masked and non-specific in immunosuppressed patients. The methodology used to test for CDAD is rapidly evolving, with the development of highly sensitive polymerase chain reaction (PCR) and antigen testing providing an improved negative predictive value compared to older enzyme immunoassay (EIA) testing. Nonetheless, in highly suggestive cases empiric treatment may be indicated even following a negative assay.

Treatment of CDAD does not differ significantly in SOT recipients as compared to other patients, and guidelines are available [40,41]. Other antibiotics should be discontinued if possible. Initiation of empiric therapy pending results of testing is recommended in more severe cases [40,41]. A summary of recommended regimens both for initial therapy and for relapse is available [40,41]. Prevention of CDAD relies on limiting the use of antimicrobial agents (both for treatment and prophylaxis), and infection control measures, including hand washing (using soap and water as alcohol-based sanitizers may not be sporocidal) and possibly the use of bleach solutions in room cleaning [41].

Infections due to multidrug resistant bacteria

Over the past decade, a significant increase in infection with multidrug resistant (MDR) organisms in hospitalized patients has occurred [42–45] and SOT recipients have been significantly

impacted by this trend [46–48]. While vancomycin-resistant enterococcus (VRE) remains a major problem, the development and licensing of antimicrobial drugs with activity against VRE has preserved treatment options for most VRE-infected patients. MDR (resistant to two or more classes of commonly used broad-spectrum antimicrobials) and extremely drug resistant (XDR; often resistant to all but tigecyline and colistin) Gram-negative organisms are an emerging clinical problem. New mechanisms of resistance and local outbreaks are constantly emerging. Accordingly, clinicians must be aware of current institutional unit antibiotic resistance patterns to appropriately select empiric therapy in critically ill post-transplant patients. Liver transplant recipients with abdominal infections and cystic fibrosis patients with postoperative pneumonia are likely at the highest risk for MDR and XDR infections. In some series, outcomes in transplant patients with MDR/XDR Gram-negative infections have been poor with mortality rates as high as 90% and higher than for controls with infection with more drug-sensitive organisms [46,47,49,50]. For XDR organisms, treatment is difficult and often associated with significant renal toxicity. Combination therapy and older antibiotics such as colistin are commonly employed [48,49,51].

Perioperative infectious complications associated with individual transplant procedures

Renal transplantation

Septicemia originating from the urinary tract, lower respiratory tract, or transplant wound accounts for most life-threatening infections in the first month after renal transplantation [21,52]. UTIs, especially pyelonephritis, are the most common infectious complication, accounting for up to 50% of episodes [53,54]. In the immediate postoperative period, UTI rates of 23–45% have been reported [55–57]. Commonly described risk factors include female gender (particularly for later UTIs), diabetes mellitus (although not in two recent studies), older age, reflux disease, acute rejection, use of ureteral stent, use of cadaveric grafts, and urological malformations of the native kidney [6,57–59]. The prolonged use of urinary catheters is likely a particularly significant risk factor in the first month after transplant [60]. While *Escherichia coli* remains the most common pathogen, *Enterococcus* spp. and other Gram-negative bacteria are commonly reported. Fungal pathogens, largely *Candida* spp., are recovered in <5% of cases. More resistant bacteria, e.g. *Pseudomonas aeuroginosa* and extended spectrum beta-lactamase (ESBL)-producing organisms, are commonly seen early in the post-transplant course, likely related to exposure to resistant hospital-acquired pathogens as well as the use of perioperative antibiotics [56,59,61]. Resistance patterns vary greatly from institution to institution; appropriate empiric selection of antibiotics for early post-operative UTI depends on knowledge of hospital- and unit-specific antibiotic resistance patterns. While immediate consequences of UTIs, e.g. need for antibiotic therapy, hospitalization, sepsis in cases of acute pyelonephritis, are obviously detrimental, controversy exists regarding the long-term outcomes on graft function and mortality resulting from UTIs [6,57–59,62]. The incidence of UTIs in kidney transplant recipients may be decreased with the use of ureteroneocystostomy and prophylactic use of daily trimethoprim-sulfamethoxazole (TMP-SMX) (see UTI prophylaxis for renal transplant recipients below) [20,63,64].

Liver transplantation

Bacterial and fungal infections are a common early problem after liver transplantation [65–68]. Intra-abdominal infection or the presence of a central venous catheter predisposes to BSI, but it can occur without an obvious source. Enteric Gram-negative organisms (which are frequently MDR) account for more than one-half of episodes. Bacterial infections involving the abdomen or surgical wound are common in most series. Post-transplant biliary tract complications and resulting infection continue to be a major problem, with anastomotic leaks and hepatic artery thrombosis the most important early problems. Biliary strictures mostly present in the later postoperative period. Recent studies describe a biliary leak rate of 4.9–18%; late leaks are often related to T-tube removal [69–72]. While in many cases of anastomotic biliary leak conservative management is successful and significant infection does not occur, many patients develop biloma infection and require prolonged and often repeated courses of antibiotics and drainage procedures. Infection with MDR organisms is common in this circumstance. Hepatic artery thrombosis—which may lead to biliary leak and hepatic necrosis with resulting abscess—is much less common, occurring in <2% of recipients [72]. In some centers, introduction of frequent surveillance Doppler studies early after transplantation to monitor development of thrombosis, coupled with the use of operative thrombectomy and thrombolysis, has essentially eliminated the development of hepatic artery thrombosis and resulting infection of the graft.

Fungal infections due to pathogens other than *Candida* are relatively uncommon in the first month after liver transplantation [26,73]. While a recent large series demonstrated that 7% of fungal infections in adult liver transplant recipients were due to *Cryptococcus neoformans*, no cases occurred prior to postoperative day 45 [73]. We have, however, observed earlier cases possibly related to subclinical infection in the recipient prior to transplant- or donor-derived infection. In contrast, *Candida* infections (typically candidemia with or without dissemination) occur more commonly in the early postoperative period. Studies in adult liver transplant recipients have identified a population at very high risk for *Candida* infections [74,75]. Risk factors include renal failure, length of operation, retransplant or reoperation for complication, colonization with *Candida* spp., high transfusion requirements, and choledochojejunostomy [74,75]. Based on these risk factors, most centers employ targeted antifungal prophylaxis in adult high-risk patients, typically for 1 month or until resolution of the risk factors (see Antifungal prophylaxis below) [75,76].

Invasive aspergillosis is rare after liver transplantation, occurring in <2% of recipients [77–79]. However, when present, a significant proportion of cases occur in the early post-transplant period. These patients have generally had difficult post-transplant courses. Risk factors for early aspergillosis include retransplantation, dialysis, graft dysfunction, and ongoing need for ICU care. Early episodes of invasive aspergillosis have occurred in children undergoing liver transplantation for cystic fibrosis [67]. Outcomes are often poor in liver transplant recipients with invasive aspergillosis [78,79].

Intestinal transplantation

An increasing number of children and adults have received intestinal transplants. Many have undergone combined transplantation of the liver and intestine or multivisceral transplant procedures. Bacterial infection occurs frequently in these patients, particularly in the first month following transplantation [1,80,81]. BSI, which can be explained in part by disruption of the mucosal barrier associated with harvest injury or rejection, is a common finding [80,81]. Coagulase-negative staphylococci, enterococci, and Gram-negative enteric bacilli account for most episodes. MDR organisms are fre-

quently seen. Candidemia can also occur in these settings, and among SOT recipients small bowel recipients are at the highest risk for fungal infection [26]. Intra-abdominal infections also occur frequently in these patients during the first month after transplantation. While this likely relates to complications of the initial transplant surgical procedures, the risk is also increased by the use of mesh to temporarily close the abdominal space when the transplanted organs are too large to allow complete surgical closure of the wound at the time of the transplant. Additional risk of intra-abdominal infection is associated with the potential need for recurrent exploratory laparotomies in this patient population. The treatment of intra-abdominal infection is similar to that used for abdominal space infections in immune competent patients. Where appropriate, drainage of collections and abscesses (intraoperatively or by interventional radiology) is recommended. Empiric antibiotics should cover enteric Gram-negative bacilli and enterococci. A prior history of infection or colonization with MDR bacteria may warrant use of agents known to cover these pathogens pending availability of cultures and sensitivities. This is particularly true in patients presenting with septic shock or other signs of significant clinical instability. Accordingly, agents such as carbapenems (for resistant Gram-negative bacilli) or linezolid (for vancomycin-resistant enterococci) are frequently initiated in this patient population. However, where possible, treatment choices should be narrowed once culture and susceptibility results are available.

Heart transplantation

Infections are an important cause of morbidity and mortality in the perioperative period following heart transplantation. Rates of infection during this time period as high as 22% have been reported [82], and infections accounted for approximately 11–18% of very early deaths after cardiac transplantation in other series [82–86]. Common sites of infection during the early time period include the lungs, bloodstream, sternum, and urinary tract [13,82,83]. The need for postoperative circulatory support, e.g. extracorporeal membrane oxygenation, intra-aortic balloon pumps, left ventricular assist devices (LVADs), increases the risk for line or device-related infection [87]. Infection of the lower respiratory tract (including both pneumonia and lung abscess) occurs at a high rate in most series of heart transplantations [13,83,88]. Due to high rates of morbidity and mortality, mediastinitis is an important early infection following heart transplantation. The reported incidence of mediastinitis in heart transplant recipients is 2.4–3.8% [83,89]. The most common pathogens associated with mediastinitis include *Staphylococcus aureus* and Gram-negative enteric bacilli. Recent studies have suggested a potential enhanced risk for the development of sternal wound infections and mediastinitis in heart transplant recipients receiving mammalian target of rapamycin (mTOR) inhibitors [82,89]. Additional risk factors beyond those seen in the non-transplant population include requirement for re-exploration of the chest, age at transplantation, duration of mechanical ventilation, and the use of ventricular assist devices prior to transplantation [89]. The diagnosis of mediastinitis may be more challenging compared to patients undergoing non-transplant thoracic surgery due to a decreased likelihood of manifesting fever, leukocytosis, or local redness. The presence of chest pain in disproportion to that expected from the sternotomy is an important diagnostic clue. The finding of mediastinal air or fluid collection on computed tomography (CT) scan can further support diagnosis with confirmation made by aspiration or surgical exploration. Once confirmed, management should include aggressive surgical drainage and debridement with excision of necrotic tissue. In addition, appropriate antimicrobial therapy should be provided.

Children who undergo heart transplantation at a young age are at increased risk for invasive infection due to *Streptococcus pneumoniae* disease [90]. Infants undergoing heart transplantation represent a unique population and have increased risk of serious bacterial or fungal disease. Backer et al. reported that over 20% of infants who underwent heart transplantation had serious bacterial infection [91]. Similarly, high rates of bacterial or fungal infection were noted in infants younger than 6 months of age who underwent heart transplantation in Pittsburgh. Further, adult patients may develop early postoperative infection (often disseminated) with invasive molds such as *Aspergillus* spp. [83,92].

Ventricular assist devices, which are used with increasing frequency as a bridge to transplantation [84], are associated with postoperative infections [13]. These devices may be chronically infected preoperatively and chronic suppression of these infections with antibiotics may lead to the presence of MDR organisms. Further, the large tract sites remaining after removal may be colonized with these organisms, resulting in difficult-to-treat deep space infections.

Lung and heart–lung transplantation

Infection accounts for 10–20% of deaths occurring in the first 30 postoperative days in both adult and pediatric lung and heart–lung transplant recipients [93]. Recipients of lung transplantation are at high risk for developing bacterial infection of the respiratory tract. Pneumonia, the most important infectious complication, is difficult to diagnose definitively because differentiation between chronic colonization and lower respiratory tract infection can be problematic. Gram-negative pathogens (often MDR organisms) and *S. aureus* can be recovered in the presence or absence of disease. Radiographic abnormalities are present almost universally in patients with pneumonia or graft rejection [94–96]. Therefore, bronchoalveolar lavage (BAL) or transbronchial biopsy is often required to help distinguish between causes.

Patients undergoing lung transplantation because of cystic fibrosis have a high rate of infectious complications. They are usually colonized with *Pseudomonas* or *Aspergillus spp*. Colonization with *Burkholderia cenocepacia* (formerly *B. cepacia genomovar* III) has been associated with excessive mortality [97–99]. BSI due to organisms present before transplantation is common after lung transplantation in patients with cystic fibrosis [100,101]. Because of the importance and difficulty in treating these bacterial complications, protocols at most transplant centers include thorough evaluation of the microbial flora of candidates prior to transplantation. This should include antibiotic synergy testing and evaluation of isolates of *B. cepacia* complex species at reference laboratories.

Fungal infection frequently complicates lung transplantation and can present early after surgery, occasionally at the anastomotic site leading to later airway complications [102,103]. Among all SOT recipients, lung recipients are at the highest risk of invasive *Aspergillus* and are the only SOT group in which infection with *Aspergillus* is more common than infection with *Candida* spp. [26]. Nonetheless, early *Candida* infections, including candidemia, deep surgical site infections, and anastomotic site infections, do occur. Early fungal infections are more likely to occur in recipients undergoing lung transplantation for cystic fibrosis who are previously colonized with *Aspergillus*. However, early infection can also occur due to the presence of occult or latent fungal disease in the donor lungs. This is particularly true for the endemic mycoses, e.g. histoplasmosis

and coccidiomycosis. The relatively high rate and clinical consequence of early fungal disease in lung transplant recipients has prompted many transplant centers to institute antifungal prophylaxis with agents with activity against *Aspergillus* [104].

Pancreas transplantation

Pancreas transplants are performed almost exclusively in adult patients with poorly controlled diabetes mellitus; thus, one risk for infection is already present. In patients who also have end-stage renal disease, the procedure may be performed simultaneously with a kidney transplant, or the procedures may be done sequentially. Pancreas or renal–pancreas transplantation has a higher early postoperative infection rate than kidney-alone transplants, likely related to technical factors, e.g. contaminated donor duodenal stump, graft thrombosis leading to necrosis and infection, anastomotic leak, increased need for immunosuppression, and higher rejection rates. One series reported a 16% rate of sepsis from bloodstream infection in the first 45 days after transplant, with intra-abdominal infection the most common source [105]. Improved surgical technique and treatment to reduce the rate of thrombosis may result in a decreased incidence of intra-abdominal infection [106]. In one registry, 1.2–1.4% of recipients died from infection, making infection the second-leading cause of death after cardiovascular disease [107]. Drainage of the pancreas may be enteric using donor duodenal stump or the exocrine pancreas may be drained into the bladder; patients with bladder drainage experience very high rates of UTI [16,17]. Pancreas recipients are at higher risk for fungal infections than kidney alone recipients, likely related to enteric leaks and UTI, with a 4% rate versus 1.3% [26].

Prevention of early postoperative infections

A variety of prophylactic strategies are generally implemented in the early postoperative period. While some of these focus on the prevention of perioperative and early infectious complications, many of the strategies that are initiated shortly after transplant will be maintained for a prolonged period of time and aim to prevent infectious complications later in the post-transplant period. General considerations for prophylaxis as well as specific circumstances felt to justify universal or targeted prophylaxis for a particular organism or class of organisms in selected high-risk organ recipients are discussed below (Table 93.2).

Perioperative antibacterial prophylaxis

Despite more than 40 years of clinical experience with organ transplantation, little data exist to inform the appropriate antibacterial perioperative prophylaxis for patients undergoing organ transplantation. General principles for perioperative prophylaxis for

Table 93.2. Preventative strategy for non-viral infections by organ type and selected infection

	Wound infection	UTI prophylaxis	Antifungal prophylaxis	PCP prophylaxis[8]	Toxoplasmosis
Kidney	Skin flora[1]	Most centers use TMP-SMX for 1–3 months post transplant	None	4–12 months Additional course of 2–3 months after high-risk events[2]	None
Kidney–pancreas or pancreas alone	Skin flora[1] Enteric flora[3]	None for pancreas alone	None	4–12 months Additional course of 2–3 months after high-risk events[2]	None
Liver	Skin flora[1] Enteric flora[3]	None	Adult high risk recipients[4] fluconazole for 1 month or until resolution of risk factor Mold active agent if ultrahigh risk[5]	4–12 months Additional course of 2–3 months after high-risk events[2]	None
Lung	Skin flora[1] Respiratory flora[6] Extended (14 days) treatment of pathogens recovered from donor or recipient lungs	None	Most centers employ universal mold active prophylaxis[7]	Minimum 12 months; lifelong prophylaxis likely justified	None
Heart	Skin flora[1] (some centers include MRSA coverage if recipient colonized) Respiratory flora[6] Additional coverage (based on sensitivity data) if known LVAD colonization or positive cultures	None	None	4–12 months Additional course of 2–3 months after high-risk events[2]	Donor positive/ recipient negative IgG serology[9]
Small intestine	Skin flora[1] Enteric flora[3]	None	None	Minimum 12 months; lifelong prophylaxis likely justified	None

[1] Commonly used antibiotics for skin flora prophylaxis include cefazolin and clindamycin.
[2] Cytomegalovirus, cell-depleting therapy for rejection, prolonged high-dose corticosteroids.
[3] Commonly used antibiotics that cover enteric organisms (Gram negative + anaerobes) include piperacillin/tazobactam, ampicillin/tazobactam, and cefoxitin, and these provide skin flora prophylaxis as well.
[4] Renal failure, length of operation, retransplant for reoperation for complication, colonization with *Candida* spp., high transfusion requirements, and choledochojejunostomy high-risk events.
[5] Risk factors above combined with graft failure, hemodialysis, prolonged intensive care unit stay.
[6] Commonly used antibiotics that cover respiratory pathogens include cefepime and piperacillin/tazobactam and these provide skin flora prophylaxis as well.
[7] Agents with activity against molds include echinocandins, voriconazole, and posaconazole.
[8] Some experts recommend lifelong PCP prophylaxis.
[9] TMP-SMX alone or dapsone or atovaquone usually combined with pyrimethamine and leucovorin.
UTI, urinary tract infection; PCP, *Pneumocystis jiroveci* (formerly *carinii*); TMP-SMX, trimethoprim-sulfamethoxazole; MRSA, methicillin-resistant *Staphylococcus aureus*; LVAD, left ventricular assist device.

standard surgical procedures have been combined with specific risk factors and circumstances associated with enhanced risk of infection for specific organ transplant recipients. One survey of 61 European liver transplant centers found general agreement in the duration of prophylaxis (median 3 days), but identified broad variability in the choice of perioperative antibacterial prophylaxis [76]. Strategies ranged from relatively narrow spectrum beta-lactams to combined therapy utilizing advanced-generation beta-lactams (e.g. third- or fourth-generation cephalosporin or piperacillin/tazobactam) in combination with vancomycin. In the absence of definitive data, perioperative prophylactic regimens should aim to cover skin organisms (for all organ transplant procedures) as well as enteric Gram-negative and anaerobic bacteria and enterococci for liver, pancreas, and intestine transplant procedures. Knowledge of pre-existing colonization with methicillin-resistant *Staphylococcus aureus* (MRSA), VRE, and MDR Gram-negative bacteria may lead to individualization of perioperative prophylactic regimens.

Several special circumstances have led to broadly accepted recommendations for more prolonged and specific prophylaxis. Many centers cover respiratory pathogens in heart transplant recipients, and will treat for 1–2 weeks after transplant if known LVAD colonization or infection or cultures of LVAD tracts are positive for resistant organisms postoperatively. For lung transplant recipients, the presence of bacterial or fungal pathogens recovered from donor BAL cultures typically prompts a 2-week course of antibacterial agents based upon the susceptibility of the recovered organisms. Additional circumstances in which the agent used for prophylaxis might be modified or prolonged include the donor being bacteremic or having infection within the graft or central nervous system.

Urinary tract infection prophylaxis for renal transplant recipients

Many centers use antibacterial prophylaxis to prevent UTI in the first 1–12 months after transplantation. A recent meta-analysis of studies conducted in the 1980s and 1990s found that antibiotic prophylaxis reduced the rate of sepsis, bacteremia, and bacteriuria, but had no effect on long-term graft outcomes [64]. To some degree, the widespread use of *Pneumocystis jiroveci* prophylaxis with TMP-SMX by >80% of US transplant centers for 3–6 months post-transplant render this question mute [108]. More recent evidence regarding increasing antimicrobial resistance (particularly to TMP-SMX among urinary isolates) of patients on prophylaxis [61] limits the efficacy of this agent and may reduce enthusiasm for extended courses of UTI prophylaxis. The use of broader-spectrum agents, e.g. fluorquinolones, is limited by more severe consequences of resistance, e.g. no available oral agents to treat UTI, as well as other adverse events and superinfections.

Antifungal prophylaxis

As discussed above, risk factors for invasive fungal infections after SOT have been described, and due to the serious nature of these infections many centers employ antifungal prophylaxis for high-risk groups. A reduction in mortality has not been demonstrated, and drug interactions and the emergence of resistance may limit the benefit of antifungal prophylaxis. The patients most commonly targeted for antifungal prophylaxis are lung and high-risk liver recipients, as discussed below.

Liver transplantation

Adult liver transplant recipients with certain risk factors (see above) are at high risk for *Candida* infection in the early postoperative period [74,75]. A number of randomized studies using either varying doses of fluconazole or itraconazole have demonstrated a reduction in fungal infections, although no reduction in overall mortality [109–111]. Due to decreased drug interactions with calcineurin inhibitors (CNIs) and easier drug delivery, fluconazole is generally preferred to itraconazole. While a 400-mg daily dose of fluconazole may be superior, many centers employ a lower dose (100 mg daily) with success. Fluconazole prophylaxis increases the rate of fluconazole-resistant *Candida* spp. [73], and about 50% of *Candida* spp. observed after liver transplantation are non-albicans [26,73]. As non-albicans species are more likely to be azole resistant, interest in using an echinocandin that is active against most non-albicans species has increased and a trial in high-risk patients is ongoing. Some experts suggest prophylaxis with a mold-active agent in critically ill recipients (retransplantation, prolonged ICU stays, graft dysfunction, hemodialysis) at higher risk for early invasive aspergillosis [75,112], although drug interactions, hepatotoxicity, drug delivery issues, and other adverse events may limit the use of drugs such as voriconazole or posaconazole in the early postoperative period. Of note, antifungal prophylaxis has not been recommended for pediatric liver transplant recipients. This may be due to differences in frequency and outcome of *Candida* infections in children undergoing liver transplantation.

Lung transplantation

Among SOT recipients, lung recipients are at the highest risk of invasive fungal infection; invasive pulmonary aspergillosis (IPA) is the most common fungal infection in this group [26]. Because of the frequency and severity of IPA, most centers employ some form of prophylaxis [104]. Randomized placebo-controlled data, however, are not available to confirm the efficacy of prophylaxis. Case series demonstrate varying results, and firm recommendations cannot be made [112–115]. Options for prophylaxis include inhaled amphotericin products, itraconazole, or voriconazole [112]. Many centers treat for 3–6 months or base duration on negative fungal cultures obtained at routine follow-up bronchoscopies [104]. Some centers have noted an increased rate of hepatotoxicity [113,115] as well as emerging adverse events, e.g. painful periostitis [116] and increased risk of skin cancer, with prolonged voriconazole use. These concerns, combined with drug interactions between azoles and CNIs, have increased interest in the use of inhaled amphotericin products. Other centers attempt to target prophylaxis at patients with additional risk factors for IPA, e.g. *Aspergillus* colonization, cell-depleting induction therapy, CMV infection [112,113]. A multicenter, randomized study is required to clarify the optimal approach to antifungal prophylaxis in this high-risk population.

Pneumocystis jiroveci prophylaxis

Prior to the routine use of prophylaxis, *Pneumocystis jiroveci* (formerly *carinii*) pneumonia (PCP) rates from 1% to 88% were reported in SOT recipients, with the highest rates observed in recipients of chest organs and during the first postoperative year [117]. Accordingly, both American and European guidelines recommend PCP prophylaxis for the first 4–12 months after SOT [118,119]. However, some experts have recommended the use of indefinite prophylaxis as the risk never returns to that of the non-immunosuppressed patient. In particular, because of the higher risk noted in lung transplant and small bowel transplant recipients, many centers employ life-long prophylaxis in these populations. Given that >85% of US transplant centers currently use PCP prophylaxis for at least 3 months after transplantation [108], the

incidence of PCP on current immunosuppression protocols is difficult to ascertain. Nonetheless, a number of more recent reports suggest that with limited or no prophylaxis, rates of PCP may be lower than expected in lower risk, e.g. renal transplant, recipients and call into question the need for universal prophylaxis [120–125]. Interestingly, some of these reports describe outbreaks of PCP likely due to human-to-human transmission after long periods with very low PCP rates [121–125]. One possibility is that the high rates of PCP noted in earlier studies reflected measurement during an outbreak. In any case, most centers do restart (or continue) prophylaxis for 2–3 months after clinical events that create higher risk of PCP, e.g. CMV infection, rejection treatment with cell-depleting agents, prolonged high doses of corticosteroids. PCP prophylaxis with TMP-SMX is highly effective, with most trials showing no cases of PCP in treated patients [126]. TMP-SMX can be administered as one double-strength tablet daily or thrice weekly. A dose of 5 mg/kg/day (trimethoprim component) is used with the same frequency for pediatric SOT recipients. Some centers prefer to use a single-strength tablet daily; dosing should be adjusted based on renal function. Other benefits of TMP-SMX include possible protection against uncommon but significant infections such at *Nocardiosis* and *Toxoplasmosis*. Patients intolerant of TMP-SMX may be treated with dapose 50–100 mg daily, atovaquone 1500 mg daily, or inhaled pentamidine 300 mg monthly. Weight-based dosing of these agents is recommended for pediatric SOT recipients. For dapsone, the dose would be 2 mg/kg given daily (maximum dose 100 mg/day) or 4 mg/kg given once per week (maximum dose 200 mg). For atovaquone, the dose varies by age. Children aged 4–24 months should receive 45 mg/kg/day once daily (maximum dose: 1500 mg/day), while those aged >24 months should be treated with 30 mg/kg/day once daily (maximum dose 1500 mg/day). The dosing frequency of inhaled pentamidine for children is every 3–4 weeks, with children <5 years of age receiving a dose of 150 mg while those >5 years receive the adult dose of 300 mg.

Toxoplasmosis prophylaxis

Toxoplasma gondii is a protozoa that establishes latent infection in approximately 10–20% of North Americans, and has a much higher prevalence in other parts of the world. The most important problem in the SOT population is activation of latent infection in the myocardium of seropositive heart donors transplanted into seronegative recipients. Thus, all heart donors and recipients should undergo serological testing for *T. gondii* to determine if the high-risk situation (donor positive, recipient negative) is present. Routine screening is not necessary for non-cardiac donors and recipients. TMP-SMX at the doses described above in the PCP section appears to be effective at preventing toxoplasmosis, although some centers prefer daily dosing for high-risk recipients [127,128]. Patients unable to tolerate TMP-SMX may be treated with dapsone or atovaquone, possibly combined with pyrimethamine and folinic acid; some centers use atovaquone alone. Any of these regimens will provide PCP prophylaxis as well. Duration of prophylaxis is unclear; many centers treat for 6 months to 1 year, but some maintain lifelong prophylaxis.

Antiviral prophylaxis

Although clinical disease due to CMV, EBV, BK virus (BKV), and hepatitis B (HBV) and hepatitis C virus (HCV) does not typically manifest until later after SOT, strategies for the prevention of infection and disease attributable to these viral pathogens are typically initiated in the perioperative time period. Specific considerations for each virus are discussed below.

Cytomegalovirus

For CMV, one of two major strategies is usually initiated. Universal chemoprophylaxis provides antiviral therapy with ganciclovir or valganciclovir to all "at-risk" transplant recipients for a specified period of time. Current recommendations tend to favor the use of oral valganciclovir for a 3–6-month period of time, though some centers have opted for even longer courses of treatment, particularly for lung transplant recipients [129–131]. Pre-emptive therapy is based on the performance of serial measurements of viral load in the blood to detect early subclinical infection to inform initiation of pre-emptive antiviral treatment. It is recommended that serial viral load measurements be obtained weekly for a defined period (e.g. 6 months) following transplantation [129,131]. Once initiated, antiviral treatment is usually continued until the CMV load becomes non-detectable. The pre-emptive strategy limits exposure to ganciclovir or valganciclovir to those with proven evidence of subclinical infection. However, the requirement that SOT recipients undergo weekly surveillance screening of their blood brings logistical challenges and costs to this strategy. Further, this strategy may not be effective in patients at high risk for CMV disease with rapid doubling times (e.g. donor-positive, recipient-negative chest organ recipients). A third strategy, known as the "hybrid approach," has evolved, particularly for pediatric centers where oral valganciclovir has only recently become available [131]. The hybrid strategy typically combines a short course of antiviral chemoprophylaxis (typically 2–4 weeks) for patients at increased risk for CMV infection and disease, followed by surveillance viral load measurements for a designated period of time. A more detailed description of the relative benefits of each of these approaches is given in Chapter 94.

Epstein–Barr virus

Despite increasing efforts and attention, definitive evidence confirming the efficacy of strategies for the prevention of EBV disease and post-transplant lymphoproliferative disease (PTLD) are lacking. With the exception of a small number of prospective, randomized trials, evidence supporting EBV prevention strategies derives from retrospective clinical series of variable quality and design. The efficacy of chemoprophylaxis with acyclovir or ganciclovir is unclear. Retrospective studies in support of this approach have lacked appropriate controls and have been confounded by changes in immunosuppression regimens over time. The use of intravenous immunoglobulin was evaluated in one multicenter randomized clinical trial. Although a trend towards benefit was seen, the study did not achieve adequate enrollment to demonstrate a statistically significant difference between the two groups [132]. The preventive strategy currently favored by most experts uses serial monitoring of EBV load in the peripheral blood to inform pre-emptive reduction in immunosuppression [132]. Data on the pre-emptive use of rituximab for patients with rising EBV loads is also emerging [133]. Studies evaluating the efficacy of this approach are generally limited by their retrospective design. In general, monitoring is only recommended for patients who are EBV seronegative prior to transplant as those who are EBV seropositive prior to transplant only rarely develop EBV disease after transplant. However, this is not true of intestinal transplant recipients where EBV seropositivity (at least in pediatric patients) is not protective against development of disease. The prevention of EBV disease and PTLD is discussed in greater detail in Chapter 96.

BK virus

Attention and effort have also focused on the prevention of BKV-associated nephropathy (BKVAN) in kidney transplant recipients. In general, the use of surveillance measurement of BKV load to identify patients at risk of progression to BKVAN is supported for kidney recipients [134]. Measurement of BKV load in urine is attractive as it is non-invasive. However, in general, the presence of an elevated urine load does not predict progression to BKVAN. Accordingly, pre-emptive interventions usually require identification of an elevated BKV load in the blood. Current consensus favors the reduction of immunosuppression in response to persistent elevated loads [134]. While interest in the potential role of cidofovir, leflunomide, intravenous immunoglobulin, and ciprofloxacin for the treatment of subclinical BKV infection or disease exists, studies are limited and most experts are skeptical that any of these are efficacious.

Hepatitis B and C virus

Without preventative strategies, HBV commonly recurs in infected liver transplant recipients and may progress rapidly in the setting of immunosuppression. Prior to the availability of effective preventative strategies, recurrent HBV resulted in significantly poorer survival for patients transplanted for HBV as compared to those transplanted for another indication [135]. Before transplant, potential recipients with active hepatitis B should be treated as per current guidelines and lower viral loads at the time of transplant may reduce the risk or recurrence [136,137]. After transplant, combination therapy with hepatitis B immunoglobulin (HBIg) and antivirals has been shown to prevent recurrent hepatitis B in most recipients and is superior to either HBIg alone or lamivudine alone [137–141]. While most studies have used lamivudine as the antiviral agent, lamivudine resistance may develop and thus the use of combination therapy or antivirals with reduced potential for resistance is preferred [137]. Future research is likely to better define the efficacy of various antivirals or antiviral combinations. Most centers employ lifelong antiviral prophylaxis; shorter courses of HBIg, e.g. 1–6 months, may be adequate, particularly in patients with low or undetectable hepatitis viral loads at the time of transplant and no history of resistance [137,142]. Similar preventative strategies are commonly employed to prevent HBV transmission from HBV-infected donors into non-infected recipients. From the perioperative standpoint, it is important to vaccinate seronegative recipients preoperatively to reduce their risk of acquiring HBV at the time of transplantation. Donor-derived HBV is discussed in further detail in Chapter 92.

HCV recurs in most infected liver transplant recipients, and no widely accepted strategy for prevention or prophylaxis exists [137]. The development and licensure of more effective and easier-to-tolerate HCV therapies provides hope for improvements in treatment or prevention of recurrent HCV in the future.

Summary

Transplant recipients are subject to numerous infectious illnesses in the perioperative period. These relate closely to the recipient's co-morbid conditions at transplant and the type of transplant received. Some infections are rather typical, mimicking those seen in the non-transplant surgical setting, but the immunosuppressed state inherent in transplantation and exposure to a donor who may be an infectious vector can predispose the transplant recipient to unique opportunistic infections that require prompt recognition and management.

CHAPTER 94

Late Infectious Disease after Organ Transplantation

Jay A. Fishman[1] and Robin K. Avery[2]

[1] Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA

[2] Division of Infectious Disease (Transplant/Oncology), Johns Hopkins University School of Medicine, Baltimore, MD, USA

Introduction

The risk of infection following solid organ transplantation (SOT) has increased with the availability of new immunosuppressive agents and the prolonged duration of allograft and patient survival. As such, treatment of transplant-associated infections requires intervention not only with effective antimicrobial agents, but also specific consideration of the burden of immunosuppression imposed for prophylaxis against allograft rejection. This chapter will provide an understanding of the dynamic relationship between the intensity of immunosuppression and new prophylactic strategies, coupled with advances in microbiologic assays, and in doing so, provide the transplant clinician with the tools needed to prevent and to treat most opportunistic infections.

In considering the transplant patient generically, a few central concepts are useful in the assessment of infectious risk:

1 Recognition of infection is more difficult in transplant recipients than in individuals with normal immune function given the diminished signs and symptoms of infection and the array of non-infectious etiologies of fever, e.g. graft rejection and drug toxicity [1,2].
2 The spectrum of potential pathogens is broad; multiple pathogens may be present at the same time, e.g. viral and molds. Improved microbiologic assays are available to guide therapy for many common pathogens [3].
3 The risk for infection is related to the nature and intensity of immunosuppression used to prevent graft rejection [1,2].
4 Infection progresses rapidly in the immunocompromised host, increasing the importance of preventing infection.
5 Rapid and specific diagnoses are needed to guide antimicrobial therapies and to limit avoidable drug interactions and toxicities. *Invasive diagnostic procedures* are often required.

Currently, available assays can help guide the optimal dosing or combination of immunosuppressive medications so as to prevent graft rejection while avoiding infections, but no assay exists to specifically indicate which immunosuppressive approach is required for an individual patient. Significant clinical management and follow-up remain paramount in navigating the transplant recipient at risk for infectious illness.

Risk for infection and the timeline of infection

The risk of infection in the transplant recipient is largely determined by two closely linked factors:

1 The *epidemiologic exposures* of the patient and the organ donor, including those unrecognized by the patient or distant in time (Table 94.1) [2,4].
2 The patient's *"net state of immunosuppression,"* including all factors contributing to the risk for infection (Table 94.2) [2].

It is easiest to consider these factors as semi-quantitative measures that evolve over time. Thus, the measure of risk is comparable to measuring the area under the curve of a formula relating epidemiology and immune function: At higher levels of immunosuppression over time, infection occurs at lower levels of infectious "exposure" or with organisms of lower degrees of native virulence or "invasiveness." With lower levels of immunosuppression, infection is less common and drug toxicities are less frequent, but graft rejection is more prevalent. Specific immune deficits, and thus specific immunosuppressive regimens, predispose to infection with specific types of organisms, e.g. T-lymphocyte depletion activates latent cytomegalovirus (CMV) and allows viral replication to occur, while corticosteroids predispose to *Pneumocystis* infection [5]. Successful preventative strategies (prophylaxis or pre-emptive therapies) reduce the burden of potential pathogens or the ability to cause invasive infection, and allow greater intensity of immunosuppression. Thus, preventative strategies must be linked to the nature of immunosuppression and other risk factors for infection. Additional information on strategies for infectious disease prophylaxis can be found in Chapter 99.

Epidemiologic exposures

Exposures can be divided into four overlapping categories: donor-derived (see Chapter 92) or pre-existing recipient-derived infections, and community or nosocomially-derived exposures. These have been discussed in some detail in previous chapters. Some salient features will be emphasized here. Any infection in the transplant recipient that is not eradicated prior to initiation of immunosuppression may re-emerge later in the recipient's course.

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Table 94.1. Significant epidemiologic exposures relevant to transplantation

- Donor-derived
- Viral:
  - Herpes group (Cytomegalovirus, Epstein–Barr virus, human herpesviruses 6, 7, and 8, herpes simplex, varicella zoster virus)
  - Hepatitis viruses (notably HBV and HCV)
  - Retroviruses (human immunodeficiency virus, human T-lymphotropic virus 1 and -2)
  - Others: West Nile virus, lymphocytic choriomeningitis virus, rabies
- Bacteria:
  - Gram-positive and Gram-negative bacteria (*Staphylococcus* spp., *Pseudomonas* spp., *Enterobacteriaceae*)
  - Mycobacteria (tuberculosis and non-tuberculous)
  - Nocardia species
- Fungi:
  - *Candida* species
  - *Aspergillus* species
  - Endemic fungi (*Cryptococcus neoformans*)
  - Geographic fungi (*Histoplasma capsulatum*, *Coccidioides immitis*, *Blastomyces dermatitidis*, *Paracoccidioides* spp.)
- Parasites:
  - *Toxoplasma gondii*
  - *Trypanosoma cruzi*
  - *Strongylodes stercoralis*
  - *Leishmania* spp.
  - *Balamuthia* spp.
- Nosocomial exposures:
  - Methicillin-resistant staphylococci
  - Vancomycin-resistant enterococci (also linezolid and quinupristin–dalfopristin resistance)
  - Multidrug resistant Gram-negative bacilli
  - *Aspergillus* species
  - *Candida* non-*albicans* strains
- Community exposures:
  - Food and water borne (*Listeria monocytogenes*, *Salmonella* spp., *Cryptosporidium* spp., hepatitis A, *Campylobacter* spp.)
  - Respiratory viruses (respiratory syncytial virus, Influenza, parainfluenza, adenovirus, metapneumovirus)
  - Common viruses, often with exposure to children (coxsackie, parvovirus)
  - Other viruses (polyomavirus, papillomavirus)
  - Chikungunya virus
  - Atypical respiratory pathogens (*Legionella* spp., *Mycoplasma* spp., *Chlamydia*)
  - Geographic fungi and *Cryptococcus*, *Pneumocystis jiroveci*
- Parasites (often distant):
  - *Strongyloides stercoralis*
  - *Leishmania* spp.
  - *Toxoplasma gondii*
  - *Trypanosoma cruzi*
  - *Naegleria* spp.

Table 94.2. Factors contributing to the "net state of immunosuppression"

- Immunosuppressive therapy: type, temporal sequence, intensity
- Prior therapies (chemotherapy or antimicrobials)
- Mucocutaneous barrier integrity (catheters, lines, drains)
- Neutropenia, lymphopenia (often drug induced)
- Underlying immune deficiency (e.g. hypogammaglobulinemia from proteinuria, systemic lupus, complement deficiencies)
- Metabolic conditions: uremia, malnutrition, diabetes, alcoholism/cirrhosis
- Viral Infection (cytomegalovirus, hepatitis B and C, respiratory syncytial virus)

Recipient and donor-derived infections

Donor and recipient screening (see Chapter 92) are critical to the development of post-transplant preventative strategies [6,7]. The strategies selected will vary by patient; these might include avoiding corticosteroids in patients infected with hepatitis B virus (HBV), pretreatment with isoniazid in individuals with latent tuberculosis or ivermectin in patients from areas endemic for *Strongyloides stercoralis*, vaccination of seronegative recipients, e.g. varicella zoster virus (VZV), or empiric antifungal therapy in recipients of organs from donors with candiduria. Antiviral strategies for cytomegalovirus (CMV) or Epstein–Barr virus (EBV) are based on an individual assessment of risk for all transplant recipients based on serologic assays (discussed below).

Some donor-derived infections, e.g. *S. stercoralis*, tuberculosis or histoplasmosis, may manifest well beyond the peritransplant period. Similarly, colonization of donor lungs, e.g. *Burkholderia, Aspergillus* or *Cryptococcus* spp., or of the recipient's urinary or biliary tracts, e.g. with vancomycin-resistant enterococcus (VRE), may cause disease only in the presence of other immunomodulatory events such a treatment of graft rejection or concomitant viral infection. Recipient-derived exposures also generally reflect latent infections or colonization activated in the setting of immunosuppression and/or technical defects. The patient with incompletely treated pneumonia or peritonitis is likely to suffer a relapse when no longer receiving appropriate antimicrobial agents.

Community exposures

Recent and remote exposures may reactivate long after transplantation. Travel, new hobbies, young children, or work may provide exposures to contaminated food or water ingestion (*Listeria, Cryptosporidium*), soil (*Aspergillus or Nocardia*), birds (*Cryptococcus*), and geographically restricted systemic mycoses (*Blastomyces dermatitidis*, *Coccidioides immitis*, *Paracoccidioides* spp., and *Histoplasma capsulatum*), or respiratory virus infection with the risk for bacterial or fungal superinfections.

Nosocomial Exposures

Nosocomial infections are of increasing importance in transplant recipients (see Chapter 93). In part, this reflects the burden of organisms with significant antimicrobial resistance in medical centers. As patients wait longer for organs, they clinically deteriorate and have often undergone multiple courses of antimicrobial therapy and greater exposure to antimicrobial-resistant nosocomial pathogens. Among the common pathogens are VRE, methicillin-resistant *Staphylococcus aureus* (MRSA), fluconazole-resistant *Candida* spp., *Aspergillus* spp., and highly resistant Gram-negative bacteria [8]. Respiratory viral infections may be acquired from medical staff and should be considered among the causes of fever and respiratory decompensation among immunocompromised individuals.

Net state of immunosuppression

The net state of immunosuppression is a conceptual measure of all factors contributing to the patient's risk for infection (Table 94.2) [2]. Among these are:

- Specific immunosuppressive therapy, including dose, duration, and sequence of agents—an "area under the curve" of immunosuppression.
- Technical problems in the transplant procedure, resulting in leaks (blood, lymph, urine) and fluid collections, devitalized tissue, poor wound healing, and surgical drainage catheters.
- Prolonged airway intubation.
- Use of broad-spectrum antibiotics.
- Post-transplant renal, hepatic, pulmonary, or cardiac dysfunction or diabetes.
- Prolonged use of urinary, vascular access, or dialysis catheters or surgical drains, or other breaks in skin or mucosal defenses.
- Infection with one of the immunomodulating viruses, including CMV, EBV, HBV or hepatitis C virus (HCV), or human immunodeficiency virus (HIV). Note that most viruses, including

Table 94.3. Immunosuppression and infection: Common associations

- Antilymphocyte globulins (lytic depletion) and alloimmune response:
  - T lymphocytes: activation of latent (herpes)viruses, fever, cytokines
  - B lymphocytes: encapsulated bacteria
- Plasmapheresis: encapsulated bacteria
- Costimulatory blockade: unknown so far; possible increased risk for Epstein–Barr virus/ post-transplantation lymphoproliferative disease
- Corticosteroids: bacteria, *Pneumocystis jiroveci* (formerly *carinii*) pneumonia, hepatitis B, possibly hepatitis C
- Azathioprine: neutropenia, possibly papillomavirus
- Mycophenolate mofetil (MMF): early bacterial infection, B cells, late cytomegalovirus
- Calcineurin inhibitors: enhanced viral replication (absence of immunity), gingival infection, intracellular pathogens
- mTOR inhibitors:
  - Poor wound healing
  - Excess infections in combination with other agents
  - Idiosyncratic interstitial pneumonitis

community-acquired respiratory viruses, have local effects that predispose to superinfection.
- Malnutrition.
- Neutropenia, which may be related to medications such as mycophenolate mofetil (MMF), azathioprine, ganciclovir, and valganciclovir.

The impact of various combinations of immunosuppressive agents on immune function in an individual patient is often not predictable. The assessment of "immunity" to specific pathogens, e.g. cellular immune function or serum antibody levels against specific organisms, is a relatively recent set of research technologies. Serologic assays determine past exposures to various pathogens but are poorly predictive of the efficacy of the immune response to specific pathogens in the immunosuppressed host. Measures of "global" immune function remain relatively crude [9]. Individual drugs are associated with increased risk for certain infections (Table 94.3) [5]; combinations of agents may enhance this risk or cause toxicity, e.g. nephrotoxicity. Few data exist, for example, on the rate of immune reconstitution against infection after T- or B-lymphocyte depletion or treatment with other antibody preparations, e.g. antibodies to tumor necrosis factor and costimulatory blockade. The effects of organ dysfunction, e.g. cirrhosis and renal dysfunction, on systemic immune function resist quantification.

Among important "immune defects" are breaches in cutaneous barriers or innate immune function. It was noted that the combination of "sticky" organisms such as VRE or *S. aureus* from colonized skin with in-dwelling catheters or drains leads to increased risk for bacteremia. These effects are amplified by neutropenia caused by drug effects [ganciclovir, MMF, azathioprine, allopurinol, trimethoprim-sulfamethoxazole (TMP-SMX), and others]. Surgical, invasive radiologic, or gastrointestinal procedures employed to repair technical complications such as bile leaks or biliary or ureteric strictures, risk dissemination of organisms from those sites with distant seeding and abscess formation in joints or ischemic regions of grafts.

Timetable of infection

As immunosuppressive regimens became more standardized, the most common infections are observed in a relatively predictable pattern depending on the time elapsed since transplantation (Figure 94.1). This is a reflection of changing risk factors over time: surgery/ hospitalization, immunosuppression, acute and chronic rejection, emergence of latent infections, and exposures to novel community infections [1]. The pattern of infection changes with alterations in the immunosuppressive regimen (side-effects, intensification for graft rejection), intercurrent viral infection, neutropenia (drug toxicity), graft dysfunction, or significant epidemiologic exposures (travel or food). The pattern also will be changed by the use of prophylactic antimicrobial agents in that infections will appear later than "normal" when delayed by effective prophylaxis. This observation suggests that a reduction in the net state of immunosuppression is desirable over time so that infection is less likely when prophylaxis is discontinued [10,11].

The timeline reflects three overlapping periods of risk for infection: (1) the perioperative period, approximately 0–30 days after transplantation (see Chapter 93); (2) the period 1–6 months after transplantation (depending on the taper of immunosuppression and the specific type, dosing, and effect of antilymphocyte "induction," which may persist); and (3) the period beyond 6-–12 months after transplantation. These periods reflect the changing major risk factors associated with infection: (1) surgery and technical complications; (2) intensive immunosuppression with viral activation; and (3) community-acquired exposures with the return of normal activities.

The timeline may be used in a variety of ways: (1) to establish a differential diagnosis for the transplant patient suspected of having infection; (2) as a clue to the presence of an excessive environmental hazard for the individual, either within the hospital or in the community; and (3) as a guide to the design of preventative antimicrobial strategies. Infections occurring outside the usual period or with unusual severity suggest the presence of an excessive epidemiologic hazard or of excessive immunosuppression [1]. The *prevention* of infection must be linked to the *risk* for infection at various times after transplantation. Routine preventative strategies from the Massachusetts General Hospital are outlined in Tables 94.4 and 94.5. It should be noted that such strategies serve only to delay the onset of infection in the face of epidemiologic pressure. The use of antibiotic prophylaxis, vaccines, and behavioral modifications, e.g. routine hand washing or advice against digging in gardens without masks, may only result in a "shift to the right" of the infection timeline unless the intensity of immunosuppression is reduced or immunity develops.

First phase post transplantation (0–30 days)

The types of infection during the first month after transplantation are outlined in Chapter 93. These are often related to complications of the transplant surgery, infections present in the donor or recipient prior to transplantation, or nosocomial infections. These infections, unless eradicated, are a common source of difficulties later in the patient's course. Recurrent infections are most often related to technical issues (strictures, leaks, graft injury) that are often difficult to resolve. The risk for infection may be reduced with attention to early removal of lines and drains, discontinuation of unneeded medications including antimicrobial agents, and meticulous wound care. Notable for their absence in the first month after transplantation are opportunistic infections, even though the daily doses of immunosuppressive drugs are at their highest during this time. The implication of this observation is that sustained administration of immunosuppressive agents is generally required to allow organisms of little native virulence to cause invasive disease. Thus, early post-transplant *Pneumocystis* pneumonia is seen in patients treated with corticosteroids, e.g. for autoimmune disorders, in advance of transplantation in the absence of prophylaxis. Early *Aspergillus* infection is the result of colonization prior to surgery or to excessive

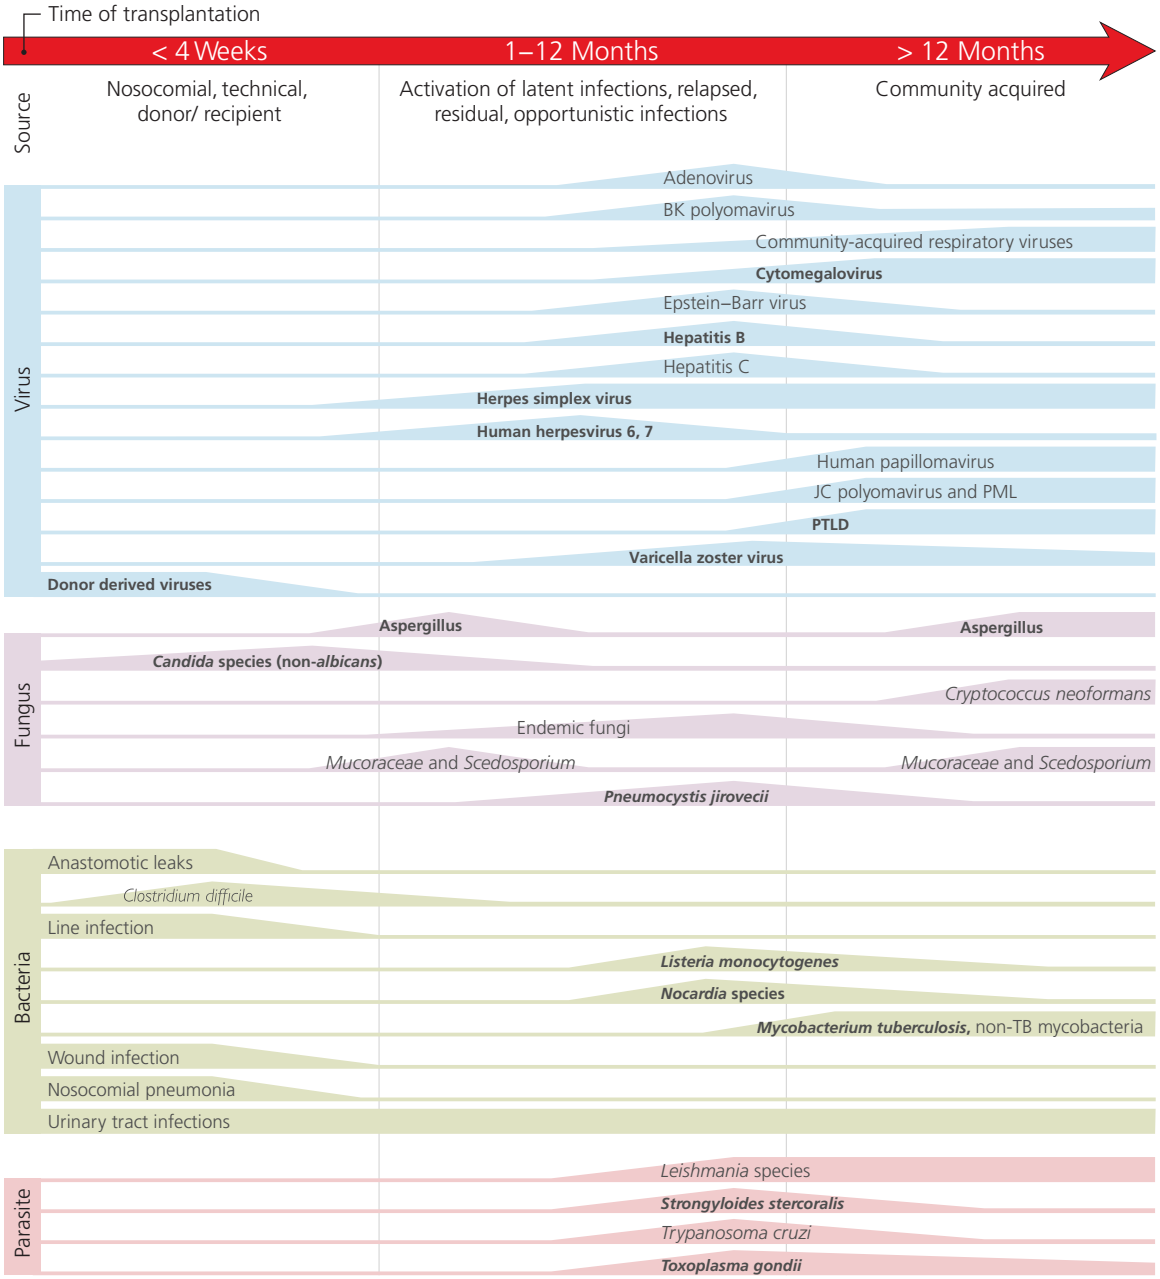

Figure 94.1. Timeline of infections following organ transplantation. The risk for infection following organ transplantation varies in a relatively standard pattern with the net state of immunosuppression and the epidemiology of infectious exposures. The potential pathogens for which the risk is modified by prophylaxis, including vaccinations and antimicrobial agents, are depicted in bold. Individual risk is modified by events such as the treatment of graft rejection or malignancy. Thickness of line indicates relative risk. Bold type indicates infections potentially preventable by prophylaxis. May be delayed until until prophylaxis is discontinued. Modified from Fishman [1] and Fisham and Rubin [2].
PML, progressive multifocal leukoencephalopathy, PTLD, post-transplantation lymphoproliferative disease.

environmental exposure in the hospital— in areas of construction or faulty air handling ducts, or in highly trafficked areas. Additional treatment of donor-derived and perioperative infections can be found in Chapters 92 and 93.

Second phase post transplantation (1–6 months)

There are multiple causes of febrile syndromes in the transplant recipient 1–6 months after transplantation. The routine use of anti-CMV therapy and TMP-SMX prophylaxis has altered the pattern of post-transplant infections. TMP-SMX eliminates *Pneumocystis jiroveci* (formerly *carinii*) pneumonia (PCP) and, given daily, reduces the incidence of urinary tract infection (UTI) and urosepsis, *Listeria monocytogenes* meningitis, some *Nocardia* spp. infections, and *Toxoplasma gondii* [12]. Notably, agents that may be substituted for TMP-SMX in the sulfa-allergic patient do not provide this benefit of prophylactic effects against these other

organisms. Effective anti-CMV prophylaxis should prevent most CMV infections (and those due to most herpesviruses) for the duration of therapy (discussed below). Thus, the differential diagnosis of infectious syndromes in this period includes:

- Graft rejection, particularly in calcineurin inhibitor (CNI)-sparing immunosuppressive regimens.
- Lingering infection from the perisurgical period, including relapsed *Clostridium difficile* colitis, inadequately treated pneumonia, or infection related to technical problems, e.g. pleural effusion, urine leak, cholangitis due to biliary ischemia, lymphocele, infected hematoma, airway necrosis, and dehiscence in lung transplant recipients.
- Nosocomial infections remaining from hospitalization.
- Viral infections including CMV, herpes simplex virus (HSV), shingles (localized or disseminated zoster due to VZV), human herpesvirus (HHV) 6 or 7, BK polyomavirus, EBV, relapsed hepatitis (HBV and HCV), and the community-acquired respiratory viruses [adenovirus, influenza, parainfluenza, respiratory syncytial virus (RSV), and metapneumovirus]. In transplant recipients, viral infection is generally more persistent and more often invasive than in normal hosts.
- Opportunistic infection due to *P. jiroveci*, *L. monocytogenes*, *T. gondii*, *Nocardia* spp., *Aspergillus* spp., and other agents. The specific opportunistic infections that occur reflect the specific immunosuppressive regimen used and the presence or absence of immunomodulating viral infection.

The herpesviruses are common and produce life-long infection for which the marker is seropositivity. The herpesviruses are prominent in transplantation due to the role of T-cell immune function in the control of these infections and the efficiency of transmission with allografts from seropositive donors. The herpesviruses tend, like other chronic viral infections, to produce systemic immunosuppression and yet, via cytokine production and other mechanisms, may predispose to graft rejection [13,14].

Table 94.4. Prophylaxis for *Pneumocystis jiroveci* pneumonia (PCP)

Background
Low dose trimethoprim-sulfamethoxazole (TMP-SMX) prophylaxis (in adults: one single-strength tablet/day orally) is well tolerated and essentially eradicates *Pneumocystis* infection from this patient population. Lower doses (3 days/week) prevent PCP but may not prevent other infections such as urinary tract infection, including those due to susceptible *Nocardia* and *Listeria*, toxoplasmosis, and a variety of gastrointestinal and pulmonary infections

Regimen
One single-strength TMP-SMX tablet (containing 80 mg of trimethoprim, 400 mg of sulfamethoxazole) p.o. q.h.s. for a minimum of 4–6 months post transplant. Patients infected with cytomegalovirus, with chronic rejection, recurrent infections, and most lung, liver, and heart recipients may be maintained on life-long prophylaxis

Alternative regimen
For patients proven not to tolerate TMP-SMX, alternative regimens include:

- A combination of atovaquone 1500 mg p.o. with meals once daily plus levofloxacin (or equivalent fluoroquinolone without antianaerobic spectrum) 250 mg once daily
- Pentamidine (300 mg IV or inhaled q 3–4 weeks)
- Dapsone (100 mg p.o. q.d to b.i.w.) ± pyrimethamine

Each of these agents has toxicities that must be considered, including hemolysis in glucose-6-phosphate-deficient hosts with dapsone. None of these alternative programs offers the same broad protection as TMP-SMX.

Table 94.5. Prophylaxis for herpes group viruses*

Background
The human herpes viruses are among the most important causes of infectious disease morbidity and mortality in the transplant recipient. Preventative regimens are determined by the clinical risk, the major determinants of which are the past experience of donor and recipient with the virus (as defined by the presence or absence of circulating antibody prior to transplant) and the nature of the immunosuppressive therapy.

CMV Universal Antiviral Prophylaxis

Cytomegalovirus (CMV) serologic status ± antilymphocyte globulin induction therapy (ALG)	Prophylaxis	Monitoring (antigenemia)
D+/R– no ALG	Intravenous ganciclovir 5 mg/kg IV (loading dose) then p.o. valganciclovir (900 mg/day corrected for renal function) or p.o. ganciclovir (3 g/day)† × 3 months	Monthly for 6 months after discontinuation of therapy*
D+ or R+ with ALG	Intravenous ganciclovir 5 mg/kg IV for first dose then either per renal function to discharge or switch to p.o. valganciclovir (900 mg/day corrected for renal function) or po ganciclovir (3 g/day)† × 6 months	Monthly for 6 months after discontinuation of therapy*
D–/R+ no ALG	Oral valganciclovir (900 mg/day corrected for renal function) × 3 months	Symptoms only
D–/R–	Oral famciclovir 500 mg p.o. q.d. × 3–4 months (or valacyclovir 500 mg b.i.d. or acyclovir 400 mg t.i.d) Use of CMV-negative or leukocyte-filtered blood	Symptoms, fever/neutropenia
Status unknown with ALG	Intravenous ganciclovir 5 mg/kg IV for first dose and q.d. (corrected for renal function) until sero-status determined	As above

Neutropenia: The dose of antiviral therapies are *not*, in general, reduced for neutropenia.
*ALG: antilymphocyte antibodies include any lytic, lymphocyte-depleting antibody preparations.
†Valacyclovir (8 g/day) has been used as an alternative agent in renal transplant recipients.

Pre-emptive therapy
Pre-emptive therapy requires a carefully organized monitoring program and patient compliance. Either a molecular CMV viral load test or a pp65 antigenemia assay may be used for monitoring. Monitoring should be performed once weekly after transplantation for 12–24 weeks. Infections indicated by positive assays are treated with either oral valganciclovir (900 mgb.i.d.) or intravenous ganciclovir (5 mg/kg b.i.d.). Full doses are used for loading after which dosing is corrected for renal function. Therapy is continued until viremia is undetectable.

Mixed prophylaxis
Many centers prefer universal prophylaxis for highest risk recipients (D+/R– or R+ with lymphocyte depletion) and pre-emptive therapy for other groups.

Background
The human herpes viruses are among the most important causes of infectious disease morbidity and mortality in the transplant recipient. Preventative regimens are determined by the clinical risk, the major determinants of which are the past experience of donor and recipient with the virus (as defined by the presence or absence of circulating antibody prior to transplant) and the nature of the immunosuppressive therapy.
CMV Universal Antiviral Prophylaxis

In this period, the stage is also set for the emergence of a subgroup of patients—the "chronic ne'er do wells," individuals who require higher than average immunosuppression to maintain graft function or who have prolonged, untreated viral infections and other opportunistic infections, which predicts long-term susceptibility to many other infections (discussed in the Third phase below) [2]. Such individuals may merit prolonged (life-long) prophylaxis (antibacterial and/or antiviral) and careful clinical and laboratory monitoring to prevent life-threatening infection.

Third phase post transplantation (>6–12 months)

Transplant recipients who are >6 months past the procedure can be divided into three groups in terms of infection risk. First, the majority of transplant recipients who have had a technically good procedure with satisfactory allograft function will have reduced maintenance immunosuppression and lower risk for reactivation of latent infections. These patients have community-acquired respiratory viruses as their major risk, which may mask or predispose them to more serious opportunistic infections. Occasionally, such patients will develop primary CMV infection (socially acquired) or infections related to underlying diseases, e.g. skin infections in diabetics.

Second, some recipients will develop relapsing viral infections with their outcome dependent upon the availability of effective antimicrobial therapy. The major challenges in this group include CMV, EBV, notably with antiviral resistance, persistent BK polyomavirus infection, HCV in liver recipients, and papillomavirus (skin warts). In the era in which there were few therapeutic options, the challenges in this group also included HBV and HIV. Emerging agents for HCV may alter the outcome of this infection also. These infections are associated with:

- end-organ damage, e.g. BK polyomavirus nephropathy, cryoglobulinemia, or cirrhosis from HCV;
- malignancy, e.g. post-transplantation lymphoproliferative disease (PTLD) due to EBV, and skin or anogenital cancer due to papillomaviruses;
- graft rejection may be provoked by these infections and also by attempts to reduce the intensity of immunosuppression to combat these infections.

The third group of patients has less than satisfactory allograft function due to poor technical outcomes, a poor quality allograft, or chronic graft rejection (cellular or humoral). Many of these patients also will suffer renal dysfunction due to the effects of chronic CNI toxicity. They also may suffer chronic viral infection, as described above. Thus, these recipients are over-immunosuppressed relative to the threshold for viral activation and also suffer inadequate graft function. These individuals are often identifiable early in the post-transplant course due to delayed or poor initial graft function, complications (bleeding, leaks, drug interactions, intensive care requirements), or recurrent disease. This subgroup of transplant recipients is often termed the "chronic ne'er do wells," who are at highest risk for opportunistic infection with pathogens such as *P. jiroveci*, *L. monocytogenes*, *Nocardia asteroides*, *Aspergillus* spp., and *Cryptococcus neoformans* [2]. Organisms more often associated with the chronic immune dysfunction of acquired immune deficiency syndrome (AIDS) (*Bartonella, Rhodococcus, Cryptosporidium,* and *Microsporidium* spp.) and invasive fungal pathogens (*Scedosporium*, *Zygomycetes*, the *Dematiaceae*, or pigmented molds) should also be considered in this group. Minimal clinical signs or symptoms merit careful evaluation in this group of "high-risk" individuals. This group may benefit from life-long TMP-SMX prophylaxis and, in the appropriate situation, life-long antifungal prophylaxis.

Selected infections and syndromes of importance to transplantation

General approaches

The spectrum of infection in the immunocompromised host is quite broad. Given the potential toxicity of antimicrobial agents and the need for rapid interruption of infection, *early and specific diagnosis* is essential in this population. Advances in diagnostic modalities, including advanced imaging and molecular microbiologic techniques, greatly assist in this process. However, the need for invasive diagnostic approaches cannot be over emphasized. While these tools carry some risk, the failure to achieve a specific diagnosis often necessitates broad, empiric therapy without clear endpoints for therapy. Initial, often empiric, therapy will target a broad range of potential pathogens with rapid narrowing of the antimicrobial spectrum as data become available.

A central consideration for the patient with an "infectious syndrome" is whether to reduce the intensity of immunosuppression as a part of therapy, risking graft rejection or an immune reconstitution syndrome (IRIS) [15]. Conversely, treatment of infection as if graft rejection were present may exacerbate infection. Given that infection and rejection are linked, such distinctions may be difficult. For example, recurrent HCV infection may increase the risk for liver graft rejection. Pneumonia, including aspiration, community-acquired respiratory viruses, CMV, and bacterial infections, will increase the rate of obliterative bronchiolitis in lung recipients [16–18]. CMV also contributes to cardiac and renal allograft rejection [19,20]. In practice, it is often possible to decrease the intensity of immunosuppression in the face of significant infection; however, as the patient improves, rejection may occur. The selection of the specific reduction in immunosuppression may depend upon the organisms isolated. Similarly, reversal of some immune deficits (neutropenia, hypogammaglobulinemia) may be possible with adjunctive therapies (colony stimulating factors or antibody) [21]. Co-infection with virus (CMV) is also an important consideration and merits additional therapy.

Cytomegalovirus

CMV remains an important pathogen in transplant recipients despite the availability of effective antiviral therapies [22,23]. CMV infection has multiple manifestations depending on the site of infection and the nature of the host response. The reservoir for latent infection appears to include cells of the monocyte lineage, but viral replication may occur in multiple differentiated cell types, including fibroblasts, epithelial and endothelial cells, and other parenchymal cells.

The manifestations of CMV infection have been traditionally termed "direct" and "indirect" effects [13]. More accurate terms might be "viremic/cytopathic" effects and "cellular/immunologic" effects. The common direct effects or clinical syndromes include:

- "CMV syndrome": fever and neutropenia syndrome with variable features of infectious mononucleosis, including hepatitis, nephritis, lymphadenitis, leukopenia, and/or thrombocytopenia;
- pneumonitis;
- gastrointestinal invasion with esophagitis, colitis, gastritis, ulcers, bleeding, or perforation;
- hepatitis, pancreatitis, myocarditis, or chorioretinitis;
- meningoencephalitis;

- hemolytic-uremic syndrome or microangiopathic thrombosis.

With the exception of chorioretinitis, the direct clinical manifestations of CMV infection usually occur 1 –6 months after transplantation in the absence of prophylaxis. Viremia and symptomatic infections are rare during effective antiviral prophylaxis [24] and so may be delayed until after cessation of prophylaxis and/or following intensification of immunosuppression, e.g. for rejection [25]. Chorioretinitis may occur at low levels of viral replication and generally occurs later in the transplant course. This is relatively uncommon in transplant recipients, in contrast to individuals with AIDS in whom retinitis is a major complication of CMV infection [26].

The clinical manifestations of the cellular and immunologic effects of CMV infection (discussed below) are the result of suppression of a variety of host defense mechanisms, predisposing to secondary invasion by such pathogens as *P. jiroveci*, *Candida*, and *Aspergillus* spp., and some bacterial infections. CMV infection also contributes to the risk for graft rejection, PTLD, HHV6 and HHV7 infection, and increased risk for death.

Patterns of transmission

Transmission of CMV in the transplant recipient occurs in one of three patterns: primary infection, reactivation infection, and superinfection.

Primary infection

The greatest risk for infection is in the setting of primary CMV infection, which occurs when seronegative individuals receive grafts from latently infected, seropositive donors [donor seropositive, recipient seronegative (D+R–)], with subsequent reactivation of the virus and systemic dissemination after transplantation [17,27]. Over 50% of these patients become viremic in the absence of prophylaxis, often without symptoms. Similarly, over 50% will become viremic after the cessation of antiviral prophylaxis, frequently (25–35%) with symptomatic disease. Primary CMV infection may also occur in seronegative individuals after transfusion or sexual contacts in the community. This disease may be severe. The greatest viral burden is thought to be in the allograft, notably as the source of infection in the D+/R–combination. The allograft is regarded as a privileged site for viral replication because the MHC-restricted, virus-specific, cytotoxic T cells have a decreased ability to eliminate virally infected cells in the presence of MHC mismatch between donor and recipient.

Reactivation infection

In reactivation infection, seropositive individuals reactivate endogenous virus after transplantation [donor seropositive or seronegative (D+ or D–), recipient seropositive (R+)]. When conventional immunosuppressive therapy is used without antilymphocyte antibody "induction" treatment, approximately 10–15% experience direct infectious disease syndromes with a higher rate with the use of induction antilymphocyte therapy or antilymphocyte therapy for the treatment of graft rejection. Up to 50% of these individuals are viremic, often without symptoms.

Superinfection

Virus derived from the donor may be reactivated in the setting of an allograft from a seropositive donor transplanted into a seropositive recipient (D+R+). Blood transfusions, even if leukocyte reduced, have a low rate (~4%) of transmission of CMV infection. Some centers use seronegative blood for seronegative recipients, while others use leukocyte-filtered blood. This observation gains importance in patients requiring significant transfusion in the perioperative setting.

Pathogenesis of infection

CMV activation occurs as the result of multiple factors, including the intensity of immunosuppression, notably pulsed-dose corticosteroids; the amount of virus in the graft; the use of lytic, T-cell depleting therapies; co-infections, notably with HHV6 and HHV7 with inflammation and fever (via proinflammatory cytokines including tumor necrosis factor (TNF)-α); and graft rejection (possibly via inflammation as well as injury to infected endothelial cells). The risk for viral activation is in the setting of intensified immunosuppression for graft rejection treated with antilymphocyte antibodies. The alloimmune response, while systemic and associated with proinflammatory cytokines and chemokines, most often targets the graft ,which is often the site of greatest viral load. While CMV activation may increase the risk for rejection, rejection will also increase the risk for viral replication. Thus, in an interesting study, Reinke et al. showed that 17 of 21 patients for whom biopsy revealed evidence of "late acute rejection" demonstrated a response to antiviral therapy [28]. Further, Lowance et al. demonstrated that the prevention of CMV infection also resulted in a lower incidence of graft rejection [20].

Cellular and immunologic effects

Seroconversion is a marker for the development of host immunity and correlates well with the presence of a cellular immune response. Control of CMV infection is largely via MHC-restricted, virus-specific, cytotoxic T-lymphocyte response ($CD8^+$ cells) [29–32]. $CD4^+$ lymphocytes play an important role in the maintenance of the cellular immune response and may directly kill some human CMV (HCMV)-infected cells [33]. The precise role of $\gamma\delta$T-cells remains to be defined [34,35]. Neutralizing antibody responses appear to be important clinically [36]. HCMV glycoprotein B (gB) is involved in cellular attachment and penetration by CMV and is a major target of neutralizing antibodies and a major component of recent HCMV vaccines [37]. HCMV interacts with Toll-like receptors (TLR9 and TLR3) to activate inflammatory cytokine pathways and costimulatory pathways [38]. Macrophages, dendritic cells, and natural killer (NK) cells participate in the innate immune response to CMV.

The cellular and immunologic effects of CMV (indirect effects) may be as important to the immunocompromised host as is invasive viral infection [30,39]. The mechanisms for these effects are complex and relate to viral strategies to evade the host's antiviral responses to allow HCMV-infected antigen-presenting cells (APCs) to travel throughout the host to spread virus [39–41]. HCMV infection blocks the differentiation of APCs from monocyte precursors, impairs APC migration, and blunts antigen presentation. HCMV gene products, e.g. UL18, inhibit NK cell activation by MHC class I molecules and suppress activating signals for cytotoxicity [42,43]. HCMV interferes with the normal $CD8^+$ T-lymphocyte MHC class I processing and presentation pathways to prevent recognition. Multiple homologs of human gene products (transmembrane G-protein-coupled, chemokine receptors, TNF receptor, regulators of complement activation) inhibit the recruitment of inflammatory cells and the killing of infected cells. CMV-encoded antiapoptotic gene products delay apoptosis of infected cells [44]. An HCMV-encoded Fc-gamma receptor may obscure viral antigens and thus protect infected cells from antibody-mediated cellular cytotoxicity [45]. These features alter many aspects of the innate and adaptive

immune response, predisposing to opportunistic infection when coupled with exogenous immunosuppression used to prevent graft rejection [30].

The bidirectional linkage between CMV infection or disease and graft rejection and injury has been observed in multiple clinical trials, including in cardiac, lung, liver, and kidney transplant patients [19,20,39,46]. Both symptomatic disease and asymptomatic infection stimulate alloimmune responses, as demonstrated in clinical trials with intensive, universal prophylaxis for CMV infection. One of the clearest links is the effect of TNF-α [47] during fever or rejection; it activates intracellular NF-κB. NF-κB translocates to the cell nucleus and controls the expression of the CMV major immediate-early (IE) promoter/enhancer required for the expression of CMV *IE* genes encoding the transcriptional regulatory proteins necessary for viral replication [48]. TNF-α and other inflammatory cytokines appear to contribute to cellular graft rejection. CMV also contributes to graft fibrosis, possibly by increasing elaboration of profibrotic and vasculopathic growth factors, such as tumor growth factor (TGF)-β, platelet-derived growth factor (PDGF), connective tissue growth factor (CTGF), vascular endothelial growth factor, and adhesion molecules, including intercellular adhesion molecule (ICAM)-1 and vascular cell adhesion molecule (VCAM)-1 [49–57]. The profibrotic effect of CMV infection likely amplifies the effects of the immune and inflammatory injury that accompany alloimmune graft rejection [58,59]. Endothelial injury allowing adhesion of platelets to the basement membrane of blood vessels with release of PDGF is coupled with increased matrix metalloproteinase (MMP)-2 activity and reduced matrix gene expression, and results in increased smooth muscle cell migration, promoting vascular neointimal hyperplasia [60–62]. CMV-encoded inhibitors of cell death mediate reduction in CMV-infected smooth muscle cell apoptosis. Increased production of interleukin (IL)-8 increases systemic inflammation with activation of neutrophils, macrophages, and endothelial cells.

Diagnosis

Clinical management of CMV has evolved rapidly over the past 20 years with the advent of sensitive and quantitative assays for the diagnosis and management of CMV infections [63–65]. Serologic tests are useful prior to transplantation to predict risk, but are of little value after transplantation in defining clinical disease [this includes measurements of anti-CMV immunoglobulin M (IgM) levels]. Should a patient seroconvert to CMV, this is evidence that the patient has been exposed to CMV and has developed some degree of immunity [66]. However, seroconversion in transplantation is generally delayed and thus, not useful for clinical diagnosis. In the past, CMV cell cultures, often coupled with immunofluorescent detection, were useful but relatively too slow and insensitive for clinical utility [64]. Further, positive CMV cultures (or shell vial cultures) derived from respiratory secretions or urine of immunocompromised hosts is of little diagnostic value; many patients secrete CMV in the absence of invasive disease. The demonstration of CMV inclusions or a positive immunostain on tissue histology in the setting of a compatible clinical presentation is the "gold standard" for diagnosis of tissue-invasive CMV disease [23,67]. Biopsy-proven immunohistologic diagnosis remains essential in the setting of possible gastrointestinal disease. In transplant recipients with ulcerative colonic, gastric lesions, diffuse erythema, or bleeding, CMV must be considered. These individuals will often have low or undetectable viremia [23,68] and intracellular inclusions are uncommonly seen histologically.

The intensity of CMV infection has been linked to the risk for infection in transplant recipients. Thus, the gold standard for the management of CMV infections in transplantation has become a quantitative assay. Two types of quantitative assays have been developed: the molecular assays for viral DNA or RNA and antigen detection assays. Either assay can be used in management. The antigenemia assay is a labor-intensive, semi-quantitative fluorescent or immunoperoxidase-based assay in which circulating neutrophils are stained for CMV early antigen (pp65), which is taken up non-specifically as a measure of the total viral burden in the body [64,69,70]. The molecular assays [direct quantitative DNA polymerase chain reaction (PCR), hybrid capture, amplification assays] are highly specific and sensitive for the detection of viremia [63,64]. Most commonly used assays include plasma-based PCR testing and the whole blood hybrid capture assay, noting that whole blood and plasma-based assays cannot be directly compared as whole blood assays often yield higher viral loads [64,65,71,72]. World Health Organization (WHO) standards exist for the standardization of laboratory CMV testing [65]. Viral loads in the CMV syndrome are variable. The highest viral loads are often associated with tissue-invasive disease, with the lowest in asymptomatic CMV infection or in gastrointestinal or central nervous system (CNS) disease [23,73,74]. In these syndromes, the CMV assays are often *negative* and invasive (biopsy) diagnosis may be needed.

Assays play a central role in the prevention and treatment of CMV (Table 94.5). The schedule for screening is linked to the risk for infection. Thus, in the high-risk patient (D+/R– or R+ with antithymocyte globulins) after the completion of prophylaxis, biweekly or monthly screening may be performed to assure the absence of infection for an additional 3–6 months [23,75]. This combined prophylactic and pre-emptive strategy is common, but practices vary widely between centers and patient populations. There are few comparative data to guide practice, although consensus guidelines have been published [23,75]. In the patient being treated for CMV infection, the assays provide an endpoint (zero positivity) for therapy and the initiation of prophylaxis.

Prevention

Prevention of CMV infection must be individualized for immunosuppressive regimens and the patient. Two strategies are commonly used: (1) universal prophylaxis and (2) pre-emptive therapy [23,76]. Universal prophylaxis involves giving antiviral therapy to all "at-risk" patients beginning at or immediately post transplant for a defined time period. In pre-emptive therapy, quantitative assays are used to monitor patients at predefined intervals to detect early disease. Positive assays result in therapy. Pre-emptive therapy incurs extra costs for monitoring and coordination of outpatient care while reducing the cost of drugs and the inherent toxicities of drug exposure [77]. Prophylaxis has the possible advantage of preventing not only CMV infection during the period of greatest risk, but also diminishing infections due to HSV, VZV, HHV6, HHV7, and EBV [27]. Further, the indirect effects of CMV, i.e. graft rejection, opportunistic infections, and mortality, are also reduced by routine, universal prophylaxis [27]. In practice neither strategy is perfect. Both breakthrough disease and ganciclovir resistance have been observed in both approaches [78–80]. Increasingly, "late" disease has been observed after the completion of prophylaxis [81,82]. The rate of late disease varies, but is thought to be as high as 17–37% in D+/R– recipients. The IMPACT study has confirmed the prolongation of prophylaxis to 200 days (vs. 100 days) in D+/R– renal recipients [11].

Given the risk for invasive infection, heart, liver, pancreas, and kidney transplant patients at risk for primary infection (CMV D+/R–) are generally given prophylaxis for 3–6 months after transplantation (Table 94.5) [23,75]. Many centers utilize 6 months of prophylaxis in CMV D+/R– or R+ patients receiving antilymphocyte antibodies [11]. Lung transplant recipients appear to benefit from prolonged (12 months) prophylaxis, as shown in a recent randomized trial of 3 versus 12 months of valganciclovir after lung transplantation [10]. Other groups are candidates for pre-emptive therapy *if* an appropriate monitoring system is in place and patient compliance is adequate [23,75]. The routine addition of CMV hyperimmune globulins on a monthly basis for 3–6 months has been used in some cardiac and lung transplantation programs [23,75,83,84].

Treatment

The standard of care for treating CMV disease is generally 3 weeks of therapy with intravenous ganciclovir (5 mg/kg twice daily, with dosage adjustments for renal dysfunction) or valganciclovir (900 mg p.o. twice daily corrected for renal function) [23,75]. In a recent clinical trial, oral valganciclovir was shown to be non-inferior to intravenous ganciclovir for the treatment of patients with mild-to-moderately severe CMV disease with modest viral loads [85]. This trial may have excluded patients with high viral loads and invasive gastrointestinal disease. Clearance of viremia within 21 days in both arms was approximately 50% [85]. In patients slow to respond clinically or virologically to therapy and who are seronegative, the addition of 3 months of CMV hyperimmune globulin in seronegative individuals (150 mg/kg/dose IV monthly) is used in some centers. Hypogammaglobulinemia merits correction during therapy [86]. Relapse does occur, primarily in those not treated beyond the achievement of a negative quantitative assay [85] and in some of those with gastrointestinal disease treated with an oral regimen. In practice, it is reasonable to initiate therapy with intravenous ganciclovir, monitor weekly to assure a response, and treat until monitoring is negative. Such patients may benefit from 2– 4 months of oral valganciclovir (900 mg daily based on creatinine clearance) administered as secondary prophylaxis after the completion of intravenous therapy [87,88]. This approach has resulted in rare symptomatic relapses and has been associated uncommonly with the emergence of antiviral resistance. It may be worth measuring the creatinine clearance to assure adequate dosing.

Ganciclovir resistance in CMV is generally uncommon with some higher rates reported in lung transplant recipients [78]. The risk for resistance is greatest in D+/R– recipients with higher viral loads, inadequate dosing of prophylactic or therapeutic ganciclovir, more intensive immunosuppression including antilymphocyte antibody induction, and prolonged antiviral prophylaxis [78,79]. Clinically, the patient's viral load or clinical syndrome fails to respond to appropriate therapy. Genetic resistance testing is useful in managing resistant CMV infection; mutations in the viral *UL97* (thymidine kinase) or *UL54* (DNA polymerase) genes can confer ganciclovir resistance [89]. Some of the common mutations in the *UL97* gene respond to higher doses of intravenous ganciclovir [90]. Combined mutations (*UL97* and *UL54*) may manifest high-level resistance to ganciclovir. Alternative therapies are available in intravenous form only. These include foscarnet and cidofovir [78]. Foscarnet is active against many ganciclovir-resistant strains of CMV, although it is associated with marked magnesium and potassium wasting, seizures (notably with CNI therapy), and some renal toxicity. Cidofovir often incurs significant nephrotoxicity and ocular toxicity. Combination therapy (ganciclovir and foscarnet) may be useful as is the addition of hyperimmune globulins [91]. Most centers try to reduce overall immunosuppression during the course of therapy. *UL54* mutations may cause resistance to foscarnet and to cidofovir depending on the nature of the mutation [89]. Multiple courses of antiviral therapy may be needed to cure resistant CMV infection. Given the toxicity of available medications, several investigational drugs are under study that may alter recommended therapies for antiviral-resistant CMV in the future [92–94].

Post-transplant lymphoproliferative disorder and Epstein–Barr virus

PTLD is a spectrum of syndromes characterized by lymphocyte proliferation from benign, polyclonal conditions to malignant, monoclonal lymphomas [95–98]. The majority of PTLD is associated with infection by EBV with B lymphocytes as the primary target. In immunosuppressed transplant recipients, primary EBV infection (and relapses in the absence of antiviral immunity) causes a mononucleosis-type syndrome, generally presenting as a B-cell lymphocytosis with or without lymphadenopathy or pharyngitis. Meningitis, hepatitis, and pancreatitis may also be observed. Remitting–relapsing EBV infection is common in children and may reflect the interplay between evolving antiviral immunity and immunosuppression. This syndrome should suggest relative over-immunosuppression. The most clearly defined risk factor for PTLD is primary EBV infection that increases the risk for PTLD by 10–76 fold [95]. PTLD may occur, however, in the absence of EBV infection or in seropositive patients.

Post-transplant non-Hodgkin's lymphoma (NHL) is a common complication of SOT. Lymphomas comprise up to 15% of tumors among adult transplant recipients (51% in children) with mortality of 40–60%. Compared with the general population, PTLD has increased extranodal involvement, poor response to conventional therapies, and poor outcomes. The spectrum of disease ranges from benign, polyclonal B-cell infectious mononucleosis-like disease to malignant, monoclonal lymphoma. The majority is of B-cell origin. T-cell, NK-cell and null-cell tumors occur in up to 37% of some adult series and are more often monomorphic and carry a worse prognosis. Other negative prognostic indicators include CNS disease, disease in multiple body sites, EBV-negative PTLD, disease of recipient origin, and the presence of mutations in proto-oncogenes or tumor suppressor genes [95,99–101].

The diagnosis of PTLD is complicated by the presence of EBV-negative PTLD or the presence of T-cell PTLD within allografts, which is easily confused with graft rejection or other viral infections. EBV-negative PTLD is more common late (>1–2 years) after transplantation in adults [95].

In addition to primary EBV infection, risk factors for PTLD include CMV donor–recipient serostatus mismatch, T-cell depletion therapies, younger age in children and older age in adults, and the overall intensity of immunosuppression [95]. PTLD can present at any time post transplantation, with primary infection common in the first 12 weeks post transplantation. Some risk is associated with the specific organ transplanted, although this may reflect the burden of virus, the presence of co-infections, and the intensity of immunosuppression. Thus, intestinal transplants in children carry a 32% incidence of PTLD, while the incidence in heart, lung, liver, and pancreas transplants is lower (3–12%) and in kidney transplants is even lower (1–2%) [95].

The clinical presentations of EBV-associated PTLD vary:

- Unexplained fever (fever of unknown origin).
- A mononucleosis-type syndrome, with fever and malaise, with or without pharyngitis or tonsillitis (often diagnosed incidentally in tonsillectomy specimens). Often no lymphadenopathy is observed.
- Gastrointestinal bleeding, obstruction, and perforation.
- abdominal mass lesions (most often with abdominal transplantation).
- Infiltrative disease of the allograft.
- Hepatocellular or pancreatic dysfunction.
- Isolated CNS disease or meningitis.
- Pulmonary infiltrative lesion.

Diagnosis

Serologic testing is not useful for the diagnosis of acute EBV infection or PTLD in transplantation. However, seronegative recipients of seropositive organs (EBV D+/R–) should be monitored for EBV infection and symptoms consistent with such infection. Any episodes of "rejection" should have biopsy tissues evaluated for evidence of PTLD. Quantitative EBV viral load testing is extremely useful in the diagnosis and management of EBV-positive PTLD [102–104]. These assays have high sensitivity but lower specificity. Some centers prefer assays using unfractionated whole blood rather than plasma samples for EBV viral load surveillance [105]. Serial assays are more useful in an individual patient than specified viral load measurements [102]. These assays are not standardized and cannot be directly compared between centers [105]. WHO standards for laboratory testing can be used for proficiency testing. In general, tissue diagnosis is essential for the diagnosis and management of PTLD. Tissues should be assessed by expert pathologists given the potential for confusion of infiltrative lesions with other processes [100]. Tissue or circulating lymphocytes should be tested using RNA in-situ hybridization for EBV-encoded small nuclear RNA (EBER) as a more sensitive assay than hybridization targeting viral DNA [106]. This is generally supplemented with immunohistochemistry for EBV latent antigens EBNA-1, EBNA-2, and LMP-1 [107,108]. These can be supplemented with studies of lymphocyte antibody clonality, oncogenes, tumor suppressor genes or chromosomes, therapeutic target markers (expression of CD20, cytotoxic T-cell epitopes), and donor or recipient origin.

Management

Clinical management depends on the stage of disease. In the polyclonal form, particularly in children, re-establishment of immune function through reduction of immunosuppression may suffice to cause PTLD to regress [95]. At this stage, it is possible that antiviral therapy might have some utility given the viremia and role of EBV as an immunosuppressive agent [103,109]. Given the role of CMV as a co-factor to PTLD, it is reasonable to use ganciclovir or valganciclovir as a prophylactic agent in EBV viremic individuals. Definitive data are limited regarding the efficacy of such therapy. With the progression of disease to extranodal and monoclonal malignant forms, reduction in immunosuppression may be useful, but alternate therapies are often required. Combinations of anti-B-cell therapy (anti-CD20, rituximab), chemotherapy (CHOP), and/or adoptive immunotherapy with stimulated T cells have been utilized [95,110,111]. The duration of response is often disappointing. In transplantation, the failure to regress with significant reductions in immunosuppression may suggest the need to sacrifice the allograft for patient survival. Rejection is uncommon in the face of active viremia, but some deaths have been associated with allograft failure after withdrawal of immunosuppression during treatment of malignancy [96]. CNS PTLD generally requires irradiation for resolution [111]. Biopsies are required to establish the diagnosis in the absence of extraneural disease.

Polyomaviruses

Polyomaviruses have been identified in transplant recipients in association with nephropathy and ureteral obstruction (BK virus) and in association with demyelinating disease of the brain (JC virus) similar to that in AIDS [112]. Adult seroprevalence is 65–90%. BK virus appears to achieve latency in renal tubular epithelial cells. JC virus has also been isolated from renal tissues but appears to have preferred tropism for neural tissues. Reactivation occurs with immunodeficiency and suppression and tissue injury, e.g. ischemia–reperfusion.

BK polyomavirus infection

BK virus (BKV) is associated with a range of clinical syndromes in immunocompromised hosts: viruria and viremia, ureteral ulceration and stenosis, and hemorrhagic cystitis [112,113]. Active infection of renal allografts has also been associated with progressive loss of graft function in some individuals and is termed "BK nephropathy" or polyomavirus-associated nephropathy (PyVAN or PVAN). Despite viral replication and viruria, PVAN is rarely recognized in recipients of non-renal organs, suggesting renal injury, e.g. ischemia–reperfusion, or other processes specific to renal transplantation are needed to cause nephropathy. Uncommonly, BKV may also cause pneumonitis, hemophagocytic syndrome, encephalitis, or polyomavirus-associated multifocal leukoencephalopathy (PVML, most often associated with JC virus) [114,115].

The clinical presentation of disease usually includes detection of cells in the urine in the absence of bacterial or fungal infection, reflecting shedding of infected tubular and ureteric epithelial cells. These cells contain sheets of virus and are detected by urine cytology as "decoy cells" [116,117]. In most cases, in the absence of screening, such cells are not detected and the patient presents with diminished renal allograft function or, less commonly, with ureteric stenosis and obstruction. In such patients, the etiologies of decreased renal function must be carefully evaluated, e.g. mechanical obstruction, drug toxicity, pyelonephritis, rejection, thrombosis, and recurrent disease, and choices must be made between *increasing* immunosuppression to treat suspected graft rejection or *reducing* immunosuppression to allow the immune system to control infection. Patients with BK nephropathy treated with increased immunosuppression have a high incidence of graft loss [112,118]. Reduced immunosuppression may stabilize renal allograft function [119] but risks graft rejection. Polyoma-associated nephropathy manifested by characteristic histologic features and renal dysfunction is found in about 1–8% of transplant patients [112].

Approximately 30–50% of renal recipients with high-level viruria can be expected to progress to PVAN. Risk factors may include ischemia–reperfusion injury, lack of BKV-specific immunity, overall intensity of immunosuppression including use of tacrolimus-based regimens, HLA mismatches, acute rejection including pulsed-dose steroids, and T-cell depletion for treatment of rejection [112]. The role of specific immunosuppressive agents has not been confirmed [120].

Screening, prevention, and diagnosis

BKV infection is often asymptomatic. Tubular epithelial cell damage and inflammation are reflected in a slowly rising serum creatinine and this is the first clinical sign of PVAN. Most centers have developed screening programs to document early disease [118,120,121]. The use of urine cytology to detect the presence of infected decoy cells in the urine has approximately 100% sensitivity for BKV infection but a low (29%) predictive value. Decoy cells are useful in screening but cannot establish a firm diagnosis [117]. Urine BKV can be detected by electron microscopy; urine BKV (DNA) loads of >7 log gEq/mL or BKV VP1 mRNA of >6 log copies/ng total urine RNA are useful diagnostically. Hirsch et al. showed that patients with BK nephropathy have a statistically significantly higher plasma viral load (>7700 BKV copies/mL of plasma; $P < 0.001$; 50% positive predictive value, 100% negative predictive value) when compared to patients without such disease [122]. A high serum viral load coupled with an elevated serum creatinine is generally considered a basis for reduction in immunosuppression, but diagnosis should be made by demonstration of BKV cytopathic changes in the renal allograft and by immunohistology for BKV proteins, or by in-situ hybridization for BKV nucleic acids in a renal biopsy [112]. PVAN is characterized by intranuclear polyomavirus inclusion bodies in tubular epithelial and/or glomerular cells. Renal biopsies will generally demonstrate cytopathic changes in renal epithelial cells, with the gradual evolution of cellular infiltration consistent with the diagnosis of interstitial nephritis. Fibrosis is often prominent, occasionally with calcification. For immunohistochemistry, cross-reacting antibodies against the large T antigen of the Simian virus 40 or antibodies against BKV VP1 or agnoprotein have been used [117]. PVAN is often focal and results in false-negative biopsies, in some cases necessitating rebiopsy in suspected cases. Graft rejection may accompany PVAN, and complicates both diagnosis and management. There is a semi-quantitative scoring system for the histologic changes of PVAN [117].

Recommendations regarding screening for BKV infection vary, but generally suggest testing once every 3 months during the first 2 years after transplantation, and at least annually for years 2–5 [112,118]. A urinary test for BKV (cytology for decoy cells or urine BKV loads of >7 log gEq/mL) is adequate for screening; if negative the risk for PVAN is quite low. Patients with high urinary BKV loads should be tested for plasma BKV DNA load [118]. Some centers screen using plasma BKV DNA loads. For patients with plasma BKV viral DNA loads of >4 log10 gEq/mL on duplicate testing 2–3 weeks apart, a presumptive diagnosis of PVAN should be made and immunosuppression reduced (see below). If screening is performed by plasma viral load, the interval between screening assays should be reduced to monthly for the first 6 months post transplant. This reflects reduced time before permanent renal injury in patients with viremia compared with urinary excretion. For patients with a rise in serum creatinine and positive BKV screening, a renal biopsy should be obtained [112].

Treatment

There is no accepted treatment for PVAN other than reduction in the intensity of immunosuppression [112,119,123]. It is possible to monitor the response to such maneuvers using plasma viral load measurements. Despite controversy, it is reasonable to reduce dosing of both CNIs and antimetabolites in a step-wise fashion while monitoring BKV plasma loads. Given the toxicity of CNIs for tubular cells, the role of injury in the activation of BKV, as well as the need for anti-BK T-cell activity, these agents should be included in initial reductions. General targets include tacrolimus trough levels of <6 ng/mL, cyclosporine trough levels of <150 ng/mL, sirolimus trough levels of <6 ng/mL, and/or MMF daily dose equivalents of ≤1000 mg. Regardless of the approach, renal function (at least one to two times per week), drug levels, and viral loads (alternate weeks), must be monitored carefully during reductions [112]. Rebiopsy may be needed for poor responses.

The use of adjunctive antiviral therapies remains controversial. Some centers advocate the use of cidofovir [124] in low doses (0.25–1 mg/kg every 2 weeks) for BK nephropathy. Of note, significant renal toxicity may be observed with this agent, especially when used in combination with the CNIs. Some data exist to support the use of alternative therapies in carefully selected individuals. These include leflunomide, an immunosuppressive agent with some antiviral activity for BKV, intravenous immunoglobulin, and fluoroquinolone antimicrobials [125,126]. Prospective clinical trial data and Food and Drug Administration (FDA) approval are lacking for these agents for this indication. These agents are best used in consultation with experienced transplant infectious disease specialists.

Retransplantation has been successful in PVAN patients with failed allografts, possibly as a reflection of immunity developing subsequent to reduction in immunosuppression [127,128]. Most centers allow retransplantation after immunosuppression has been discontinued for some period (6 months) and BKV is undetectable in blood and low in urine. In the future, measurements of BKV-specific cellular immunity after discontinuation of immunosuppression may help to determine the optimal time for retransplantation [129]. Surgical removal of the allograft does not protect against future BKV infection or PVAN, but may be needed if immunosuppression cannot be reduced (double transplants, allosensitization) and/or elevated viral loads persist.

JC virus

Infection of the CNS by JC polyomavirus has been observed uncommonly in transplant recipient as progressive multifocal leukoencephalopathy (PML) [130]. This infection may present with focal neurologic deficits or seizures, as well as with more slowly progressive neurologic lesions, and may progress to death following extensive demyelination. PML may be confused with calcineurin neurotoxicity; both may respond to a reduction in drug levels. No proven therapies exist for PML, although a reduction of immunosuppression is commonly employed, based on the analogy to immune reconstitution in AIDS patients with PML.

Fungal infections

Transplant recipients are at risk for opportunistic infection with a variety of fungal agents, the most important of which are *Candida* spp., *Aspergillus* spp., *C. neoformans,* and the endemic mycoses or geographic fungi [131–134]. With prolonged survival and epidemiologic exposures, many additional species have been observed [135].

Candida species

The most common invasive fungal pathogen in transplant recipients is *Candida*, with *C. albicans, C. tropicalis*, and *C. glabrata* accounting for approximately 90% of these infections [134]. While the exact distribution of *Candida* infections and the incidence of fluconazole resistance varies by institution, most centers report an increased detection of non-*albicans Candida* species in transplant recipients. Mucocutaneous candidal infection, e.g. oral thrush,

esophageal infection, cutaneous infection at intertriginous sites, and candidal vaginitis, occurs particularly in the setting of poorly controlled diabetes with immunosuppression, as a result of poor oral hygiene, and with broad-spectrum antibacterial therapy. These infections are usually treatable through correction of the underlying metabolic abnormality and topical therapy with clotrimazole or nystatin. A special problem in renal transplant recipients is candiduria, which is often asymptomatic [136,137]. Particularly in individuals with poor bladder function, obstructing fungal balls can develop at the ureteropelvic junction, resulting in obstructive uropathy, ascending pyelonephritis, and the possibility of systemic dissemination.

Candidemia is most common as a nosocomial infection in the early post-transplant setting in association with surgery, vascular access catheters, surgical drains, bladder catheters, antimicrobial use, peripheral hyperalimentation, and diabetes [134,138]. However, in liver recipients with biliary and anastamotic issues, candidemia may be observed as the result of antibacterial therapy for persistent cholangitis. In such liver transplant recipients with a choledochojejunostomy, the risk for *Candida* infection is increased over duct-to-duct anastomoses. Bile leaks and hematomas may be superinfected with *Candida* species. Pancreas transplant recipients have a high rate of operative infection due to yeasts with fluconazole prophylaxis generally employed [139]. Longer term, enteric drainage is associated with a greater risk of invasive candidiasis than is bladder drainage. Other factors associated with candidemia include kidney and liver allograft dysfunction, intensive care unit (ICU) stays, large volume blood transfusions, re-exploration surgery after abdominal transplantation, graft pancreatitis, parenteral hyperalimentation, colonization, and broad-spectrum antimicrobial therapy [134] Infections are generally diagnosed based on blood cultures. Positive blood cultures merit therapy in all cases in addition to removal of foreign bodies, including vascular access catheters. Delay in therapy is associated with significant mortality. All *Candida* isolates from sterile sites should be tested for susceptibility to antimicrobial therapy to assure successful responses as fluconazole-resistant species such as *C. glabrata* and *C. krusei* are increasingly common [140]. A retinal examination should be obtained to exclude retinitis. It should be noted that pulmonary candidiasis is very rare, while colonization of the pharynx is common. The sole exception to this rule is the tracheal anastomosis of lung recipients where direct visualization is possible [141]. *Candida* spp. may also superinfect esophageal lesions due to HSV or CMV. Vascular anastomotic infections may lead to the development of mycotic aneurysms with risk for rupture. These events have, in some studies, been associated with contamination of graft preservation fluid with *Candida* spp. [142]; distinction of contamination of preservation fluid from surgical contamination at the time of procurement is often difficult.

Aspergillus species

Invasive aspergillosis is a medical emergency in the transplant recipient. The portal of entry is generally the lungs and sinuses. Metastatic spread to the CNS is common and may define the clinical presentation. Early in the course of transplantation, when most *Aspergillus* infections are observed, CNS involvement in fungal infection is most often due to *Aspergillus* spp.; >1 year after transplantation, other fungi (zygomycetes, dematiaceous fungi) are increasingly prominent [143,144]. The incidence of invasive aspergillosis varies from 1% to 15% depending on the organ transplanted [145]. General risk factors include colonization, CMV infection, neutropenia, graft rejection with therapy, ICU stays, renal dysfunction, and requirement for dialysis [133]. In addition organ-specific risk factors include re-exploration (liver and lung), HCV infection, retransplantation (liver), tracheal ischemia, and acquired hypogammaglobulinemia (lung) [146]. Special considerations include the role of *Aspergillus* in infection of tracheal anastomoses in lung transplantation [141] and in patients suffering neutropenia due to viral infections, drug toxicities, or following combined hematopoietic stem cell and solid organ transplantation.

Early diagnosis is essential to a successful outcome—often requiring biopsy. Detection of *Aspergillus* in airway samples carries a high risk for invasive infection in heart, lung, and liver recipients. The utility of the galactomannan test for the early diagnosis of invasive aspergillosis has not been as great as for neutropenic individuals [147]. The use of the galactomannan assay for the diagnosis of invasive aspergillosis in transplant recipients has been most useful in bronchoalveolar lavage samples [148]. Tissue or culture diagnosis of *Aspergillus* is essential given that other molds, with differing susceptibility patterns to antifungal agents, may also infect this population. Each of the effective antifungal agents has limitations. Liposomal amphotericin carries some risk of nephrotoxicity in association with CNI therapy; voriconazole and other azoles have significant interactions that increase serum levels of CNIs and sirolimus; the echinocandins are approved but static for molds, may carry some hepatotoxicity, and have no activity against the zygomycetes and *Cryptococcus* spp.

Central nervous system infection and *Cryptococcus neoformans*

CNS infection in the transplant recipient is a medical emergency. The spectrum of causative organisms is broad and the outcome of infection is often related to the rapidity of treatment. Many infections are metastatic to the CNS, often from the lungs. Thus, a "metastatic work-up" is a component of evaluation of CNS lesions, including those due to *Aspergillus, Cryptococcus*, and *Nocardia* spp, or *S. stercoralis*. Viral infections include CMV (nodular angiitis), herpes simplex meningoencephalitis, JC virus (PML), and VZV. Common bacterial infections include *L. monocytogenes*, mycobacteria, *Nocardia* spp., and occasionally *Salmonella* spp.. Brain abscess and epidural abscess may be observed with MRSA, penicillin-resistant *Streptococcus pneumoniae*, and quinolone-resistant streptococci, all of which are problematic therapeutically. Metastatic fungi include *Aspergillus* and *Cryptococcus*, but also spread from the sinuses (*Mucoraceae*), skin (*Dematiaceae*), and bloodstream (*Histoplasma* and *Pseudallescheria/Scedosporium, Fusarium* spp.). Parasites include *T. gondii* and *Strongyloides*.

Given the spectrum of etiologies, precise diagnosis is essential. In particular, empiric therapy must "cover" *Listeria* (ampicillin), *Cryptococcus* (fluconazole or amphotericin), and HSV (acyclovir or ganciclovir), as well as the more common forms of bacterial meningitis (pneumococcal, *Haemophilus influenzae*) and known colonizing pathogens of the lungs while awaiting data from lumbar puncture, blood cultures, and radiographic studies. Included in the differential diagnosis are non-infectious etiologies, including CNI toxicity, lymphoma, as well as metastatic cancer. Biopsy is often needed for a firm diagnosis.

Cryptococcus neoformans

Cryptococcal infection is common, but rarely seen in the transplant recipient until >6 months after transplantation and generally >16

months post transplantation [132]. In the relatively intact transplant recipient, the most common presentation of cryptococcal infection is that of an asymptomatic pulmonary nodule, often with active organisms present. In other patients, meningitis or pneumonia or skin involvement at sites of tissue injury (catheters), cellulitis, nodular or papular lesions may be observed. Cryptococcosis should be suspected in transplant recipients who present with unexplained headaches (especially when accompanied by fevers), decreased state of consciousness, failure to thrive, pneumonia, or unexplained focal skin disease (which requires biopsy for culture and pathologic evaluation) more than a year after transplantation [132]. Risk factors include exposures to bird and bat excreta, donor-derived infectious infections, and T-cell depletion. Liver recipients are at the greatest risk among transplant recipients.

Diagnosis is often achieved by serum cryptococcal antigen detection, but all such patients should have a lumbar puncture for cell counts, cultures, cerebrospinal fluid (CSF) pressure measurement, and cryptococcal antigen studies. Initial treatment response is best with lipid amphotericin and 5-flucytosine followed by high-dose fluconazole until the cryptococcal antigen is cleared from blood and CSF. Life-long suppression is recommended with fluconazole. IRIS or scarring may cause obstruction with increased CSF pressure and hydrocephalus [15].

Strongyloides stercoralis

S. stercoralis infection may activate >30 years after initial exposure with immunosuppressive therapy. Such reactivation can result in either a diarrheal illness and parasite migration with hyperinfestation syndrome (characterized by hemorrhagic enterocolitis, hemorrhagic pneumonia, or both) or disseminated infection with accompanying (usually) Gram-negative bacteremia or meningitis [149,150]. Patients from tropical areas and the south-eastern US should be screened with *Strongyloides* IgG serology prior to transplantation, and should be treated with ivermectin pre-emptively if seropositive [6].

Fever, pneumonitis, and *Pneumocystis* infection

The spectrum of potential pathogens of the lungs in transplantation is broad. Some general concepts are worth consideration. As for all infections in transplantation, invasive diagnostic techniques are often necessary for the diagnosis of pneumonia. The depressed inflammatory response of the immunocompromised transplant patient may greatly modify or delay the appearance of pulmonary lesions on radiography. As a result, computed tomography (CT) of the chest should be considered to define the anatomy of pulmonary lesions early in the course of evaluation or when the chest radiographic findings are negative or non-specific, and also to guide invasive diagnostic approaches, e.g. bronchoscopy versus needle or surgical biopsy. CT is also essential to the definition of the extent of the disease process and the possibility of multiple simultaneous processes. Focal or multifocal consolidation of acute onset on chest radiographs will quite likely be caused by bacterial infection. Similar multifocal lesions with subacute to chronic progression are more likely secondary to fungi, tuberculosis, or nocardial infections. Large nodules are usually a sign of fungal or nocardial infection or PTLD, particularly if they are subacute to chronic in onset. Subacute disease with diffuse abnormalities, either of the peribronchovascular type or miliary micronodules, are usually caused by viruses (especially CMV) or *P. jiroveci.* Additional clues can be found by examining pulmonary lesions for cavitation; cavitation suggests such necrotizing infections as those caused by fungi (*Aspergillus* or *Mucoraceae*), *Nocardia*, *Staphylococcus*, and certain Gram-negative bacilli, most commonly with *Klebsiella pneumoniae* and *Pseudomonas aeruginosa*.

Pneumocystis jiroveci pneumonia

The risk of infection for PCP is greatest in the first 6 months after transplantation and during periods of increased immunosuppression [151]. Lung transplant recipients more than other groups retain a life-long risk for *Pneumocystis* infection [152]. Given universal prophylaxis for PCP, the onset of *Pneumocystis* pneumonia may occur beyond prophylaxis and should be suspected in individuals presenting with significant hypoxemia out of proportion to minimal or subtle chest examination and radiologic findings. The natural reservoir of infection remains unknown. Aerosol transmission of infection has been demonstrated by a number of investigators in animal models and clusters of infections have developed in clinical settings, including between HIV-infected persons and transplant recipients [153]. Activation of latent infection remains a significant factor in the incidence of disease in immunocompromised hosts. In the SOT recipient, chronic immunosuppression that includes corticosteroids is most often associated with pneumocystosis. Bolus corticosteroids, cyclosporine, or co-infection with CMV or community-acquired respiratory viral infection may also contribute to the risk for *Pneumocystis* pneumonia.

In patients not receiving TMP-SMX (or alternative drugs) as prophylaxis, most transplant centers report an incidence of *P. jiroveci* pneumonia of ~10% in the first 6 months post transplant [151]. There is a continued risk of infection in three overlapping groups of transplant recipients: (1) those who require higher than normal levels of immunosuppression for prolonged periods of time due to poor allograft function or chronic rejection; (2) those with chronic CMV infection; and (3) those undergoing treatments that increase the level of immune deficiency, such as cancer chemotherapy or neutropenia due to drug toxicity. The expected mortality due to *Pneumocystis* pneumonia is increased in patients on cyclosporine when compared to other immunocompromised hosts. The hallmark of infection due to *P. jiroveci* is the presence of marked hypoxemia, dyspnea, and cough, with a paucity of physical or radiologic findings. In the transplant recipient, *Pneumocystis* pneumonia is generally acute to subacute in development. Atypical *Pneumocystis* infection (radiographically or clinically) may be seen in patients who have co-existing pulmonary infections or who develop disease while receiving prophylaxis with second choice agents, e.g. pentamidine or atovaquone. Patients outside the usual period of greatest risk for PCP may present with indolent disease confused with heart failure. In such patients, diagnosis often has to be made by invasive procedures [151].

Rapamycin (sirolimus) toxicity may contribute to diffuse interstitial pneumonitis [154]; it is not known whether this syndrome is directly attributable to rapamycin or reflects concomitant infections such as those due to influenza, RSV, PCP, or CMV.

Diagnosis

The characteristic hypoxemia of *Pneumocystis* pneumonia produces a broad alveolar–arterial Po_2 gradient. The level of serum lactic dehydrogenase (LDH) is elevated in most patients with *Pneumocystis* pneumonia (>300 IU/mL). However, many other diffuse pulmonary processes also raise serum LDH levels. Like many of the "atypical" pneumonias (pulmonary infection without sputum production), no diagnostic pattern exists for *Pneumocystis* pneumonia

on routine chest radiography. The chest radiograph may be entirely normal or develop the classical pattern of perihilar and interstitial "ground glass" infiltrates. Microabscesses, nodules, small effusions, lymphadenopathy, asymmetry, and linear bands are common. Chest CT scans will be more sensitive to the diffuse interstitial and nodular pattern than routine radiographs. The clinical and radiologic manifestations of PCP are virtually identical to those of CMV. Indeed, the clinical challenge is to determine whether both pathogens are present. Significant extrapulmonary disease is uncommon in the transplant recipient [151].

Identification of *P. jiroveci* as a specific etiologic agent of pneumonia in an immunocompromised patient should lead to successful treatment. A distinction should be made between the diagnosis of *Pneumocystis* infection in AIDS and in non-AIDS patients. The burden of organisms in infected AIDS patients is generally greater than that in other immunocompromised hosts and non-invasive diagnosis (sputum induction) more often achieved. In general, non-invasive testing should be attempted to make the initial diagnosis, but invasive techniques should be used when clinically feasible. The diagnosis of *P. jiroveci* infection has been improved by the use of induced sputum samples and immunofluorescent monoclonal antibodies to detect the organism in clinical specimens, and molecular diagnostic assays. Antibodies bind to both cysts and trophozoites. The cyst wall can be displayed by a variety of staining techniques; of these, the Gomori methenamine–silver nitrate method (which stains organisms brown or black) is most reliable, even though it is susceptible to artifacts. Calcofluor white is also commonly used for detection of *Pneumocystis*. Sporozoites and trophozoites are stained by polychrome stains, particularly the Giemsa stain, but organisms are less easily visible to non-experts than by other methods.

Therapy

Early therapy, ideally with TMP-SMX is preferred; few transplant patients will tolerate full-dose TMP-SMX for prolonged periods of time. While the treatment dose is higher than the prophylactic dose, recommended dosing (15–20 mg/kg/day of the trimethoprim component) has not been well studied in adults with less than normal renal function. The toxicity is the result of the elevation of creatinine due to trimethoprim (competing for secretion in the kidney) and the toxicity of sulfa agents for the renal allograft. Hydration and the gradual initiation of therapy may help. Alternate therapies are less desirable, but have been used with success, including: intravenous pentamidine, atovaquone, and clindamycin with primaquine or pyrimethamine. While a reduction in the intensity of immunosuppression is generally considered a part of anti-infective therapy in transplantation, the use of short courses of adjunctive steroids with a gradual taper is useful in transplant recipients as in AIDS patients [151].

The importance of preventing *Pneumocystis* infection cannot be overemphasized. Low dose TMP-SMX is well tolerated and should be used in the absence of concrete data demonstrating true allergy or interstitial nephritis. Alternative prophylactic strategies, including dapsone, atovaquone, inhaled or intravenous pentamidine, are less effective than TMP-SMX, but useful in the patient with significant allergy to sulfa drugs. TMP-SMX is the most effective agent for prevention of infection due to *P. jiroveci*. The advantages of TMP-SMX include increased efficacy, lower cost, the availability of oral preparations, and possible protection against other organisms, including *T. gondii*, *Isospora belli*, *Cyclospora cayetanensis*, *N. asteroides*, and common urinary, respiratory, and gastrointestinal bacterial pathogens. It should be noted that alternative agents lack this spectrum of activity [151].

Summary

Transplant infectious disease has increasingly become a field characterized by a preventative approach and early therapies based on sensitive molecular diagnostic tests. Compared with the early days of transplantation, considerable advances have been made regarding prevention of CMV and other opportunistic pathogens, but infection still poses a problem for many recipients. In the future, management of transplant recipients will be improved by the availability of assays for pathogen-specific immune function, enhanced microbiologic screening of donors and recipients, data regarding host risk factors including genetic polymorphisms of receptors and immunoregulatory elements, and advances in the individualization of transplant immunosuppression.

CHAPTER 95

General Malignancy after Organ Transplantation

Oriol Bestard, Josep M. Cruzado, and Josep M. Grinyó
Renal Transplant Unit, Nephrology Department, Bellvitge University Hospital, University of Barcelona, Barcelona, Spain

Introduction

Solid organ transplantation (SOT) has increased the life expectancy of patients suffering from numerous causes of irreversible chronic organ failure. Despite substantial improvement over the last decades in short-term allograft outcome, as a result largely of the advent of novel and more potent immunosuppressive combinations, long-term graft and patient survival has not achieved a similar improvement. Co-morbidity as a result of the permanent use of immunosuppressants is thought to reduce graft and recipient survivals. In addition to opportunistic infections and cardiovascular events, development of de-novo malignancies is a well-established major adverse outcome after SOT [1,2].

Multiple studies have estimated a general two- to 500-fold increased risk of cancer among transplanted patients as compared to the general population, with the variation dependent on the transplant setting and the specific type of malignancy considered. However, these data are not precise, mainly because of the different study methodologies and patient selection methods used. Indeed, there is significant diversity in reported studies in the literature [3–11]. It is also worth noting that histologic forms and incidences of malignancies vary depending on the geographic region, population served by the transplant center, and type of immunosuppressants used. Regardless of this variation, it is clear from the data reported from the preponderance of sources that transplant recipients have a substantially increased risk of developing cancer.

Once cancer has developed, the survival of transplant recipients is poor, and treatment options are limited by the transplant, the need for immunosuppression to sustain a life-saving organ, and co-morbidities. It is therefore important to understand the main underlying risk factors, as well as to precisely characterize those cancers that are significantly increased in the transplant population. This will inform patients of their risks, and allow a systematic, rational approach for screening and surveillance after organ transplantation. Toward this end, significant efforts are being made among the scientific community for a better characterization of the predominant risk factors, oncogenic mechanisms, and antitumor immunologic responses that may influence the advent of de-novo malignancies after SOT.

Epidemiology

It is widely accepted that chronic immunosuppression is associated with a markedly increased risk of de-novo malignancies after organ transplantation. Cancer registries for transplant populations from distinct geographic regions have allowed a better knowledge of the prevalence, incidence, and outcome of cancers in organ transplant recipients, and the recognition of the main underlying risk factors.

It is difficult to precisely ascertain, using data from small, single center studies, the incidence of most tumors or to compare their rates of occurrence with those in the general population. There have been few reports from transplant registries of the incidence of cancer [1–5]. In a recent study reported from a UK registry audit [4] comparing the incidence of malignancy in recipients of different types of organs to that in the general population, it has been shown that 10 years after transplantation, recipients have an overall incidence rate of 90 per 1000 patients. Reporting of cancer to registries is often incomplete, and as such, it is difficult to determine the extent to which registry data underestimate the true incidence of cancer [12–16]. However, in addition to immunosuppression, a variable risk of cancer that depends on both recipient age and gender has been demonstrated in cohort studies; increasing age of transplant recipients is a clear confounding factor influencing the incidence of malignancies. Specifically, the risk of developing cancer is only two-fold greater for 65-year-old patients, whereas young transplant recipients have a 15–30-fold increased risk compared with an age-matched general population.

Large-scale registry linkage studies document a widely variable cancer risk among transplant recipients. Some malignancies may arise from the loss of immunologic control of oncogenic viruses, but others are unrelated to known infections. Additional contributing factors for some cancers may include other effects of chronic immune disturbance or inflammation, underlying medical conditions, or medication toxicity. Malignancies associated with viral infections such as Epstein–Barr virus (EBV)-associated non-Hodgkin lymphomas [NHLs; post-transplant lymphoproliferative disorder (PTLD)], human herpes virus 8 (HHV 8)-associated

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Kaposi's sarcoma, some other specific malignancies such as non-melanoma skin cancer (both basal cell and squamous cell carcinomas), and lip and anal cancer are increased in SOT recipients compared with the general population [6].Some other cancers common among the general population have a higher incidence in transplant patients, e.g. colon, lung, or liver cancers, while the incidence of other malignancies, e.g. breast or prostate cancers, is similar to that in the general population (Table 95.1). The progressive increase of cancer with time of observation has been illustrated by the Australian experience. In this high-risk population of fair-skinned individuals with intense exposure to sunlight, the cumulative incidence of skin cancer, calculated by life-table analysis, increases progressively from 7% after 1 year of immunosuppression, to 45% after 11 years, to 70% after 20 years [17].

Cancer pattern variance by transplanted organ

It is of note that the incidences of different types of malignancies differ according to the organ transplanted (Table 95.1). While non-melanoma skin cancers (NMSCs), PTLD, lip and anal cancers are the most frequent malignancies after SOT, regardless of the type of organ transplanted, ranging from standardized incidence ratios (SIRs) of 7.5 to up to 61.4 as compared to the general population, other cancers have a remarkably increased risk among selected subgroups of transplant recipients such as lung, liver and kidney transplant recipients [4,18].

Reported data from kidney transplant registries have shown significantly increased SIRs for developing various malignancies after transplantation as compared to the general population. The overall SIR of all cancers in transplant recipients was 3.27 (95% CI 3.09–3.46); the increase in risk of developing cancer was less during dialysis (SIR 1.35, 95% CI 1.27–1.45) and before renal replacement treatment (1.16, 95% CI 1.08–1.25). NHL and NMSC were the most common malignancies, and colorectal and renal cell cancers (RCCs) were the most common solid organ tumors [6,19].

The reported SIR of developing any de-novo solid organ malignancy in recipients of liver transplants has been reported to be 2.7, as compared with the general population, with higher risks for colon, oropharyngeal, liver, and RCCs. In addition, cancer-related mortality ranged from 0.6% to 8% [20]. Of note, the SIR for NHL in liver transplant patients has been described as higher than that in kidney transplant recipients, with higher SIRs within the first year after transplantation and in patients between the ages of 35 and 50 years [21].

It has been reported that cardiac transplant recipients experience relatively higher rates of de-novo malignancies after transplantation than recipients of other solid organs, potentially due to the relatively higher level of immunosuppression that heart recipients receive as compared to other transplanted organ patients [22,23]. Solid organ tumors are the most common malignancies in heart transplant patients, and among these lung cancer has been reported to be highly prevalent in some studies [24,25], although this has not been confirmed in another study of 572 patients [26].

Up to 10–15% of deaths in recipients of lung transplants are the consequence of cancer during follow-up [27].

The reported incidence of de-novo malignancies in intestinal or multivisceral transplant recipients is 15%, of PTLD is 13%, and of non-lymphoid cancer is 3.2%. Children are at a significantly higher risk of PTLD, and adults are more vulnerable to non-lymphoid cancers [28]. PTLD in this transplant population seems to be strongly associated with EBV infection and graft-versus-host disease.

Table 95.1. Cancer risk categorized by standardized incidence ratio (observed/expected cases) for all solid organ transplant patients in the US, and kidney transplants in Europe (UK) and Australia/New Zealand. The incremental risk increases from bottom to top

Cancer	USRTR [18] 175 732 patients (1987–2008)	UKRA [4] 25 104 patients (1980–2007)	ANZDATA [1, 14] 12 633 patients (1980–2002)

Etiology and risk factors

A better understanding of cancer risk factors among SOT recipients logically would help to clarify the role of the immune system, infections, and other factors in the development of malignancy, and could identify opportunities to improve transplant safety. In general, it is difficult to precisely define the pathogenesis of cancer development post transplantation. While certain malignancies are associated with specific risk factors, others relate to accumulative risk factors. Regardless, it is generally accepted that a substantial portion of the excess risk of developing de-novo malignancies is due to chronic immunosuppression, with the range of cancers resembling that observed among patients infected with human immunodeficiency virus (HIV) [11]. Although HIV-related data suggest that the increased frequency of malignancies in allograft recipients results mainly from immunosuppression, this simple fact cannot explain the distinct increased risk of the different types of neoplasias in transplant recipients in comparison with the general population. It would therefore appear that in addition to immunosuppression, other risk factors, such as those associated with the primary diseases that lead patients to require transplantation, likely also play a relevant role.

There are multiple factors implicated in malignancy onset in the general population, including genetic susceptibility and carcinogenic factors such as smoking, alcohol, and intense exposure to sunlight in fair-skinned individuals. Moreover, there is an especially high likelihood for certain malignancies in patients exposed to some chronic or latent viral infections, including NHL (due to EBV), Kaposi's sarcoma (related to HHV 8), anogenital cancers [facilitated by human papillomavirus (HPV)], or liver cancer (due to hepatitis C and B viruses). The increased risk in these cases is in part due to the immunosuppressive-related loss of viral control. However, direct effects of the viruses have also been implicated. In addition, DNA damage, either by interference with normal DNA repair mechanisms, induction and promotion of cancer promoters

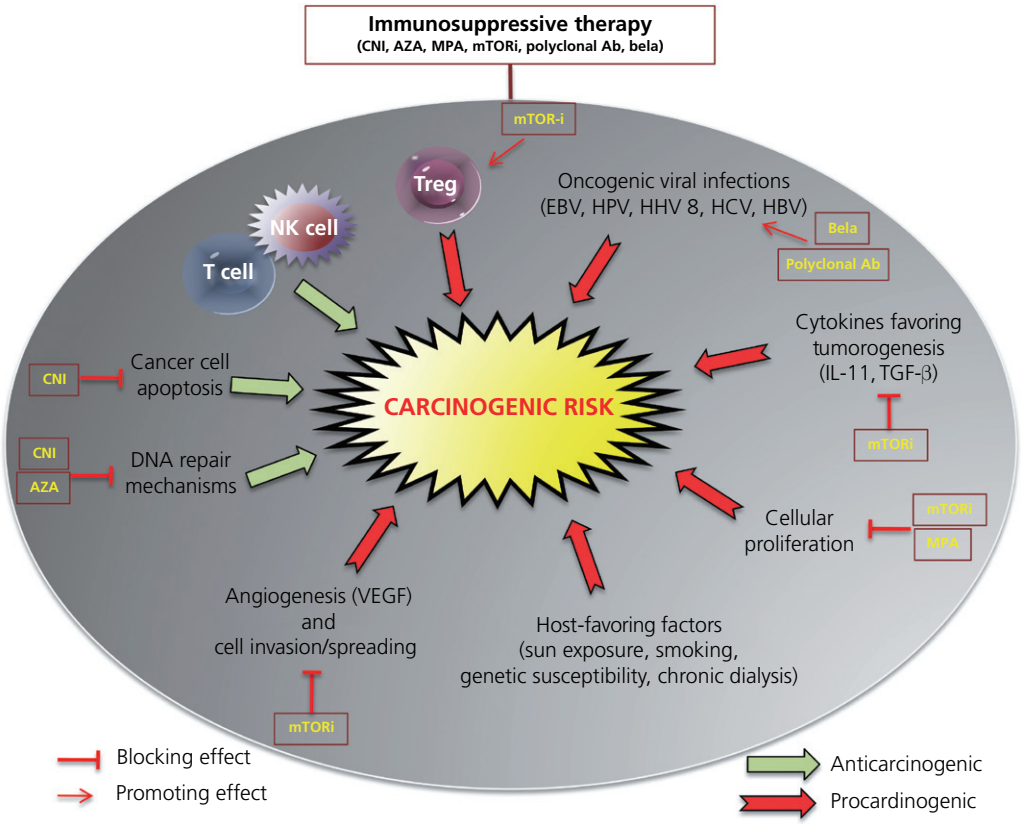

Figure 95.1. Associated mechanisms of pathogenesis in de-novo transplant malignancies.
CNI, calcineurin inhibitor, AZA, azathioprine; MPA, mycophenolic acid; mTORi, mTOR inhibitor; Ab, antibodies; bela, belatacept; EBV, Epstein–Barr virus; HPV, human papilloma virus; HHV 8, human herpes virus 8; HCV, hepatitis C virus; HBV, hepatitis B virus; IL, interleukin.

such as transforming growth factor-β (TGF-β) and vascular endothelial growth factor (VEGF), or by intercalation at the DNA level inhibiting splicing and eliciting codon misreads, is well described for current immunosuppressants, such as cyclosporine, tacrolimus or azathioprine. Finally, impairment of immunosurveillance, which usually prevents the growth and development of malignancies, is a generalized effect to which all transplant recipients are exposed due to chronic immunosuppressive therapy (Figure 95.1) [29,30].

Conventional and geographic risk factors

Usually the known risk factors for the general population that favor malignancy apply to transplant recipients. Among them, advanced age, tobacco, alcohol, some diets, and analgesic abuse are well-described risk factors for post-transplant malignancies [31,32].

Another important point to take into account when analyzing risk factors of post-transplant malignancy is geographic variation. For example, it is well known that in Japan, gastrointestinal malignancies (mainly liver, stomach, colon, rectum) are the most frequently observed post-transplant malignancies, and this is consistent with the generally high prevalence of gastrointestinal cancers in this country. Thus, endemic risks are superimposed on the risks imposed by the transplant experience. Similarly, among organ recipients from Australia and New Zealand, the risk of developing post-transplant skin cancer, particularly spinocellular carcinoma, is extremely high. The preferential explanation is that a fair-skinned Caucasian population is extremely exposed to excessive ultraviolet light [33]. In Europe and the US, the most frequent post-transplant malignancies are NMSC, NHL, RCC, carcinoma of the digestive system, and Kaposi's sarcoma [10,34]. In Saudi Arabia and some Mediterranean countries, where HHV 8 is more prevalent than in northern Europe [35], the most frequent malignancies are Kaposi's sarcoma, infection lymphoma (particularly in children), skin malignancy (with melanoma being more frequent in children than in adults), and anogenital cancers [36]. In South-East Asia, where hepatitis B and C infections are endemic, the frequency of liver cancer after renal transplantation is rather high [37].

Genetic factors

As in the general population, genetic factors may facilitate and promote the development of malignancies. In fact, there are some well-described diseases such as Von Hippel–Lindau disease that are associated with an intrinsically higher risk of developing RCC with an aggressive clinical course. When such patients receive a renal allograft, the frequency of RCC increases further [38]. This phenomenon may also be observed in patients with Wiskott–Aldrich syndrome or Drash syndrome in whom the risk of carcinoma is also markedly increased. In transplant recipients with these uncommon syndromes, an excessive frequency of lymphoma and Wilms' tumor has also been described [39,40]. The assumption that there might be a genetic predisposition in the genesis of post-transplant malignancies that relates to the etiology of the original organ failure is also sustained by the fact that patients with malignancies after transplantation often have more than one type of tumor [39]. In

Table 95.2. Viruses related to malignancies after organ transplantation

Viral agent	Malignancy (target organ)
Hepatitis B virus (HBV)	Hepatocellular carcinoma (liver)
Hepatitis C virus (HCV)	Hepatocellular carcinoma (liver)
Epstein–Barr virus (EBV)	Nasopharynx, Hodgkin and non-Hodgkin lymphoma
Human herpes virus 8 (HHV 8)	Kaposi's sarcoma (vascular)
Human papillomaviruses (HPV)	Cervix, penis, vulvar carcinomas
Human papillomavirus 58 (HPV 58)	Bowen's disease
Human papillomavirus 8, 19 (HPV 8, 19)	Non-melanoma skin cancer
Human papillomavirus 16, 20 (HPV 16, 20)	Skin and tonsillar carcinoma

patients with two malignancies, the most common secondary malignancy is a skin tumor [34].

Oncogenic viral agents

It has been well described that certain chronic viral infections can facilitate particular types of malignancies in transplanted patients (Table 95.2). There are several reported mechanisms by which viral agents can promote uncontrolled cell proliferation. These include viral-mediated disengagement of the machinery controlling the progress of cell cycling and division, escape of immunosurveillance by oncogenic cells carrying viral-derived particles on their surface, and viral inhibition of host cell apoptosis [41,42]. Inhibiting cellular apoptosis is of especial relevance as it is thought to be requisite for unceasing growth after transformation of the host cell by oncogenic viruses. A class of proteins, FLIPs (FADD l-like interleukin 1B converting enzyme-like protease inhibited proteins), interfere with the initiation of apoptosis through several apoptosis-reducing receptors, including CD95, TNF-R1, TRAMP/DR3, and TRAIL-R1, that presumably share common signaling pathways [43,44]. Herpes viruses such as herpes virus Saimiri (HVS) or HHV 8 encode some FLIPs. All viruses encoding vFLIPs can transform cells in vitro and are associated with tumors in susceptible hosts. HVS causes lymphoma and leukemia in susceptible primates and induces stable growth transformation of human T cells in vitro. Another important pathway for virus-induced malignancy is interference with the *p53* tumor suppressor gene, which induces cell cycle arrest or apoptosis in response to DNA damage [45]. Small DNA viruses use distinct mechanisms to counter p53. They either bind directly to p53 or inhibit p53-mediated transcriptional activation, or they promote the degradation of p53 via the ubiquitin pathway. HPV proteins E6 and E7 inhibit the *p53* gene and are thought to be involved in the induction of carcinoma. In addition, exposure of the skin to ultraviolet (UV) radiation causes DNA mutations by formation of thymidine dimmers, leading to inactivation of the *p53* gene. Malignant proliferation is thought to be a result of the failure to repair such mutations.

EBV has been frequently associated with lymphoma (both Hodgkin's and non-Hodgkin's) and HHV 8 is frequently associated with Kaposi's sarcoma [46,47], especially in those receiving monoclonal or polyclonal antibodies as induction or rescue therapy for steroid-resistant rejection [48]. Several varieties of HPV have been associated with skin, cervical, penile, or anogenital carcinomas [49]. Moreover, the polyoma BK virus, a double-stranded DNA virus that induces acute interstitial nephritis in renal transplant recipients [50], has been shown to have tumorogenic faculties by transforming cells mainly by the action of the middle T antigen [51,52].

Table 95.3. Proposed waiting times after primary malignancies before solid organ transplantation

Malignancy	Recommended pretransplant waiting time (years)
Lung	2
Colon:	
Stage I	2
Stage II or higher	5
Breast:	
Carcinoma in situ	2
Cancer	5
Prostate	2
Liver	Not recommended (except in liver transplant patients)
Bladder:	
Non-invasive	2
Invasive	5
Melanoma in situ	5
Non-melanoma skin cancer:	
Squamous cell carcinoma	2
Basal cell carcinoma	No waiting time
Multiple myeloma	Not recommended (bone marrow and kidney transplantation)
Leukemia	2
Genital cancers:	
Testicular	2
Cervical/uterine	2

Role of immunosuppression

As discussed throughout this chapter, there is substantial evidence regarding the significantly increased risk of developing malignancy after organ transplantation, suggesting that immunosuppressive therapy plays a key role in its promotion. Accordingly, it is typical for clinicians to wait between 2 and 5 years after cure of malignancy before proceeding with transplantation. This practice is predicated on the assumption that immunosuppression will accelerate residual tumor growth. General guidelines are provided in Table 95.3 and presented with the acknowledgment that the data supporting these guidelines are not particularly robust. General considerations regarding the variance of maintenance immunosuppression based on malignancy risk are described in Chapter 66. Supporting this concept, in a very illustrative population-based cohort study from Australia [6] in patients with end-stage kidney disease, it was shown that kidney transplantation was associated with a more than three-fold increased risk of cancer, whereas this increased susceptibility was not observed before transplantation. Likewise, the observation that patients with autoimmune diseases such as rheumatoid arthritis, systemic lupus erythematosus, or dermatomyositis develop tumors if they receive immunosuppressive therapy also supports the assertion that the action of immunosuppressive drugs is responsible in part for the increased incidence of tumors in transplant recipients [53–55]. Indeed, it seems intuitive that the overall amount of immunosuppression is a relevant factor in establishing the risk of post-transplant malignancy [56]; as already mentioned, cardiac transplant recipients, who receive a relatively higher immunosuppressive load, display higher rates of malignancies after transplantation than other solid organs recipients, who receive less intensive immunosuppression [22]. However, the relative carcinogenicity of individual immunosuppressive agents or combinations is still poorly understood, basically limited by a selection bias due to the absence of random allocation to treatments, limited recording of

drug exposures in the majority of studies, and lack of reported information regarding cancer outcomes. All of these issues hamper proper evaluation of confounding variables [2,6,57]. Nonetheless, relevant associations between diverse immunosuppressants and increased cancer susceptibility have been reported.

A clear relationship has been shown between the use of polyclonal or monoclonal lymphocyte-depleting antibodies for induction or rescue therapy and an increased incidence of PTLD (see Chapter 96). This has especially been observed among both renal and cardiac transplant recipients [58,59], but is not a relationship that holds for all agents in all malignancies [60].

Glucocorticoids have been widely used in SOT. They have been shown to have antiapoptotic and proliferation-promoting effects on carcinoma cells from different tumor types [61,62]. Although there is evidence suggesting its pro-oncogenic role among non-transplanted patients receiving glucocorticoids only, mainly favoring NMSC [63], there are few epidemiologic data showing their potential carcinogenic role after SOT.

In addition to inhibition of the calcineurin complex, calcineurin inhibitors (CNIs), including both cyclosporine A (CyA) and tacrolimus (TAC), particularly when used at higher dosages, enhance production of TGF-β and expression of VEGF. Both of these actions have been suggested to be responsible for tumor invasiveness, spread, and tumor angiogenesis [64–66]. Initial reports suggested that the introduction of CyA was followed by a higher frequency of cancer [67–69], especially among those transplant recipients on triple drug regimens of CyA, azathioprine (AZA), and corticosteroids, and those with maintained elevated doses as compared to transplant recipients receiving AZA only [22,68,70–73]. Nonetheless, in a recent study by Gallagher et al. [74], 489 recipients of first-deceased donor renal transplants were treated with either AZA and corticosteroids, CyA monotherapy, or CyA monotherapy followed by a switch to AZA and corticosteroids after 3 months. The different incidence rates of post-transplantation malignancies (non-skin and skin cancer) during a median follow-up of 20.6 years were compared. Interestingly, in the multivariate analyses, treatment allocation did not associate with development of either form of cancer; instead, general risk factors for development of cancer such as increasing age, previous smoking history, non-brown eye color, and fairer skin were the independent risk factors for carcinogenicity after kidney transplantation. Comparisons between CyA and TAC have suggested a slightly higher cumulative incidence of PTLD among TAC-treated patients, but other solid tumors actually seem to have a lower incidence in these patients compared to cyclosporine-treated patients [75–80].

In a large, 3-year follow-up, observational cohort study comparing two groups of renal transplant recipients who received or did not receive mycophenolate mofetil (MMF)-based immunosuppression from two large registries [Organ Procurement and Transplantation Network (OPTN)/United Network for Organ Sharing (UNOS) and Collaborative Transplant Study (CTS)], a trend was shown toward a lower risk of malignancy in those patients receiving MMF-based immunosuppression [81]. This potential antioncogenic effect could be explained by the observation that the inosine monophosphate dehydrogenase enzyme that is inhibited by MMF is significantly elevated in many types of malignancies [82,83].

As well as immunosuppressive effects, mammalian target of rapamycin (mTOR) inhibitors [mTORi; sirolimus (SRL) and everolimus (EVL)] have also been shown to have antiproliferative properties. This is thought to be due to their interference with cell cycle and several growth-related processes, such as signal translation, ribosome biogenesis, and transcription of many genes encoding for different metabolic and biosynthetic pathways [84]. Although mTOR complex II is partially insensitive to SRL/EVL, it may also be partially blocked by these agents, leading to inhibition of the PI3K/Akt/mTOR signaling pathway. Importantly, both upstream and downstream signaling components of mTOR, including aberrant activation of the PI3K/Akt/mTOR pathway and/or altered regulation of the cell cycle process, may frequently be altered in multiple human malignancies [85]. Furthermore, there have been reports of an antiangiogenic effect of mTORi through interference with the VEGF signaling pathway, leading to an abrogation of tumor growth and even metastatic processes as compared to CNI drugs both in vitro and in vivo [86,87]. Together, the multiple biologic effects of such immunosuppressive agents have increased interest among the transplant community in evaluating the potential for prevention of post-transplantation malignancies among solid organs recipients [88].

Several retrospective studies with short-term follow-up (between 2 and 3 years after transplantation) have compared the incidence of post-transplantation malignancies in renal transplant recipients receiving CyA- or SRL-based regimens post transplant; a slightly lower incidence of overall cancer and especially of NMSC was seen in the SRL-treated group [89]. A retrospective study of the OPTN/UNOS database [90] compared the incidence of post-transplant malignancies among kidney transplant recipients receiving only an mTORi, an mTORi in combination with a CNI, or a CNI-based regimen, with a censored follow-up of 963 days to allow comparable follow-up among the treatment groups; a significantly reduced incidence was seen of any malignancy of 0.60% for both SRL or EVL alone and for SRL/EVL plus a CNI, in comparison with 1.81% for a CNI alone. The incidence rates for de-novo solid malignancies were 0% for SRL or EVL, 0.47% for SRL/EVL in combination with a CNI, and 1.0% for a CNI alone. Multivariate analysis indicated that mTORi maintenance immunosuppression was associated with a 60% reduced risk of any post-transplant malignancy and a 55% reduced risk of solid malignancy. In a recent report evaluating conversion from a CNI to a mTORi with 24 months of follow-up in kidney transplant recipients receiving either a CNI-based regimen (either TAC or CyA) or an mTORi-based regimen (SRL), both with AZA or MMF and corticosteroids, a reduction in non-skin cancer risk in those patients switched to SRL was shown [91,92]. Another recent 4-year report from a European prospective study in kidney transplant recipients converted from CyA to SRL at 3 months after transplantation showed fewer de-novo malignancies within the SRL-treated patients (three vs. nine) [93]. However, contradictory observations have been reported by other trials or meta-analysis, showing no clear benefits of mTOR inhibition in the reduction of malignancies after transplantation [94,95].

Importantly, although a general trend toward reduced incidence of general malignancies has been reported among patients receiving a mTORi-based immunosuppressive regimen, there is a lack of prospective and randomized studies with long-term follow-up addressing the prevention of malignancies after transplantation. An interesting case report involves a hepatic recipient who experienced complete regression of three pulmonary metastases of hepatocellular carcinoma after conversion of maintenance immunosuppression from CyA and AZA to SRL and MMF [96].

Of note, the incidences of NMSCs and especially Kaposi's sarcoma in patients treated with SRL is significantly lower than those in non–SRL-treated patients. Moreover, successful regression

of Kaposi's sarcoma has been shown by switching patients from a CNI to a mTORi [97–99].

While waiting for more robust and conclusive data from prospective, randomized studies with longer-term follow-up, many transplant groups suggest that patients with malignancies prior to transplantation should receive a mTORi agent or switch to it when a cancer develops. Nonetheless, it is also generally accepted that for larger, aggressive, and metastatic malignancies, there is less likelihood of response to conversion [100].

Novel immunosuppressants continue to be developed with the aim of improving graft and patient survival, and it is generally considered that drugs with more specific sites of action will have a reduced risk of fostering malignancies. One of the most promising agents, and one that has been recently introduced for use in renal transplantation, is belatacept, a costimulatory blockade fusion protein that binds to the B7 family members CD80/86 on antigen-presenting cells. So far, there have been three prospective core studies using belatacept at two different dosages, all compared to a control group receiving CyA. In a 2.4-year median follow-up, a greater risk of PTLD [specifically located in the central nervous system (CNS)] was reported in the belatacept groups, especially in EBV-seronegative patients and with the more intensive dose [101]. No significantly increased risk of solid organ tumors has been described, although a longer follow-up is needed.

Immunosurveillance of malignancies

It is now clear that the immune system recognizes not only self versus pathogen or self versus non-self, but also the subtler differences that exist between self and transformed self. This realization prompted the hypothesis of cancer immunosurveillance, which encompasses the dual opposing functions of immunity in the cancer setting: host protection versus tumor promotion. These functions form the conceptual basis for a process that is currently known as cancer immunoediting in which the immune system is capable of either blocking tumor growth, development, and survival, or facilitating tumor outgrowth by sculpting tumor immunogenicity or by inhibiting host-protective antitumor responses [102–105]. The recognition of tumor cells in order to eliminate them is performed by the innate and the adaptive immune systems. Interestingly, the local immune environment of malignancies has been described as playing a crucial role. Galon et al. showed that the presence, location, and density of T cells and their products within colorectal tumors were a much better predictor of a cancer patient's survival than the commonly used tumor staging criteria, which are based on the size and spread of a tumor [106]. Identification of tumor antigens that are recognized by T cells from melanoma and other cancers has set the stage for developing more effective, antigen-specific immunotherapy against cancer, as well as vaccination with peptides or dendritic cells (DCs) pulsed with antigenic peptides derived from various melanoma antigens; these advances have great potential in cancer therapy [107–109]. In addition, interesting forthcoming studies will focus on the role of regulatory T cells (Tregs) as potential markers for predicting tumor outcome. In the general population with cancer, the presence of increased numbers of Tregs within the tumor and peripheral circulation has been associated with poor prognosis [110–113]. Interestingly, blocking the function of Tregs in murine tumor models resulted in strong cellular antitumor immunity and even complete tumor destruction [114–118], indicating a crucial role for Tregs in tumor immunity. Furthermore, natural killer (NK) cells have also been shown to play an important role in the host's defense against malignancy—either controlling or inhibiting the advent of cancer both in vitro and in vivo [119–121].

It seems, therefore, obvious that the antitumor immune responses in transplant recipients under immunosuppression will be significantly hampered, thereby facilitating the onset and progression of malignancies. In fact, attempts have been made to define those patients at increased risk for cancer after transplantation by measuring lymphocyte subsets. In two studies, a low CD4 count predicted those at risk for any cancer after transplantation, including squamous cell carcinoma (SCC) [122,123]. However, although predictive, CD4 T-cell count in this population had limited clinical utility. Similarly, among kidney transplant recipients with SCC, it has been recently reported that high and low numbers of peripheral $Foxp3^+$ Tregs and NK cells, respectively, are significantly associated with increased risk for new SCC development, and the ratio of CD8/Foxp3 expression within the cancer itself correlates with development of new cutaneous SCCs [124]. These recent data suggest that monitoring components of the immune system could facilitate prediction of cancer development.

Donor cancer transmission

Transmission of an undiagnosed malignancy from the donor is relatively unusual, especially from living donors because they are thoroughly evaluated before donation; however, for deceased donors there is a greater possibility and this should be considered in the differential diagnosis of malignancy after transplantation. Under immunosuppression, (micro)malignancies or even metastases from a donor could more easily disseminate after transplantation. According to data from the OPTN/UNOS, a donor-related malignancy incidence of 0.2% was reported among a total of 108 062 evaluated transplant recipients [125].

There are some cancers with a higher risk of transmission as compared to others. This is the case for melanoma or choriocarcinoma tumors, whereas RCC confined within the renal capsule without vascular invasion or CNS tumors carry a very low risk. A relevant consideration is viral-transmitted malignancies: EBV donor transmission to seronegative recipients may result in subsequent development of PTLD, especially if the recipient is receiving specific immunosuppressants such as polyclonal antibodies or belatacept.

In an interesting report, it was shown that 50% of patients receiving an allograft from a donor carrying a cancer did develop the malignancy, half of them with metastatic disease [81]. In some patients, eliminating immunosuppressive treatment led to rejection of the donor-derived malignancy without the need for further therapy. However, in most patients with donor-transmitted malignancies, in addition to reducing immunosuppression, specific antitumor therapy is also necessary. The overall mortality from donor-related malignancies is 38%, with that from transmitted tumors at 46% and that derived from de-novo tumors at 33%. Overall, deceased donor-related tumor mortality is 0.007% (eight of 108 062 recipients) [125].

Cancer types

Non-malignant and malignant skin lesions

NMSCs, both basal cell carcinomas (BCCs) and SCCs carcinomas, are the most frequent malignancies after SOT [126], accounting for the majority of skin cancers and being ten- to 200-fold more frequent than in the general population, respectively [127]. Moreover, the normal ratio of each tumor type in the general population

is reversed in transplanted patients (SCC/BCC, 4:1) [128]. Although with lower frequency than for NMSCs, SOT patients also display increased risk of other skin malignant lesions such as melanoma (3.6 times higher risk), Merkel cell carcinoma (10 times), and Kaposi's sarcoma (80 times) [129–131]. The incidence of NMSCs increases with time after transplantation. The incidence in the US and Europe at 2, 10, and 20 years after kidney transplantation has been described as 5%, 10–27%, and 40–60% [10,132,133]. These skin lesions may appear in younger individuals and although considered to be less severe than other solid malignancies, they have been described as having a much more aggressive behavior in transplant recipients than in the general population, growing more rapidly, recurring locally after resection, and capable of metastasizing much more frequently [134].

The development of NMSCs has been associated with several conditioning features such as a greater degree of immunosuppression with direct oncogenic properties, intense sun exposure, association with previous keratotic skin lesions, decrease in immunosurveillance, and interaction with some oncogenic viruses. Cumulative sun exposure is a crucial responsible carcinogen, as these lesions primarily occur in sun exposed skin areas and the incidence is clearly higher in sunnier countries. Age is another important risk factor for skin cancer, as shown by the significantly increased risk of developing skin cancer among patients older than 55 years as compared to younger recipients [135].

Furthermore, mutations of the *p53* tumor suppressor gene have been described as a common genetic disorder in skin cancers. These mutations predispose to skin patches, which in turn appear to be a risk factor for SCC [44].

As previously mentioned, HPV infection is also associated with an increased risk of skin cancer [136,137]. Immunosuppressants such as CNIs (especially CyA at maintained standard doses) [55], due to their pro-oncogenic properties related to the production of certain cytokines, may facilitate angiogenesis resulting in tumor growth and even metastasis. Similarly, due to the sensitization of skin cells to UVA-induced skin damage, AZA has also been associated with skin cancer development [138]. Conversely, there have been reports of lower malignancy rates, especially of NMSCs, in renal allograft recipients receiving SRL/EVL de novo or converted from other immunosuppressants, basically CNIs [93]. Nonetheless, there is still a lack of controlled clinical trial data to support conversion to an mTORi-based immunosuppressive regimen specifically to induce tumor regression, with the probable exception of Kaposi's sarcoma, for which conversion from a CNI to SRL enhanced regression [98,99]. It is unclear whether the Kaposi's lesions regressed due to elimination of the CNI, specific effects of SRL, or both. Controversy exists because in another report eight of 24 patients with Kaposi's sarcoma had a complete tumor response to reduction/cessation of immunosuppressive drug therapy [139].

Risk of malignant melanoma seems to be only slightly increased among SOT patients. However, the mortality from melanoma is significant. Moreover, melanoma in transplant recipients has been associated with a worse overall survival in comparison to the non-transplant population. Despite the scarcity of reported data, it seems that the thickness of the lesion determines the prognosis; patients with a malignant melanoma of <0.76 mm do as well as the general population, whereas those in whom the malignant melanoma is >0.76 mm may experience worse outcomes with increased mortality [140].

Solid cancers

Renal cell cancer and other cancers of the urinary tract

Urinary cancers are the second most common tumors in transplant recipients. The excess risk of RCC varies among different reports, ranging from five- to even 100-fold greater than in the age- and gender-matched general population [141–143]. The majority of RCCs most likely occur in the native kidneys rather than in the renal allograft. A significant increased risk is evident in patients with polycystic kidney disease.

There are no homogeneous recommendations for screening for renal cancer in the kidney transplant population. The American Society of Transplantation and the Kidney Disease Improving Global Outcomes (KDIGO) Clinical Practice Guidelines for the Care of the Kidney Transplant Recipient found no evidence to support routine screening for renal cancers in recipients of kidney transplants and did not recommend screening using ultrasonography in average-risk transplant recipients [144,145], but guidelines from the European Association of Urology recommended annual screening of the native and the graft kidneys using ultrasonography for recipients at high risk [146]. Because there is no clear and precise definition of patients at risk, there are concerns regarding routine screening for renal cancers in terms of cost-effectiveness for kidney transplant recipients [147]. Nonetheless, annual surveillance of the native kidney by ultrasound is recommended and, importantly, patients with or without adult polycystic kidney disease (APKD) who have Bosniak I or II cysts should undergo renal ultrasounds twice a year [148].

Like RCC, there is also an increased incidence of developing cancers of the native urinary tract, and among these, prostate cancer is significantly increased [149]. The US Renal Data System shows a 3-year cumulative incidence of 3.1% for prostate cancer, 2.2% for RCC, 0.7% for bladder cancer, and 0.1% for testicular cancer. Moreover, patients undergoing renal transplantation for analgesic nephropathy are at high risk of developing transitional cell carcinoma of the upper urinary tract [150,151]. Current cancer screening guidelines advocate screening for prostate cancer, although a survival advantage has not been demonstrated, and there is even the potential for over-diagnosis of trivial malignancy.

Colorectal cancer

Whether or not the incidence of colorectal cancer is increased among renal transplant recipients is a controversial question. Some groups have reported increased rates, both in men and women as compared to the general population [10], but these reports have been questioned by others [152,153]. However, the risk of colorectal cancer is clearly increased in patients with primary sclerosing cholangitis receiving a liver allograft and with a relevant history of inflammatory bowel disease [154].

Anogenital cancers

There is a clear increased incidence of anal cancer among all transplant recipients. Gynecologic cancers such as cervical carcinoma in situ, vulvar, ovarian, and cervical malignancies are also significantly increased after transplantation. All of these malignancies are related to HPV 16 or HPV 18 infections, and accounted for 2–3% of all cancers in patients who underwent a transplant [155,156]. However, the role of HPV vaccination is controversial. Vaccination post transplantation might be ineffective for HPV-naïve patients because

these patients might have lower secondary responses and more rapid decline of antibodies as compared to the general population [157]. These cancers tend to be extensive or multiple, especially in women, 30% of whom have concurrent cervical cancer. Therefore, gynecologic examinations should be performed annually.

Lung and breast cancer

Lung and breast cancer are increased two-fold in SOT recipients. In two studies with a significant number of patients receiving a SOT, up to 0.3% of patients developed lung cancer, with a higher incidence in non-smokers compared with smokers in contrast to the general population, and with a rapid progression in patients who had not undergone tumor resection [158,159]. A study by Jimenez et al. [160]. showed that patients being transplanted for alcoholic cirrhosis had significantly higher rates of lung cancer than those transplanted for other causes (4.3% vs. 0.7%). This result, however, could be confounded by the fact that patients who drink alcohol are more likely to smoke cigarettes as 73.3% of de-novo lung cancer patients in this study were both heavy drinkers and intermediate or heavy smokers.

There is some controversy regarding the incidence of breast cancer in female SOT recipients. While one study in female heart transplant recipients reported a reduced incidence of breast cancer as compared to the general population [161], another study showed an increased incidence of breast cancer in women receiving a liver transplant [162]. However, a higher biologic aggressiveness of breast cancer in transplant recipients compared with the general population has been described [163]. In such cancers, adherence to the routine screening guidelines established for the general population is also appropriate for transplant recipients.

Cancer screening in solid organ transplant patients

The well-established increased risk of developing cancer after SOT has led international transplant organizations to investigate regular tumor screening in SOT patients [144,155,164–166]. However, there are important concerns regarding the specific recommendations for cancer screening among transplanted patients as the main guidelines have been completely extrapolated from data for the general population. Differences between the general population and transplanted recipients, differences in diagnostic tests, and competing risks for death from other causes such as cardiovascular disease with reduction of overall life expectancy all question the validity of these recommendations in the SOT population. Guidelines developed for the general population need to be assessed for applicability to the SOT population, balancing the benefit of screening with the costs and potential harm to the individual [167]. Additional information regarding preventative healthcare screening in transplant recipients is given in Chapter 88.

Nonetheless, several international transplantation societies have reported guidelines or recommendations for cancer screening in different types of SOT. In general, advice such as avoidance of excessive immunosuppression if possible, avoidance of repeated contact with depleting antilymphocyte antibodies, screening of donors and recipients for cancer, and the avoidance of carcinogenic factors such as persistent high sun exposure should be the initial approach to preventing the advent of de-novo malignancies. Moreover, the rising age of transplant patients together with the length of time spent on the waitlist increase the risk of malignancy escaping detection and therefore recipients with pre-existing tumors receiving transplants.

After observing the primary prevention of skin cancers with the avoidance of intensive sun exposure, use of protective clothing, and effective sunscreen, the next important practice is examination to detect skin tumors. Monthly skin self-examination and total body skin examination every 6 to 12 months by expert physicians and dermatologists are highly recommended; in high-risk patients, e.g. those who have previously been diagnosed with SCC, more frequent examinations are mandatory.

In women, yearly gynecologic examinations, and transvaginal ultrasonography in those without hysterectomy, are also strongly recommended to exclude vulvar, perineal, and uterine malignancies. As cervical cancer is a virus-related neoplasia that is more aggressive among immunocompromised patients, the European and American transplantation societies recommend annual cervical cancer screening with Pap smear and pelvic examination in all adult female renal transplant recipients [145,165].

Multicystic alteration of native kidneys in patients with chronic kidney disease is a well-known precancerous condition. Although there is no precise definition of patients at risk of RCC, ultrasonographic examination of the recipient's kidney should be performed every year, especially in those showing Bosniak type I or II cysts.

A urologic examination is indicated in patients with a history of analgesic nephropathy who develop microhematuria and in patients who have received cyclophosphamide, especially if the cumulative doses exceeded 20 g [168]. Some authors also recommend urologic examination in patients who have been treated with AZA for >10 years [169].

Periodic screening of feces for occult blood is advisable because colorectal carcinoma is more frequent after transplantation. However, recommendations for flexible sigmoidoscopy are not clear; this is currently recommended every 5 years beginning at age 50 years. Colorectal cancer after liver transplantation is more often a right-sided lesion, is more aggressive, and is associated with a higher rate of metastasis. In addition, those liver transplant recipients with primary sclerosing cholangitis and inflammatory bowel disease, who are at an increased risk for developing a colonic carcinoma after liver transplantation, require more frequent screening/surveillance with annual follow-up screening examination with colonoscopy and random colorectal mucosal biopsies for early detection [170].

For other solid organ cancers such as prostate and breast, guidelines published for screening and prevention of solid organ cancers in the general population should be strictly adhered to in transplant recipients. For breast cancer, both the American and European transplant societies recommend screening all female transplant recipients between 50 and 69 years of age at recommended intervals of between 12 and 24 month [171–173]. Women between 40 and 49 years of age can still undergo screening mammography every 1 or 2 years, but there is no evidence for or against screening in this age group [145,165]. Prostate cancer screening is a persistent topic of debate both for the general population and for SOT recipients. Nevertheless, both the American and European transplantation societies encourage annual prostate cancer screening with digital rectal examination (DRE) and prostate-specific antigen (PSA) measurement in all male renal transplant recipients who are older than 50 years and have a life expectancy of at least 10 years [145,165].

Management of de-novo malignancies after solid organ transplantation

Management of transplanted patients who have developed a de-novo malignancy is challenging and will vary depending on the type and stage of the cancer and aim of the treatment, i.e. whether it is curative or palliative. However, the same preventative recommendations that are given to the general population should always be given. These include modification of lifestyle such as following a healthy diet, regular exercise, and smoking cessation. Then, specific therapeutic strategies for the particular tumor type, either with surgery extirpation, radiotherapy, or chemotherapy, can be used as appropriate [174].

Along with the specific therapeutic management of a cancer, the general advice for immune responsive tumors is for a careful reduction or withdrawal of immunosuppression, keeping in mind the competing risks of organ failure and malignant progression. Wholesale elimination of immunosuppression for a life-sustaining organ, e.g. heart, lung, or liver, cannot be recommended, particularly for malignancies that are unlikely to have been induced by immunosuppression. However, elimination can be more freely considered for immune-responsive malignancies, e.g. EBV-driven lymphomas, or in kidney transplantation. Conversion to alternative immunosuppressive regimens based on mTORi also can be considered. However, the benefit of changing to an immunosuppressant with antiproliferative activity to overall success of treatment is still unknown. Liver transplant recipients can be maintained on minimum concentrations of prednisolone and AZA/MMF or even converted to an mTORi, as acute rejection is unusual late after transplantation, typically mild, and generally easy to reverse. In kidney transplant recipients, CNI concentrations should be reduced to a minimum and SRL/EVL seriously considered as a CNI alternative [175,176]. Management of baseline immunosuppression among other SOT recipients, such as heart, lung, or intestinal transplant recipients, should follow the same recommendations, although for these consideration needs to be given to the consequences of rejection of a vital organ.

A change to a immunosuppressive regimen with an antiproliferative effect, such as MMF and particularly mTORi, might help to decrease the incidence of graft rejection and even to regress the malignancy. This strategy should be followed especially in patients with NHL, skin cancer, Kaposi's sarcoma, or donor-derived malignancies [177–179]. Although growing evidence seems to indicate that mTORi agents have beneficial effects in terms of cancer regression and patient survival in the early stages of post-transplantation malignancies [175], long-term prospective clinical trials are needed to truly define their role in this setting.

When a patient develops a serious malignancy, minimization or even complete cessation of immunosuppression should be considered, particularly for completely HLA-matched patients. Although immune responses seem to be relatively impaired with severe malignancies due to a generalized anergy [180], graft monitoring at short intervals is necessary, particularly in the early stages after transplantation; otherwise fulminant rejection may be diagnosed too late, with the potential consequence of graft loss. The degree to which loss of the allograft is of primary concern varies based on the stage of the malignancy, its immune responsiveness, and in the terminal situation, the degree to which quality of life will be impaired should graft loss occur. In the setting of a donor-derived malignancy, some degree of allograft rejection may be required to facilitate elimination of the malignancy.

Interestingly, immunotherapy of some cancers such as melanoma [181], colorectal cancer [182], and RCC [183] is currently under investigation in non-transplant patients. Whether or not these treatment modalities will be also useful in organ transplantation needs further study.

Summary

In summary, malignancies are sufficiently common in transplant recipients to warrant their consideration in all patients receiving a solid organ allograft. Relevant risk factors or tumor development should be taken into account and systematically monitored in detail. Furthermore, the prompt detection of cancer allows for effective therapeutic decisions to be made. Given the numerous competing risks of graft failure and metastatic progression, and the related morbidity and mortality of each, the care of a patient with a post-transplant malignancy should involve a multidisciplinary team. Given the complexity of dealing with post-transplant malignancies, prevention should be a major objective of transplant physicians.

CHAPTER 96

Post-Transplant Lymphoproliferative Disorders

Michael Green[1] and Steven A. Webber[2]

[1] University of Pittsburgh School of Medicine, Pittsburgh, PA, USA

[2] Department of Pediatrics, Vanderbilt University School of Medicine, Nashville, TN, USA

Introduction

Solid organ transplantation (SOT) is increasingly accepted as treatment for end-stage disease of the heart, kidney, lung, liver, and intestine. Recognition of the importance of post-transplant lymphoproliferative disorders (PTLDs) in recipients of SOTs has grown in parallel with the growth and success of this field. While this is particularly true for pediatric organ transplant recipients, owing in large part to their increased likelihood of Epstein–Barr virus (EBV) naïve status at the time of transplant, the development of PTLD in adults is also an important cause of morbidity and mortality [1]. Although the majority of PTLD lesions have been associated with the presence of EBV, EBV-negative PTLD also occurs [2,3]. Despite a growing understanding of the pathobiology of PTLD, much remains unresolved and its optimal management in SOT recipients remains controversial. This chapter will review the biology, pathology, epidemiology, clinical manifestations, diagnosis, and management of PTLDs, and will also discuss possible prevention of PTLDs in SOT recipients. This chapter complements Chapter 95, which covers post-transplant malignancy in general.

Historical perspectives

The association between therapeutic immunosuppression in the transplant recipient and the development of lymphoid tumors was first recognized in 1968 [4]. As surgical and immunosuppressive strategies evolved, cases of lymphoid malignancy increasingly emerged among organ transplant recipients. Despite ongoing concern for this complication, it was not until a series of seminal observations from the University of Minnesota in the early 1980s that the role of EBV in the development of PTLD was established [5,6]. With ongoing evolution and introduction of more specific and potent anti–T-cell immunosuppression, the problem of PTLD became increasingly apparent, prompting an increased focus on the cause and potential therapeutic response to this condition. Subsequent studies confirmed the central pathogenic role that EBV plays in the majority of patients undergoing organ transplantation who experience this complication. However, the availability of molecular probes for EBV also revealed that a substantial subset of cases of PTLD (especially in adults or in children long out from transplant) do not appear to demonstrate any relationship with EBV [2,3]. Regardless of the involvement of EBV, these cases emphasized the role of intact immune surveillance in the prevention of the development of neoplasms, particularly those driven by viral infection.

EBV-associated PTLDs include a spectrum of conditions that straddle the borders between infection and malignant neoplasms [1]. EBV disease in SOT recipients manifests a continuum of clinical and histopathologic findings ranging from non-specific febrile illness to PTLD, including frank lymphoma associated with various genetic alterations [1,7]. Thirty years of efforts to understand factors that determine the severity and outcome of EBV-associated disease have identified the adequacy of the host immune response and the level of extrinsic immunosuppression as major determinants. The initial observations by Starzl et al. of the potential reversibility of PTLD lesions with lowering of immunosuppression support the validity of these observations [8]. The recognition of the role of EBV in the majority of PTLD lesions raised questions as to the potential role of antiviral therapy in the treatment of this condition. Hanto et al. provided initial evidence for the use of acyclovir in the treatment of PTLD in the 1980s [5]. Subsequently, the greater potency of ganciclovir led many clinicians to use this agent in the treatment of EBV disease and PTLD [9]. However, an understanding of the disease pathogenesis of EBV-associated PTLD, particularly its relationship to viral latency (see below) rather than lytic infection in its progression, reconciles well with a lack of definitive data supporting the efficacy of antiviral therapy in either the treatment or prevention of PTLD, and raises doubt about the utility of these agents.

Work underway since the late 1980s identified an association between the presence of elevated EBV loads in the peripheral blood and the presence of EBV-associated disease in transplant recipients [10]. The growing availability of EBV load assays has led to their widespread use. Twenty years of experience with these tests has emphasized both their promise and their limitations [11]. An elevated EBV load identifies the majority of newly infected EBV-naïve patients at risk for, or presenting with, EBV-associated disease. However, a few patients experiencing this complication will not have an elevated EBV load, while others with elevated loads may not currently manifest and will not develop clinical illness. Nonetheless, the fact that EBV loads become positive and rise to high levels weeks before the development of clinical disease has led to a growing acceptance that the following of serial measurements can inform pre-emptive strategies aimed at the prevention of EBV disease in patients who are seronegative for EBV at the time of

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

transplantation [1,11]. EBV load monitoring is of less clear value for the prediction of PTLD in patients who are EBV seropositive at the time of transplantation.

Biology of Epstein – Barr virus-associated post-transplant lymphoproliferative disorder

EBV is a double-stranded DNA virus of the gammaherpes family [12]. The virus is most frequently transmitted through saliva, though it can be transmitted from the donor, likely by way of passenger leukocytes. Whether through saliva or passenger leukocytes, EBV infection is primarily manifested through the infection of B lymphocytes. Infection of the B lymphocyte progresses through one of two phases. In the lytic phase, EBV actively replicates within infected B cells with subsequent production and release of infectious virions, which can spread infection to non-infected B cells. The second or latent phase is more complex [12,13]. EBV-associated latency involves several different latency gene programs. One of these, termed latency type III, is characterized by cellular activation and autonomous proliferation of the infected B cell. Affected B cells resemble antigen-activated B lymphoblasts in immunocompetent individuals, where the presence of a competent immune system and the development of EBV-specific cytotoxic T lymphocytes (CTLs) eventually control both lytic infection and the outgrowth of EBV-activated lymphoblasts. In the normal host, latency type III infection progresses first to latency type II infection, which takes place in B-cell follicles of secondary lymphoid tissue, and then to latency type I infection within resting memory B cells [13]. This progression, which is mediated in part by the development of EBV-specific T-cell immunity, involves both migration of infected B cells to secondary lymphoid tissue and sequential expression of different genes, culminating in minimal gene expression in latency type I infection in resting memory B cells despite maintenance of the EBV episome. In essence, the sequence of EBV latency programs co-evolved with the human immune system to establish life-long latent infection in a manner that typically does not result in chronic or serious disease. However, in transplant recipients, the presence of immunosuppression disrupts the development of an adequate host immune response, potentially leading to continued expansion of B cells in latency type III infection and thus manifestations of EBV disease including PTLD [12–14].

The outgrowth of latency type III lymphoblasts during primary infection in immune competent individuals is primarily controlled by the presence of EBV-specific $CD8^+$ CTLs [13]. Subsequently, seropositive immunocompetent individuals chronically devote a significant proportion of their T-cell repertoire to controlling EBV, including EBV-specific T cells specific for both lytic and latent epitopes. Less is known about the $CD4^+$ T-cell response to EBV and the role of humoral responses in protecting against PTLD in organ transplant recipients is also unclear. Although the exact pathway from infection to PTLD remains unclear, the absence of an adequate immune response to drive and contain EBV through its normal pattern of infection is clearly the key to the development of EBV-related PTLD.

Epstein–Barr virus-negative post-transplant lymphoproliferative disorder

Although the majority of PTLD lesions have been shown to be associated with EBV infection, a growing number of lesions have been found to have no evidence of EBV [2,3]. As many as 21–34% of histologically proven PTLDs are EBV negative [2,3] and this number may be increasing. At least some of these lesions have been identified as being T-cell PTLD [7,15]. EBV-negative cases typically occur later than EBV-positive cases, are often of T-cell origin, and if B cell in nature, typically demonstrate monomorphic histology. They also tend to have a worse prognosis [3].

A variety of etiologies have been considered as potential causes of EBV-negative PTLD. The possibility that unidentified infectious agents might stimulate the lymphoproliferative process has been widely discussed. Vilchez et al. found evidence of SV40 large tumor antigen sequences in two of 16 cases of PTLD, including one case of EBV-negative T-cell disease [16]. Rare cases have been associated with human herpesvirus 8 (HHV 8) infection [17]. Regardless of their etiology, evidence suggests that EBV-negative PTLDs appear to represent a distinct subset of lesions with differences in biologic behavior, therapeutic responsiveness, and prognosis [2,3].

Table 96.1. WHO classification of the post-transplant lymphoproliferative disorders

- Early lesions
  - Plasmacytic hyperplasia
  - Infectious mononucleosis-like
- Polymorphic PTLD
- Monomorphic PTLD (B and T/NK cell types)*
- Classical Hodgkin's lymphoma type PTLD

*Further classified according to the lymphoma they resemble.
PTLD, post-transplant lymphoproliferative disorders; NK, natural killer.
Data from Swerdlow et al. [7].

Pathology

PTLDs are a spectrum of lymphoid and plasmacytic proliferations occurring in the post-transplant setting. As discussed above, they are frequently, but not always, associated with EBV infection. Most PTLDs in SOT patients are of host origin, but they are of donor origin in bone marrow/stem cell transplant recipients. The classification of these disorders has evolved over the last two decades, and at times has been confusing for both clinicians and pathologists. The World Health Organization (WHO) has developed a standard classification, which is now used in most centers [7]. In the 2008 revision of the WHO classification, four main categories were defined (Table 96.1). It should be noted that individual patients may demonstrate different types of PTLD, sometimes clonally unrelated, or even of different cell origin. These may occur simultaneously or at different times. Recurrences may show evidence of progression from polymorphic lesions to B-cell or T-cell monomorphic PTLD or Hodgkin's lymphoma [15,18].

It is important to exclude the possibility of other lymphoid or plasmacytic inflammatory lesions. In the allograft, distinction from rejection must be made. In rare circumstances, PTLD and rejection can occur concurrently. PTLD remains a pathologic diagnosis, and wherever there is a high index of suspicion, biopsy should be performed. Excision biopsy or core biopsy [often computed tomography (CT) or ultrasound guided], but not cytology, are appropriate. Tissue should be handled in the same manner as for work-up of lymphoma in the immunocompetent host, and the pathologist should be informed whenever a biopsy for this diagnosis is being performed. Evaluation should include histologic sections, fresh material for immunophenotypic studies, and fresh/frozen material for potential genotypic studies. Classical cytogenetic studies may be valuable in some instances [7].

Early lesions

These are non-destructive lymphoplasmacytic proliferations that are further divided into two subgroups: plasmacytic hyperplasia and infectious mononucleosis-like PTLD. Some lesions do not fall into either category, but represent florid follicular hyperplasia, e.g. of the lingual tonsil. These lesions may cause significant symptoms, including airway obstruction, yet traditionally have not been categorized as PTLDs. This remains controversial. Early lesions may resemble reactive changes seen in lymphoid tissues in the immunocompetent host. In general, these lesions are non-clonal and cytogenetic abnormalities are unusual.

Polymorphic PTLD

This is the form most commonly seen in children and the lesions are generally positive for latent EBV, expressing non-coding EBV RNAs (EBERs) or EBV nuclear antigen (EBNA) by immunohistochemistry (Figure 96.1a,b). These are destructive lesions but do not fulfill the criteria for any of the classic lymphomas seen in the non-transplant population. The distinction from cases of infectious mononucleosis-like PTLD or monomorphic PTLD can at times be difficult. The lesions include lymphocytes of various types, sizes, and shapes, and at various stages of maturation, as well as plasma cells. There is usually a mixture of variably sized B cells and heterogeneous T cells. Transformed B cells/immunoblasts tend to be in the minority and may resemble Reed–Sternberg cells. These lesions do not clearly fulfill the criteria for one of the classic malignant lymphomas. Nonetheless, B-cell/plasma cell clones are often identified by molecular studies. *Bcl-6* mutations are reported in some polymorphic PTLDs, but abnormalities in tumor suppressor genes and oncogenes are generally not expected [19].

Monomorphic PTLD

Monomorphic PTLDs most often fulfill criteria for diffuse large B-cell lymphoma (DLBCL) (Figure 96.1c); Burkitt's lymphoma (Figure 96.1d), plasma cell neoplasia, and one of the T/natural killer (NK)-cell lymphomas recognized in immunocompetent hosts are also observed. They are categorized based on the type of lymphoma they most closely resemble in the non-transplant population. At the current time, the small B-cell lymphomas are not considered PTLD, though MALT lymphomas are observed in transplant patients.

B-cell monomorphic PTLDs are typically composed predominantly of numerous transformed lymphoid cells at one maturational stage, i.e. monomorphic. However, some degree of cellular pleomorphism is generally present. These lesions are expected to be monoclonal. The greatest frequency of EBV-negative cases is found in monomorphic PTLD. DLBCL are CD20 positive; Burkitt's lymphomas typically have a $CD20^+$, $CD10^+$, bcl-6^+, bcl-2^- phenotype. Plasma cell neoplasms usually lack B-cell markers and are $CD138^+$ and typically demonstrate light chain class restriction. Monomorphic B-cell PTLDs often demonstrate abnormalities of

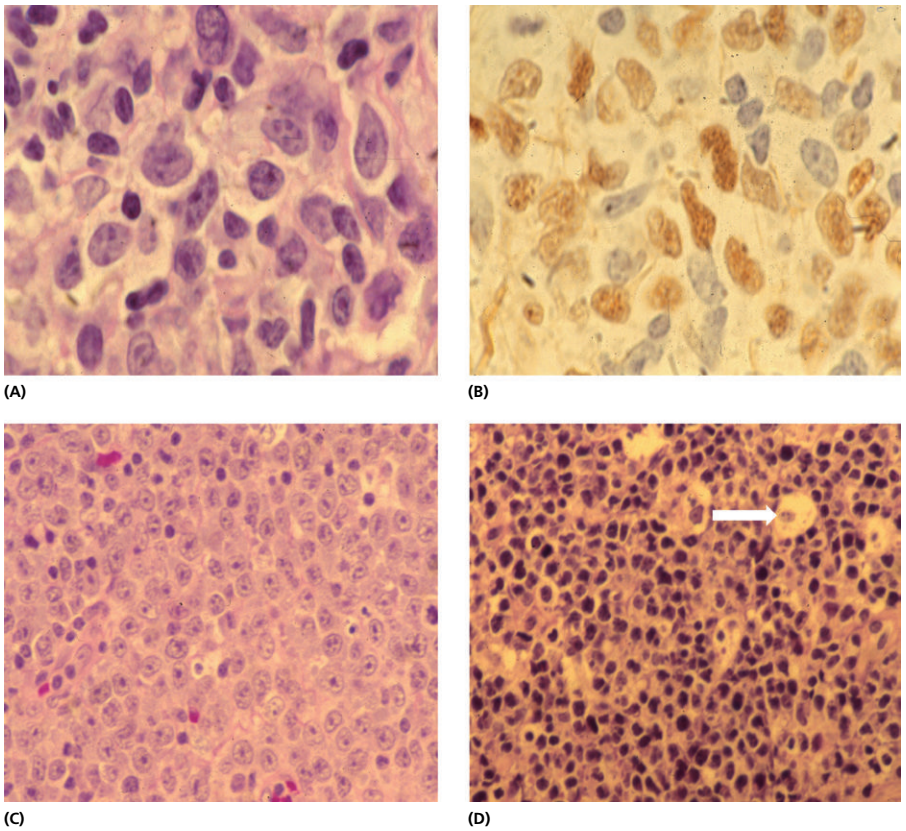

Figure 96.1. Histology of post-transplant lymphoproliferative disorders (PTLD). (A,B) Polymorphic PTLD.(A) Shows significant pleomorphism of these lesions, as well as the presence of numerous abnormal transformed cells. (B) Shows positive staining for non-coding Epstein–Barr virus (EBV) RNAs (EBERs) by immunohistochemistry, indicating the presence of latent EBV (dark brown appearance) in many cells from the lesion shown in (A). (C) Shows a monomorphic PTLD. There is a high degree of cellular monotony in this lesion. (D) Shows another monomorphic PTLD demonstrating the typical features of Burkitt's disease. The so-called starry sky appearance represents areas of macrophage ingestion of dying cells (arrow).

tumor suppressor genes (e.g. *TP53*), oncogenes (*N-RAS*), and sometimes *BCL6* mutations. Translocations such as of *MYC* are a typical feature of Burkitt's lymphomas [7]. Other cytogenetic abnormalities are relatively common.

Monomorphic T-cell PTLDs fulfill the WHO criteria for one of the T-cell neoplasms and in contrast to DLBCL, are not typically composed of monomorphic large transformed cells. Most commonly, they resemble peripheral T-cell lymphoma. The histopathology for the T-cell PTLD is very variable as is seen among T-cell lymphomas in the immunocompetent host. Because many T-cell lymphomas appear heterogeneous, confusion with reactive lesions and polymorphic PTLD may occur. Immunophenotypic studies are critical to the diagnosis. Molecular studies help identify clonal T-cell populations. Occasionally, lymphomas of NK cells are observed.

Classical Hodgkin's lymphoma

Rarely post-transplant cases of classical Hodgkin's lymphoma are observed in the transplant population. These lesions fulfill the same criteria as those for classical Hodgkin lymphoma in immunocompetent hosts. Most cases in the transplant setting fulfil the criteria for the mixed cellularity type and most are EBV positive. As mentioned earlier, cells resembling Reed–Sternberg cells are seen in many different types of PTLD including polymorphic lesions. Although some groups have described "Hodgkin-like" PTLD [20], these are not included with the classical Hodgkin's type PTLD within the WHO classification [7].

Epidemiology

The epidemiology of PTLD has recently been reviewed by Dharnidharka et al. [21]. This section focuses on the incidence/prevalence of PTLD and the risk factors for its development.

Incidence

The risk of PTLD is highest in the first year after transplantation, yet the patient remains at risk indefinitely while under iatrogenic immunosuppression [22]. The time to PTLD varies with age, organ transplanted, and donor/recipient EBV status, among other factors. There has been a trend to earlier onset with more potent immunosuppressive regimens and disease tends to be earlier in children, especially those who are EBV naïve at transplant and receive organs from EBV-positive donors [22]. Early-onset disease is more likely to be polymorphic, of B-cell origin, and EBV positive, at least in children [23].

The frequency of occurrence in any series will depend on post-operative survival and length of follow-up, as well as on case definition. Patients dying soon after transplant are "at risk" for only a very short period. Some reports have, therefore, quoted the frequency among 30-day survivors. Most reports appear to exclude so-called "early lesions" and report only destructive forms of disease. The following cumulative percentage "incidences" have been reported for pediatric recipients at 5 years post transplantation: kidney 3%, heart 5%, liver 6%, and lung 11% [21]. Among adult recipients, the 5-year cumulative risk is nearer to 1% [24], but appears to be slightly higher for both liver and lung (2–4%) [21].

More appropriate methods of analysis for time-related events with variable follow-up include incidence density or "survival analysis" techniques. The latter is particularly helpful when the hazard for disease development is continuously changing. In a recent study, the incidence and hazard for PTLD were evaluated for 3170 primary heart transplants performed between 1993 and 2009 at 35 pediatric programs [22]. PTLD was documented in 147 pediatric recipients with freedom from PTLD of 98.5% at 1 year, 94% at 5 years, and 90% at 10 years after transplantation (Figure 96.2). The overall risk for PTLD declined in the most recent transplant era (2001–2009). This is in keeping with the impression (unproven at this time) of many pediatric transplant physicians that viral load monitoring and other preventive strategies may be reducing the burden of early PTLD. However, the Pediatric Heart Transplant Study (PHTS) dataset demonstrates a worrying phenomenon [22]; the increasing hazard for late-onset PTLD in very long-term follow-up (Figure 96.2). These late PTLDs are more likely to be monomorphic in nature and include very aggressive lesions such as Burkitt's disease [25,26].

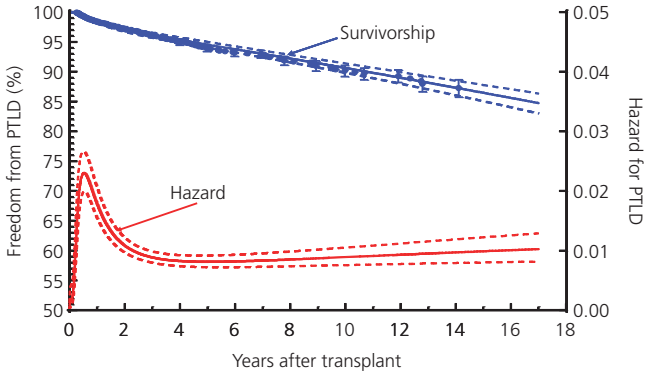

Figure 96.2. Freedom from post-transplant lymphoproliferative disorders (PTLD) in the Pediatric Heart Transplant Study (1993–2009). Note the high initial hazard for disease in the first year, followed by a second phase of slowly rising hazard late out from transplantation. (Modified from Chinnock et al. [22], with permission from John Wiley & Sons.)

Risk factors

Many different risk factors for PTLD development have been described [21]. These include infection-related factors (notably recipient and donor EBV serostatus), host-related factors such as age, primary disease-related factors, and intensity and types of immunosuppression. EBV status is probably the single strongest risk factor and has most influence in pediatric transplantation, since a much higher proportion of these recipients are naïve to this virus at the time of transplant. Positive donor EBV status was a very strong risk factor for PTLD in the seronegative recipients in the PHTS [22], but with the magnitude of the risk being dependent on recipient age at the time of transplantation. Nearly 25% of EBV-seronegative recipients aged 4–7 years at transplant with EBV-positive donors developed PTLD. In some series, cytomegalovirus (CMV) co-infection is also a risk factor [27]. Among host risk factors, beyond age, Dharnidharka et al. demonstrated that male gender and Caucasian race were risk factors among children receiving kidney transplants followed within the United Network for Organ Sharing (UNOS)/Organ Procurement and Transplantation Network (OPTN) and North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) registries [28].

Many studies have focused on the impact of various immunosuppressive regimens as risk factors for PTLD. Few of these were randomized trials, and it has been very difficult to ascertain whether specific drugs are especially guilty in this regard, or whether the risk primarily relates to global intensity of immunosuppression,

especially that targeting T-cell immunity (the primary mechanism of surveillance of EBV-infected B cells; see above). PTLD was observed in the azathioprine-steroid era, but there was an increase in the number of reports that followed the introduction of cyclosporine [6]. OKT3 was also implicated as a specific risk factor by Swinnen et al. at the end of the 1980s [29]. Several reports emphasize the complexity of placing blame on specific agents. In a recent randomized trial of steroid withdrawal after pediatric kidney transplant, patients received basiliximab induction, calcineurin inhibitor (CNI), sirolimus, and corticosteroids. PTLD developed in an unacceptably high 6.9% of patients [30]. These data do not provide support for "blame" of a specific agent, but simply tell us that the total immunosuppression burden in this population was too high. Since the original report by Swinnen et al. [29], there has been concern that T-cell–depleting antibodies might be associated with increased incidence of PTLD. In an analysis of the Scientific Registry of Transplant Recipients (SRTR), Kirk et al. examined the use of depletional induction in kidney transplant recipients, demonstrating that both OKT3 and polyclonal rabbit antithymocyte globulin were associated with an increased risk of PTLD, while non-depleting induction with interleukin (IL)-2-receptor–specific agents was not, compared to patients without induction therapy [31]. Interestingly, the use of the depleting agent alemtuzumab was not associated with an increased risk of PTLD, perhaps reflecting lower levels of maintenance therapy associated with the practice patterns of this agent, e.g. steroid avoidance and lower CNI target levels, or the fact that alemtuzumab depletes both T and B cells, and thus may eliminate some of the latent EBV reservoir concomitant with the T-cell depletion. Finally, it should be noted that belatacept usage has been associated with an increased rate of PTLD development in EBV-seronegative adults after kidney transplantation, leading to specific exclusion of EBV-naïve patients [32]. Longer-term follow-up and experience in other populations will be required to understand the full implications of this observation.

Prevention of Epstein–Barr virus-associated post-transplant lymphoproliferative disorders

The importance of EBV infections in PTLD has led to an interest in the prevention of EBV disease. Potential approaches to the prevention of EBV disease can be categorized as immunoprophylaxis, chemoprophylaxis, and pre-emptive therapeutic strategies.

Immunoprophylaxis

Immunoprophylaxis can be categorized as active or passive. Active immunoprophylaxis would be accomplished through the use of an EBV vaccine. Immunization of all EBV-seronegative recipients with an effective vaccine prior to transplantation would likely dramatically reduce the risk of EBV disease and PTLD following transplantation. Unfortunately, progress in the development of an EBV vaccine has been limited, making availability of an effective vaccine unlikely in the near future [33–35]. Passive immunoprophylaxis is accomplished by providing anti-EBV antibody through the infusion of intravenous immunoglobulin (IVIG). A protective effect of IVIG against the development of EBV disease has been demonstrated in a severe combined immunodeficiency (SCID) mouse model [36,37]. These experimental data supported initiation of a multicenter, randomized, controlled trial in EBV-seronegative pediatric liver transplant recipients [38]. Although statistically significant differences were not observed, the study demonstrated a trend towards decreased rates of EBV disease and PTLD in patients receiving CMV-IVIG compared to those receiving placebo. The absence of a statistically significant effect of CMV-IVIG in this study may have been due to limitations of sample size, a lack of efficacy of the drug, or the confounding effect of pre-emptive reductions in immunosuppression based upon the presence of an elevated EBV load following introduction of polymerase chain reaction (PCR) assays in the later years of this study. Finally, the use of EBV-specific cytotoxic T lymphocytes as adoptive immunotherapy could serve as a third potential immunoprophylactic strategy. Unfortunately, although this approach has been proven to be efficacious in stem cell transplant recipients, efforts to translate these benefits to the prevention of EBV disease and PTLD in SOT recipients have not been fully realized at this time [39].

Chemoprophylaxis

Chemoprophylaxis, using antiviral agents such as acyclovir and ganciclovir, is another possible approach to the prevention of EBV disease and PTLD. Both acyclovir and ganciclovir actively inhibit lytic EBV replication in vitro, but neither agent has any effect on EBV in its latent state or on the proliferation of EBV-transformed B cells. Accordingly, if EBV disease progression is dependent upon expansion of EBV immortalized B cells independent of the lytic phase of EBV replication, the use of ganciclovir or acyclovir is unlikely to effectively prevent the development of EBV disease. Unfortunately, only limited clinical evidence is available to address the efficacy of antiviral therapy in the prevention of EBV/PTLD in humans. Published reports supporting the potential efficacy of antiviral agents have been largely retrospective or lacking in appropriate control groups [40,41]. Other reports have attempted to address the potential efficacy of antiviral therapy in the prevention of EBV disease through analyses of large registries [42,43]. Results from these two studies were contradictory, with Funch et al. concluding that antiviral therapy appeared to prevent EBV disease [42], while Opelz et al. found no protective benefit associated with the use of antiviral therapy [43].

To date, only a single randomized controlled trial has been completed evaluating the role of antiviral agents in the prevention of EBV/PTLD [44]. This randomized trial compared 2 weeks of intravenous ganciclovir alone to 2 weeks of ganciclovir followed by 50 weeks of high-dose oral acyclovir in pediatric liver transplant recipients. No difference was observed between the study arms. This suggests that the prolonged use of acyclovir did not prevent EBV/PTLD. It is possible that prolonged use of the more potent ganciclovir might have resulted in a different outcome; however, it is of interest to note that development of PTLD has been observed in patients while receiving prolonged courses of intravenous ganciclovir [45].

Viral load monitoring and pre-emptive strategies of prevention

Surveillance monitoring of EBV loads to inform pre-emptive reductions in immunosuppression has resulted in a decreased incidence of EBV disease and PTLD compared to historical controls. McDiarmid et al. reported a decreased incidence of PTLD from 10% to 5% using EBV viral load monitoring to guide the combined use of reduced immunosuppression and intravenous ganciclovir in pediatric liver transplant recipients with rising EBV loads [41]. Using decreased immunosuppression alone without ganciclovir in response to elevated EBV loads, Lee et al. noted a decline in the incidence of PTLD from 16% to 2% in a group of pediatric liver

transplant recipients when compared to historical controls [46]. Ganschow et al. also showed that lowering immunosuppression in response to results of frequent viral load monitoring was associated with low rates of PTLD in pediatric kidney transplant recipients (0.9%) [47].

More recently, Martin et al. explored the use of EBV load monitoring to inform the pre-emptive use of the anti-CD20 monoclonal antibody, rituximab, in EBV donor-positive/recipient-negative adult kidney transplant recipients who developed symptoms or persistent EBV viremia [48]. Although the authors suggested an efficacious effect of this strategy, given its small size, the relatively short period of observation prior to the use of rituximab and the concomitant reduction of immunosuppression, additional experience is needed to confirm these results. There are no randomized trials to establish the role of rituximab in PTLD prevention at this time.

Clinical presentation and diagnosis

EBV infection is associated with a wide range of disease manifestations in organ transplant recipients [1]. The spectrum of clinical disease ranges from a non-specific viral syndrome to PTLD. It is important to note that significant overlap exists in clinical manifestations of patients with EBV disease independent of whether or not they are subsequently shown to have PTLD. Similarly, patients presenting with EBV-negative PTLD may manifest clinical symptoms that are indistinguishable from EBV-associated disease.

The diagnosis of PTLD (and EBV disease) is based on clinical history and physical examination in combination with laboratory confirmation (Table 96.2). The most important factor in making this diagnosis is maintenance of a high index of suspicion at all times. In contrast to early experiences with PTLD, increased awareness and improved diagnostic tools have made presentation of PTLD in critically ill patients with disseminated disease much less common. To achieve earlier diagnosis, attention must be paid to more subtle symptoms of lethargy, malaise, weight loss, and fever, which have become more common presentations of PTLD. An additional history of vomiting and/or diarrhea (which may be guaiac positive) is suggestive of gastrointestinal involvement, which has been increasingly recognized to be a common site of disease.

Table 96.2. Diagnostic evaluation of patient with suspected post-transplant lymphoproliferative disorders

Routine	Selected patients
CBC, platelets, WBC with differential	GI endoscopy
Serum electrolytes, calcium, BUN, and creatinine	Bone scan
Liver function tests	Bone marrow biopsy
Uric acid	Brain CT/MRI
Lactate dehydrogenase	Lumbar puncture
Quantitative immunoglobulins	Screen for co-morbid infection
Serum protein electrophoresis	PET scan
EBV serologies	
EBV viral load by quantitative PCR	
Stools for occult bleeding	
Chest radiograph (AP and lateral)	
CT scan of chest/abdomen/pelvis	
Core needle or excisional biopsy of lesion(s)	

GI, gastrointestinal; WBC, white blood count; EBV, Epstein–Barr virus; AP, anteroposterior; PCR, polymerase chain reaction.

This is especially true in intestinal transplant recipients, nearly all of whom present with involvement of either the transplanted intestinal allograft or their native intestine. Intestinal hemorrhage, obstruction, and perforation may also be seen in patients with intestinal PTLD. Surprisingly, the highest risk period for the latter may be during therapy when necrosis of transmural lesions may develop.

Additional sites of involvement vary with the type of organ transplant received. Pulmonary disease is very common in cardiac recipients and is almost invariably present in lung recipients. Pulmonary presentation ranges from asymptomatic nodule(s) on a routine chest radiograph to life-threatening pulmonary dysfunction in the lung allograft. The latter may resemble lung rejection on a chest radiograph with rather diffuse consolidation without clearly defined mass lesions. This may lead to inadvertent augmentation of immunosuppression with severe consequences [49]. Involvement of the liver with EBV disease and PTLD is seen most frequently in liver transplant recipients. Disease may present as a diffuse hepatitis or with nodular lesions of the liver. Interestingly, the heart is the only organ transplant in which there is no strong tendency for the disease to involve the allograft. In most other SOTs, allograft dysfunction may be a manifestation of PTLD and may mimic acute or chronic rejection.

Other presentations include persistent sore throat, adenopathy, and cutaneous nodules, as well as seizures, headaches, and focal neurologic lesions with central nervous system (CNS) disease. PTLD is also sometimes diagnosed following elective removal of enlarged tonsils and adenoids in children. Thus, all surgically removed adenoid and tonsilar tissue should receive pathologic evaluation in the transplant recipient.

Although physical examination may not reveal specific findings, there will frequently be evidence of pallor, weight loss, peripheral adenopathy, or hepatosplenomegaly. A full physical examination is essential and should include thorough neurologic examination. Examination of the entire skin and sites of all lymph nodes is warranted. Careful examination of the oropharynx is required.

An overview of the laboratory evaluation for the diagnosis of PTLD is given in Table 96.2. Initial evaluation should include a complete blood count with white cell differential and platelets. Leukopenia, often in association with atypical lymphocytosis, and thrombocytopenia are frequent findings. Anemia is common and may be normocytic and normochromic or may demonstrate findings of iron deficiency when occult gastrointestinal bleeding is present. Rarely, evidence of hemolytic anemia may also be present. Stools should be tested for blood. End-organ function (liver, kidney) should be evaluated. Elevations in uric acid and lactate dehydrogenase are common and should also be sought on blood chemistry testing. Immunoglobulin levels may be elevated. This is particularly true of IgE, perhaps due to a Th2-predominant cytokine environment that may be present with PTLD. Some centers also routinely perform serum protein electrophoresis to look for evidence of monoclonal gammopathy. Although many patients do not demonstrate a monoclonal or oligoclonal gammopathy, if present, this provides an additional means of following the patient's response to therapy.

A variety of imaging tests are helpful in the evaluation of the transplant recipient with suspected PTLD. A chest radiograph often reveals evidence of pulmonary nodular disease and/or of mediastinal lymphadenopathy. The most informative diagnostic study is usually contrast-enhanced CT evaluation of the chest, abdomen, and pelvis. Evidence of nodal or extranodal disease will

frequently be apparent on CT at one or more sites. In the chest, small pulmonary nodules or enlarged mediastinal lymph nodes may be apparent even in the presence of a normal chest radiograph. In the abdomen, disease may be found at normal lymph node sites, within the gastrointestinal tract, or at extranodal sites, including the liver, spleen, and kidneys. Some centers routinely perform CT or magnetic resonance imaging of the brain. These studies should always be performed if there is any clinical suggestion of CNS disease.

The potential role of positron emission tomography (PET) with ^{18}F-fluorodeoxyglucose (FDG) in the diagnosis and assessment of clinical response to treatment of PTLD has gained increasing attention [50]. Potential advantages over routine CT scanning include enhanced sensitivity to detect lesions at the time of diagnosis, as well as the ability of PET scans to potentially differentiate between viable tumor and residual necrotic or fibrotic lesions on follow-up during or after completion of therapy. Additional experience is needed to determine whether routine use of PET scanning will result in improved clinical outcomes.

Other studies performed on selected patients as directed by the clinical findings are shown in Table 96.2. Upper and/or lower gastrointestinal endoscopy should be performed when there are gastrointestinal symptoms or evidence of occult gastrointestinal bleeding. Lumbar puncture should be performed when there is evidence of CNS disease. Bone marrow evaluation should be performed when there is evidence of bone marrow failure and in the presence of monomorphic disease before commencement of therapy. It is less clear that this needs to be performed in patients with early lesions or polymorphic disease (mostly pediatric patients).

Measurement of EBV viral load in the peripheral blood with PCR has been evaluated as a diagnostic tool for patients with symptomatic EBV disease including PTLD [10,11,48,51,52]. A growing experience suggests elevated EBV viral loads will be present in the vast majority of children with EBV-associated PTLD as well as many adults. This is most apparent when EBV-driven PTLD develops in the recipient who is EBV seronegative at the time of transplantation. It is important to note that the height of the EBV viral load is often comparable among patients with EBV-associated viral syndromes and those with PTLD. In addition, viral loads may be elevated in the absence of active disease, with some patients becoming chronic high load carriers after asymptomatic primary EBV infection [25]. Thus, while measurement of the EBV viral load is a useful screening procedure for suspected EBV disease, the test lacks specificity and it cannot replace histologic examination of suspected sites of involvement when the diagnosis of PTLD is contemplated. Finally, clinicians should not rely on serologic tests to make the diagnosis of PTLD as many patients will have positive EBV titers on the basis of passive immunization from blood products (or of maternal origin in infant recipients) and others may seroconvert without manifesting any clinical symptoms. In addition, the immunosuppressive agents used in transplant recipients might result in some patients having falsely negative serologic results.

Treatment

Despite a growing understanding of the pathophysiology of PTLD, its optimal management remains controversial. There is an increasing armamentarium of treatments available to the clinician, but with little evidence base to define how and when to use these treatments, or how best to combine therapies. Of note, no pivotal randomized trials of any form of therapy have been performed. The choice of therapy is often arbitrary, e.g. institutional preference, but may also be driven by predictive factors (real or perceived) such as pathologic findings, age at onset, organ transplanted, disease stage, presence or absence of EBV, co-morbid conditions, and prior rejection history.

The optimal treatment regimen for PTLD is one that rapidly eradicates the disease, does not increase the risk of allograft rejection (acute or chronic), and is simple to give, cost-effective, and associated with minimal adverse events. It is apparent that no single treatment fulfills all these criteria. Furthermore, the treatment must be geared to the individual patient, since the appropriate treatment for severe PTLD in a lung recipient early after transplant with adverse rejection profile, for example, is likely to be very different from that for a renal recipient with benign rejection history late out from transplant. These considerations underscore the enormous challenges involved in designing clinical trials for a rare disease with such clinical heterogeneity. Clinical response is also likely to depend on intrinsic characteristics of the tumor, such as rate of mitosis, presence of oncogenes, presence or absence of EBV, and the ability to be controlled by reconstitution of T-cell immune surveillance. Unfortunately, it is currently very hard to predict tumor behavior, even after extensive pathologic evaluation is completed.

Reduction of immunosuppression

In 1984, Starzl et al. reported the reversibility of PTLD by reduction of immunosuppression in cyclosporine-treated patients [8]. This strategy remains the initial therapy for most patients with early lesions or polymorphic disease in most centers. It is also used as first-line therapy in monomorphic disease by some groups (especially in children), although more often modern regimens include adjunctive therapies such as anti–B-cell monoclonal antibodies from time of diagnosis for this histology. Regardless, immunosuppressive reduction should be considered as a critical part of a response to PTLD. The goal of reduction (or cessation) of immunosuppression is to allow the host to recover natural immune surveillance and subsequently gain control over the proliferation of latent EBV-infected B cells. Reconstitution of immune surveillance may also be associated with resolution of EBV-negative PTLD, though this seems to occur with lower frequency [53]. The majority of PTLD in children (especially polymorphic lesions) will respond to reduction in immunosuppression, though with significant rates of rebound acute cellular rejection that may vary by organ [23,54]. The reported response rates of PTLD to reduction of immunosuppression among adults are highly variable, with acceptable results reported by some groups for low-risk patients [55] and very poor results by others [56,57]. These diverse outcomes may reflect differing referral patterns and patient characteristics, differences in range of pathology, e.g. proportion with polymorphic versus monomorphic disease, and perhaps differences in use of adjunctive therapies (such as antiviral agents) that are not always well described. As for children, rebound rejection rates in adults are significant and are an important cause of death after treatment of PTLD by reduced immunosuppression, especially after heart transplantation [56].

In general, most patients show evidence of clinical response within 2–4 weeks of reduction of immunosuppression, though a delayed response has been observed as long as several months in some patients. Complete responses to reduced immunosuppression

in DLBCL [53,57], post-transplant Hodgkin's disease, and other rarer PTLDs, e.g. T-cell lymphoma, are less likely, and if they do occur, are often incomplete or not durable. There is, therefore, increased reluctance to use reduction in immunosuppression as sole initial therapy for these histologies.

The approach to reduction in immunosuppression varies widely. Many groups initially hold CNIs and adjunctive antiproliferative agents, and maintain any corticosteroids that the patient might be receiving. Tacrolimus and cyclosporine levels may initially be high due to impaired hepatic metabolism. Subsequent practice varies widely. Among liver transplant programs, there is a tendency to withhold CNIs long term or even indefinitely [54]. This is unlikely to be possible in thoracic and intestinal transplantation. There has been considerable interest in replacing CNIs with inhibitors of the mammalian target of rapamycin (mTOR) once immunosuppression is reintroduced. Sirolimus has frequently been used in this setting. Interest in the use of this group of agents in PTLD, in part, reflects their antineoplastic properties, including inhibition of EBV-driven B-cell lymphomas. However, mTOR inhibitors are also potent T-cell inhibitors, so will impair T-cell immune surveillance. In the clinical setting, it is hard to know whether use of mTOR inhibitors is beneficial because they may suffice to prevent graft rejection (without the need for reintroduction of CNIs), or whether these agents are actually exhibiting anti-PTLD properties in vivo. Of note, patients managed with CNI-free immunosuppression, by using mTOR inhibitors, may still develop PTLD [58].

Surgery and radiation therapy

Excisional biopsy, generally performed for diagnostic purposes, may be curative for solitary PTLD lesions, but is usually combined with some reduction in immunosuppression. Thus, almost all patients receive a systemic approach to treatment and PTLD is probably best thought of as a systemic process. Surgery may also be indicated for management of local complications such as gastrointestinal hemorrhage, obstruction, or perforation.

Radiation therapy has a limited role in the management of PTLD, although many lesions will be responsive. It has been used when rapid local responses are required, e.g. when there is acute airway compression from tumor mass, or compression of other critical structures. It may also have a role in the treatment of some cases of CNS PTLD (see below).

Antiviral therapy

Initial interest in the role of antiviral chemotherapy for treatment of PTLD arose in 1982 when Hanto et al. described a patient whose EBV-associated PTLD lesion appeared to wax and wane in association with starting and stopping acyclovir [5]. As outlined above, both acyclovir and ganciclovir inhibit lytic EBV DNA replication in vitro and may be of value in treating the lytic phase of EBV infection. However, neither acts on latent infection or effectively treats proliferation of immortalized B cells; thus, the rationale for their use for the treatment of PTLD is far from clear. Nonetheless, use of these agents for the treatment of PTLD has become routine in many centers.

There has been progress in the development of other types of antiviral agents for the treatment of severe HHV infections, including those due to EBV [59,60]. Drugs that act independently of the viral enzyme target, thymidine kinase, may be particularly suitable candidates for investigation for the treatment of PTLD. Cidofovir has potential in this regard, but has important toxicities. Work suggests that lipid ester analogs of cidofovir and cyclic cidofovir may have much greater activity against EBV than the parent drug and may be suitable drugs for phase I clinical studies [60].

Another antiviral strategy is to induce EBV thymidine kinase in EBV-infected tumors, thus making the tumors sensitive to nucleoside-type antiviral agents such as ganciclovir. One agent that may achieve this goal is arginine butyrate. In a phase I/II clinical trial in 15 adults with refractory EBV-positive lymphoid tumors, continuous infusion of arginine butyrate along with standard doses of ganciclovir led to significant antitumor responses in two-thirds of patients [61]. More recently, it has been shown that short, discontinuous exposure to arginine butyrate (in contrast to continuous infusion) may suffice to initiate lytic phase EBV gene expression and thymidine kinase induction [62]. This therapy holds promise for patients with EBV-driven PTLD.

Interferon and other cytokines

The use of interferon (IFN) has been described in anecdotal reports as a therapeutic option in the management of PTLD [63,64]. IFN is both a proinflammatory cytokine and a natural antiviral agent, and appears capable of controlling proliferation of EBV-infected B cells. Since it is a non-specific immune stimulant, antidonor responses are often seen and severe rejection can develop during therapy. In a series of adult PTLD patients unresponsive to reduction in immunosuppression, only one of 13 (7%) achieved durable complete remission with IFN-α2b [57]. At the present time, most centers are not routinely using IFN in the management of PTLD.

IL-6 has been described as a growth factor for EBV-infected B cells. For this reason, an anti–IL-6 monoclonal antibody has been tested in a phase I/II clinical trial [65]. It was well tolerated and complete response was observed in approximately 40% of patients who had not responded to a brief period of reduction in immunosuppression. It is not currently used in routine clinical care.

As the biology of EBV-PTLD is further unraveled [12], more targets for biologic intervention are likely to be identified.

Intravenous immunoglobulin

A potential role for the use of IVIG for the treatment of PTLD has also been suggested. Several reports have documented an association between losses or absences of antibody against at least one of the EBNAs in EBV-infected organ recipients and the subsequent development of PTLD [66]. In addition, a correlation between increasing levels of anti-EBNA antibodies (including those introduced through transfusions) with a decrease in EBV viral load has been demonstrated. Taken together, these reports may provide a rationale for considering the use of antibodies in the prevention and/or treatment of EBV disease and PTLD, even though the primary mechanism for controlling EBV infection appears to be cytotoxic T-cell–mediated immunity. IVIG has been used alone and in combination with IFN-α as treatment for PTLD [64]. Both IVIG and CMV-IVIG have been used in the treatment of some patients with PTLD. As with the use of antiviral agents and IFN, there are no comparative trials evaluating the role of IVIG in general, or CMV-IVIG in particular, in the treatment of PTLD.

Anti–B-cell antibodies

Most PTLDs are of B-cell origin and most express CD20. The anti-CD20 human/mouse chimeric monoclonal antibody rituximab (Genentech Inc. and IDEC Pharmaceuticals) is currently commercially available for the treatment of certain $CD20^+$ B-cell non-Hodgkin's lymphomas in adult non-transplant recipients. In 2000,

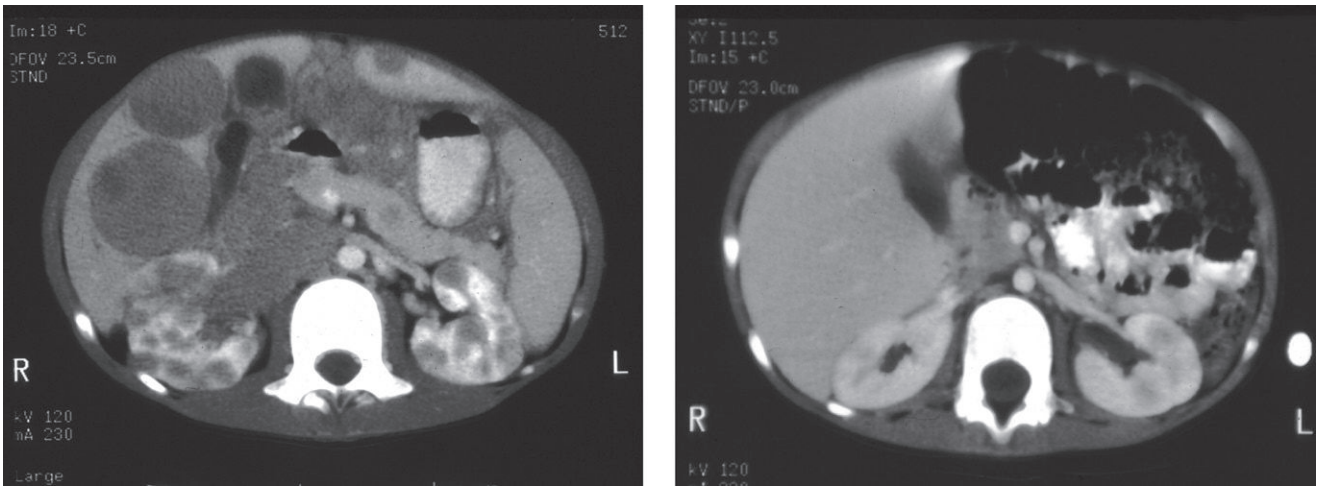

Figure 96.3. Burkitt's lymphoma in a pediatric heart transplant recipient. (A) There is diffuse disease throughout the abdomen, as well as disease in the jaw and orbit. (B) There was almost complete resolution of disease after two courses of chemotherapy. Sustained complete response was achieved. (Reproduced from Dharnidharka V, Green M, Webber SA (2010). Post-transplant lymphoproliferative disorders (figure 9.2), with kind permission from Springer Science+Business Media B.V. Copyright 2010, Springer–Verlag)

clinical investigators in France published a retrospective analysis of the use of rituximab in 32 patients with PTLD [67]. The overall response rate was 65% in SOT recipients, most of whom experienced long-term remission. However, relapse of PTLD developed in approximately 20% of responders a median of 7 months after completing their therapeutic course of rituximab. Several subsequent reports have emerged from single centers [53,68–70] and from multicenter phase II trials [71,72]. Overall response rates for adults vary significantly, with complete response rates ranging from 28% to 59% when rituximab is used as second-line therapy after failed reduction of immunosuppression [68,71,72]. However, late follow-up of a large series of 60 patients has revealed that 57% had progressive disease 1 year after completing treatment, with a median progression-free survival of only 6 months [73]. Despite the suboptimal results of rituximab in adults with PTLD, it has been pointed out that the drug is well tolerated, that a significant number will achieve durable complete responses without the need for chemotherapy, and those that do demonstrate progressive disease or relapse can still undergo chemotherapy [53]. Interestingly, rituximab may also be effective in some patients who have previously been treated with chemotherapy and have refractory or relapsed disease [74].

The results with rituximab may be superior in children, although less data are available to support this premise. In a small prospective multicenter phase II trial, 80% of children with refractory PTLD achieved complete response after four or eight doses, but with relapse in 25% [75].

There are several important questions regarding the use of rituximab in the transplant setting:

- Will the prolonged elimination of B cells result in additional opportunistic infections or other sequelae?
- Should rituximab be used in all patients at diagnosis, or only those who fail an initial period of reduced immunosuppression?
- If relapse occurs after the use of rituximab, how should management proceed?
- Is maintenance therapy every 6 months justified?
- Is the high relapse rate with rituximab due to use primarily in high-risk patients, i.e. those with refractory disease, or could therapy per se somehow be associated with subsequence risk of relapse?
- Are clinicians less aggressive in immunosuppression reduction when they use rituximab from the time of diagnosis?

It seems likely that durable remission cannot be achieved unless restitution of EBV-CTL responses is achieved [76]. Finally, it should be noted that there has been very little experience with newer radioconjugates of anti–B-cell antibodies (so-called radioimmunotherapy). Do these agents offer any advantage over rituximab and are they safe? Hopefully, ongoing and future studies will answer some of these important questions.

Chemotherapy

Chemotherapy is usually used as first-line treatment for aggressive post-transplant lymphomas such as Burkitt's disease (Figure 96.3) or T-cell lymphomas, and also for most cases of post-transplant classic Hodgkin's disease. As discussed earlier, it is unclear whether patients with monomorphic disease with histology of DLBCL should receive a trial of reduction in immunosuppression with or without rituximab, or whether they should receive chemotherapy as primary treatment. This is one of the most controversial areas in the current management of PTLD, with little evidence base to guide therapy.

Pediatric patients with refractory polymorphic PTLD have quite high initial response rates to "low-dose" chemotherapy with cyclophosphamide and prednisone, though 2-year event-free survival is suboptimal at around 58% [77]. The addition of rituximab to this regimen has also recently been studied [78]. It is unclear whether chemotherapy has a role before a trial of rituximab has been completed, since rituximab alone has given encouraging results in pediatric refractory disease [75]. Low-dose chemotherapy has not been compared directly to rituximab in children failing to respond to reduced immunosuppression. Chemotherapy should be given to children with progressive disease on rituximab, and is also useful for the rare cases of active PTLD with concomitant allograft rejection. Burkitt's disease in children and adults responds well to multidrug chemotherapy regimens (with or without rituximab; Figure 96.3), though the optimal regimen

remains to be defined [26,79,80]. We do not recommend rituximab alone for this condition.

The indications for chemotherapy in adults are broadly similar to those in children. Centers are divided on whether DLBCL (the most common pathology in adults) should be treated primarily with chemotherapy, or only after failure to respond to reduced immunosuppression and rituximab. Chemotherapy will generally protect the graft against rejection and impaired graft function [81], but is associated with higher infectious morbidity and mortality than comparable regimens used in the non-transplant setting [53]. Multiple different chemotherapeutic regimens have been used including cyclophosphamide-prednisone (with or without rituximab), "CHOP," "CHOP–rituximab," "ACVBP," and "ProMACE-CytaBOM" [53,57,77–86]. None has been directly compared to each other in controlled trials. Overall response rates are of the order of 65–80%, though late mortality appears to be significant [87].

Cellular immunotherapy

Inadequate EBV-specific T-cell responses are an important, if not critical, pathologic step in the development of EBV-driven PTLD, though other mechanisms may contribute. Infusion of EBV-specific CTLs has been employed both as treatment and prophylaxis against PTLD in bone marrow/stem cell transplantation [88]. In this setting, the PTLD are generally of donor origin, and the donor is usually available to provide a source of CTLs for the recipient. The success of this adoptive immunotherapy in stem cell recipients has stimulated investigation into applying this approach as a therapy for PTLD in SOT recipients [89]. This is a logical therapy as it is directed against the PTLD and should, in theory, cause little anti-donor response, i.e. rejection. However, the use of CTL infusions in solid organ recipients is made more difficult by the fact that the EBV-infected cells within PTLD lesions are typically of recipient origin. EBV-specific CTLs should ideally be HLA haplo-identical. For this reason, autologous CTLs are the obvious source for the development of EBV-specific CTL infusions for SOT recipients. However, the development of EBV-specific CTLs from organ recipients is challenging since most patients at risk for EBV-PTLD are EBV naïve at transplant, CTL generation is impaired by the presence of immunosuppression, and T-cell responses are further severely suppressed at the time of development of PTLD. Accordingly, techniques for adoptive immunotherapy of EBV-associated PTLD in SOT recipients have focused on developing strategies to "immunize" and stimulate the organ recipient's own T cells against EBV ex vivo and then subsequently infusing these EBV-specific CTLs back into the recipient at a time when the patient develops refractory EBV infection/PTLD [39,89,90]. Such an approach could also be used for prevention, with infusion performed when EBV viral loads start to climb after primary post-transplant EBV infection [39]. Ideally, the cells for culture should be obtained prior to transplantation and the initiation of immunosuppression in high-risk recipients (EBV seronegative at transplantation). Such an approach is expensive and labor intensive, as most candidates will never require CTL therapy. Furthermore, at this time, the success of adoptive immunotherapy using autologous CTLs after SOT has not paralleled that seen after bone marrow/stem cell transplantation. An alternative approach that has met with some success is the use of allogeneic T-cell infusions from EBV-positive blood donors who are as closely matched as possible to the recipient's HLA type. Success in about 50% of patients was observed in a phase II clinical trial using this approach [91]. While the use of adoptive immunotherapy represents an exciting advance in the management of PTLD after SOT, it remains a research tool at this time, limited to a very small number of SOT centers that offer cell-based therapies. Current research is focusing on the optimal strategy for developing ex-vivo cultures with high cytotoxicity against EBV-infected target cells. The nature of the stimulating cells, e.g. lymphoblastoid cell lines or dendritic cells loaded with EBV antigens, and the cytokine milieu of the culture, e.g. addition of IL-7 and IL-12, may be critical determinants in the success of development of ex-vivo generated CTL bulk cultures for clinical infusion [92,93].

Role of combination therapies

Since no therapies have been tested in large randomized controlled trials, it is evident that the use of combination therapies is also not evidence based. Nonetheless, as with other diseases, there may be logic in combining therapies that work by different mechanisms of action. The use of combination therapies also makes it very challenging to identify the efficacious components of a treatment regimen. For example, autologous EBV-specific CTLs immediately following polychemotherapy have been used successfully combined with rituximab [90]. Combination therapies are likely to remain largely empiric given the enormous challenges of performing randomized controlled trials in this disease.

Central nervous system disease

CNS disease may be primary [94,95] or may be an additional site of disease in patients with extracranial disease [94]. Disease is frequently multifocal, and may occur at any site, though is most commonly seen in the cerebral hemispheres [96]. Almost all lesions show contrast enhancement. The differential diagnosis includes other malignancies and infection, especially fungal. Biopsy is generally warranted to ensure the correct diagnosis. Prognosis has generally been considered to be very poor [94,95]. The CNS is generally considered a protected site in which it is harder for normal immune surveillance to gain control of disease. Nonetheless, normal immune surveillance may be sufficient to control disease in rare cases (Figure 96.4). Unfortunately, this occurs with insufficient frequency to justify reduction in immunosuppression as the only therapy. In renal transplant patients, complete cessation of immunosuppressive therapy seems justified until disease is eradicated. Adjunctive therapies are generally given, though their efficacy has been hard to establish. These have included systemic or intrathecal rituximab, chemotherapy (especially with use of high-dose methotrexate), and radiation.

Prognosis and outcome

Outcomes after PTLD are highly variable, and pooled estimates of graft and patient survival across age groups, e.g. pediatric versus adult, and across organ transplant types provide little useful information to guide the physician in individual patient management. When specific populations are studied, it is clear that PTLD does have a significant negative impact on long-term graft and patient outcomes [23]. Furthermore, death due to progressive disease is not necessarily the dominant force in determining outcome, with acute and chronic rejection being important determinants of outcome after diagnosis of PTLD [23]. Thus, therapeutic strategies must attempt to protect the graft during reduced immunosuppression as well as effectively treat the PTLD [81].

Factors predicting outcome have recently been reviewed [97] and are also the topic of several recent reports [98–100]. In many series,

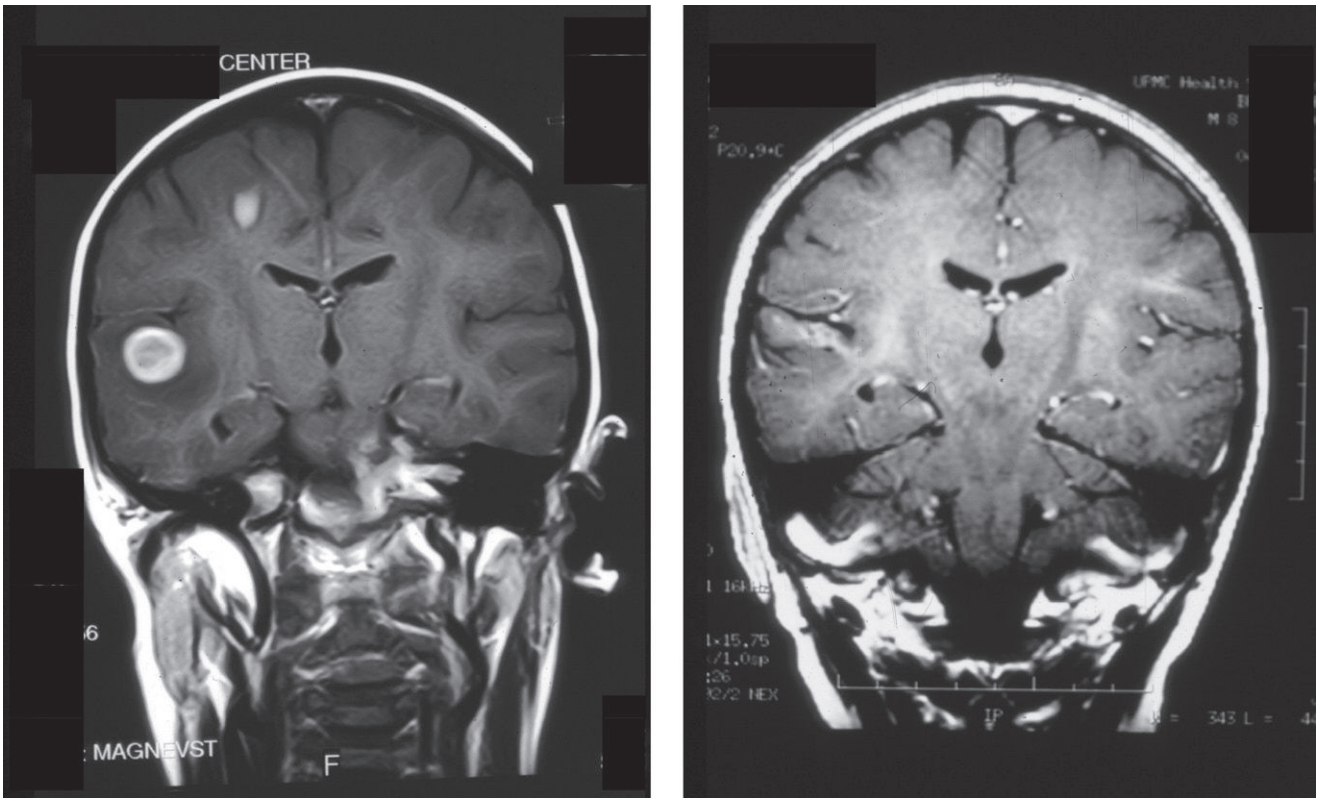

Figure 96.4. (A) Central nervous system monomorphic post-transplant lymphoproliferative disorder (PTLD) presenting with sixth nerve palsy and multiple contrast-enhancing space-occupying lesions (panel A). (B) There was complete resolution of disease after temporary withholding of immunosuppression. (Reproduced from Dharnidharka V, Green M, Webber SA (2010). Post-transplant lymphoproliferative disorders (figure 9.3), with kind permission from Springer Science+Business Media B.V. Copyright 2010, Springer–Verlag).

poor prognostic factors are similar to those for traditional non-Hodgkin's lymphomas in the non-transplant setting and include poor performance index, multifocal disease, bone marrow involvement, and increased age [97,100]. T-cell PTLDs and CNS PTLD are also associated with poor prognosis in most series, though recent data suggest that aggressive therapy can result in sustained remissions in some patients with CNS disease [96]. There is less consistency among series that monomorphic histology, absence of EBV, or late-onset disease are adverse prognostic factors. In the future, it seems likely that a more detailed understanding of the biology and molecular pathology of PTLD will improve our understanding of disease behavior and lead to individualized therapies [101]. Central to this goal is the understanding that PTLDs are a heterogeneous group of disorders clumped together under a common label and it is therefore unlikely that one optimal therapy will be appropriate for all PTLDs. Encouragingly, recent data suggest that new therapies may be modifying disease outcomes with evidence of improving survival in the current era [98].

Summary

PTLD continues to be an important potentially mortal condition in organ transplant recipients. Its association with EBV biology has provided important insights regarding the effects of immunosuppression on viral-driven malignancy, and has helped shape recognition of its clinical risk factors and the development of regimens for its treatment. Consensus has been reached on the classification of PTLD and this classification directs clinical therapy. Improvements in early diagnosis and treatment have been realized, but PTLD continues to contribute to post-transplant morbidity and mortality, especially in pediatric transplant recipients, and EBV-naïve recipients of organs from EBV-seropositive donors. Cognizance of the EBV status of all transplant patients is important and should be incorporated into the clinical routine of transplant clinicians.

Introduction

Transplantation is the preferred therapeutic option for many patients with end-stage organ failure. The first successful human kidney transplant took place in December 1954 [1]. However, it was not until the 1960s that immunosuppression became available and not until the 1980s, with the introduction of cyclosporine, that consistently acceptable graft and patient survival was achieved (see Chapter 1). With the restoration of organ function, patients experience an overall improvement in their health, increased libido, and return of fertility. It is thus a natural consequence of successful transplantation that transplant recipients desire the same opportunities for parenthood as the general public, and indeed, one of the clearest measures of the success of transplantation in general, is the capacity for patients to experience this fundamental life goal. The first post-transplant pregnancy occurred in March 1958 and was reported in 1963 [2]. It occurred in a patient who had received a kidney from her identical twin. This pregnancy resulted in the cesarean delivery of a healthy boy.

As transplantation has improved, pregnancies have been reported in recipients of each organ type, though most outcomes reported are in kidney transplant recipients [3–10]. While successful pregnancy is possible, it is not without significant differences compared to a low-risk pregnancy in the general population. Issues that must be considered include maternal graft function and maternal health, the immediate and long-term effects of pregnancy on graft function, and the effect of the medications and graft function on the developing fetus. There is also the question of whether more subtle and long-term effects, although not apparent at birth, might affect the growth and development of the offspring of these recipients or future generations [11,12].

In this chapter we will review the current recommendations for contraception, the available guidelines for prepregnancy and prenatal management, and the available pregnancy outcome data in the solid organ recipient groups.

Contraception for the transplant recipient

Female transplant recipients should use safe and effective contraception and plan for pregnancy if so desired. In spite of the risks of pregnancy, many transplant recipients are not counseled about the need for contraception nor use any form of birth control [13,14]. In two recent questionnaire studies in renal transplant recipients, one from Iran and one from China, 29.1% and 88.2% of pregnancies in transplant recipients were unwanted or unplanned, respectively [15,16]. Of note, in the Chinese study, 94% of women who did not become pregnant used a method of contraception, whereas only 56% of those who became pregnant did so. Most women who did not use contraception in this study were unaware that fertility is often restored after transplantation [16]. Data regarding contraception failure in western countries are surprisingly sparse.

Currently there are myriad contraceptive options in the US: estrogen-containing patches, rings, and pills; progesterone-only pills; implants and intrauterine devices (IUDs); emergency contraception; as well as various methods of barrier contraception and sterilization. Many of these methods have non-contraceptive benefits as well as specific risks and side-effects.

In 2010 the Centers for Disease Control and Prevention (CDC) published the first US Medical Eligibility Criteria for Contraceptive Use and "solid organ transplantation" was included as a condition for which recommendations were given. This condition was further subdivided into "complicated: graft failure (acute or chronic), rejection, cardiac allograft vasculopathy" and "uncomplicated." Each method was categorized as: 1 = there are no restrictions for use of this method; 2 = the advantages of using this method generally outweigh the theoretical or proven risks; 3 = the theoretical or proven risks generally outweigh the advantages of using this method; and 4 = there is an unacceptable health risk if the method is used [17]. Risk assignments were based on a thorough review of the literature as well as expert opinion. Risks of other co-morbidities such as hypertension and coagulopathy were also taken into

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Table 97.1. Benefits and risk of different contraceptive methods in transplant recipients

Method	Benefits	Problems	Issues related to transplant	CDC category uncomplicated*	CDC category complicated*
Copper T IUD	Most effective Long acting	Heavy menses	Macrophage-mediated action not affected by most immunosuppressants	2	3 (initiation) 2 (continuation)
Progestin IUD	Most effective Long acting Decreased anemia	Irregular bleeding		2	3 (initiation) 2 (continuation)
DMPA	Highly effective Decreased anemia	Decrease in BMD Irregular bleeding	Possible cholestatic effect	2	2
Progestin implant	Most effective Long acting No decrease in BMD	Irregular bleeding		2	2
Combined oral contraceptive (COC)	Decreased anemia Menstrual regulation		First-pass liver metabolism- Metabolized in liver; levels may be affected by immunosuppressants Contraindicated in uncontrolled hypertension, active liver disease, and history of myocardial infarction, stroke, or deep venous thrombosis May be used if stable organ function and no contraindication Gastrointestinal disturbance by some immunosuppressants may decrease absorption Possible hyperkalemia caused by some immunosuppressant precludes use of drospirenone containing COCs	2 (do not use in women with a history of Budd–Chiari syndrome)	4
Contraceptive patch	First-pass liver metabolism avoided	Higher circulating levels of estrogen	Contraindicated in uncontrolled hypertension, active liver disease, and history of myocardial infarction, stroke, or deep venous thrombosis May be used if stable organ function and no contraindication	2 (do not use in women with a history of Budd–Chiari syndrome)	4
Vaginal ring	Lower circulating estrogen First-pass liver metabolism avoided		Contraindicated in uncontrolled hypertension, active liver disease, and history of myocardial infarction, stroke, or deep venous thrombosis May be used if stable organ function and no contraindication	2 (do not use in women with a history of Budd–Chiari syndrome)	4
Progestin-only pill		Less effective than COCs	*First-pass liver metabolism	2	2
Condoms	Protects against sexually transmitted infections No drug interactions	Less effective		1	1
Cervical cap/ diaphragm	No drug interactions	Less effective		1	1
Emergency contraception	Effective after sexual intercourse	Not effective as ongoing method		1	1
Withdrawal (coitus interruptus)	No drug interactions	Least effective		N/A	N/A

*CDC categories briefly defined: 1, no restriction for use; 2, advantages of using the method outweigh the risks; 3, risks outweigh the advantages of using the method; 4, unacceptable risk.
IUD, intrauterine device; DMPA, depot medroxyprogesterone acetate; BMD, bone mineral density.

account. A summary of the findings is given in Table 97.1 and discussed below.

Estrogen-containing contraception

Estrogen-containing contraceptives such as the combined oral contraceptives (OCs), contraceptive patch, and vaginal ring are often avoided in transplant recipients due to perceived thrombotic risk as well as possible liver toxicity. These formulations are thought to have many benefits: decreased menstrual bleeding, anemia, dysmenorrhea, acne, hirsutism, as well as ovarian and endometrial cancer [18]. The main risks of these compounds are related to thrombogenesis and increase in blood pressure.

Combined OCs currently available in the US vary in estrogen and progesterone formulations and doses, but are mostly considered "low dose." The contraceptive patch generally achieves higher blood estradiol levels and may have a slightly higher risk of venous thromboembolism (VTE) than OCs [19]. This risk, however, is lower than the risk of VTE during pregnancy. The contraceptive ring results in lower circulating estrogen levels, and avoids the first-pass effect in the liver; thus, it may be associated with lower VTE risk, but this remains unproven [19].

Studies regarding estrogen-containing contraceptives in transplant recipients are limited to small case series and several case reports. There are two prospective cohort studies of kidney transplant recipients treated with low-dose OCs (26 women) or the contraceptive patch (ten women) [20]. One of the recipients developed a thrombophlebitis after 18 months of combined OC use and a second developed rejection associated with deterioration of liver function approximately 10 years after transplant. In these studies there were no significant changes in liver enzymes, cholesterol, serum creatinine, and glucose after 18 months of use. There was, however, an increase in glucose and creatinine (from 1.31 mg/dL to 1.47 mg/dL; $P < 0.01$) at 6 months. Several women in these series required modification of their antihypertensive medications for

proper blood pressure control [20]. There was a significant increase in hematocrit in both OC and patch users. In a retrospective study of 15 liver transplant recipients, there were no changes noted in liver function, glucose metabolism, blood pressure, or body mass index (BMI) with combined OC use [21]. A case report identifies a recipient who was given a high-dose OC to control menorrhagia and she developed cholestasis which resolved upon withdrawal of the combined OC [22]. The recent questionnaire study from China included 34 recipients who used combined OCs, four of whom had unwanted pregnancies [16].

Based on the data from these small studies as well as expert opinion, the CDC guidelines assign a category 4 for use of combined hormonal contraception in "complicated" solid organ transplantation (SOT) (i.e. the health risks for these patients with use of combined hormonal contraception are unacceptable) [17]. For "uncomplicated" SOT, the risk is category 2 (i.e. the benefits generally outweigh the theoretical or proven risks) [17]. Therefore, in recipients with stable organ function and well-controlled hypertension who otherwise do not have other contraindications to estrogen-containing compounds, it is reasonable to offer estrogen-containing contraception.

As with any systemic medication, there is concern that the estrogen-containing contraceptives theoretically could affect immunosuppressant levels and vice versa. Estrogen is metabolized in the liver and immunosuppressants may activate the cytochrome P450 3A4 system. Thus, these medications may in theory decrease circulating levels and the efficacy of combined OCs. Existing data, however, suggest that interactions are minor and combined OCs remain effective in transplant recipients [19]. In addition, combined OCs may affect levels of immunosuppressants, though this has not been studied [23]. Therefore, women who have undergone SOT and are treated with estrogen-containing contraceptives must be closely monitored for hypertension, side-effects, and changes in immunosuppressant levels.

Progesterone-only hormonal contraception

Progesterone-containing systemic contraception such as depot medroxyprogesterone acetate (DMPA), etonorgestrel implant, and progestin-only pills has often been advocated in patients with contraindications to estrogen therapy. These products use different types and doses of progesterone. The progestin-only pill is taken daily, may have higher failure rates, and undergoes a first-pass effect in the liver. DMPA can be administered subcutaneously or intramuscularly every 12 weeks. It is metabolized in the liver and should be avoided in women with active liver disease, but its metabolism does not appear to be affected by other drugs [19]. Studies revealing reversible bone density decreases with DMPA use and the increase in osteoporosis in transplant recipients suggest that bone mineral density may need to be monitored (see Chapter 100). In addition, DMPA is associated with a delay in return of fertility and thus may not be the best method for a woman who wants a future pregnancy. The implant is one of the most effective methods of contraception and has a similar benefit profile to that of DMPA. Additionally, the implant does not decrease bone mineral density [19].

To date there are no studies evaluating these progesterone-only methods in transplant recipients. The CDC guidelines assign a category 2 for all three of the progesterone contraceptives in both "complicated" and "uncomplicated" cases of SOT [17]. Therefore, these forms of contraception are considered safe in transplant recipients.

Intrauterine devices

Currently in the US, two IUDs are available: the copper IUD and the levonorgestrel (progesterone)-containing IUD (LNG-IUD). The copper IUD can be associated with increased menstrual bleeding and should not be used in patients with Wilson's disease. The LNG-IUD has been shown to significantly decrease menstrual bleeding and increase hemoglobin [24]. A case report of a kidney recipient treated with a LNG-IUD for fibroids and menorrhagia noted significant improvement in dysmenorrhea and menorrhagia after 1 year of use [25].

IUDs are one of the most effective methods of birth control and yet in a study of renal transplant recipients, only 5.2% were recommended the IUD post transplant [14]. Two case reports from 1981 of pregnancy in renal transplant patients using the copper IUD for contraception sparked the speculation that immunosuppressive agents decrease the effectiveness of IUDs, but the evidence suggests that macrophages play the most important role in the destruction of ova. Macrophage function is minimally affected by current immunosuppressants [19,26]. In addition, in the recent Chinese questionnaire study, none of the 178 women who used the IUD became pregnant. The type of IUD used by these women was not reported [16]. Another study evaluating the ease of insertion of IUDs included 12 transplant recipients who received the LNG-IUD; no pregnancies were reported in this study after 1 year [27].

Another concern regarding IUD use is the risk of infection. Although there are no studies evaluating infection with IUD use in transplant recipients, studies in women with human immunodeficiency virus (HIV)/autoimmune immunodeficiency syndrome (AIDS) reveal a low incidence of pelvic inflammatory disease [28].

The CDC guidelines distinguish between *initiation* and *continuation* of the IUD. For women with "uncomplicated" SOT, both the copper and the progesterone-coated IUDs are assigned a category 2 (i.e. the benefits of the IUD generally outweigh the risks) [17]. The same category is assigned to "complicated" cases of SOT if the woman is *continuing* with this method (i.e. it is not necessary to remove an IUD if the recipient develops rejection, organ failure, or cardiac vasculopathy) [17]. For recipients with "complicated" SOT, *initiation* of either IUD is assigned a category 3 (i.e. the theoretical or proven risks of a condition usually outweigh the advantages of using the method) [17].

Emergency contraception

There are several methods used for emergency contraception: progesterone-only pills, antiprogesterone pills, combined OCs, as well as insertion of a copper IUD. It is important to stress that the risk of combined OC and progesterone-only pills when used as emergency contraception are classified as category 1 in the CDC guidelines. There should be no restrictions for use of this method in SOT recipients [17]. This recommendation is based on expert opinion only as there are no reports in the literature of emergency contraception in transplant recipients.

Barrier methods, withdrawal, and sterilization

Barrier methods and tubal ligation have been the most commonly used methods of contraception in renal and liver transplant recipients [14,16,29]. It is important to keep in mind that condoms have high failure rates but are the only method that prevents sexually transmitted infections. Patients often choose withdrawal to prevent pregnancy but the aforementioned study from Iran revealed that

92% of unwanted pregnancies resulted from coitus interruptus. In the Chinese study, use of the rhythm method, condoms, and withdrawal were the methods most often associated with unwanted pregnancy [16].

Sterilization in women can be performed through the laparoscope as well as the hysteroscope. The latter can be performed as an office procedure and may thus be a useful alternative for transplant recipients.

In summary, transplant recipients are at risk of unwanted pregnancy and should be counseled repeatedly about contraceptive options, beginning prior to transplant, specifically during the evaluation process. There are many options for these women. When considering a contraceptive method, it is important to consider the contraceptive and non-contraceptive benefits as well as risks and possible drug interactions (Table 97.1). Long-acting contraceptives such as IUDs and the progesterone implant are some of the most effective methods for preventing pregnancy [17]. These methods remain reversible, provide non-contraceptive benefits, and based on expert opinion, may be the best choice for women with SOT in whom unintended pregnancy could be associated with significant risks [17].

Pregnancy after transplantation

As already mentioned, this first pregnancy in a transplant recipient, Edith Helm, occurred in March 1958 [2]. The pregnancy was uneventful and worries about graft compression were allayed by a normal excretory urogram. A normal male infant weighing approximately 3300 g was delivered by cesarean section, undertaken to avoid the theoretical possibility of trauma to the transplant kidney as the fetus descended through the birth canal. There was no effect on transplant function. In 1960 the recipient had a second successful pregnancy with cesarean delivery of a healthy girl. The excretory urogram during pregnancy revealed prompt excretion but interestingly, there was less than the normal physiologic dilatation of the renal pelvis. It was concluded therefore that a solitary kidney transplanted into the pelvis could sustain a pregnancy and there were no compression problems. Indeed, Edith Helm lived to the age of 76 years, with her sister's kidney functioning 53 years post transplant.

In 1967 Hume et al. reported the first successful pregnancy in a kidney recipient with immunosuppression (azathioprine and prednisone) [30]. In 1976, one of the authors (JMD) and his colleagues in the UK published a report of the close follow-up of a kidney transplant recipient during a planned pregnancy [31]. This experience, with the authors' analyses of the available literature, led to the formulation of guidelines for counseling female kidney transplant recipients contemplating pregnancy. These guidelines have been only slightly modified through the years. Revisions have been incorporated into Consensus Guidelines through the American Society of Transplantation [32] (see below), with earlier European Best Practice Guidelines also available [33].

Given the need to provide better information for the transplant community, the National Transplantation Pregnancy Registry (NTPR) was established at Thomas Jefferson University in 1991, with the goal of maintaining an ongoing database to assess the safety of pregnancy in female transplant recipients as well as pregnancies fathered by male transplant recipients [3,9]. All reported pregnancy outcomes are analyzed, including livebirths, spontaneous abortions, therapeutic abortions, stillbirths, and ectopic pregnancies. The data include the follow-up of parents and offspring to determine long-term effects of post-transplant pregnancy for the recipient, graft, and offspring.

Table 97.2. NTPR: Pregnancies in female transplant recipients [3]

Organ	Recipients	Pregnancies	Outcomes*
Kidney	922	1490	1525
Liver	179	319	325
Liver–kidney	5	7	8
Intestine	2	2	2
Pancreas–kidney	50	90	95
Pancreas alone	2	5	6
Heart	60	105	109

NTPR, National Transplantation Pregnancy Registry, December 2011.

Table 97.4. NTPR: Pregnancies in female recipients transplanted at <21 years of age

Organ	Recipients	Pregnancies	Outcomes*
Kidney	299	499	511
Liver	76	150	153
Liver–kidney	2	4	5
Intestine	1	1	1
Pancreas–kidney	0	0	0
Pancreas alone	0	0	0
Heart	24	45	45
Heart–lung	0	0	0
Lung	1	1	1
Totals	**403**	**700**	**716**

*Includes twins, triplets, and quadruplets.
NTPR, National Transplantation Pregnancy Registry, January 2012.

Tables 97.2 and 97.3 show entries into the NTPR as of December 2011, totaling 2054 pregnancies in 1247 female recipients and 1257 pregnancies fathered by 830 male recipients. Numbers of pregnancies in recipients transplanted before the age of 21 years are listed in Table 97.4.

A National Transplant Pregnancy Register was established in the UK in 1997, but discontinued in 2002, the last report on pregnancy outcomes in the UK being published in 2007 [34,35]. Data from the UK report indicate outcomes similar to those of the NTPR [3,35] (Table 97.5).

Table 97.5. Pregnancy outcomes in kidney transplant recipients

	NTPR [3]	UK Transplant Pregnancy Registry [35]

Table 97.6. Food and Drug Administration (FDA) pregnancy categories for immunosuppressive drugs commonly used in transplantation [3]

Drug	FDA pregnancy category*
Corticosteroids (prednisone, prednisolone, methylprednisolone)	B or C
Azathioprine (Imuran®)	D
Cyclosporine (Sandimmune®)	C
Cyclosporine modified (Neoral®)	C
Tacrolimus (Prograf®)	C
Mycophenolate mofetil (Cellcept®)	D
Enteric-coated mycophenolate sodium (Myfortic®)	D
Sirolimus (Rapamune®)	C
Belatacept (Nulojix®)	C
Antithymocyte globulin (Atgam®, ATG)	C
Antithymocyte globulin (Thymoglobulin®)	C
Muromonab-CD3 (OKT3®)	C
Basiliximab (Simulect®)	B
Daclizumab (Zenapax®)	C

*FDA categories briefly defined: B, no fetal risk, no controlled studies; C, fetal risk cannot be ruled out; D, evidence of fetal risk.

Issues to be considered in pregnant transplant recipients

Although most of the outcomes have been positive, pregnancy after transplantation is a complex situation and the following issues must be considered:

1 The mother: risks to her long-term health and her ability and/or survival to be a parent.
2 The allograft: risks of allograft dysfunction and/or loss related to the pregnancy itself, the potential for changes in drug metabolism during pregnancy that could increase the susceptibility to rejection.
3 The fetus/neonate: potential teratogenic risks associated with immunosuppression and other medications, manifest not only as morphologic defects but as subtle developmental changes that might not become apparent until later during childhood, or could possibly have an effect on future generations.

Other long-term issues to be considered are the ability of a parent with a transplant to cope with unexpected illnesses and/or graft dysfunction while child rearing, and the impact on the child if the transplanted parent is ill or dies.

Immunosuppressive agents and teratology

The US Food and Drug Administration (FDA) pregnancy categories for immunosuppressive drugs are listed in Table 97.6. The mechanisms of action of these agents are covered in Chapters 98–102.

Corticosteroids

In animal studies, corticosteroids have caused cleft palate, although this has not been seen in humans [36,37]. Clinically, these agents are associated with an increased risk of preterm rupture of the membranes and adrenal insufficiency in newborns [38]. Prednisone has been used for >45 years for maintenance therapy in transplantation, as well as in other clinical areas, e.g. rheumatology.

Azathioprine (Imuran®)

Azathioprine at high doses along with prednisone was used for immunosuppression before the introduction of cyclosporine, and much clinical experience was accrued. Clinical data do not support the early concerns about teratogenicity, nor has a predominant structural malformation pattern been identified. Reviews show occasional attributable newborn problems, including thymic atrophy, leukopenia, anemia, thrombocytopenia, transient chromosomal aberrations, sepsis, and reduced immunoglobulin levels [39–41]. Although listed as pregnancy category D (evidence of fetal risk), azathioprine at adjunctive doses is considered a safe option for maintenance immunosuppressive therapy during pregnancy with respect to teratogenic risk.

Cyclosporine (Sandimmune®, Neoral®, Gengraf®, others)

The first calcineurin inhibitor (CNI), cyclosporine, became the mainstay of immunosuppression in the early 1980s. Cyclosporine is listed as pregnancy category C (fetal risk cannot be ruled out). Fetal toxicities and abnormalities have been reported in animal studies, but these occurred at dosages much higher than used clinically [42–44]. Although early reports suggested a greater risk of fetal growth restriction, this was not apparent in later studies [7]. The teratogenic risk appears minimal with no predominant pattern of newborn malformations reported. In the largest analysis of structural birth defects in the offspring of cyclosporine-treated kidney recipients, amongst 479 female kidney recipients maintained on cyclosporine reported to the NTPR, there were 362 (76%) livebirths [45], of whom 18 had birth defects, representing 5% of livebirths, which is reassuringly similar to the 3–5% rate reported in the general population [46].

Tacrolimus (Prograf®, others)

Since its introduction in 1995, tacrolimus has steadily replaced cyclosporine as maintenance CNI therapy in kidney transplantation in the US. In animal studies, fetal resorption occurred at dosages much higher than used clinically [47]. Transient neonatal hyperkalemia has been reported [48], as has a higher incidence of maternal diabetes. Similar to cyclosporine, no specific pattern or number of malformations has been identified with tacrolimus

exposure during pregnancy. The incidence of birth defects reported to the NTPR in kidney transplant recipients on CNIs, without adjunctive use of mycophenolic acid products [49], is similar to that in the general population.

Mycophenolic acid products (mycophenolate mofetil, CellCept® and others; and enteric-coated mycophenolate sodium, Myfortic®)

FDA-approved in 1994, mycophenolic mofetil (MMF) has supplanted azathioprine as adjunctive therapy with CNIs. In contrast to CNIs, there is greater concern about the risk of teratogenicity with mycophenolic acid products, based on reproductive toxicity studies in animals. Developmental toxicity in rats and rabbits included malformations and intrauterine growth restriction. Fetal death occurred at dosages that appeared to be within the recommended clinical dosages based on body surface area [50,51]. In the NTPR database, clinical data have demonstrated both an increased incidence of and a pattern of malformations, with additional reports of problems in newborns exposed to MMF [52–60]. Since 2007 the package inserts of CellCept® and Myfortic® have included a change in FDA category from C to D [29,30], and emphasized that females of childbearing potential taking mycophenolic acid products must use contraception, because during pregnancy there are increased rates of fetal loss and congenital malformations. This is also the recommendation of the European Best Practice Guidelines [33]. In combination with NTPR data, post-marketing data collected by Roche Laboratories, Inc. between 1995 and 2007 demonstrated that among 77 women exposed to systemic MMF during pregnancy, 25 had spontaneous abortions and 14 had a malformed infant or fetus. Six of these 14 had ear abnormalities.

Sirolimus (Rapamune®)

Sirolimus, a mammalian target of rapamycin (mTOR) inhibitor, has been approved as adjunctive therapy with a CNI since 2000, and concerns have been expressed about its use during pregnancy. Teratogenicity has not been noted in animal studies, but decreased fetal weight and delayed ossification have been reported [61]. In conjunction with cyclosporine in pregnant animals, fetal resorption and loss rates were increased, suggesting increased toxicity. There is, however, a paucity of clinical pregnancy outcome data [52,62–66].

Males treated with sirolimus have a significantly lowered sperm count and spermatozoa motility, as well as a decrease in the fathered pregnancy rate [67]. Thus, male recipients who are taking sirolimus should be informed of this potential side-effect.

Other agents

Other agents used for induction or rejection have a minor role in pregnancy. In a small series of patients, muromonab-CD3 (OKT3®) [68], corticosteroids, and Thymoglobulin® were used to treat in pregnancy. Rituximab has been used to treat rejection, although there are no pregnancies reported with exposure.

The recently approved belatacept (Nulojix®) is a selective T-cell costimulation blocker used for maintenance immunosuppression. No pregnancy outcome data have yet been reported to the NTPR.

Organ groups

Kidney recipients

Literature surveys from the azathioprine era of the 1970s and 1980s attest to thousands of successful post-transplant pregnancies in kidney transplant recipients. The spontaneous abortion rate was approximately 14%, and the therapeutic abortion rate was approximately 20%. Of pregnancies that continued beyond the first trimester, >90% were successful. Renal impairment occurred in approximately 15% of women, and hypertension complicated approximately 30% of these pregnancies. Preterm delivery was common, affecting 45–60% of pregnancies, with fetal growth restriction occurring in approximately 20% [69,70].

Initial reports of cyclosporine exposure during pregnancy raised concerns because there was a higher incidence of fetal growth restriction and hypertension, which may have been related to the higher doses used in the early 1980s [43]. There were suggestions that cyclosporine might not be optimal for use in pregnancy and that recipients be switched back to azathioprine-based regimens due to the longer experience with this drug. As familiarity with the use of cyclosporine increased, case and individual transplant center reports and registry data reported increasing numbers of successful pregnancies, but some potential risks to mothers and newborns were apparent [71]. Outcomes of pregnancies in kidney recipients on CNIs as reported to the NTPR are detailed in Table 97.7 [3].

Maternal outcomes

Overall, compared with the general population, female transplant recipients are at greater risk for hypertension and pre-eclampsia during pregnancy. As reported to the NTPR, 53–64% of kidney recipients on CNIs have drug-treated hypertension during pregnancy. Kidney recipients are more likely to have pre-existing hypertension and this alone is a risk factor for worse pregnancy outcomes, including low birthweight [72]. Pre-eclampsia occurs in 7–10% of pregnancies in the general population, but is up to three times more common in transplant recipients. As many transplant recipients have pre-existing hypertension, pre-eclampsia can be more difficult to diagnose [70].

The use of insulin during pregnancy has been reported in up to 12% of kidney transplant recipients on CNIs reporting to the NTPR. Optimal glucose control is desired, especially in the first trimester given the association between gestational diabetes and birth defects [73]. Additionally, mild gestational diabetes not requiring insulin therapy has not been evaluated, so the actual frequency of gestational diabetes may be higher than reflected in the NTPR data.

The most common infectious complications reported to the NTPR during pregnancy are urinary tract infections. These typically can be successfully treated with the appropriate antibiotics.

Graft function

Clinical studies as well as those in animal models in the non-transplant population have shown that long-term renal function is unaffected by gestation if function prior to pregnancy is stable [74]. Similarly, in the transplant population, well-designed, case–control studies have demonstrated that pregnancy does not cause deterioration of graft function when prepregnancy graft function is stable [75–79]. A case–control study by Sturgiss and Davison [76], followed by an update [77], however, suggested that pregnancy may have a minor deleterious effect on kidney allograft function, but this was not statistically significant.

Rejection

The incidence of graft rejection during pregnancy is low, and does not appear to be any higher than reported in the non-pregnant transplant populations. Similarly, graft loss within 2 years of

delivery does not typically appear to be precipitated by pregnancy. Irreversible and unpredictable graft events occur more often in recipients with impaired prepregnancy function.

From NTPR data, 2% of kidney recipients have reported biopsy-proven acute rejection during pregnancy. Treatment consists of pulsed steroids, lymphocyte depleting agents, and/or adjustment of baseline immunosuppression, and viable outcomes are possible. Rejection during pregnancy is associated with poorer outcomes for the newborn and graft [80]. Development of rejection during pregnancy or immediately postpartum represents a significant risk factor for kidney graft loss within 5 years after pregnancy [81].

Reports to the NTPR evaluating recipient and newborn variables do not reveal significant differences in the outcomes of pregnancies in living donor compared to deceased donor kidney transplant recipients [82].

Multiple and successive pregnancies

Many recipients have had successful successive pregnancies, and some have had successful outcomes with multiple gestations or in-vitro fertilization [82–87]. Of 478 recipients with a first pregnancy, 189 had one to four subsequent pregnancies. The proportion of livebirths was not statistically different between the groups. With successive pregnancies there was a trend toward increased gestational age, leading to a significant decrease in the number of preterm newborns of both low and very low birthweights. There were similar rejection rates among the groups [82]. Successive pregnancies were not associated with adverse fetal outcomes or increased maternal graft loss. Therefore, kidney transplant recipients with adequate allograft function who desire more than one pregnancy should not be discouraged in this.

Predictors of adverse events

Successful pregnancy outcomes for both recipients and newborns are the norm when kidney function is satisfactory and remains stable during gestation and after delivery. Pregnancy success, defined as livebirth, low risk of maternal and fetal complications, and preservation of kidney allograft function, is related to stable prepregnancy serum creatinine [88] (Table 97.8).

Women starting pregnancy with poorer allograft function [i.e. serum creatinine >1.5 mg/dL, (>133 μmol/l)], have a greater likelihood of allograft dysfunction during and after pregnancy [89]. Moreover, an increase in serum creatinine during pregnancy is more likely to be associated with adverse graft effects, as well as poorer newborn outcomes [88]. An upward trend in serum creatinine during pregnancy should not be attributed to pregnancy alone, and it warrants prompt investigation. As serum creatinine normally decreases during pregnancy due to increased glomerular filtration rate, allograft rejection during gestation may be signaled by only a minor increase in serum creatinine.

An NTPR analysis of 133 female kidney transplant recipients maintained on tacrolimus showed that a high level of serum creatinine before pregnancy and the development of rejection during pregnancy or immediately postpartum represent significant risk factors for kidney graft loss within 5 years post pregnancy. If serum creatinine before pregnancy was >1.3 mg/dL (>115 μmol/l), the relative risk of graft loss within 5 years post pregnancy was 3.3 ($P = 0.005$), while for a prepregnancy creatinine of >1.6 mg/dL (>140 μmol/L), the risk of graft loss increased to 7.4 ($P = 0.00001$) [81].

Deshpande et al. performed an international systematic review and a meta-analysis of 50 studies from 25 countries [90]. Overall, successful outcomes have been reported after kidney transplantation and the trends are consistent at an international level. As already described, factors associated with an adverse pregnancy outcome included prepregnancy hypertension, elevated serum creatinine, and proteinuria.

Newborn outcomes

Kidney transplant recipients, on average, deliver 1 month early, with a preterm (<37 weeks) delivery rate of 50% and mean birthweight of approximately 2500 g. Two large reports on the two primary CNIs, cyclosporine and tacrolimus, examined the prevalence of malformations in newborns. In the offspring of cyclosporine-treated recipients, the malformation rate was 4.1% (14 of 339 births) in a meta-analysis [91]. NTPR data on the offspring of cyclosporine-treated kidney recipients showed malformations in 5% of 362 liveborn infants [45]. The types of malformations varied among different systems, with no predominant type noted. In a report of recipients treated with tacrolimus during pregnancy (84 women, 100 pregnancies), four of 71 liveborn infants (5.6%) had evidence of structural malformations, but no specific pattern was evident [92].

A higher incidence of structural malformations was seen with MMF exposures during pregnancy compared to the overall kidney transplant offspring [52]. NTPR data and case reports have suggested a pattern of malformations. The phenotype includes craniofacial malformations affecting the oral cavity (cleft lip and cleft palate), the ears (microtia), and ocular anomalies (hypertelorism) [3,52–60]. Some fetal malformations may be detected on prenatal ultrasound [93].

Genetic considerations must be taken into account in the assessment of risk to the development of the newborn, especially if these contributed to organ failure in the mother. Of additional concern is the potential for more subtle effects that may not be apparent at birth, but may affect long-term growth and development in the next generation as well.

Long-term follow-up of offspring

Clinical reports note that children of solid organ recipients are developing well, although there is concern that alterations in T-cell subpopulations may affect vaccinations or long-term immunity [11,12,94,95]. A series of 175 newborns of cyclosporine-treated kidney recipients reported to the NTPR showed no evidence of an increased incidence of developmental delays over that expected [11]. Similarly, study of neurodevelopment in children aged 3–15 years who had been exposed to cyclosporine in utero did not show significant differences in full-scale IQ or behavioral outcomes compared with unexposed children [12]. Long-term neurocognitive development of the children of kidney transplant recipients is reassuring considering their high rate of preterm delivery and low birthweight.

Pancreas–kidney recipients

Reports regarding pregnancy after pancreas–kidney (PK) transplant have appeared in the literature [4,96–101]. When compared to kidney-only recipients, issues of concern in the PK population are assessment of pancreas graft dysfunction and glycemic control, higher incidences of hypertension and lower newborn birthweight, as well as whether graft survival is more adversely affected. Data are limited in this group.

The 94 outcomes (including twins and triplets) of 89 pregnancies in 50 PK transplant recipients reported to the NTPR are shown in Table 97.9. Immunosuppression was CNI based in 88 of the 89 pregnancies (eight with mycophenolic acid product exposure) and MMF in one [3]. Three recipients (all with adequate pancreas function prior to pregnancy) reported insulin use during pregnancy. In total, 11 recipients lost five pancreata and four kidneys, with two recipients losing both grafts within 2 years postpartum; rejection occurred in five during pregnancy. Mean gestational age of the 65 liveborns was 34.1 ± 3.2 weeks; 75% were premature (<37 weeks). The mean birthweight was 2075 ± 709 g; 63% were low birthweight (<2500 g). There was one neonatal death in a 26-week gestation newborn due to sepsis. At last follow-up of these children (mean age 8.5 ± 5.6 years), all 64 were reported healthy and developing well. There were some continuing issues reported: one child was medicated for attention deficit hyperactivity disorder (ADHD), one had insulin-dependent diabetes mellitus (IDDM), one had ADHD and IDDM, and one had ADHD and is being treated for epilepsy. At last maternal follow-up (mean 11.2 ± 5.3 years), both pancreas and kidney function were reported adequate in 30 (60%) recipients; seven recipients had died and 13 had varying degrees of graft dysfunction/losses.

Successful pregnancies after PK transplant in women with a low incidence of insulin use during pregnancy have also been reported to the NTPR. There is certainly a high incidence of preterm delivery and low birthweight in the offspring of this recipient group, so these pregnancies must be considered high risk and managed by an interdisciplinary team. Furthermore, the long-term impact of pregnancy on transplant survival in PK recipients requires continued surveillance.

It must be emphasized that many of the management approaches outlined for kidney recipients are applicable to all transplant groups. The following sections will review the issues that are specific to non-renal organ recipients.

Liver recipients

Amenorrhea or menstrual abnormalities with decreased fertility occur in up to 50% of women with chronic liver disease [102–113]. A successful transplant almost uniformly leads to a prompt return of normal menstrual cycles and to reproductive functions because of the recovery of the gonadotrophic function [104,109,110].

CyA, cyclosporine; NTPR, National Transplantation Pregnancy Registry.

This is an important component of the social rehabilitation for recipients of child-bearing age, as evident from the increasing number of post-transplantation pregnancies reported worldwide [5,48,102–113].

Maternal and newborn outcomes

In contrast to kidney recipients, pregnancies in liver recipients are characterized by lower incidences of hypertension and pre-eclampsia during pregnancy, and a higher percentage of term deliveries. The current outcomes of pregnancies in liver recipients reported to the NTPR are shown in Table 97.10 [3].

Among liver recipients transplanted under the age of 21 years, 75% of pregnancies resulted in a livebirth. Pregnancy, potential risks for the mother and newborn, and long-term maternal survival should be discussed with the recipient and with the parents of the recipient, if the transplant recipient is a minor [108].

Graft function

Pruritus and cholestasis occur frequently during pregnancy. Elevated alkaline phosphatase levels are found in approximately 35% of "normal" pregnancies after liver transplantation. Graft rejection needs to be considered and differentiated from other conditions. Hemolysis, low platelets syndrome, and anemia have been reported [104].

Rejection

The incidence of biopsy-proven acute rejection ranges between 2% and 8% [3,9,105]. When acute rejection is suspected, percutaneous liver biopsy is not contraindicated in pregnant patients, although ultrasound visualization is recommended to reduce the risk of complications. Evaluation of transplant dysfunction includes liver Doppler ultrasound to exclude an anatomic source of graft dysfunction. Although rejection is a concern, it can usually be successfully managed with adjustment of immunosuppressive medications. For more serious rejections, the use of steroids as antirejection therapy is safe. There have been reports of lower birthweights and preterm births in mothers who had experienced rejection during pregnancy [105].

Particular attention should be reserved for patients with infrarenal aortic grafts for hepatic arterial flow. One death as a result of clotting of the graft by external compression from the gravid uterus has been reported [111].

Multiple and successive pregnancies

The NTPR analyzed pregnancy outcomes in liver recipients who had more than one pregnancy. Of the 125 liver recipients who had a first pregnancy, 61 had between one and four subsequent pregnancies. There were 217 outcomes of 213 pregnancies, including twins. There were no significant differences in newborn outcomes, rejection during pregnancy, and graft loss within 2 years of delivery of subsequent pregnancies. Therefore, female liver recipients with excellent graft function without significant recurrent disease or chronic rejection who wish to have more than one pregnancy should not be discouraged from conceiving [49].

Predictors of adverse effects

An NTPR analysis of 161 female liver recipients showed that the strongest risk factor for graft loss within 5 years of delivery is represented by rejection during pregnancy, followed by younger age at the time of conception [112]. Although viral hepatitis did not remain significant in the final model, it was the only liver disease etiology among those analyzed that was associated with graft loss within 5 years of delivery.

Coffin et al. performed a population-based survey using data from the 1993–2005 US Nationwide Inpatient Sample database [113]. They compared obstetric hospitalizations in liver transplant recipients (n = 206) with a control group (n = 4060), with the majority of pregnancies in liver recipients having favorable

outcomes. Variables that were significantly higher in liver recipients included fetal mortality, antepartum admission, and maternal and fetal complications, prompting the conclusion that both mothers and their infants have an increased risk of complications.

Etiology of liver disease

Recurrent liver disease, especially viral hepatitis, appears to be a serious risk for both mother and child. Vertical transmission of hepatitis B virus (HBV) occurs in 10–20% of HBsAg-positive (HBeAg-negative) non-transplant mothers without immunoprophylaxis. For prevention of vertical transmission, all babies born to HBsAg-positive women should receive immunoprophylaxis [hepatitis B immunoglobulin (HBIg)] and HB vaccine within 12 h of birth. This combination prevents >90% of neonatal HBV infection [114]. The vertical transmission rate in pregnant hepatitis C (HCV) RNA-positive subjects is about 3–5% (in the absence of other viral co-infections) [115]. Special attention should be given to patients with high viral load post transplant, since this is a well-documented risk factor for vertical transmission of HCV.

Recipients transplanted for autoimmune hepatitis (AIH) typically require more immunosuppression than those transplanted for other causes. The NTPR analyzed pregnancy outcomes for women with the diagnosis of AIH [3]. The AIH liver transplant recipients were on average older at transplant and at conception, and had shorter transplant to conception intervals, yet there were no significant differences in maternal, pregnancy, and newborn outcomes between the AIH and non-AIH liver recipients.

Heart recipients

In recent years a greater proportion of young patients with complex congenital heart disease have been referred for heart transplant, and therefore there is a greater need to assess the potential for parenthood in this population [116].

In a heart transplant recipient contemplating pregnancy, there should be baseline tests including an electrocardiogram (ECG), echocardiogram, and potentially coronary angiography, with the option of right heart catheterization and endomyocardial biopsy (EMB) if clinically indicated [117]. Avoidance of pregnancy is recommended in heart transplant female recipients who have allograft dysfunction or cardiac allograft vasculopathy.

In contrast to the outcomes in kidney recipients, pregnancy outcomes in cardiac recipients are typically characterized by a greater percentage of term deliveries, lower pre-eclampsia rates, and lower incidence of graft loss within 2 years of delivery. However, maternal survival, independent of pregnancy-related events, should be considered as part of prepregnancy planning. Table 97.11 shows the outcomes of pregnancies in heart recipients on CNIs [3].

Graft function

Effects of pregnancy on the transplanted heart include increased cardiac workload, increased cardiac output, and elevated maternal oxygen consumption [118,119]. The transplanted heart appears to adapt well to these changes when graft function is stable [120,121].

Rejection

Monitoring for rejection in patients with a cardiac transplant may require EMB. Graft rejection during pregnancy was reported in 11% of 103 pregnancies in 57 heart recipients reported to the NTPR, with many of the episodes being low grade and without clinical consequence [3]. Treatment of rejection included corticosteroids, increased cyclosporine dose, or no change in several recipients with low-grade rejection [122]. One report that heart transplant recipients developed antibody-mediated rejection postpartum, so heart recipients who develop rejection during or after pregnancy should be assessed for anti-HLA antibodies [123].

Table 97.11. NTPR: Pregnancy outcomes in heart transplant recipients exposed to a calcineurin inhibitor during pregnancy [3]

Some recipients may have had more than one pregnancy on a different calcineurin inhibitor. Not included in this table are those recipients on other regimens or for whom the regimen could not be determined.
*Includes twins.
CyA, cyclosporine; NTPR, National Transplantation Pregnancy Registry.

Statins

Statins are a common part of therapy in heart transplant recipients, but are not recommended during pregnancy due to their potential teratogenic effects. A study from the Motherisk program suggested that the actual risks for an exposed pregnancy appear to be small and exposure itself does not warrant termination of pregnancy [124]. It is advisable to avoid the use of these drugs in order to reduce fetal risks as much as possible. In the NTPR, ten pregnancies have been evaluated in heart recipients exposed to a statin drug, with six livebirths and no structural birth defects in these neonates [125].

Labor and delivery

Vaginal delivery is the recommended method of delivery in heart transplant recipients, similar to all other solid organ recipients [32]. Cesarean section should be performed only for obstetric indications. In cardiac recipient pregnancies reported to the NTPR, 40% were cesarean deliveries. During labor, ECG monitoring is mandatory because of the increased risk of arrhythmias, but more invasive cardiovascular monitoring is generally not necessary. Epidural anesthesia reduces pain-induced sympathetic responses and may reduce acute blood pressure fluctuations during labor [13]. Healthcare providers must be aware that cardiac recipients may have an unpredictable response to vasoactive medications and may not respond to vasolytics (atropine) as the heart is denervated.

Maternal outcomes

Most patients maintain adequate graft function following pregnancy. Among 57 heart recipients reported to the NTPR, 40 maintained adequate transplant function postpartum (70%). Two recipients had graft loss within 2 years of pregnancy, one died 17 years after transplant, and the second loss occurred 9 months after delivery necessitating retransplant; the latter recipient is currently healthy with adequate function [3]. Maternal death was reported in 16 of the 57 female heart recipients by the NTPR, all occurring >2 years after pregnancy. Causes of death included vasculopathy, atherosclerosis, acute rejection, sepsis, pneumonia, and sepsis. As emphasized previously, prepregnancy counseling must include the potentially limited lifespan of the heart transplant recipient.

Lung recipients

By comparison to heart recipients, lung recipients have a higher incidence of more significant rejection as well as graft loss in the peripartum period, with smaller newborns [8,126]. Given the overall higher risk for this recipient group, there has been less enthusiasm for advocating pregnancy. Management guidelines have not been published specific to this population.

Thirty-one pregnancies in 22 female lung recipients with 33 outcomes (including one triplet pregnancy) have been reported to the NTPR [3] (Table 97.12). Immunosuppressive regimens included: cyclosporine based (eight recipients), cyclosporine modified (two), and tacrolimus based (21). All recipients experiencing rejection were maintained on a cyclosporine-based regimen and received their transplant prior to 1996. Eleven of the 22 recipients were transplanted for cystic fibrosis and accounted for 13 of the pregnancy outcomes (eight livebirths, three spontaneous abortions, and two therapeutic abortions). Three cystic fibrosis recipients had rejection during pregnancy. At last recipient contact, 14 had adequate function, one had reduced function, five had died (two with cystic fibrosis), and one had a non-functioning transplant (single lung transplant removed; regain of native function). Mean gestational age of the 19 liveborns was 33.9 ± 5.0 weeks and mean birthweight was 2206 ± 936 g. There were two neonatal deaths in a triplet pregnancy born at 22 weeks (one spontaneous abortion at 14 weeks). At last follow-up, all 17 surviving children were reported healthy and developing well.

Table 97.12. NTPR: Pregnancy outcomes in 22 lung transplant recipients [3]

Organ	Lung

* Includes triplets.;
† Triplet pregnancy: one spontaneous abortion at 14 weeks; two born at 22 weeks and died within 24 h of birth.
NTPR, National Transplantation Pregnancy Registry.

Successful pregnancy is possible after lung transplantation, including in those recipients with a diagnosis of cystic fibrosis. More rejection during pregnancy was evident in recipients transplanted before 1996. Analyses of a larger number of cases is needed to identify trends in pregnancy after lung transplantation. The impact of pregnancy on long-term maternal survival also requires further study.

Intestine recipients

Pregnancy after small bowel transplant has been reported in the literature and to the NTPR [3,6,127], but outcome data are limited in this group. Two cases of pregnancy post small bowel transplant have been reported to the NTPR. Both recipients delivered term infants with no malformations. Both recipients reported no transplant complications during pregnancy or in the postpartum period.

Other organ groups

Limited data are available, but successful pregnancy outcomes have been reported in female liver–kidney and heart–lung recipients [3].

Breastfeeding

Breastfeeding for female transplant recipient mothers remains an area of controversy [3,32,128–132]. The NTPR has received data from women who have chosen to breastfeed on various immunosuppressive regimens. Sixty-four kidney recipients have breastfed their 80 infants, 21 liver recipients their 28 infants, one liver–kidney recipient her infant for 3.5 months, and three PK recipients their four infants [3]. Two lung recipients have reported breastfeeding their infants; one for 10 weeks and another for 3 months. Six heart recipients have reported breastfeeding their 10 children, ranging from a few days up to 2 years. At last follow-up no specific problems related to breastfeeding in any of these children had been reported.

Table 97.13. Pregnancy after transplantation management options

Prepregnancy
- Patients should defer conception for at least 1 year after transplantation, with adequate contraception
- Assessment of graft function (organ specific):
  - Recent biopsy
  - Proteinuria
  - Hepatitis B and C status
  - CMV, toxoplasmosis, herpes simplex status
- Maintenance immunosuppression options:
  - Azathioprine
  - Cyclosporine
  - Tacrolimus
  - Corticosteroids
  - Mycophenolate mofetil
  - Enteric-coated mycophenolate sodium
  - Sirolimus
  - Everolimus
  - Belatacept
- The effect of co-morbid conditions, i.e. diabetes and hypertension, should be considered and their management optimized; non-renal recipients should have their baseline kidney function assessed
- Vaccinations should be given if needed, i.e. rubella, etc.
- Explore etiology of original disease; discuss genetic issues, if relevant
- Discuss the effect of pregnancy on renal allograft function
- Discuss the risks of intrauterine growth restriction, prematurity, low birthweight

Prenatal
- Accurate early diagnosis and dating of pregnancy
- Clinical and laboratory monitoring of functional status of transplanted organ and immunosuppressive drug levels:
  - Every 4 weeks until 32 weeks
  - Every 2 weeks until 36 weeks
  - Then weekly until delivery
- Monthly urine culture
- Surveillance for rejection with biopsy if it is suspected
- Surveillance for bacterial or viral presence, i.e. CMV, toxoplasmosis, hepatitis
- Fetal surveillance
- Monitor for hypertension and nephropathy
- Surveillance for pre-eclampsia
- Screening for gestational diabetes

Labor and delivery
- Vaginal delivery is optimal; cesarean delivery for obstetric reasons
- For heart/heart–lung/lung recipients:
  - Vigilance for poor or absent cough reflex, the need for airway protection
  - Unpredictable response to vasoactive medications
  - Judicious use of intravenous fluids

Postnatal
- Monitor immunosuppressive drug levels for at least 1 month postpartum, especially if dosages increased during pregnancy
- Surveillance for rejection with biopsy if it is suspected
- Breastfeeding discussion
- Contraception counseling

Adapted from Armenti et al [88], with permission from Elsevier.

Thus, while any immunosuppressive drug exposure to the infant could potentially exceed the threshold for safety, the relatively small amount of drug transferred and the lack of reported adverse effects together with the documented benefits of breastfeeding may outweigh the theoretical risks of this exposure. The breastfed infant should have a blood level checked for the mother's immunosuppressant; a detectable level is an indication to stop breastfeeding. Continued study in this area is warranted, especially the subtle effects of infant drug exposure on immunologic development.

Management options

Recommendations for the management of pregnancy after transplantation have been published in detail elsewhere [3,32,133–140]. A summary of management guidelines is given in Table 97.13.

Prepregnancy counseling

Transplantation restores fertility so recipients should be counseled about contraceptive options prior to transplant and early post transplant. An interval from transplant to conception is advisable in all transplant recipients to allow establishment of stable graft function and reduction of immunosuppression to maintenance levels. NTPR data have shown a higher incidence of pregnancy termination and peripartum rejection with transplant-to-conception intervals of <6 months compared with longer intervals in cyclosporine-treated kidney recipients. While the shortest safe interval from transplant to conception has not been established, 1 year is a reasonable milestone, given the prerequisites of stable, adequate graft function and maintenance level immunosuppression [32,141,142].

Immunosuppressive medications

The potential teratogenicity of mycophenolic acid products highlights the dilemma of protecting the transplanted organ from rejection versus fetal risk. There are no definitive pregnancy outcome data available on the risks of switching patients to alternative regimens that have a presumed lower risk of malformations to the newborn and no reliable data on rejection prophylaxis. Thus, for each recipient contemplating pregnancy, an individual assessment and decision must be made. One must judge the risk to the transplanted organ of switching immunosuppressants, particularly since organ function directly affects fertility and the ability to safely carry a pregnancy. This must be weighed against the risk of continuing a prepregnancy immunosuppressive regimen that could potentially harm the fetus. At this time, such decisions are best made preconception with the involvement of the patient, her partner, and the transplant team. Unplanned pregnancies do occur, however, such that decisions may have to be made after exposure has occurred.

Antihypertensive medications

Many transplant recipients have hypertension and may be receiving a combination of antihypertensive medications. Angiotensin-converting enzyme inhibitors and angiotensin II receptor antagonists are contraindicated during pregnancy, although some controversy exists with regard to the timing of greatest exposure risk [32,143]. If dosage adjustments or changes to hypertensive agents are needed, these could be made in anticipation of pregnancy.

Maternal co-morbid conditions

In addition to hypertension and pre-eclampsia, attention should focus on other co-morbidities that are likely to occur, including infections and gestational diabetes. Infectious complications during pregnancy are most often urinary tract infections. A monthly urine culture should be performed during pregnancy. Occasionally, yeast infections, pneumonia, sepsis, or unspecified viral infections complicate pregnancy. Cytomegalovirus (CMV) is usually asymptomatic but can be detected by serologic, antigen, or viral monitoring. CMV acute infection is the most common type of infection in the first year post transplant. It is particularly dangerous in early pregnancy. CMV infection is a causative agent of congenital malformation (microcephaly, cerebral palsy, sensorineural deafness) or congenital liver disease. Such abnormalities are seen in approximately 10–15% of infected pregnancies. The antiviral agents used for prophylaxis and treatment of CMV infection are ganciclovir and valganciclovir. The safety of their use during pregnancy has not been established [105].

The rate of HCV transmission from mother to child in the non-transplant population is 5% [144]. Recipients with HBV infection may also transmit this to their offspring [114]. As mentioned above, administration of HBIg and HBV vaccine to the newborn within a few hours of birth usually prevents transmission. Estimates of the incidence of acute infection with toxoplasmosis are 0.2–1%, with most cases undiagnosed and asymptomatic. Congenital toxoplasmosis can have severe consequences, and the diagnosis is dependent on culture, direct antigen detection, or serologic tests [145].

Scrutiny for hypertensive changes and pre-eclampsia is essential, although the diagnosis of pre-eclampsia may be difficult because serum uric acid levels and urinary protein excretion may be well above expected normal ranges without pre-eclampsia, as a result of drug nephrotoxicity. Other potential complications include the HELLP syndrome, ureteral obstruction, and complications of cesarean delivery. Peripartum ultrasound assessment to exclude urinary obstruction is warranted if serum creatinine rises.

Rejection

Unless immunosuppressive toxicity or rejection occurs, it is best to maintain prepregnancy immunosuppressive dosing and blood levels. Blood concentrations are likely to decrease during pregnancy, given the increased maternal volume of distribution as well as fetal metabolism of drugs. On occasion, a recipient may be non-compliant, choosing to stop medications during pregnancy for fear these might harm the fetus. Reports to the NTPR show that, in most pregnancies, immunosuppressive doses have been kept the same or increased during pregnancy. Regardless of dosing during pregnancy, changes that occur during the peripartum period mandate that postpartum immunosuppressive dosing be managed by determining blood concentrations when possible.

Rejection during pregnancy, although not common, must be considered in the differential diagnosis of graft dysfunction. The usual pattern for the serum creatinine level is a slight decrease in early pregnancy, with a return towards baseline postpartum. In kidney recipients, any increase in serum creatinine of ≥15% during pregnancy and postpartum must be evaluated. For all SOT recipients, any deterioration in graft function should be assessed by biopsy, and if the diagnosis of acute rejection is made, then appropriate antirejection treatment is necessary. Given the risks of rejection and of pre-eclampsia, more frequent monitoring is warranted from mid pregnancy onward, including blood pressure, assessment of graft function, and measurement of immunosuppressive drug levels.

Labor and delivery

A high incidence of cesarean sections has been reported for pregnant transplant recipients, ranging from 29% to 69% (Tables 97.7, 97.9, 97.10, 97.11, 97.12). However, it is recommended that cesarean delivery be performed for obstetric indications only. Immunosuppression must not be interrupted during labor and delivery. Prophylactic antibiotics are advisable.

Postnatal care

Most oral maintenance medications are easily absorbed and treatment can be resumed shortly after cesarean section. When oral treatment cannot be resumed, intravenous formulations are available for most, but not all agents. Immunosuppressive drug levels should be monitored and dosage adjusted appropriately, which may then affect blood pressure, renal function, and other toxicities. One must be aware of postpartum depression among transplant

Table 97.14. NTPR: Selected pregnancies fathered by male transplant recipients [3]

	Kidney	Liver	Pancreas–kidney	Heart
Number of recipients	594	69	34	106
Pregnancies	915	109	43	157
Outcomes*	930	115	45	160
Livebirths (%)	93	89	91	88
Mean gestational age (weeks)	39.1 ± 2.2	39.1 ± 1.9	38.7 ± 2.4	38.9 ± 2.3
Mean birthweight (g)	3329	3296	3321	3440
Newborn complications (%)	16	19	15	19

*Includes twins and triplets.
NTPR, National Transplantation Pregnancy Registry.

recipients, as medications may be missed or not taken. Therefore, close monitoring is required for several months postpartum.

As already mentioned, breastfeeding remains controversial. Although exposure of the newborn to any immunosuppressive drug may be detrimental, the amount present in the breast milk is thought to be minimal. The benefits of breastfeeding may possibly outweigh the minimal risk.

Pregnancy after living donation

Pregnancy after living kidney donation was first described by Murray et al. in 1963 [2]. Earlier studies concluded that donor nephrectomy is not detrimental to the prenatal course or the outcome of a future pregnancy [146–148]. Two recent studies, however, extend our current knowledge and do highlight some concerns [149,150].

Reisæter et al. examined the data from the Medical Birth Registry of Norway. They described 326 female kidney donors, with 620 pregnancies before donation and 106 pregnancies after donation, and used as control a random sample from the Norwegian birth registry [149]. There was no difference in maternal and newborn outcomes between kidney donors and the general population, except for a higher incidence of pre-eclampsia post donation compared to predonation (5.7% vs. 2.6%). As the number of pregnancies at risk and the number of events was extremely low, the results should be interpreted with caution. Most importantly, pregnancy outcome after donation was good for both mother and child, and similar to non-donor controls.

Ibrahim et al. surveyed 1589 female donors regarding pregnancy pre and post donation from a single large-volume transplant center in the US; 1085 donors reported 3213 pregnancies [150]. Fetal and maternal outcomes after kidney donation were similar to those for the general population. However, when post-donation pregnancies were compared to predonation pregnancies, it was apparent that post-donation pregnancies are associated with a higher likelihood of adverse outcomes such as a lower proportion of term infants, higher incidences of fetal loss, gestational diabetes, gestational hypertension, proteinuria, and pre-eclampsia. It is worth mentioning that the rates of adverse outcomes in predonation pregnancies were exceedingly rare, suggesting a selection bias; and it is conceivable that women with a history of gestational diabetes, hypertension, or pre-eclampsia are excluded from donation and are less likely to come forward to become kidney donors.

The existing data are reassuring that kidney donation is not associated with increased incidence of adverse maternal and fetal outcomes compared to the general population. Nevertheless, it is prudent to closely monitor pregnancies in kidney donors, including with blood pressure, urine protein excretion, and fetal ultrasound [151].

Table 97.15. Key points

- Recommendations to optimize pregnancy outcomes include consideration of the following:
  - Good general health ≥1 year since transplant
  - Stable graft function [ideally with serum creatinine <1.5 mg/dL (<130 μmol/L)] and no evidence of recent graft rejection
  - Well-controlled or no hypertension
  - Minimal or no proteinuria (<1 g/24 h)
  - Stable immunosuppressive regimen with suitable medication(s)
- Potential maternal and fetal complications include pre-eclampsia, preterm birth, fetal growth restriction, and low birthweight
- Pregnancy in and of itself does not affect previously stable allograft function
- The effect of co-morbid conditions, i.e. diabetes and hypertension, should be considered and their management optimized
- Maintenance of current immunosuppression in pregnancy is usually recommended, except for mycophenolic acid products, for which fetal risks should be discussed and alternatives sought if possible

The timing of pregnancy after kidney donation is not well established. A consensus conference recommended delaying pregnancy until at least 2 months after nephrectomy to assess renal compensation prior to conception [152]. Others have suggested 1 year post nephrectomy to allow a woman to recover from the emotional process of becoming a living donor and to adapt to a new level of kidney function [151]. Issues related to pregnancy post donation and potential concerns should be discussed with all potential donors of child-bearing age and their recipients [151,153,154].

Of interest, Soyama et al. have managed a woman who conceived within 6 months of a right liver lobe donation and she had a successful obstetric outcome [155].

Male recipients

Table 97.14 shows the percentages of livebirths and neonatal outcomes among selected pregnancies fathered by male transplant recipients reported to the NTPR, including pregnancies fathered by recipients after multivisceral transplantation. Overall, the outcomes of pregnancies fathered by male transplant recipients appear similar to those of the general population. The NTPR continues to collect pregnancy outcome data on male recipients who have fathered pregnancies after SOT. Issues related to fertility in male transplant recipients require additional studies.

Summary

The key points for pregnancy following transplantation are summarized in Table 97.15.

With the constant new developments and modifications in immunosuppressive regimens in transplant medicine, clinicians are responsible for providing pregnancy counseling in all pre- and post-transplant recipients of child-bearing age. As individual physicians and centers accrue experience with these major therapeutic decisions, it is critical that both positive and negative pregnancy outcomes be reported in appropriate settings. For the future, efforts also need to be directed toward developing better and more organ-specific management guidelines. Continued close collaboration among specialists will help to better identify potential pregnancy risks in these populations, particularly as new immunosuppressive agents are developed.

Acknowledgment

The authors acknowledge Lisa A. Coscia, RN, BSN for her invaluable assistance in the preparation of this manuscript.

The NTPR acknowledges the co-operation of transplant recipients and the personnel in over 250 centers in North America who have contributed their time and information to the registry. The NTPR has been supported by grants from Novartis Pharmaceuticals Corporation, Astellas Pharma US, Inc., Genentech, Inc., Pfizer Inc., Teva Pharmaceuticals USA, Sandoz, Inc., and Bristol-Myers Squibb Company. To contact the NTPR, email: NTPR@giftoflifeinstitute.org (http://www.NTPRegistry.org).

CHAPTER 98

Drugs Specifically Approved for Transplant Indications

Winston A. Ally[1] and Avinash Agarwal[2]

[2] Department of Surgery, University of Virginia, Charlottesville, VA, USA

Introduction

The Food and Drug Administration (FDA) regulates over a trillion dollars of products, ranging from 80% of the US food supply to all human healthcare products, electronic products that emit radiation, animal products, and cosmetics. This includes $466 billion in food sales, $275 billion in drugs, and $60 billion in cosmetics [1]. The FDA is expected to protect citizens of the United States (US) from harm through a vigorous and at times daunting approval and monitoring process. The FDA is expected to approve agents in an expeditious manner while balancing the risks of potential safety concerns or unpredicted adverse events. Given the nature of scientific advancement, it is no surprise that this agency and its statutory framework remain a work in progress attempting to evolve to meet emerging needs.

This chapter will provide a brief overview of the practical aspects of the FDA work model and the process of drug approval, as a prominent example of the complexities of immunosuppressive drug approval. While each country has specific rules that govern the approval process, the general themes covered here are similar to those used in most countries. It will also provide a summary description of those products that have received approval from the FDA for one or more transplant indications, and list the recommendations based on the approved label for each drug; this is often not the way the drugs evolve into common clinical use. In reality, drug regimens used in clinical practice are a hybrid of drugs being used as indicated, and drugs being used "off-label," that is used in a manner that was not part of their approval testing. This is necessary to allow for drug use in situations where efficacy can be reasonably assumed based on a drug's mechanism of action, but where the target population, or specific use is limited so as to preclude practical demonstration of efficacy in a fiscally practical clinical trial. This chapter should thus be considered in tandem with Chapter 101, which covers off-label drug use. The details of the mechanism of actions of the drugs listed in this chapter are covered in Chapter 17, and the practical clinical application of these agents are addressed in the many organ-specific chapters on post-operative management and treatment of rejection. Consideration should also be given to relating the content of this Chapter to that in Chapter 135, which deals with clinical trial design, as FDA approval is often a primary consideration in trial design.

Disclaimer: The opinions offered in this chapter are the personal opinions of the authors and should not be interpreted as the official policy of the U. S. Food and Drug Administration.

The evolution of the FDA

Prior to 1902, the US government had minimal role in the regulation of drugs. There were no laws, regulations, nor standards that existed for clinical efficacy. The US Pharmacopeia (USP) was established in 1820 as the first official registry of agents. The USP set standards for strength and purity to guide pharmacists and clinicians who would extract and compound the agents. The first American drug regulatory law was passed in 1848, the Drug Importation Act; it was enacted in response to US troops serving in Mexico who were adversely affected by contaminated quinine. This law required laboratory inspection and destruction of product that did not meet established standards.

The origins of the FDA are most often traced to the US Department of Agriculture's Division of Chemistry [2]. Under Dr. Harvey W. Wiley, appointed chief chemist in 1883, this division began to investigate the nation's food and drugs. Through controlled human clinical trials, he was able to demonstrate that many of America's foods and drugs were "adulterated" and products had inadequate labeling. Contemporaneously with Dr. Wiley's efforts, the nation was becoming more aware of the hazards of the food industry especially the publications of Upton Sinclair's *The Jungle* (which described the putrid conditions of meat industry). In 1902, the Virus, Serum, and Toxins Act (Biologics Control Act) was passed in response to tetanus-infected diphtheria antitoxin, which was produced by a small laboratory in St. Louis. Here, a horse named "Jim", a retired milk wagon horse was used to develop the diphtheria antitoxin. Unfortunately, he contracted tetanus and was humanely destroyed. Yet, his serum samples were not screened for tetanus and thus more than ten school-age children died as a result of the tainted serum.

In 1906, Congress passed and President Theodore Roosevelt signed the first food and drug law, the United States Pure Food and

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Drug Act (USPDA, also known as the Wiley Act). The Wiley Act prohibited the interstate sales of contaminated foods or misbranded drugs based on their labeling. Subsequently, in 1927, the Bureau of Chemistry was reorganized under a new USDA body called the Food, Drug and Insecticide Organization which evolved to the FDA for short [3]. Unfortunately, judicial decisions restricted the newly formed FDA to only enforce if the product's ingredients were incorrectly labeled even if intentionally false therapeutic claims were made. In 1937, a tragedy occurred that changed the future of modern medicine [4]. Sulfa was seen as a miracle drug that was used to treat life-threatening infections. Unfortunately it was unpleasant to consume and companies sought ways to create a palatable product. S.E. Massingill Co. of Bristol TN developed a raspberry liquid called Elixir of Sulfanilamide. However, it used diethylene glycol to dissolve the sulfa. Over 100 people died as a result of this single agent.

The result was the passage of one of the most comprehensive acts in American healthcare law, the federal Food Drug and Cosmetic Act of 1938 (FDCA). This law required all new drugs to be tested by their manufacturers and that those tests are submitted for review by the government for marketing approval via a new drug application (NDA). The FDCA still represents the broad basis for the statutory authority of the FDA today. In 1962, the Kefauver-Harris Act was implemented [5]. The critical component of this act was that all new drug applications would have to demonstrate convincing evidence of the drug's efficacy for the proposed indication in addition to previously required safety data. In addition, documented "informed consent" needed to be obtained prior to any human trials. Yet these new regulations led to emergence of a lengthy process for drug development. In 1984, Congress passed the Price Competition and Patent Restoration Act or better known as Waxman-Hatch Act [6]. This legislation was composed of two parts or "titles." The first one benefited generic pharmaceutical industry and allowed for easier market access to copies of pioneer drugs as long as they were not "significantly" different in absorption, action, and dosage. The second arm of this law was aimed at encouraging industry development of novel products by extending the patent life of the products for time lost during the FDA "review" process.

The length of the drug approval process fell under severe scrutiny during the emergence of the acquired immunodeficiency syndrome (AIDS) epidemic [7]. Pressures from AIDS activists in particular were critical in changing the rule. In 1992, the US Congress passed the Prescription Drug User Fee Act (PDUFA) which allowed the FDA to collect fees from drug sponsors to fund the new drug approval process [8]. In order to continue to collect such fees, the FDA is subjected to meet certain benchmarks; specifically the speed of certain activities within the review process. The law provided for exemptions and waivers for applications from small businesses, drugs aimed at orphan diseases or unmet public needs. In 1997, Congress expanded the scope and authority of the FDA with the FDA Modernization Act (FDAMA) in order to further develop with the evolving need of its citizens [8].

The FDA now has the authority to create an accelerated approval and a fast track process to speed lifesaving therapies to market. The fast track development program is a designation by the FDA that accelerates the approval of investigational new drugs which show promise in treating serious, life-threatening medical conditions where there are no other agents that either exist or work well. This status simply allows for more frequent meetings with the FDA to discuss drug development that should facilitate earlier drug approval and access by patients. This is distinct from the accelerated approval status. Here, the FDA allows a drug to be approved on the basis of an alternative or surrogate endpoint, which is reasonably likely to predict clinical benefit. A common approach is to identify a biological marker that "correlates" with the clinical efficacy endpoint and to document the effect of the novel therapy on this biomarker. For instance, in oncology, one approach is to report effects on tumor size or improved levels of biomarkers such as prostate-specific antigen (PSA). This would be distinct in that the traditional primary end-points, such as patient survival, would often require larger sample size or longer follow-up.

The structure of the FDA

As described above, the FDA originated in 1906 and is one of several divisions within the US Department of Human Health Services (HHS). Other agencies of the HHS include CDC, NIH, and the Centers for Medicare and Medicaid Services (CMS). The FDA is organized into a number of offices/centers. It is led by a commissioner who is appointed by the President and requires Senate confirmation. Figure 98.1 demonstrates the complexity of its responsibilities and operations. The FDA is headquartered in Silver Springs, Maryland where most of its operations are based. There are currently six centers: the Center for Drug Evaluation and Research (CDER), Center for Biologics Evaluation (CBER), Center for Devices and Radiological Health (CDRH), Center for Food Safety and Applied Nutrition (CFSAN), Center for Tobacco Products, and Center for Veterinary Medicine. There are additional offices which have unique responsibilities for drug development such as: Office of Combination Products and Special Programs, the Office of Ombudsman, and the Office of Orphan Products Development; the Office of Regulatory Affairs serves as the lead role in establishing and maintaining the standards and protocols for this organization. Each of these entities has their own defined role. However, with the rapidly advancing technologies, it is not surprising that there may be overlap in oversight. Drugs that are small molecular products are under the supervision of CDER, any of the other centers or offices may become involved as necessary. Biologics are substances that are derived from, or made by, the aid of living organisms such as antitoxins, serums, blood products, recombinant proteins, and cell therapies. Manufacturers of biologics must hold a license of the products that are issued by CDER. CBER is responsible for polyclonal antibody preparations and blood/tissue product derivatives such as IVIG or vaccines. If the drug is part of a combination product that has been deemed device, then it is under CDRH.

New drug development process

The FDA considers a "new" drug to be any substance that has a pharmacodynamic effect when administered with the intent for the diagnosis, treatment, or prevention of a disease state [9]. The critical piece is the intended use or the "indication" of the substance which reflects the foundation for its labeling and the necessary studies to demonstrate safety and efficacy. A "new" drug can also apply to an already FDA approved agent if there is a new intended use of the agent, new route of administration, or any other significant clinical difference [10]. In these situations, the substance must undergo the proper testing and FDA approval as if it was a novel agent. These are typically submitted as supplemental NDA (sNDA), which have the advantage of focusing on clinical studies, as the preclinical (e.g.

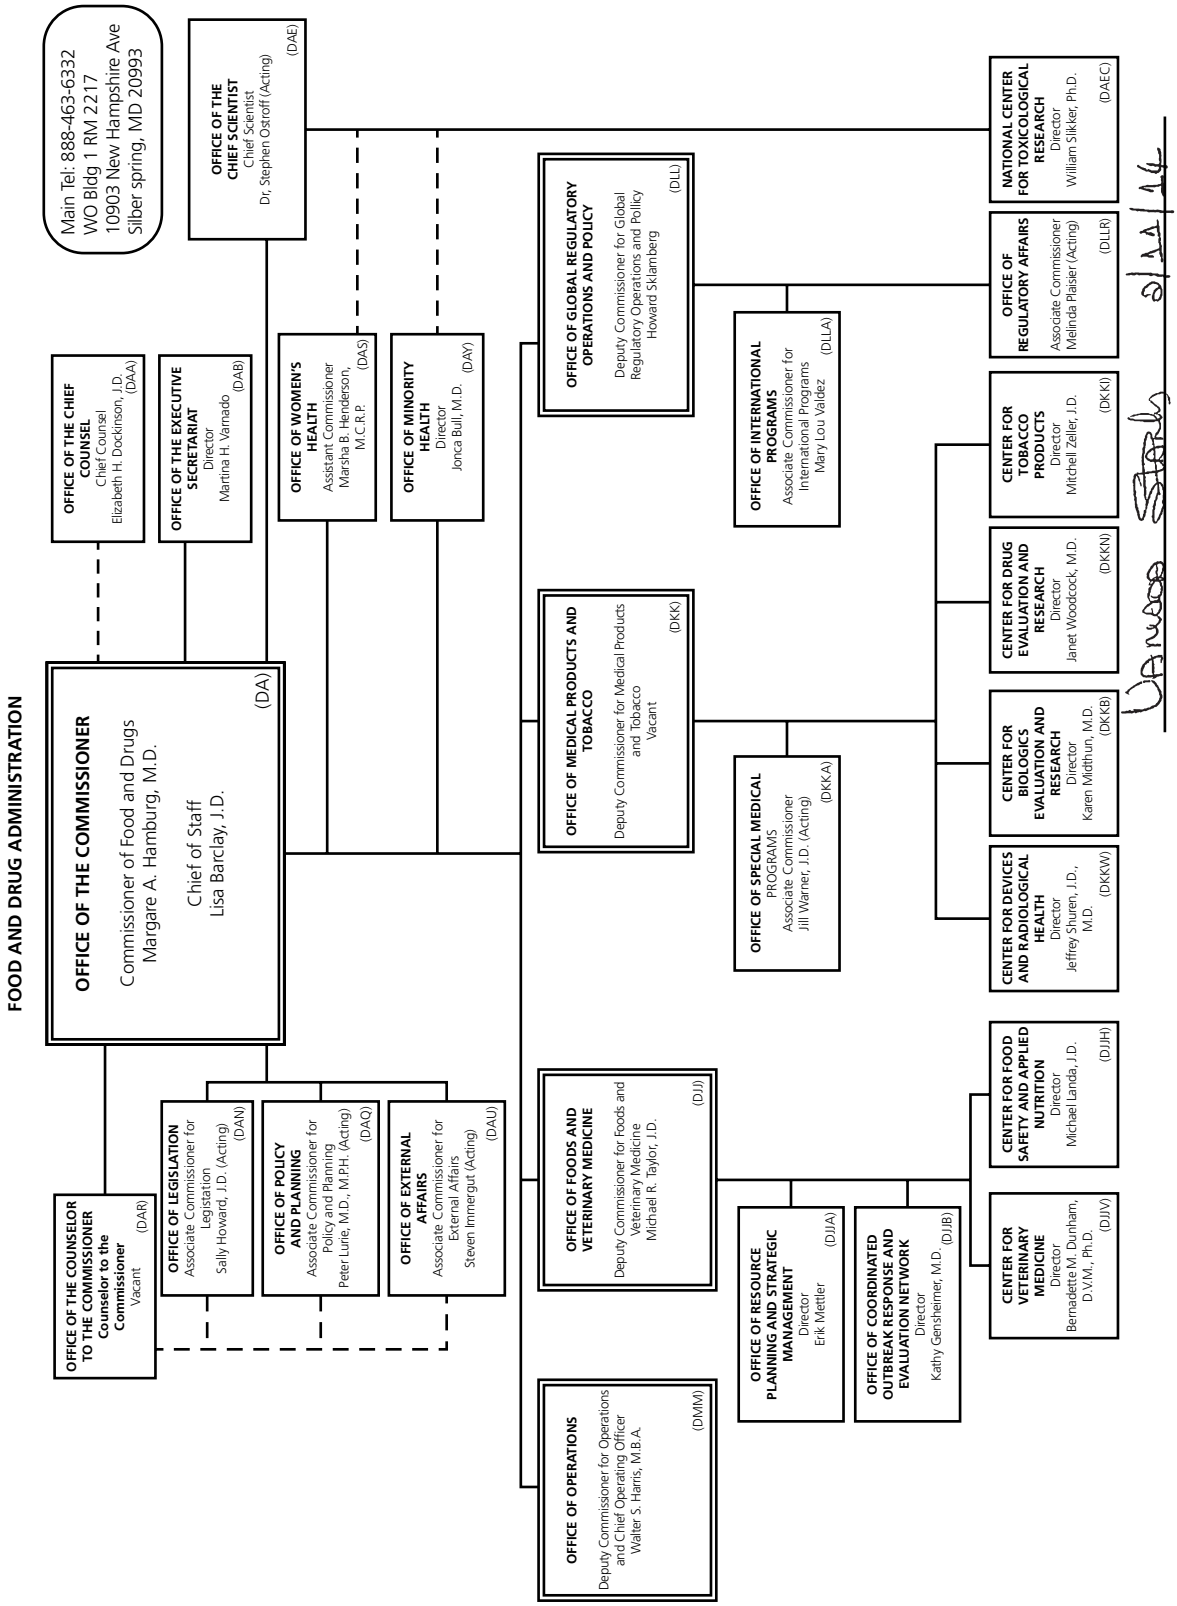

Figure 98.1. FDA Organization Chart. Reproduced from http://www.fda.gov/downloads/AboutFDA/CentersOffices/OrganizationCharts/UCM291886.pdf.

toxicology, animal studies, etc.) have already been reviewed in the original NDA. Briefly, the process begins with non-clinical studies, which involve in vitro studies and animal subject trials. This precedes the three phases of human clinical trials. Pertinent sections in the US Code of Federal Regulations (CFR) describe the elements of an adequate and well-controlled investigation, including details regarding the role of objectives, endpoints, controls, proper statistical analysis, and eligibility criteria. The regulations also include provisions regarding the importance of randomization and blinding. Importantly, the FDA through the CFR and FDA guidances makes clear that specific quantitative standards exist for proof of efficacy (whereas determinations of safety and overall risk-benefit generally rely on qualitative or semi-quantitative analyses). The FDA will review the results of these trials to determine final approval of the agent. Drugs are also subject to a fourth phase, known as post-market surveillance, which may include further education and patient monitoring.

Non-clinical investigations

A new molecular entity whose clinical safety has not been previously established will be required to undergo preclinical in vitro and in vivo animal testing. This represents the first major step in the drug development process. The principal goal of these investigations is to collect the necessary data to support the safety of early human trials [11]. The initial step is the drug discovery stage in which compounds are screened to determine if there is the desired pharmacologic activity. Subsequently, more complete in vitro studies are intended to elucidate the mechanisms of action, dose-response relations, and the pharmacodynamic effects of the novel agent. Pharmacokinetics analyses are performed in multiple species in order to provide information on the extent and duration of the systemic exposure to the new agent. These experiments are designed to describe the drug's absorption, distribution, metabolism, and excretion (ADME profile). Toxicity studies are critical to determine the short and long term physiological adverse effects. The "lethal" dose 50 (represents the dosage level that kills 50% of tested animals) has been replaced by the single dose with increasing dosage approach. The goal is to determine the no observed adverse (toxic) effect level (NOAEL) or the lowest dose necessary to see the desired pharmacological effect without adverse effects. The FDA does not regulate the conduct of non-clinical studies. However, to ensure the quality of the data produced, the laboratories must comply with Good Laboratory Practice (GLP) regulations. These establish basic standards for the organization, personnel, maintenance, and operating procedures of the facilities [12]. The FDA will perform on-site inspections to monitor compliance with GLP.

The investigational new drug application (IND)

The FDA carefully monitors clinical trials to protect the health of human subjects and to assure the highest level of integrity and value of the obtained data. Once the preclinical phase has accumulated sufficient evidence that the new agent exhibits the anticipated pharmacological effect to justify human experiments while demonstrating that it should be safe to proceed, then the sponsor will submit an investigational new drug application (IND). The IND is a process in which the FDA is notified of intent to initiate clinical trials with an investigational agent. Technically, an IND is a request for exemption from the Federal Food, Drug, and Cosmetic Act (FD&C) from prohibiting the interstate commerce of a new drug. Simply speaking, an IND allows one to legally ship an unapproved drug. The IND application provides the FDA with the necessary data to decide whether the proposed study is reasonably safe to proceed. An IND is required anytime one wants to perform clinical trials of an unapproved drug (such as novel indication, new dosage form, in combination with another drug) [13]. The regulations also exempt studies of approved drugs if the following criteria are met [14].

1. It is not for a new indication, or change in labeling or advertising for the product.
2. It will not involve a novel route of administration or dose level or patient population.
3. The studies will be in compliance with an IRB and informed consent.

The sponsor will submit the IND application to the FDA which primarily consists of: introductory statement, basic investigator plan, comprehensive protocols, the investigator brochure (the preclinical studies such as animal pharmacology and toxicology studies, pharmacological effects of the agent, pharmacokinetics studies), manufacturing information, and information on the investigators. After submission, the sponsor must wait 30 days prior to initiating any clinical studies. The FDA does not actually approve an IND, but rather would place a clinical hold if there were any objections to proceeding. Prior to any human testing, a clinical study protocol also must be reviewed and approved by an Institutional Review Board (IRB). The IRB is a committee of medical and ethical experts who oversee clinical research and are commissioned to uphold the most vigorous standards to ensure the safety of human subjects. Once the IRB has reviewed and approved the protocol and the necessary documents including the informed consent form, then human testing can begin. Clinical trials are classically conducted in three phases each with their specific purpose.

Phase I — "first in man" — studies, are designed to confirm the preclinical data in human subjects. Its purpose is to determine the pharmacokinetics actions, and confirm the safety of the agent's administration into healthy humans. These studies will often investigate if there was the desired pharmacological effect, although they often are not statistically designed to confirm this. Phase II studies are the clinical trials where subjects with the disease or condition are introduced to the new agent. This represents a fundamental shift on the focus of the process away from safety towards effectiveness. These studies will sometimes involve hundreds of human subjects. The purpose of this phase is to determine if the new agent has the desired efficacy against the disease. Typically, the investigational agent at several different treatment doses is compared to a placebo. Again, the results of this study are analyzed and used to design future protocols. A critical component of Phase II trials is the observed magnitude of treatment effect which will be used to determine the sample size for Phase III studies. At the end of the Phase II trial, the FDA and the sponsor will meet to discuss the results and plans for future studies.

Finally the "pivotal" Phase III study is conducted where the new agent is compared to FDA recognized and approved standard of care. These trials are designed to involve the patient population and clinical scenario that the sponsor seeks a label for. These studies are usually very large and involve hundreds to thousands of subjects. The larger patient pool allows the investigators to identify potential adverse effects, which are often relatively rare. At the conclusion of the trial, the investigators must be able to demonstrate "substantial evidence" or evidence from well-controlled investigations that could fairly be concluded by experts that the drug will have the effect under the conditions it is prescribed. With rare exception, at

least two adequate studies are necessary in order to obtain FDA approval to meet the scientific standards of reproducibility. However, the two studies do not have to be identical design; they could be performed in patient populations with different severities of disease or, in the case of transplantation, in different types of donors. Once all of the data has been collected and analyzed and the investigational agent has met the predetermined end-points of the Phase III study, then the sponsor is ready to ask the FDA for market approval for the intended indication.

Guidances relevant to FDA standards for establishing efficacy

Since a critical component of drug approval process involves efficacy, great care and foresight must be placed on this issue during trial design. Laws and regulations can outline general expectations, but the interpretations of their wording are often as important. As the agency responsible for their enforcement, FDA must regularly make determinations regarding the intent of the laws and regulations. In some instances, FDA may choose to issue guidance documents to elucidate its current thinking on a given topic. Although guidances do not have the force of law and do not bind the FDA to adhere to a given policy, they can provide important insight and may prove helpful to stakeholders interested in product development.

To date, no guidances specifically addressing transplantation trial design have been published. FDA, however, has produced several guidances regarding standards for clinical evidence. For instance, "Guidance for Industry: Providing Clinical Evidence of Effectiveness for Human Drugs and Biological Products" published in 1998 describes the quantity of evidence necessary to support efficacy — including the usual requirement for at least two adequate and well-controlled trials, but also contexts where reliance on a single trial may be appropriate [15]. Three other guidances, produced in conjunction with the regulatory bodies of the European Union and Japan as part of the International Conference on Harmonisation (ICH) Tripartite Guidelines, are also particularly worthy of notice: ICH E8 (General Considerations for Clinical Trials), ICH E9 (Statistical Principles for Clinical Trials), and ICH E10 (Choice of Control Group and Related Issues in Clinical Trials) – published in 1997, 1998, and 2000, respectively [15]. These three ICH documents provide considerable insight into the FDA view on a variety of design issues, including substantial discussions about the use of non-inferiority comparisons to active concurrent controls, for trials intended to support product approval.

Superiority and non-inferiority trials

Demonstrations of efficacy may be achieved through either superiority or non-inferiority trials. In superiority trials, the demonstration of efficacy for a given indication requires that the test product shows statistical superiority, typically using 95% confidence intervals, for a pre-determined primary clinical or surrogate endpoint. The interpretation of such a trial design is straightforward: if the endpoint is met, one would conclude, with the appropriate degree of confidence, that the product has at least some efficacy for the indication studied. Non-inferiority trials (previously known at FDA as equivalence trials), on the other hand, demonstrate the efficacy of a product by proving that the new treatment is not substantially inferior to an already marketed product. Non-inferiority trials seek to show that the differences between the two treatments are small enough to allow the investigators to conclude that the new drug has efficacy. A successful well conducted superiority trial has results that are fully interpretable, that speak for themselves. Non-inferiority trials are based on an assumption that the novel therapy has the expected effect which is used to determine assay sensitivity (the ability to determine an effective from non-effective agent) which relies on external or historical information.

New drug application

Since landmark legislation in 1938, the New Drug Application (NDA) has been the pathway for drug development in the United States. A sponsor would submit thousands of pages of documents covering the nonclinical and clinical data and analyses, the drug brochure, and information on many different areas. The information compiled here will serve as the basis to support the proposed labeling of the drug that the sponsor intends to market the drug. The NDA is reviewed by a panel of highly specialized experts who collectively decide whether to approve the application. A Biologics License Application (BLA) is used for biologic product rather than a NDA though the review process is similar. The required content of the NDA is outlined in the Food, Drug, and Cosmetic Act and Title 21 of the US Code of Federal Regulations (CFR). Applicants must provide significant evidence to allow the reviewers to decide that: the drug is safe and effective in its proposed use, the benefits of the drug outweigh the risks of using it or not having access to it, the drug's proposed labeling is appropriate, and the manufacturing of the agent is adequate. In addition, the FDA has established numerous guidance documents that may represent the current thinking process on the NDA review process [15]. As described earlier, the Prescription Drug User Fee Act (PDUFA) requires a speedier, more efficient review and establishes a time frame for a response to the sponsor.

The "clock" starts when the NDA arrives at the Controlled Document Room and the FDA was 60 days to decide whether to review the NDA. In order to file an NDA and begin the review process, the sponsor must pay the Prescription Drug User Fee, currently (for 2013) at $1,958,800 for an application requiring clinical data and $979,400 for an application not requiring clinical data [15]. The NDA is assigned a project manager who will perform a preliminary review to assure all the necessary components are present and there are no deficiencies. Next, the project manager will forward the appropriate sections of the NDA to different members of the review team, which may include clinicians, pharmacists, toxicologists, statisticians, and chemists to perform a second review to determine if the NDA should undergo a formal review (usually occurs with 45 days of receiving the NDA). Finally, the NDA is subjected to a formal review, which will include inspections of the drug manufacturing sites and potentially the clinical trial sites. Each member of the team will prepare a written evaluation of his or her section of the NDA. An "approval" means that the drug is ready to be marketed under its label. The review team could also recommend "approvable" which mean the sponsor needs to resolve additional issues before it can be marketed. Finally, the review team could recommend "nonapprovable" which would require justification for this decision.

Review of NDA and BLA applications received from sponsors represents a top priority of the Center for Drug Evaluation and Research (CDER) and the Center for Biologics Evaluation and Research (CBER) at FDA. The system has the advantage of allowing an efficient allocation of resources within FDA, as the onus of producing and organizing the data supporting an NDA or BLA

application lies with its sponsor. The system relies on economic forces to provide incentive to sponsors to conduct the necessary trials and submit the relevant data to the FDA for review. An important consequence of the system is that applications determine the approvals (and many of the other labeling changes) considered by the FDA – a fundamental prerequisite of the FDA granting an approval for an indication related to solid organ transplantation is the submission of an application by a sponsor.

The public may infer that all FDA approved products have demonstrated their safety and efficacy in studies submitted to and reviewed by FDA. The absence of an FDA approval for a given indication implies that either an application has not been submitted or that the application has not yet been determined to be adequate to demonstrate the safety and efficacy of the product in the relevant context. In special circumstances, the FDA can require the sponsor to place a boxed warning, "black box warning", on the labeling of a prescription drug and in literature describing it. It is the strongest warning that the FDA requires, and signifies that medical studies indicate that the agent carries a significant risk of serious or even life-threatening adverse effects [16].

Post marketing surveillance

Over the past decade, a series of safety issues arose with a number of drugs after their approval, including rofecoxib, rosiglitazone, and natalizumab. Even after the NDA is approved, the applicant must conduct post-marketing monitoring for safety and newly reported adverse events. Since drugs are approved on the basis of well controlled clinical trials, post-marketing monitoring can further define the safety of the drug after it is introduced to the general population who has a wide variety of medical conditions. In 2007, Congress passed legislation called FDA Modernization Act of 2007 (FDAAA) which contained new strategies and safety programs specifically to evaluate and minimize the risks of new agents. Congress introduced the concept of risk evaluation and mitigation strategies (REMS) and post marketing requirements (PMR) that provide FDA greater authority to mandate risk aversion strategies.

Under Title IX, Subtitle A, Section 901 of the FDAAA created Section 505-1 of the Federal Food, Drug and Cosmetic Act, the FDA has the authority to require a company, at the time of NDA or any time after approval, to submit REMS if the agency determines it necessary to ensure that the benefits of the drug outweigh its risks [17]. REMS is defined as a strategy to manage known or potential serious risk associated with the use a drug. All REMS must have specific goals and the elements constitute the tools by which the goals are achieved. The elements of the REMS may include one or more of the following: medication guide and/or Patient Package Insert (PPI), Communication Plan for Healthcare Providers, and Elements to Assure Safe Use (ETASU). Medication guides are designed to provide potential patients with information about the safe use of the product. The purpose of the guide is to prevent serious adverse events by potentially affecting the patient's decision to use or continue the medication, or when specific instructions can aid in improving patient's adherence. PPI are designed to instruct patients on the safe use of the drug product. The medication guide, but not the PPI, must be provided to the patient every time the produce is dispensed [18]. Communication plans are designed to educate healthcare providers on the appropriate and safe use of the product through various communications means including letters or materials to the providers. Finally, ETASUs are utilized when safe access for patients to products with known risks are otherwise unavailable. ETASUs may include special certification of healthcare providers who prescribe the product or special certification of pharmacies that dispense the product, or restrictions of product distribution (limited to patient enrolled in a registry, or in specific treatment settings). As part of REMS, the sponsor must demonstrate a post-marketing plan to monitor for the potential risk and provide the FDA with an assessment no less frequent than 18 months, three years, and seven years post approval. This report should comment on the success of the REMS elements in achieving their goals. Between 2008 and 2011, roughly 35% of all NDAs have required REMS; though the majority has only required a medication guide. Of the 178 REMS, there have been 48 REMS which required a communication plan and only 21 have an ETASU [15]. In the setting of a generic drug requiring REMS, both innovator and generic medications will share the same REMS, including the systems required by an ETASU.

Orphan drugs

Orphan drugs are approved using most of the processes described above with a few significant differences. An orphan drug is one that is used to treat a "rare" disease defined as a disease that afflicts fewer than 200 000 patients in the United States. Importantly, organ transplantation is considered an orphan indication by these standards and, as such, this policy is relevant to every drug being developed for a transplant indication. In addition, the drug's development would ordinarily be of limited interest to commercial manufactures because of the inability to recover the financial costs. The Orphan Act of 1993 offers financial incentives to sponsors to promote the development of these necessary agents such as federal grants for clinical research, tax credits for development, and seven year market exclusivity for sponsor who obtains federal approval.

Abbreviated new drug applications

The FDA approves generic drugs through the abbreviated new drug application (ANDA) pathway. The manufacturer is able to submit this abbreviated application so that the approval will be effective immediately once the patent on the original product has expired. Unlike NDA applications, ANDA applications are not required to include clinical trial data to establish safety and efficacy. Instead, the FDA approves ANDA applications based on data establishing the bioequivalence and pharmaceutical equivalence of a generic drug to the approved innovator product. It is important to note that equivalence is defined as not being statistically significantly different. The FDA has set the range for pharmacokinetic data for the new product to be within 80–125% of the PK of the branded product. The field of transplantation has recently entered an era where generic versions of the mainstay agents such as mycophenolate mofetil (MMF) and tacrolimus have become widespread.

Challenges in drug development specific in solid organ transplantation

Efficacy endpoints considered in transplantation maintenance immunosuppression trials

Products approved as either initial or maintenance immunosuppressive agents since the advent of cyclosporine have generally

used a combined endpoint of acute rejection, graft loss, and death as a primary efficacy endpoint. In transplant literature, this combined endpoint has sometimes been referred to as the "traditional FDA combined endpoint". While such analyses have been used to establish the effectiveness of newer agents, it may be worth noting that FDA does not consider such analyses to represent either an "FDA" endpoint or a "combined" endpoint. Rather, during those reviews, the FDA agreed that acute rejection represented a significant clinical event constituting a treatment failure for therapies intended to modulate immune responses. From the FDA perspective, the endpoint of those trials has been acute rejection. Patients with missing data – whether due to death, graft loss, or loss to follow up – were simply imputed to have had episodes of acute rejection.

The use of an endpoint based on the incidence of acute rejection for the approval of immunosuppressive agents in transplantation has well-recognized limitations. The endpoint does not weigh, for instance, clinically important elements such as the severity of the rejection episodes. It has been suggested that use of alternative endpoints, such as those based on glomerular filtration rates (GFRs) and protocol biopsies, might augment the evaluation of patient outcomes in transplantation trials of immunosuppressive regimens. Indeed, for instance, GFR endpoints were considered during the reviews of both the belatacept and everolimus NDAs.

FDA is open to examining alternative endpoints, both for the prophylaxis of acute rejection as well as for more novel indications. However, the mandate to establish efficacy based on adequate and well-controlled investigations is non-identical with the desire of clinicians to identify optimal treatment regimens using randomized controlled trials. The most important function of a primary efficacy endpoint is to provide quantitative evidence of the effectiveness of an investigational agent. It should afford a clear demonstration of the contribution of the test product. Not all outcome measures, regardless of clinical importance, are well suited to this end in all contexts. Acute rejection endpoints have remained relevant because of the wealth of experience and data from past trials using such endpoints that are available to inform the design and interpretation of new trials.

Currently available immunosuppressive maintenance regimens offer reasonably potent efficacy as measured by endpoints based on acute rejection. But as in all drugs, they are associated with known toxicities (including reversible and non-reversible decreases to GFR as well as some particular nephrotoxicities evident on histopathology). Given the potency of the marketed products, the effectiveness of newer products is frequently established using trials designed to determine the non-inferiority rather than the superiority of the test product. Non-inferiority trials examine whether a newer product is not much less effective than the active control.

In order to perform a meaningful non-inferiority analysis, one must know the contribution to the effect of the element of the active control that the test product is replacing. To determine this contribution, one must have access to historical trials, which studied the desired endpoint by comparing outcomes with patients who received the active control and patients who received the putative placebo. Establishing non-inferiority margins for transplantation trials using endpoints based on acute rejection is challenging but sometimes possible, as many historical trials exist which captured reliable data for such endpoints. Establishing non-inferiority margins for trials using novel endpoints is often not possible as the requisite historical data do not exist or are not available.

Given the paucity of relevant historical trial data, more novel endpoints often must rely on trials designed to test the superiority of the investigational agent over the active control agent. As currently available therapies are potent, it can be challenging to prove that an experimental product is more effective than a marketed product. As marketed products have known toxicities, which limit their usefulness, it may be possible to demonstrate that use of a novel product results in a better outcome due to the absence of the relevant toxicity. Caution must be exercised, however, when designing such trials: absence of toxicity cannot itself constitute the efficacy of a test product. If an outcome is confounded by a known toxicity of the active comparator, the outcome may not be appropriate for use as a primary endpoint in a trial intended to support product approval.

Previous experience with GFR and CAN as efficacy endpoints for indications related to maintenance immunosuppression in kidney transplantation

GFR in kidney transplantation trials is illustrative of an important clinical outcome that is not always amenable to use as a primary efficacy endpoint. As a measure of kidney function, GFR would appear to represent a reasonable measure of the efficacy of an immunosuppressive agent in the setting of a kidney transplant: in the absence of effective immunosuppression, immune-mediated injury to the kidney will lead to a deterioration of kidney function and decreased GFR. Indeed, FDA might agree that such an endpoint would be interpretable in the setting of a placebo-controlled trial. Frequently, however, its use has been proposed in clinical trials where an investigational agent replaces a calcineurin inhibitor in the active comparator arm. In theory, one might pursue a non-inferiority trial design, but one would require reliable historical data regarding GFR outcomes associated with the putative placebo. Rather, sponsors typically propose to study GFR using a trial design to establish the superiority of the newer product. Calcineurin inhibitors (particularly cyclosporine), however, are known to cause vasoconstriction of the afferent renal artery, resulting in a physiologic decrease in GFR secondary to hemodynamic (not immunosuppressive) effects. The observation of statistically superior GFRs among patients randomized to the investigational arms, then, does not necessarily prove that the test products have greater (or even equivalent) efficacy. The deficiencies of previous trial designs do not preclude the use of GFR as a primary efficacy endpoint in the context of a maintenance immunosuppression trial; such trials, however, should rely on designs that ensure the endpoint is not confounded.

Protocol allograft biopsies have also been proposed as alternative efficacy endpoints in trials of newer products intended for maintenance immunosuppression but face similar challenges. Sponsors have proposed comparing the incidence of histopathologic diagnosis such as chronic allograft nephropathy (CAN) across study arms. CAN is a non-specific term used to describe various changes in renal histology thought to occur secondary to immunologic and non-immunologic injury. Insufficient historical trial data have been submitted and reviewed to allow the determination of non-inferiority margins based on a protocol biopsy endpoint. Furthermore, the use of CAN as a primary endpoint for a trial design intended to show the superiority of the test product is problematic for two reasons: 1) calcineurin inhibitor toxicity is one of the potential sources of non-immunologic injury to the kidney and 2) the clinical significance of a diagnosis of CAN is uncertain. If the incidence of CAN can be attributed, in at least some cases, to exposure

to the active control agent, the absence of CAN cannot prove the efficacy of the test agent. Proper use of efficacy endpoints based on protocol biopsies to show efficacy in the context of a maintenance immunosuppression trial would require trial designs that avoid confounding and that rely on a histopathologic finding with validated clinical significance.

FDA approved products for solid organ transplant

Immunosuppressants

The purpose of this section is to briefly review the immunosuppressive agents that have an FDA approved indication and are currently utilized in the US. Briefly, the critical features of the prescribing information will be reviewed in addition to the results of the clinical trials that led to each respective drug approval. The reader will quickly note that the approved indication of most drugs is substantially more limited than the common use of the drug in transplantation. Furthermore, it is apparent to any transplant practitioner that institutional dosing guidelines frequently stray from the approved dosing, and indeed, it is reasonable to say that there is no established regimen that clearly stands out as "best" for even the most common indications in transplantation. Furthermore, there are no guidelines included in approved labels recommending alterations in dosing over time, and with patients now on these drugs for decades, it is common for dosing to be generally reduced, without any clear regulatory approval of that practice. A comprehensive review of the mechanisms of action of these agents, and more detail on the "off-label" use of these and other medications will be discussed in Chapters 17 and 101, respectively. Practical uses are described in organ specific chapters on post transplant management. Several medications with FDA approved indications in organ transplant are not discussed due to the fact that they are no longer available for use in solid organ transplant recipients. These medications include: equine anti-thymocyte globulin, daclizumab, and muromonab-CD3.

Azathioprine (Imuran)

Azathioprine and steroids were considered the backbone of immunosuppression in organ transplantation from the early 1960's to early 1980's. Azathioprine received FDA approval in March of 1968 based on the NDA submitted by Prometheus Laboratories [19]. Currently, azathioprine is available as a generic through several companies who have submitted ANDAs. Azathioprine is indicated as an adjunct therapy option for the prevention of rejection in renal transplantation. According to the prescribing information, "experience with over 16 000 transplants shows a 5-year patient survival of 35% to 55%" [20]. This statement was made with the caveat that this was dependent on several factors including: the donor, match for HLA antigens, anti-donor or anti-B cell alloantigen antibody, and other variables not tested in controlled trials. Azathioprine is thought to suppress cell-mediated hypersensitivities and causes variable alterations in antibody production with little effect on established graft rejections or secondary responses. The safety and efficacy of azathioprine in pediatric patients has not been established. Dosing recommendations in the prescribing information include an initial dose of 3 to 5 mg/kg daily, beginning at the time of transplant. Therapeutic plasma level monitoring is of little predictive value due to the extensive metabolism of azathioprine, conversion to 6-mercaptopurine, and subsequent conversion to thiopurine nucleotides. Patients with reduced levels of thiopurine S-methyl transferase (TPMT) may be at an increased risk for severe, life threatening abnormalities, requiring reduced doses of azathioprine. TPMT genotyping or phenotyping can be used to identify patients at risk in conjunction with complete blood count monitoring for all patients. Finally, it appears that the data resulting in the FDA approved indication for renal transplantation does not necessarily reflect current transplant medication practices, as the prescribing information does not contain information regarding the use of azathioprine in conjunction with other maintenance immunosuppressants [20].

Cyclosporine (Sandimmune/Neoral/Gengraf)

Cyclosporine is a powerful immunosuppressive medication that revolutionized organ transplantation as the first of the calcineurin inhibitors. The impact of using cyclosporine occurred not only in kidney transplantation, but also heart and liver transplantation as well. Cyclosporine received its original FDA approval in November of 1983 for oral and injectable solutions; however, due to its poor bioavailability newer formulations were developed and approved in 1990 and 1995 respectively. The capsule formulation of cyclosporine, marketed under the brand name Sandimmune® was approved in 1990 with the original patent held by Novartis (Basel, Switzerland) [21]. Modified cyclosporine, also produced by Novartis and marketed under the brand name Neoral®, received FDA approval in 1995 [22].

Both cyclosporine and modified cyclosporine are indicated for the prophylaxis of organ rejection in kidney, liver, and heart allogeneic transplantations. However, there are slight variations between the indications for cyclosporine and cyclosporine modified. The prescribing information for cyclosporine states that it is always to be used with adrenal corticosteroids and may be used in the treatment of chronic rejection in patients previously treated with other immunosuppression agents [23]. The prescribing information for modified cyclosporine states that it has been used in combination with azathioprine and corticosteroids [24]. The differences in the prescribing information are also reflected in the clinical pharmacology for the two agents. The clinical pharmacology of cyclosporine is predicated by the statement that the exact mechanism of action of cyclosporine is not known, but "experimental evidence suggests the effectiveness of cyclosporine is due to specific and reversible inhibition of immunocompetent lymphocytes in the G0 or G1 phase of the cell cycle" [23].

Dosing recommendations for cyclosporine and modified cyclosporine are reflective of the differences in the pharmacokinetic properties of the formulations, and it is safe to say that the approved dosing is infrequently followed in modern clinical practice. An initial oral dose of cyclosporine of 15 mg/kg is recommended to be administered 4 to 12 hours prior to transplantation. This single daily dose should be continued for up to 2 weeks followed by a tapering strategy of a 5% daily dose reduction to doses as low as 3 mg/kg/day [23]. Modified cyclosporine can be given 4–13 hours prior to transplantation or postoperatively, with doses ranging from 7 to 9 mg/kg/day administered in two equally divided doses. Subsequent doses should be adjusted to obtain the target cyclosporine blood concentrations. The target range for trough levels is identical between cyclosporine and modified cyclosporine, although patients will receive greater exposure of modified cyclosporine at any given target range as compared to cyclosporine. Therefore, lower target troughs of modified cyclosporine may provide adequate immunosuppression. In addition, converting patients from modified cyclosporine to cyclosporine utilizing a 1 : 1 ratio may result in lower cyclosporine blood concentrations [24]. The prescribing information for both formulations also includes

dosing recommendations for adjunct therapy with adrenal corticosteroids with a 2-month tapering strategy. Though no adequate and well controlled pediatric studies have been conducted, patients as young as 6 months of age have received the drug with no "unusual" adverse effects. Pediatric dosing recommendations are weight based using adult dosing with similar pharmacokinetic differences between formulations observed [23,24].

Multiple ANDA applications for cyclosporine have been approved, utilizing both cyclosporine and modified cyclosporine as the reference product. In order to differentiate between all of the products available, the following are the full generic names utilized for each formulation. Cyclosporine capsules, USP and cyclosporine oral solution, USP refers to the oil-based product Sandimmune®, whereas cyclosporine capsules, USP Modified and cyclosporine oral solution, USP Modified refers to the microemulsion product, Neoral®. Branded generic modified cyclosporine is available under the trade name Gengraf® with the following generic drug name: cyclosporine capsules, USP Modified.

Tacrolimus (Prograf®)

Tacrolimus is an immunosuppressive agent that has significantly improved clinical outcomes in liver and kidney transplantation. Unlike other agents, tacrolimus first received FDA approval in 1994 for use in liver, as opposed to kidney, allograft transplantation recipients [25]. In 1997, tacrolimus received an indication for use in kidney transplantation allograft recipients. Finally, tacrolimus received an indication for use in heart allograft transplantation in 2006, representing the most recent indication to be added to tacrolimus. Since 2009, the FDA has approved several ANDA applications for generic versions of tacrolimus [26].

The full FDA approved indication for tacrolimus is for prophylaxis of organ rejection in kidney, liver, and heart transplant. Tacrolimus is recommended to be used concomitantly with azathioprine or MMF and adrenal corticosteroids for kidney and heart transplant. For liver transplant patients, tacrolimus is recommended to be used concomitantly with adrenal corticosteroids [27]. As described in the prescribing information, tacrolimus inhibits T-lymphocyte activation by binding the intracellular protein FKBP-12. This complex then binds with calcium, calmodulin, and calcineurin to prevent the formation of lymphokines, which prevents T-lymphocyte activation [27]. As with cyclosporine, the actual use of tacrolimus strays significantly from its indicated regimen.

Due to its significant intersubject variability and based on its pharmacokinetic properties, tacrolimus requires individualized dosing for optimal therapy. Tacrolimus is incompletely and variably absorbed, with decreased absorption associated with the presence of food. The trough blood level at 10 to 12 hour post-dose or Cmin level was found to correlate with the AUC in small pharmacokinetic studies with tacrolimus. Tacrolimus is 99% plasma protein bound and undergoes extensive hepatic metabolism by the cytochrome P-450 system, specifically CYP3A4. Tacrolimus is 92.6% fecally eliminated, as demonstrated by a small study in healthy volunteers using radiolabeled tacrolimus. Although pharmacokinetic studies for tacrolimus in the pediatric transplant population is limited, there was sufficient experience with pediatric liver transplant patients for the inclusion of pediatric liver transplantation dosing recommendations in the prescribing information.

The FDA approved dosing recommendations for tacrolimus are included for adult heart, liver, and kidney transplant patients as well as for pediatric liver transplant patients in Table 98.1. All doses are weight based in milligrams per kilogram of body weight, administered as two divided doses 12 hours apart. The prescribing information includes the following starting doses for tacrolimus with the target whole blood trough concentrations for individualized dose titration. In addition, the prescribing information suggest that both African American and pediatric liver transplant patients may require higher doses of tacrolimus per body weight in order to reach the target trough level [27].

Table 98.1. Summary of Initial Oral Dosage Recommendations and Observed Whole Blood Trough Concentrations

Patient Population	Recommended Initial Oral Dosage[a]	Obrerved Whole Blood Trough Concentrations
Adult kidney transplant patients		
In combination with azathioprine	0.2 mg/kg/day	mouth 1–3: 7–20 ng/mL mouth 4–12: 5–15 ng/mL
In combination with MMF/IL-2 receptor antagonist[b]	0.1 mg/kg/day	month 1–12: 4–11 ng/mL
Adult liver transplant patients	0.10–0.15 mg/kg/day	month 1–12: 5–20 ng/mL
Pediatric liver transplant patients	0.15–0.20 mg/kg/day	month 1–12: 5–20 ng/mL
Adult heart transplant patients	0.075 mg/kg/day	month 1–3: 10–20 ng/mL month ≥4: 5–15 ng/mL

[a] Note: two divided doses, ql 21 h.
[b] In a second smaller study, the initial dose of tacrolimus was 0.15–0.2 mg/kg/day and observed tacrolimus concentractions were 6–16 ng/mL during month 1–3 and 5–12 ng/mL during month 4–12 (see **CLINICAL STUDIES**).
Reproduced from [27] with permission.

As mentioned previously, the clinical trials that resulted in the original FDA approval of tacrolimus in 1994 were first conducted in liver transplantation. The safety and efficacy of a tacrolimus-based regimen was assessed in two prospective, randomized, non-blinded phase III multicenter trials. The studies evaluated 12-month patient and graft survival, comparing a regimen consisting of tacrolimus and adrenal corticosteroids to a regimen of cyclosporine, azathioprine, and adrenal corticosteroids. The first study was conducted in the US (n = 529) [28] while the other was conducted in Europe (n = 545) [29]. Both studies reported similar one-year patient and graft survival between treatment arms. Overall outcomes were also similar between the two studies in terms of patient and graft survival. The study reported trough blood concentrations up to one-year post transplant that ranged from 9.8 ng/ml to 19.4 ng/ml. As a result, of these studies, tacrolimus was found to be equivalent to cyclosporine-based regimens and received FDA approval for liver transplantation.

Subsequent trials with tacrolimus in renal transplantation resulted in the addition of kidney transplantation as an FDA approved indication for tacrolimus in 1997. Tacrolimus was initially evaluated in combination with azathioprine and corticosteroids in a Phase III randomized, multicenter, non-blinded prospective study [30]. All patients (n = 412) received induction immunosuppression therapy consisting of an antilymphocyte antibody preparation, corticosteroids, and azathioprine. Patients were randomized to either tacrolimus (n = 205) or cyclosporine (n = 207) with the first dose being initiated once the serum creatinine was less than 4 mg/dl. In terms of one-year outcomes, there were no significant differences in patient or graft survival in comparing tacrolimus and cyclosporine. Patient survival was 95.6% and 96.6% respectively, whereas graft survival was 91.2% and 87.9% respectively. However, there was a significant reduction in biopsy proven acute rejection in the tacrolimus treatment group (30.7% vs. 46.4%, P = 0.001). The authors

Table 98.2. Estimated creatinine clearance at 12 months in renal transplant patients

Group	eCLcr [mL/min] at Month 12[a]				
	N	MEAN	SD	MEDIAN	Treatment Difference with Group C (99.2%CI[b])
(A) CsA/MMF/CS	390	56.5	25.8	56.9	−8.6 (−13.7, −3.7)

[a] 95% confidence interval calculated using Fisher's Exact Test.

concluded that tacrolimus was more effective at reducing acute rejection episodes as compared to cyclosporine, while reducing the amount of antilymphocyte antibody preparation needed [30]. This study resulted in FDA approval of tacrolimus for use in conjunction with adrenal corticosteroids in liver or kidney transplant patients.

More recently, two phase III studies evaluated the combination of tacrolimus with MMF for use in kidney transplant patients. The ELITE-Symphony study involved 1589 kidney transplant patients, who were randomized into four treatment arms consisting of tacrolimus (Group C, n = 401), sirolimus (Group D, n = 399), or one of two cyclosporine regimens (Group A (standard dose), n = 390 and Group B (low dose), n = 399) [31]. In addition to MMF and corticosteroids, all groups with the exception of Group A received induction immunosuppression therapy with daclizumab. The primary outcome of the study was a comparison of renal function at 12 months using the estimated creatinine clearance (calculated by Cockcroft-Gault). Patients receiving tacrolimus had improved renal function at 12 months with significantly higher calculated creatinine clearance when compared to the other treatment groups (Table 98.2).

In terms of the secondary outcomes, treatment failure was defined as biopsy proven acute rejection, graft loss, death, and/or patient lost to follow up. Patients receiving tacrolimus (Group C) demonstrated fewer treatment failures, with the differences between Group C and each treatment group achieving statistical significance. Of note, patients receiving tacrolimus in combination with MMF were more likely to develop diarrhea and diabetes [31].

The second study was a phase III, randomized (1:1:1) open-label, multicenter, three arm noninferiority study conducted in the United States, Canada, and Brazil [32]. This study compared three regimens consisting of MMF, corticosteroids, and basiliximab induction for kidney transplant patients in combination with: extended release tacrolimus (n = 214), standard tacrolimus (n = 212), and cyclosporine (n = 212). The primary endpoint of this study was a combined efficacy failure at 1 year comprising of biopsy proven acute rejection, graft loss excluding death, mortality, and lost to follow up. Extended release tacrolimus is not currently FDA approved and, therefore, the prescribing information only reports the results of this study with regard to the standard tacrolimus treatment group (Table 98.3), although both tacrolimus groups achieved noninferiority to cyclosporine in terms of the primary outcome. Although the difference in mortality was not statistically significant, there was a higher mortality in the standard tacrolimus group (4.2% tacrolimus vs. 2.4% cyclosporine). No trends were identified, although three deaths attributed to sepsis were identified in the tacrolimus group as compared to none in the cyclosporine group. As a result of this study, as well as the ELITE-Symphony study, tacrolimus received an indication for kidney transplantation in combination with MMF [32].

Tacrolimus received an FDA approved indication for heart transplantation in 2006 as a result of two Phase III studies that compared the safety and efficacy of tacrolimus-based and cyclosporine-based regimens. The first study was conducted in Europe (n = 314) and stratified patients to treatment for 18 months with either tacrolimus or modified cyclosporine in combination with antibody induction, corticosteroids, and azathioprine [33]. The second study (n = 331) was conducted in the US and stratified patients to treatment for one year according to three groups consisting of: corticosteroids plus tacrolimus and sirolimus, tacrolimus plus MMF, or cyclosporine modified plus MMF for 1 year [34]. In each study, there was no significant difference in patient/graft survival at the treatment endpoint of either 18 months (91.7% tacrolimus vs. 89.2% cyclosporine) or 1 year (91.7% tacrolimus vs. 86.1% cyclosporine) respectively. The sirolimus arm of the study conducted in the US did find an increased risk of wound healing complications and insulin dependent post-transplant diabetes mellitus, and is therefore not recommended [34].

Mycophenolate mofetil (Cellcept)

Mycophenolate mofetil is a powerful anti-metabolite that was first approved for use in kidney transplantation in 1995 [35]. Subsequent studies resulted in additional indications added for heart and liver transplantation in 2000. Since 2009, the FDA has approved several ANDA applications for generic versions of MMF [36]. The current FDA approved indication of MMF is the prophylaxis of organ rejection in patients receiving allogeneic kidney, heart, and liver transplants [37]. The prescribing information also states that MMF is to be used in combination with cyclosporine and corticosteroids. Mycophenolate mofetil is a prodrug of mycophenolic acid, which is the active metabolite. Mycophenolic acid is a potent, selective, uncompetitive and reversible inhibitor of inosine monophosphate dehydrogenase that inhibits de novo purine synthesis. Due to the fact that T- and B-lymphocytes lack a salvage pathway for

purine synthesis, mycophenolic acid is able to prevent lymphocyte proliferation [37].

The pharmacokinetic properties of MMF are well described. It is rapidly absorbed following oral administration and hydrolyzed to form mycophenolic acid. The mean absolute bioavailability of oral versus intravenous MMF is 94%. There is evidence to suggest that mycophenolic acid undergoes enterohepatic recirculation, which contributes to sustained plasma concentration levels. Due to its teratogenic effects, MMF is pregnancy category D. The use of MMF in pregnancy is associated with increased risk of first trimester pregnancy loss and congenital malformations. This is based on animal reproductive toxicology studies and data from the National Transplantation Pregnancy Registry (NTPR) [38]. This risk is currently being addressed by the FDA in the form of a Risk Evaluation and Mitigation Strategy program for all MMF containing compounds, implemented in November of 2012 [38].

Mycophenolate mofetil received approval for use in kidney transplantation based on three randomized double blind, multicenter prospective trials. All three studies compared two doses (1 gram and 1.5 gram) of MMF twice daily with either azathioprine (2 studies) or placebo (1 study). All of studies utilized concomitant cyclosporine and corticosteroid therapy, with one study utilizing equine antithymocyte globulin. One study was conducted in the United States (n = 499; Table 98.4), the second study was conducted in Europe (n = 503), and the last study was conducted in Europe, Canada, and Australia (n = 491) [39–41]. The primary efficacy end-point of all three studies was treatment failure within the first six months, defined as biopsy proven acute rejection, death, graft loss, and early termination from study. Patients receiving MMF had a statistically significant reduced incidence of treatment failure within the first 6 months following transplantation. More patients receiving MMF discontinued therapy without biopsy proven acute rejection, death, or graft loss than in the control arms, with the highest discontinuation rates in the MMF 3 grams per day groups. This was likely due to increased drug intolerance at the higher dose. There was no advantage to MMF compared to control with respect to one year patient or graft survival [37].

In 2000, MMF received an indication for heart transplantation based on the results of a double-blind, randomized, parallel-group, multicenter study, the results of which are summarized in Table 98.5 [42]. This multination study was conducted in primary cardiac transplant recipients, who received either MMF 1.5 g (n = 289) twice daily or azathioprine (n = 289) in combination with cyclosporine and corticosteroids. The two primary end-points were endomyocardial biopsy-proven rejection with hemodynamic compromise and graft failure or death in the first six months, and the proportion of patients who died or were retransplanted in the first 12 months. There were no differences between the treatment groups for the incidence of biopsy proven rejection or patient survival. Based on this study, MMF was shown to be at least as effective as azathioprine with respect to rejection and survival [42].

The final indication for liver transplantation was approved by the FDA in 2000 based on the results of a double blind, randomized, comparative, parallel group multinational, multicenter study in primary liver transplant patients [43]. Patients (n = 565) receive modified cyclosporine and corticosteroids in combination with either MMF 1 gram twice daily intravenously for 14 days followed by MMF 1.5 g twice daily or azathioprine intravenously followed by oral azathioprine. The two primary end-points were as follows: the proportion of patients with biopsy proven rejection, death, or retransplantation within the first six months; and the proportion of patients with graft loss due to death or retransplantation within the first 12 months. The study (summarized in Table 98.6) found that patients on MMF mofetil experienced significantly lower rates of

Table 98.4. Incidence of treatment failure in renal transplant patients within 6 months post-transplant

USA Study[a] (N = 499 patients)	**MMF 2 g/day (n = 167 patients)**	**MMF 3 g/day (n = 166 patients)**	**Azathioprine 1 to 2 mg/kg/day (n = 166 patients)**
All treatment failures	31.1%	31.3%	47.6%
Early termination without prior acute rejection[b]	9.6%	12.7%	6.0%
Biopsy-proven rejection episode on treatment	19.8%	17.5%	38.0%

All treatment failures	38.2%	34.8%	50.0%
Early termination witout prior acute rejection[b]	13.9%	15.2%	10.2%
Biopsy-proven rejection episode on treatment	19.7%	15.9%	35.5%
Europe Study[d] (N = 491 patients)	**MMF 2 g/day (n = 165 patients)**	**MMF 3 g/day (n = 160 patients)**	**Placebo (n = 166 patients)**
All treatment failures	30.3%	38.8%	56.0%
Early termination-without prior acute rejection[b]	11.5%	22.5%	7.2%
Biopsy-proven rejection episode on treatment	17.0%	13.8%	46.4%

[a] Antithymocyte globulin induction/MMF or azathioprine/cyclosporine/corticosteroids.
[b] Does not include death and grafc loss as reason for early termination.
[c] MMF or azathioprine/cyclosporine/corticosteoids.
[d] MMF or placebo/cyclosporine/corticosteroids.

Table 98.5. Rejection at 6 months and death or retransplantation at 1 year in cardiac transplant patients

	All Patients		**Treated Patients**	
	AZA N = 323	**MMF N = 327**	**AZA N = 289**	**MMF N = 289**
Biopsy-proven rejection with hemodynamic compromise at 6 months[a]	121 (38%)	120 (37%)	100 (35%)	92 (32%)
Death or retransplantation at 1 year	49 (15.2%)	42 (12.8%)	33 (11.4%)	18 (6.2%)

[a] Hemodynamic compromise occurred if any of the following criteria were met: pulmonary capillary wedge pressure ≥20 mm or a 25% increase; cardiac index <2.0 L/min/m2 or a 25% decrease; ejection fraction ≤30%; pulmonary artery oxygen saturation ≤60% or a 24% decrease; presence of new S3 gallop; fractional shortening was ≤20% or a 25% decrease; inotropic support required to manage the clinical condition.

Table 98.6. Rejection at 6 months and death or retransplantation at 1 year in liver transplant patients

	AZA N = 287	**CellCept N = 278**
Biopsy-proven, treated rejection at 6 months (includes death or retransplantation)	137 (47.7%)	107 (38.5%)
Death or retransplantation at 1 year	42 (14.6%)	41 (14.7%)

acute rejection at six months when death or retransplantation were included as part of the primary endpoint.

When the primary endpoint of rejection was censored for graft loss due to death or retransplant, the difference between MMF and azathioprine did not retain statistical significance. With regards to patient survival at one year, there were no differences in graft loss between treatment groups [43].

Enteric-coated acid as mycophenolate sodium (Myfortic)

Mycophenolate sodium delayed release tablets are an enteric coated formulation that directly delivers the active moiety mycophenolic acid. Enteric-coated mycophenolate sodium (EC-MPS) was approved in 2004 for the prophylaxis of organ rejection in patients receiving allogeneic renal transplants in combination with cyclosporine and corticosteroids [44]. Mycophenolate sodium has an identical mechanism of action to MMF due to the fact that they share the same active metabolite. EC-MPS is an uncompetitive and reversible inhibitor of inosine monophosphate dehydrogenase, which inhibits de novo purine synthesis and therefore, proliferation of B- and T-lymphocytes, which lack a salvage pathway for purines [45].

Due to its enteric-coated formulation, mycophenolate sodium has unique pharmacokinetic properties. There is an anticipated delay in the rise of mycophenolic acid concentration that ranges from 0.25 to 1.25 hours, with a median time to max concentration ranging from 1.5 to 2.75 hours. In comparison, the median time to max concentration of MMF ranged from 0.5 to 1.0 hours. The absolute bioavailability of EC-MPS was 72%. In terms of equimolar dosing, mean systemic mycophenolic acid exposure as determined by the AUC was similar in both single and multiple-dose cross-over trials with doses of mycophenolate sodium 720 mg and MMF 1000 mg, both dosed twice daily. Similarly to MMF, EC-MPS is pregnancy category D [45]. The use of EC-MPS in pregnancy is associated with an increased risk of first trimester pregnancy loss and congenital malformations. This is based on animal reproductive toxicology studies and data from the National Transplantation Pregnancy Registry (NTPR). This risk is currently being addressed by the FDA in the form of a Risk Evaluation and Mitigation Strategy program for all mycophenolate containing compounds, implemented in November of 2012 [38]. The safety and effectiveness of EC-MPS in pediatric de novo renal transplant patients has not been established. In stable pediatric renal transplant patients (ages 5 through 16), the safety and effectiveness is supported by adequately controlled adult studies; however, there is limited pharmacokinetic data [45].

The prescribing information for EC-MPS includes dosing recommendations for both adult and pediatric patients. The recommended adult dose of EC-MPS is 720 mg twice daily on an empty stomach, one hour before, or two hours after food intake. The delayed release tablet should not be chewed, crushed, or cut prior to ingestion. The recommended pediatric dose of EC-MPS is 400 mg/m^2 twice daily with a maximum dose of 720 mg twice daily, rounded to the nearest whole 180 mg tablet. Pediatric patients with a body surface area less than 1.19 m^2 [2] should not receive EC-MPS as the dose cannot be accurately administered with the currently available tablet formulations [45].

Mycophenolate sodium received FDA approval for use in kidney transplant patients based on two Phase III multicenter, randomized, trials in de novo and maintenance renal transplant patients. Both studies compared EC-MPS at a dose of 1.44 grams per day to MMF 2 grams per day. The de novo study was a multinational study with patients randomized either to MMF (n = 213) or EC-MPS (n = 210) within 48 hours post-transplant in combination with modified cyclosporine and corticosteroids [46]. Of note, the use of antibody induction was not controlled with only 41% of patients receiving antibody induction. The primary end point of the study was treatment failure, defined as first occurrence of biopsy proven acute rejection, graft loss, death, or lost to follow up at 6 months. The results of this study, shown in Table 98.7, suggest that there was no difference in the occurrence of treatment failure at 6 or 12 months between EC-MPS and MMF.

Table 98.7. Treatment failure in *de novo* renal transplant patients at 6 and 12 months therapy in combination with cyclosporine* and corticosteroids

	EC-MPS 1.44 g/day (n = 213)	mycophenolate mofetil 2 g/day (n = 210)
6 Months	**n (%)**	**n (%)**

Lost to follow-up**	5 (2.3)	0

* USP (MODIFIED).
** Lost to follow-up indicates patients who were lost to follow-up without prior biopsy-proven acute rejection, graft loss or death.
*** Lost to follow-up indicates patients who were lost to follow-up without prior graft loss or death (9 Myfortic patients and 4 mycophenolate mofetil patients).
# 95% confidence interval of the difference in treatment failure at 6 months (Myfortic – mycophenolate mofetil) is (−8.7%, 8.0%).

The maintenance study was conducted in 322 patients who were at least six months post transplant and were on MMF with modified cyclosporine with or without corticosteroids [47]. Patients were randomized to either mycophenolate sodium or MMF with a primary end point of treatment failure, as defined by the first occurrence of biopsy proven acute rejection, graft loss, death, or loss to follow up at 6 or 12 months. Once again, there were no observed differences in the primary endpoint between treatment groups at either time point (Table 98.8).

Sirolimus (Rapamune)

Sirolimus is the original member of a relatively new class of immunosuppressive agents that inhibits the mammalian target of rapamycin (mTOR). Sirolimus was approved by the FDA in 1999 for use in kidney transplantation [48]. Sirolimus binds to FK506 binding protein-12 to form an immunosuppressive complex that inhibits the mTOR. By inhibiting mTOR, sirolimus prevents protein synthesis, cell cycle progression from G1 to S, and ultimately T-lymphocyte proliferation [49].

Sirolimus is indicated for the prophylaxis of organ rejection in patients aged 13 years or older receiving renal transplants. Combination therapy with cyclosporine and corticosteroids is also recommended initially post-transplant based on immunologic risk. It is recommended that patients at low or moderate immunological risk should withdraw cyclosporine therapy 2 to 4 months after transplantation. For patients at high immunologic risk, it is recom-

Table 98.8. Treatment failure in conversion transplant at 6 and 12 months therapy in combination with cyclosporine* and with or without corticosteroids

[#]95% confidence interval of the difference in treatment failure at 6 months (Myfortic – mycophenclate mofetil) is (−7.4%, 2.7%).

mended that triple therapy with sirolimus, cyclosporine, and corticosteroids be continued for the first year after transplantation. High immunologic risk is defined as black recipients, patients with a high panel-reactive antibodies (peak PRA >80%), or those undergoing re-transplantation who have lost a previous kidney allograft for immunologic reasons [49]. It is important to note that the post approval experience has shown substantial synergistic exacerbation of cyclosporine-associated nephrotoxicity and as such, the use of sirolimus with cyclosporine as indicated on the label is relatively uncommon in modern practice.

The prescribing information includes the following dosing recommendations for sirolimus for patients greater than the age of 13. An initial loading dose of sirolimus should be administered equivalent to three times the maintenance dose (i.e. 6 mg loading dose, followed by 2 mg daily). An initial maintenance dose of 2 mg is recommended although 5 mg daily has been reported in clinical studies. Patients older than the age of 13, who are less than 40 kg, should be dosed based on body surface area (loading dose of 3 mg/m^2, maintenance dose of 1 mg/m^2). Sirolimus oral solution and tablets were found to be clinically equivalent in a randomized, multicenter controlled trial for the prevention of organ rejection following kidney transplantation. Due to the long elimination half-life of sirolimus of 62 hours, frequent dose adjustment with non-steady state levels can result in overdosing or underdosing. Therefore, a new maintenance dose should continue for at least 7 days prior to being adjusted based on a trough level. Several target blood trough concentrations are described in the prescribing information, ranging from 10–15 ng/ml for high immunologic risk patients on concomitant cyclosporine therapy to 16–24 ng/ml for low to moderate risk patients who have withdrawn cyclosporine therapy. In reality, these target levels are substantially higher than those used in modern practice. It is important to note that different assay methodologies are available to measure sirolimus levels [49]. As a result, levels from one assay are not interchangeable with levels from another.

Sirolimus is one of the few immunosuppressive agents with two distinct "black box" warnings. According to the prescribing information, the safety and efficacy of sirolimus in liver or lung transplant patients has not been established and therefore is not recommended. For liver transplantation, the warning is specific for excess mortality, graft loss and hepatic artery thrombosis in de novo liver transplant patients. For lung transplantation, sirolimus is not recommended for use in de novo lung transplant patients due to the risk of potentially fatal bronchial anastomotic dehiscence [49].

Two studies involving the use of sirolimus in de novo liver transplant patients (either with tacrolimus or in combination with cyclosporine) demonstrated excess mortality, graft loss, and increased incidence of hepatic artery thrombosis. In the first study, the use of sirolimus with tacrolimus was found to have increased mortality and graft loss at a rate of 22% versus 9% on tacrolimus alone [50]. The combined incidence of hepatic artery thrombosis from the two studies was 7% in patients receiving sirolimus compared to 2% in the control arm. Most cases occurred within 30 days post-transplant and resulted in graft loss or death [49]. In addition, in a 2 : 1 randomized, multicenter controlled clinical study of stable liver transplant patients converted from a calcineurin inhibitor based regimen to sirolimus, an increased number of deaths were observed in the sirolimus cohort compared to those remaining not converted (3.8% vs. 1.4%, P = NS) [51]. Sirolimus is not recommended for de novo lung transplant due to numerous cases of bronchial anastomotic dehiscence, most of which have been fatal [49].

The safety and efficacy of sirolimus oral solution for the prevention of renal allograft rejection was assessed in two Phase III randomized double-blind, multicenter, controlled trials. The first study (Table 98.9a) compared sirolimus 2 mg daily (n = 284), sirolimus 5 mg daily (n = 274), and azathioprine (n = 161), all in combination with cyclosporine and corticosteroids [52]. The second study (Table 98.9b) compared sirolimus 2 mg daily (n = 227), sirolimus 5 mg daily (n = 219), and azathioprine (n = 130), all in combination with cyclosporine and corticosteroids [53]. In both studies, antilymphocyte antibody induction was prohibited. The primary endpoint was efficacy failure, defined as biopsy proven acute rejection, graft loss, or patient death at six months. In both studies, sirolimus at either dose (2 mg or 5 mg) significantly reduced efficacy failure compared to either azathioprine or placebo. Patient and graft survival was similar between treatment groups at 1 and 2 years for the first study and 1 and 3 years for the second study. The mean glomerular filtration rate at later time points was found to be lower in patients receiving sirolimus for both studies. When the patients in the first study were stratified by race, sirolimus 5 mg daily had a reduced efficacy failure rate compared to azathioprine in black patients. However, the use of higher dose sirolimus in black patients must be weighed against the increased risk of dose-dependent adverse events observed in this cohort [52].

The use of a calcineurin inhibitor withdrawal strategy with sirolimus was evaluated in a Phase III, randomized multicenter controlled study (Table 98.10) [54,55]. All patients received sirolimus, cyclosporine, and corticosteroids for the first three months prior to randomization into either continuing cyclosporine (n = 215) or withdrawal of cyclosporine (n = 215). The primary end-point was graft survival at 12 months post-transplant. There was no difference in patient or graft survival at 1, 2, or 3 years post-transplant. There was a significant increase in the occurrence of biopsy proven acute rejection for patients receiving renal allografts with 4 or more HLA mismatches (15.3% cyclosporine withdrawal vs. 3.0% cyclosporine). For patients receiving allografts with 3 or less HLA mismatches, there was no difference in rejection rates

Table 98.9a. Incidence (%) of efficacy failure at 6 and 24 months for study 1[a,b]

Parameter	Sirolumus Oral Solution 2 mg/day (n = 284)	Sirolumus Oral Solution 5 mg/day (n = 274)	Azathioprine 2–3 mg/kg/day (n = 1.61)

between groups. The mean glomerular filtration rate was significantly higher at 1, 2, and 3 years post transplant for patients receiving sirolimus with cyclosporine withdrawal compared to those continuing cyclosporine [54,55].

The de novo use of sirolimus without calcineurin inhibitors has not been established in kidney transplantation. A Phase III study conducted in de novo renal transplant patients compared sirolimus versus cyclosporine in combination with IL-2 receptor antagonists, MMF, and steroids. The sirolimus cohort had significantly higher acute rejection rate and numerically higher death rates [49]. Finally, conversion from a calcineurin inhibitor (CNI) to sirolimus was

Table 98.10. Calculated glomerular filtration rates (ml/min) by Nankivell equation at 12, 24, and 36 months Post Transplant: study 3[a,b,c]

Parameter	Sirolumus with Cyclosporine Therapy	Sirolumus Following Cyclosporine Withdrawal
Month 12		
Mean ± SEM	53.2 ± 1.5 (n = 208)	59.3 ± 1.5 (n = 203)
Month 24

[b] Patients who had a graft loss were included in the analysis and had their GFR set to 0.0.
[c] All patients received corticosteroids.

assessed in stable renal transplant patients at least 6 months post-transplant. This study was a randomized, multicenter, global study involving 111 centers and 830 patients [56]. The study was intended to demonstrate that renal function would improve through conversion from a calcineurin inhibitor to sirolimus. However, there was no benefit associated with conversion and a greater incidence of proteinuria in patients converted to sirolimus. In addition, the enrollment of patients with a glomerular filtration rate less than 49 was discontinued due to higher rates of serious adverse events.

Everolimus (Zortress)

Everolimus is the second member of the mTOR inhibitor class of immunosuppression agents. Everolimus received FDA approval in the US for an indication in transplantation in 2010 under the trade name Zortress® [57]. Everolimus is also available in the US under the trade name Afinitor® for use in oncology. Additionally, it is interesting to note that everolimus has been available since 2003 in more than 70 countries outside the US under the trade name Certican® for use in organ transplantation [58].

Everolimus is indicated for the prophylaxis of organ rejection in adult patients at low-moderate immunological risk receiving a kidney transplant [59]. Everolimus should be used with basiliximab and low doses of cyclosporine and corticosteroids. This lower dose recommendation reflects the post approval experience gleaned from sirolimus, in which standard dose cyclosporine was found to be prohibitively toxic. The prescribing information also includes several limitations to the use of everolimus. As mentioned previously, everolimus is an mTOR inhibitor that prevents T- and B-lymphocyte proliferation. Everolimus binds FK506 binding protein-12 to form an immunosuppressive complex that inhibits mTOR, thereby preventing protein synthesis and cell proliferation. The prescribing information for everolimus specifically warns of an increased risk of kidney arterial and venous thrombosis, resulting in graft loss, mostly within the first 30 days post-transplant. Additionally, the prescribing information includes warnings of increased mortality in a clinical trial of de novo heart transplant patients. Therefore, the use of everolimus is not recommended in heart transplantation. The safety and efficacy of everolimus in pediatric patients has been established at this time.

The FDA approved dosing recommendations for everolimus are for an initial dose of 0.75 mg orally twice daily for adult patients with reduced dose cyclosporine. Doses should be adjusted to target the recommended therapeutic range for whole blood trough

Table 98.11. Efficacy Failure by Treatment Group (ITT Population) at 12 Months

Efficacy Endpoints[3]	Everolimus 1.5 mg/day With reduced dose CsA N = 277 n (%)	Mycophenolic Acid 1.44 gm/day With standard dose CsA N = 277 n (%)

Loss to Follow-up[2]	14 (5.1)	11 (4.0)

[1] Includes treated BPAR, graft loss, death or loss to follow-up by month 12 where loss to follow-up represents patient who did not experience treated BPAR, graft loss or death and whose last contact date is prior to 12 month visit.
[2] Includes treated BPAR, graft loss, death or loss to follow-up by month 12 where loss to follow-up represents patient who did not experience treated BPAR, graft loss or death.
[3] Loss to follow-up (for graft loss, death or loss to follow-up) represents patients who did not experience death or graft loss and whose lost contact is prior to 12 month visit.

concentration levels of 3 to 8 ng/mL. Again, the reduced target levels are consistent with the practical migration of sirolimus dosing to lower target levels. Due to the long elimination half-life of 30 hours, it is recommended that dose adjustments be made at 4 to 5 day intervals to reach the therapeutic range. The prescribing information as includes recommendations for reduced whole blood trough concentrations for cyclosporine, with target ranges starting at 100–200 ng/ml in the first month post-transplant titrated down to 25–50 ng/ml between months 6 and 12 post-transplant [59].

The safety and efficacy of concentration controlled everolimus dosing was evaluated in a 24-month, multi-national, open-label, randomized trial in kidney transplant patients, the results of which are shown in Table 98.11 [60]. This was a three arm study comparing two different everolimus doses in combination with basiliximab, reduced dose cyclosporine, and corticosteroids versus the control arm (n = 277) receiving basiliximab, standard dose cyclosporine, mycophenolic acid, and corticosteroids. The two everolimus doses evaluated were 1.5 mg per day with target trough levels of 3 to 8 ng/mL (n = 277) and 3 mg per day with target trough levels of 6 to 12 ng/mL (n = 279). The study population consisted of patients undergoing their first renal transplant, who were at low to moderate immunologic risk (ABO compatible transplant, Class I PRA <20%, and negative T-cell cross-match). The primary end point of the study was efficacy failure at 12 months defined as biopsy proven acute rejection, death, graft loss, or patients lost to follow. Everolimus dosed at 1.5 mg per day was found to be comparable to the control arm with respect to efficacy failure at 12 months (25.3% everolimus 1.5 mg per day vs. 24.2% control). In addition, renal function at 12 months, as measured by the calculated glomerular filtration rate was found to be comparable between everolimus 1.5 mg per day (54.6 ml/min/1.73 m^2) and the control group (52.3 ml/min/1.73 m^2). Discontinuation of everolimus at a higher dose (3 mg/day) was 34% including 20% due to adverse events and therefore is not recommended.

Fixed dosing of everolimus without therapeutic drug monitoring was evaluated by two multicenter double blinded, randomized trials for de novo renal transplant patients [61,62]. Both studies compared two different fixed doses of everolimus (1.5 mg per day and 3 mg per day) in combination with standard cyclosporine and corticosteroids versus control patients treated with cyclosporine, MMF, and corticosteroids. The 12 month analysis of renal function utilizing the glomerular filtration rate demonstrated increased rates of renal impairment in both everolimus groups as compared to the control patients. As a result of these studies, it was concluded that therapeutic drug monitoring should be performed to maintain everolimus trough levels of 3 to 8 ng/ml. In addition, the doses of cyclosporine should be reduced when used with everolimus in order to avoid renal dysfunction [59].

Belatacept (Nulojix)

Belatacept is the first in a new class of immunosuppressive agents targeting specific costimulation molecules and pathways. The FDA approved belatacept in 2011 for use in kidney transplantation [63]. Belatacept is indicated for the prophylaxis of organ rejection in adult kidney transplant patients who are Epstein-Barr virus (EBV) seropositive [64]. It is to be utilized in combination with basiliximab, mycopheonolate mofetil, and corticosteroids. The use of belatacept to prevent rejection in transplanted organs other than the kidney has not been established.

Belatacept is a novel immunosuppressive agent that provides selective T-lymphocyte costimulation blockade. It is a fusion protein that binds to CD80 and CD86 on antigen presenting cells, thereby blocking the CD28 mediated costimulation of T-lymphocytes. This inhibition prevents signal 2 of T-lymphocyte activation, thereby inhibiting cell proliferation and production of the cytokines interleukin-2, interferon-γ, interleukin-4, and TNF-α. Belatacept has an extended elimination half-life of 9.8 days for the 10 mg/kg dose and 8.2 days for 5 mg/kg dose. As a result, the FDA approved dosing regimen for belatacept is 10 mg per kg intravenous infused once on day 1, 5, and the end of weeks 2 and 4; then every 4 weeks through week 12 post-transplantation. Starting on week 16, belatacept 5 mg per kg intravenous should be infused every 4 weeks thereafter. Doses should be calculated based on the actual weight of the patient at the time of transplant and should not be modified during the course of therapy, unless the patients has a change in body weight greater than 10%. All doses of basiliximab should be infused over 30 minutes [64].

The prescribing information for belatacept contains a black boxed warning for post-transplant lymphoproliferative disorder (PTLD), infection, and other malignancies. Patients receiving belatacept have an increased risk for the development of PTLD with predominantly central nervous system (CNS) involvement as compared to those on a cyclosporine-based regimen. In addition, CNS PTLD, PML, and other CNS infections occurred more frequently in patients receiving a higher cumulative and higher frequency dosing regimen of belatacept as compared to the FDA approved dosing regimen. Six of the eight cases of PTLD in this treatment regimen presented with CNS involvement. Therefore, the administration of this higher regimen is not recommended. Overall in patients treated with belatacept, the rate of PTLD was 9-fold higher in those who were EBV seronegative or with unknown serostatus (8/139) compared to those who were EBV seropositive (5/810). Therefore, belatacept should not be utilized in patients who are EBV seronegative or with unknown serostatus due to the increased risk of PTLD in patients without immunity to EBV. As a result of these safety concerns, the manufacturer was required to incorporate a Risk Evaluation and Mitigation Strategies program as part of the product approval [64].

Table 98.12. Efficacy outcomes by years 1 and 3 for BENEFIT: Recipients of living and standard criteria deceased donor kidneys

Parameter	Belatacept Recommended Regimen N = 226 n (%)	Cyclosporine (CSA) N = 221 n (%)	Belatacept-CSA (97.3% CI)

Year 3	65.8 (27) (n = 190)	44.4 (23.6) (n = 171)	21.4 (15.4, 27.4)

* GFR was measured using the cold-iothalamate method.
† Measured GFR was not assessed at Year 3.
‡ GFR was calculated using the MDRD formula.

In addition, belatacept carries a black boxed warning recommending against use in liver transplantation due to increased risk of graft loss and death. This black box warning was based on the results of a Phase III trial [64]. Belatacept was utilized at dosing regimens with more frequent administration than those studied in kidney transplantation, in combination with MMF and corticosteroids. Belatacept therapy was associated with a higher rate of graft loss and death as compared to the tacrolimus treatment arms. In addition, there were two cases of PTLD involving the liver allograft (one fatal) and one case of fatal PML [64].

The safety and efficacy of belatacept in de novo kidney transplantation was assessed in two open-label, randomized, multicenter trials [65,66]. Two different dosing regimens of belatacept were compared to a cyclosporine based regimen with all patients receiving basiliximab, MMF, and corticosteroids. The two belatacept regimens were the currently recommended regimen, and a regimen with higher cumulative and more frequent dosing. All treatment groups received basiliximab induction with concurrent MMF and corticosteroids. Both studies excluded patients at high immunologic risk, defined as having a panel reactive antibody (PRA) >50%, re-transplants with PRA >30%, HIV, Hepatitis C, active TB, or active Hepatitis B. Efficacy failure at one year was defined as biopsy proven acute rejection, graft loss, death or patients lost to follow-up.

The first study (BENEFIT) only included kidney transplant recipients with living donor and standard criteria donors [65,67]. The rate of biopsy proven acute rejection at one and three years was higher in both belatacept groups compared to cyclosporine (Table 98.12). Among the patients who experienced acute rejection in the belatacept groups, 70% of patients experienced rejection by month three and 84% experienced rejection by month six post-transplant. In addition, patients receiving belatacept experienced biopsy proven acute rejection by one year, classified as Banff Grade IIb or higher more frequently than the control patients (6% belatacept vs. 2% control). However, there was no difference in patient and graft survival at one- and three-years post-transplant. Renal function was assessed at one and two years by glomerular filtration rate measurement and calculated using the Modification of Diet in Renal Disease equation at one-, two-, and three-years post-transplant. Both measured and calculated glomerular filtration rates were higher in patients receiving belatacept as compared to cyclosporine across all time points (Table 98.13). In interpreting the endpoint for renal function in this study, the FDA utilized the glomerular filtration data to assess the safety of belatacept with regards to renal function, rather than as an efficacy measure [68].

The second study (BENEFIT-EXT) included kidney transplant recipients with extended criteria deceased donors, and is the first trial ever to specifically seek indication in the ECD population [66,69]. This study found that there were no differences in the rate of biopsy proven acute rejection at one- and three-years post-transplant. The proportion of biopsy proven acute rejection classified as Banff Grade IIb or higher by one year was also comparable between treatment groups (5% in belatacept compared to 4% in cyclosporine-treated patients). There was no difference in patient and graft survival at one- and three-years post-transplant. Additionally, both measured and calculated glomerular filtration rate was higher in patients treated with belatacept compared to patients treated with cyclosporine (Figure 98.2). Similarly to the first study, the FDA interpreted these glomerular filtration rate results as a safety assessment of belatacept for renal function, rather than as an efficacy measure [68].

Rabbit anti-thymocyte globulin (Thymoglobulin)

Rabbit anti-thymocyte globulin (Thymoglobulin®, RATG) is a potent immunosuppressive agent that initially received FDA approval in December 1998 becoming the second anti-thymocyte globulin available on the market [70]. The first anti-thymocyte globulin preparation (ATGAM®) was horse derived and initially FDA approved in 1981. However, it has since been replaced by RATG as the anti-thymocyte agent of choice at the majority of transplant centers in the US [71].

It is important to note that despite its use for the prophylaxis of organ rejection in solid organ transplant patients, the only FDA approved indication for RATG is the treatment of adult renal

transplant acute rejection in conjunction with concomitant immunosuppression. RATG is a polyclonal antilymphocyte preparation that is obtained by immunizing rabbits with human thymocytes. It is a gamma immune globulin product that consists of polyclonal cytotoxic antibodies directed against T-lymphocyte antigens. The mechanism of action of RATG for inducing immunosuppression is not fully understood, but may involve T cell clearance, activation modulation, homing and cytotoxic activity. RATG is contraindicated in patients with allergy or anaphylaxis to rabbits or in those with acute or chronic infections for whom immunosuppression would be contraindicated [71].

The approved dosing and administration recommendations for RATG in the treatment of acute rejection is 1.5 mg per kg of body weight daily for 7 to 14 days administered intravenously via a high flow vein. It should be infused through a 0.22 micrometer filter over a minimum of 6 hours for the first infusion and 4 hours for subsequent infusions. Infusion associated reactions consistent with cytokine release syndrome occur with the first or second infusions due to the lysing of lymphocytes. Signs and symptoms of cytokine release syndrome include: fever, chills, rigors, dyspnea, hypotension, hypertension, nausea, vomiting and diarrhea, malaise, rash or headache. Both a reduction in the infusion rate and premedication with acetaminophen, corticosteroids, and antihistamines has been shown to decrease the incidence of infusion reactions. Serum sickness has been reported with signs and symptoms consisting of: fever, rash, arthralgias, and myalgia with symptom onset 5 to 15 days post therapy. Significant adverse events associated with RATG include leukopenia, thrombocytopenia, infection, and malignancy.

The prescribing information references one Phase III study conducted in the US that resulted in the approval of RATG [72]. This double blind, multicenter, parallel group randomized non-inferiority trial compared patients receiving RATG versus ATGAM for the treatment of acute graft rejection in kidney transplant patients. Patients were included in the study if they had biopsy proven Banff Grade II, III or steroid resistant Grade I acute cellular rejection in their first or second renal transplant. Rejection treatment was administered for 7 to 14 days with either 1.5 mg/kg/day of RATG (n = 82) or 15 mg/kg/day of ATGAM (n = 81). The primary endpoint of this study was the reversal of acute rejection episode, defined as a return to baseline serum creatinine levels within 14 days of rejection diagnosis. RATG was found to have a clinically significant higher rejection reversal rate than ATGAM (88% vs. 76%, $P = 0.027$) with rejection recurrence 90 days post therapy occurring less frequently in patients treated with RATG (17% vs. 36%, $P = 0.011$). Adverse events and one-year patient and graft survival were comparable between treatment groups. Although off protocol use of tacrolimus and mycophenolate occurred in both treatment groups during the second half of the study, there was no effect on the overall result. The overall weighted treatment difference was 11.1% (RATG-ATGAM success rate) with a lower confidence bound of 0.07% (Table 98.14). As a result, RATG was found to be at least as effective as ATGAM in the reversal of acute graft rejection in renal transplant patients [72].

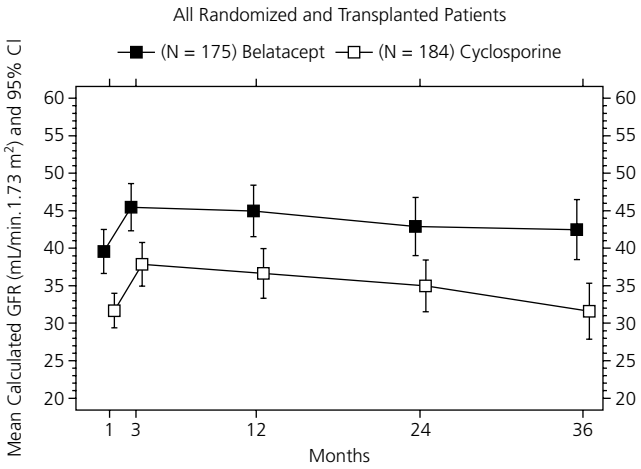

Figure 98.2. Calculated (MDRD) GFR through Month 36; Study 2: Recipients of extended criteria donor kidneys.

Basiliximab (Simulect)

Basiliximab is a non-lymphocyte depleting induction immunosuppression agent that received FDA approval in May 1998 [73]. Basiliximab is a member of the class of medications known as the interleukin 2 receptor antagonists [74]. The other member of this medication class was daclizumab (Zenapax®), which received FDA

Table 98.14. Response to Study Treatment by Rejection Severity and Study Half

approval in 1997 [75]. In 2010, the manufacturer discontinued production of daclizumab due diminishing market demand for the drug. As a result, basiliximab is the only interleukin 2 receptor antagonist available for use in the US.

Basiliximab is indicated for the prophylaxis of acute organ rejection in renal transplant patients as part of an immunosuppression regimen consisting of modified cyclosporine, and corticosteroids [74]. It is a chimeric (murine/human) monoclonal antibody designed to inhibit signal 3 of T cell activation. This occurs due to the high affinity of basiliximab for interleukin 2 receptor alpha (also known as the CD25 antigen) on the surface of activated T-lymphocytes. The duration of interleukin 2 receptor alpha saturation in adult and pediatric patients was 36 days when used in combination with modified cyclosporine and corticosteroids, whereas the duration was 50 and 59 days respectively when used in combination with modified cyclosporine, corticosteroids and either azathioprine or MMF. Basiliximab is generally well tolerated with the majority of reported adverse events consisting of gastrointestinal disorders (nausea, vomiting, constipation, abdominal pain, dyspepsia, and diarrhea).

The prescribing information contains dosing recommendations for both adult and pediatric patients. For adults, the recommended dosing regimen consists of two doses of basiliximab 20 mg intravenous. The first dose should be administered two hours prior to surgery and the second dose should be administered 4 days post-transplant. The pediatric dosing regimen is stratified based on weight according to the same schedule as adult dosing, with patients less than 35 kg receiving two doses of 10 mg and patients greater than 35 kg receiving two dose of 20 mg.

There were four adult, randomized, double blind, placebo controlled clinical trials and a pediatric pharmacokinetic safety study that resulted in FDA approval for basiliximab in kidney transplantation [74]. The initial studies utilized basiliximab in combination with modified cyclosporine and corticosteroids. The first study was conducted in Europe and Canada, whereas the second study was conducted in the US [76,77]. Although both studies were conducted in patients receiving deceased donor kidney transplants, the US based study also included living donor kidney transplantation. Patients were stratified to treatment with basiliximab or placebo. The primary efficacy endpoint for both studies was the incidence of death, graft loss, or acute rejection episodes during the first 6 months post-transplant. Secondary end points included biopsy proven rejection at 6 and 12 months, all the primary endpoints evaluated at 12 months, and 1 year patient and graft survival. In comparing patients from the European and Canadian study who received basiliximab (n = 190) versus placebo (n = 186), there was a statistically significant reduction in the incidence of the primary efficacy endpoint in patients receiving basiliximab (42% vs. 57%, $P = 0.003$) [76]. In comparing patients from the US based study who received basiliximab (n = 173) versus placebo (n = 173), there was a statistically significant reduction in the incidence of the primary efficacy endpoint in patients receiving basiliximab (38% vs. 55%, $P = 0.002$) [51,77]. In terms of secondary end points for both studies, the significant reduction in the primary efficacy endpoint was maintained at 12 months, as well as a significant reduction in the incidence of rejection episodes at 6 and 12 months. Patient and graft survival at 12 months were comparable between groups for both studies. The five-year graft and patient survival was evaluated in 71% of patients from the European/Canadian study and 58% of the patients from the US based study. There was no difference in graft survival in both studies. For the US based study, patient survival was comparable between groups; however, for the European/Canadian study, there was a numerically lower patient survival (87% basiliximab vs. 95% placebo). The prescribing information states that the cause of this difference is unknown with no increase in malignancy or infections noted [74].

The use of basiliximab in triple therapy based maintenance immunosuppression regimens was evaluated in two double blind, randomized, placebo-controlled studies. Both studies were conducted in deceased or living donor adult kidney transplant patients receiving their first or second transplant. The primary endpoint for both studies was acute rejection episodes 6 months post-transplant. The first study compared patients treated with (n = 168) or without (n = 172) basliximab in combination with cyclosporine, corticosteroids and azathioprine [78]. For the primary end point, there was a significant reduction in acute rejection episodes in patients treated with basiliximab (21% basiliximab vs. 35% placebo $P = 0.005$). The second study compared patients treated with (n = 59) or without (n = 64) basiliximab in combination with cyclosporine, corticosteroids and MMF [79]. For the primary end point in this study, there was no significant difference in biopsy proven acute rejection at 6 months (15% basiliximab vs. 27% placebo, $p > 0.05$). Patient and graft survival were comparable at 12 months for both studies.

A safety and pharmacokinetic study was conducted in 41 pediatric patients with a median age of 8.1 years (ages 1–11 years [n = 27] and ages 12–16 [n = 14]) [80]. These patients were treated with basiliximab in addition to standard immunosuppression with modified cyclosporine, azathioprine, MMF, and/or corticosteroids. Acute rejection rates at 6 months were found to be comparable with adult patients receiving triple therapy based immunosuppression with a comparable adverse event profile. The most frequent adverse events reported were fever, hypertrichoses, hypertension, rhinitis, and urinary tract infections [74].

Anti-viral agents

All transplant patients receive a cocktail of prophylactic agents to prevent the adverse effects of the immunosuppressants used. While peri- and post-transplant management of infection prophylaxis is covered in depth in Chapters 94, most agents used are not specifically approved for use in transplantation. The following agents are described as they have been formally approved for use in the solid organ transplant setting.

Ganciclovir sodium (Cytovene-IV)

Ganciclovir sodium is a synthetic guanine derivative active against cytomegalovirus (CMV), which was initially approved by the FDA in 1989 for the treatment of CMV retinitis in patients with acquired immunodeficiency syndrome (AIDS) [81]. In 1992, ganciclovir received an expanded indication for the prevention of CMV disease in transplant recipients at risk for CMV disease [82]. Initially, ganciclovir was only available intravenously in the form of ganciclovir sodium; however in 1994, an oral ganciclovir formulation was introduced to the market [81]. Oral ganciclovir was indicated for the prevention of CMV disease in patients at risk for CMV disease, including solid organ transplant recipients and patients with AIDS. Recently, oral ganciclovir was discontinued from the market after a prolonged drug shortage.

The pharmacokinetic properties of intravenous and oral ganciclovir have been well described. In terms of absorption, oral ganciclovir is poorly bioavailable as compared to intravenous ganciclovir with a reported absolute bioavailability of 8.53% [83]. The major elimination pathway for ganciclovir is via renal excretion of

Table 98.15. Dosing for patients with renal impairment

Creatinine Clearance* (mL/min)	Ganciclovir-IV Induction Dose (mg/kg)	Dosing Interval (hours)	Ganciclovir-IV Maintenance Dose (mg/kg)	Dosing Interval (hours)
≥70	5.0	12	5.0	24
50–69	2.5	12	2.5	24
25–49	2.5	24	1.25	24
10–24	1.25	24	0.625	24
<10	1.25	3 times per week, following hemodialysis	0.625	3 times per week, following hemodialysis

*Creatinine clearance according to Cookcroft-gault-equation.

unchanged drug. As a result, careful adjustment for renal impairment is needed when dosing ganciclovir. With regards to pediatric patients, the pharmacokinetics properties are similar to those observed in adults. However, since ganciclovir is not indicated for use in pediatric patients, no dosing recommendations are included in the prescribing information. Finally, women of childbearing age are advised to use proper contraception while being treated with ganciclovir due to the mutagenic and teratogenic potential of ganciclovir [82].

The recommended FDA approved dosing of ganciclovir for patients with normal renal function for the prevention of CMV disease in transplant recipients is 5 mg/kg every 12 hours for 7 to 14 days, then 5 mg/kg once daily (seven days per week) or 6 mg/kg once daily (five days per week). The duration of treatment is dependent on the degree of immunosuppression with no clear recommendations from the prescribing information.

Ganciclovir dosing should be adjusted for renal impairment based on the creatinine clearance, as described in Table 98.15 [82].

Ganciclovir was evaluated in three randomized, controlled trials of prevention of CMV disease in organ transplant patients. The first Phase III study was conducted in 149 heart transplant patients who were at risk for CMV disease, defined as either CMV recipient seropositive or donor seropositive and recipient seronegative [84]. Patients were randomized to receive either ganciclovir (n = 76) for a total of 28 days or placebo (n = 73). There was a statistically significant reduction in the overall incidence of CMV disease in patients treated with ganciclovir (12/76 or 16%) as compared to placebo (31/73 or 43%) during the 120-day post-transplant observation period. The second study was a randomized, double-blinded, placebo-controlled trial of 72 bone marrow transplant patients with asymptomatic CMV infection (CMV positive culture of urine, throat, or blood) [85]. Patients were stratified to receive either placebo or ganciclovir for a total of 100 days. There was a statistically significant reduction in the incidence of CMV disease in patients receiving ganciclovir at day 100 and 180. In addition, the overall rate of survival was also significantly higher in ganciclovir treated patients at day 100 and day 180. The third randomized open label study evaluated 40 allogeneic bone marrow transplant recipients at risk for CMV disease [86]. Patients underwent bronchoscopy and bronchoalveolar lavage on post-transplant day 35. Those with histologic or virologic evidence of CMV infection in the lung were then randomized to observation or treatment with ganciclovir. The incidence of CMV disease was significantly lower in the ganciclovir-treated patients with 4 of the 20 (20%) patients treated with ganciclovir and 14 of the 20 (70%) control patients developing interstitial pneumonia. These results were found to be consistent with the previously mentioned study in bone marrow transplant recipients.

Valganciclovir (Valcyte)

Valganciclovir is a prodrug of ganciclovir that was initially approved by the FDA in 2001 for the treatment of CMV retinitis in patients with AIDS [87]. In 2003, the FDA expanded the indications to include the prevention of CMV disease in specific types of solid organ transplant for both adult and pediatric patients at high risk for CMV, defined as patients who are CMV IgG donor positive and recipient negative. The FDA approved indication for valganciclovir is the prevention of CMV disease in kidney, heart, or kidney-pancreas adult transplant patients at high risk for CMV and in kidney or heart pediatric (ages 4 months to 16 years) transplant patients at high risk for CMV [88]. It is important to note that valganciclovir is not indicated for use in adult or pediatric liver transplant patients.

Valganciclovir is an L-valyl ester of ganciclovir that is rapidly converted to ganciclovir by intestinal or hepatic esterases. The pharmacokinetics of valganciclovir has been evaluated in solid organ transplant patients, as compared to ganciclovir. The mean systemic exposure to ganciclovir was 1.7 × higher following 900 mg of valganciclovir daily compared to 1000 mg ganciclovir three times a day [88]. The systemic exposures attained were comparable for kidney, heart and liver transplantation. The pharmacokinetics of valganciclovir was similar in pediatric organ transplant recipients compared to adult patients. Due to its active metabolite of ganciclovir, valganciclovir should be considered a potential carcinogen.

The dosing recommendations for valganciclovir include both adult and pediatric dosing recommendations for patients at high risk for CMV. For adult heart or kidney pancreas transplant patients, the recommended dose is 900 mg orally once daily starting within 10 days post-transplant to be continued until postoperative day 100. For adult kidney transplant patients, the recommended dose is 900 mg orally once daily starting within 10 days post-transplant to be continued until postoperative day 200. Of note, all adult doses of valganciclovir should be adjusted for renal function based on the creatinine clearance as calculated by the Cockcroft-Gault equation. In heart or kidney pediatric transplant patients, the once daily dose of valganciclovir should be started with 10 days post-transplant and be dosed according to the following equation:

$$\text{Pediatric Dose (mg)} = 7 \times \text{body surface area} \times \text{CrCl (as calculated using a modified Schwartz formula, not to exceed 150 ml/min/1.73 m}^2\text{)}.$$

$$\textit{Mosteller BSA}\,(m^2) = \sqrt{\frac{\textit{Height}\,(cm) \times \textit{Weight}\,(kg)}{3600}}$$

$$\textit{Schwartz Creatinine Clearance}\,(mL/\text{min}/1.73\,m^2) = \frac{k \times \textit{Height}\,(cm)}{\textit{Serum Creatinine}\,(mg/dL)}$$

where k =

0.45 for patients aged 4 months to <1 year,

0.45 for patients aged 1 to <2 years (note k value is 0.45 instead of the typical value of 0.55),

0.55 for boys aged 2 to <13 years and girls aged 2 to 16 years, and

0.7 for boys aged 13 to 16 years.

Table 98.16. Percentage of Patients With CMV Disease, Tissue-Invasive CMV Disease or CMV syndrome by Organ Type: Endpoint Committee, 6 Month ITT Population

Organ	CMV Disease[1]		Tissue-Invasive CMV Disease		CMV Syndrome[2]	
	VGCV (N = 239)	GCV (N = 125)	VGCV (N = 239)	GCV (N = 125)	VGCV (N = 239)	GCV (N = 125)
Liver (n = 177)	19% (22/118)	12% (7/59)	14% (16/118)	3% (2/59)	5% (6/118)	9% (5/59)

GCV = oral ganciclovir: VGCV = valganciclovir.
[1] Number of patients with CMV disease = Number of patients with tissue-invasive CMV disease or CMV syndrome.
[2] CMV syndrome was defined as evidence of CMV viremia accompanied with fever ≥38°C on two or more occasions separated by at least 24 hours within a 7-day period and one or more of the following: malaise, leukopenia, atypical lymphocytosis, thrombocytopenia and elevation of hepatic transaminases.

Table 98.17. Percentage of Kidney Transplant Patients With CMV Disease, Tissue-Invasive CMV Disease or CMV Syndrome, 12 Month ITT Population

	CMV Disease[1]		Tissue-Invasive CMV Disease		CMV Syndrome[2]	
	100 Days VGCV (N = 163)	200 Days VGCV (N = 155)	100 Days VGCV (N = 163)	200 Days VGCV (N = 155)	100 Days VGCV (N = 163)	200 Days VGCV (N = 155)
Cases	36.8% (60/163)	16.8% (26/155)	1.8% (3/163)[3]	0.6% (1/155)	35.0% (57/163)	16.1% (25/155)

VGCV = valganciclovir.
[1] Number of patients with CMV disease = Number of patients with tissue-invasive CMV disease or CMV syndrome.
[2] CMV syndrome was defined as evidence of CMV viremia accompanied with at least one of the followings: fever ≥38°C), severe malaise, leukopenia, atypical lymphocytosis, thrombocytopenia, and elevation of hepatic transaminases.
[3] Two patients m the 100 day group had both tissue-invasive CMV disease and CMV syndrome; however, these patients are counted as having only tissue-invasive CMV disease.

With respect to the indication of organ transplantation, there are three major clinical trials that are referenced in the prescribing information. The first was a double blind, double-dummy active comparator study conducted in 372 liver, kidney, heart, and kidney pancreas transplant recipients who were considered high risk for CMV (donor CMV seropositive and recipient CMV seronegative) [89]. Patients were randomized 2:1 to valganciclovir 900 mg daily (n = 239) or oral ganciclovir 1000 mg three times daily (n = 125) starting within the first 10 days until 100 days post-transplant. The proportion of patients who developed CMV disease during the first six months post-transplant was comparable between valganciclovir (12.1%) and ganciclovir (15.2%). The authors concluded that once daily valganciclovir was as clinically effective and well tolerated as oral ganciclovir three times daily in high-risk solid organ transplant patients. However it is important to note that when stratified by organ type, liver transplant patients receiving valganciclovir were found to have a significantly higher incidence of tissue-invasive CMV disease compared to the ganciclovir group (see Table 98.16) [89].

The second study was designed to assess the safety and efficacy of extending CMV propylaxis from 100 to 200 days [90]. This was a double-blind, placebo controlled study in 326 CMV high risk kidney transplant patients, who were randomized to receive valganciclovir 900 mg daily for either 200 or 100 days followed by 100 days of placebo. The extended CMV prophylaxis regimen with valganciclovir was superior in preventing CMV disease within the first 12 months post-transplant (see Table 98.17). However, by 24 months post-transplant, the CMV disease rate was similar between treatment groups.

Finally, the third study was conducted in pediatric transplant patients, ages 4 months to 16 years old to assess the safety and efficacy of valganciclovir in preventing CMV [91]. A total of 63 pediatric solid organ transplant patients, who were at risk for CMV disease, were enrolled into an open-label safety, pharmacokinetic study of oral valganciclovir. The pediatric patients included 33 kidney, 17 liver, 12 heart, and 1 kidney liver transplant patients. The daily dose of valganciclovir was calculated based on body surface area and creatinine clearance. The pharmacokinetics of ganciclovir was similar across organ transplant types. The mean daily ganciclovir exposures were comparable to the adult recipients receiving 900 mg daily. It is important to note that because valganciclovir is not approved for use in adult liver transplantation; it is also not recommended in pediatric liver transplant patients.

Cytomegalovirus immune globulin intravenous (CytoGam)

Cytomegalovirus (CMV) Immune Globulin Intravenous (CMV-IGIV) is a fractionated plasma product consisting of immunoglobulin G (IgG) that contains a standardized amount of antibody specific to cytomegalovirus. CMV-IGIV was initially approved in 1991 for the attenuation of primary CMV disease in kidney transplant patients at high risk for CMV infection, defined as patients who are CMV IgG donor positive and recipient negative [92]. The indication was expanded in 1998 to include other transplanted organs. The current FDA approved indication of CMV-IGIV is for the prophylaxis of CMV disease associated with kidney, lung, liver, pancreas, and heart transplantation. For transplant patients at high risk for CMV infection, except for those undergoing kidney transplantation, CMV-IGIV should be considered in combination with ganciclovir [92].

CMV-IGIV is derived from a large pool of adult human plasma selected for high CMV antibody titers. As a result, the globulin contains a relatively high concentration of antibodies directed

Table 98.18. Dosing instructions for *Cytomegalovirus immune globulin intravenous (CytoGam)*

	Type of Transplant	
	Kidney	Liver, Pancreas, Lung, Heart
Within 72 hours of transplant:	150 mg/kg	150 mg/kg
2 weeks post transplant:	100 mg/kg	150 mg/kg
4 weeks post transplant:	100 mg/kg	150 mg/kg
6 weeks post transplant:	100 mg/kg	150 mg/kg
8 weeks post transplant:	100 mg/kg	150 mg/kg
12 weeks post transplant:	50 mg/kg	100 mg/kg
16 weeks post transplant:	50 mg/kg	100 mg/kg

against CMV. When administered, it can raise the CMV antibody to sufficient levels to attenuate or reduce the incidence of serious CMV disease. Since CMV-IGIV is derived from human plasma, it carries the possibility for blood-borne viral agent transmission as well as the theoretical possibility of Creutzfeldt-Jakob disease agent transmission. Additionally, since CMV-IGIV is an immune globulin based product, it carries risk for adverse events that have been associated with other immune globulin products [92]. Aseptic meningitis syndrome typically begins within hours to days following treatment and is associated with severe headache, nuchal rigidity, drowsiness, fever, and photophobia. Noncardiogenic pulmonary edema has been reported in patients 1 to 6 hours after receiving IGIV therapy and is associated with severe respiratory distress, pulmonary edema, normal left ventricular function, fever and hypoxemia. Renal dysfunction, thrombosis, and hemolysis have also been rarely reported in association with IGIV. The FDA approved recommended total dosage per infusion of CMV-IGIV is 150 mg/kg. Complete dosing recommendations based on time post-transplant are described in Table 98.18.

CMV-IGIV was initially shown to be effective for CMV prophylaxis in kidney transplant patients based on two clinical trials published in 1987 and 1991. The first randomized trial demonstrated that the incidence of CMV syndrome was significantly reduced from 60% in control patients (n = 35) to 21% in CMV-IGIV treated patients (n = 24) [93]. The incidence of serious CMV disease was reduced from 46% to 13% in patients receiving CMV-IGIV. In the second non-randomized trial 36 renal transplant patients were treated with CMV-IGIV and were found to have a 36% incidence of CMV associated syndrome [94]. In addition, the rate of serious CMV disease, concomitant fungal, and parasitic superinfection were also lower in both studies, as compared to the control group from the first study.

Additional studies utilizing CMV-IGIV in other transplanted organs allowed for the FDA approved indication of CMV-IGIV to be modified in 1998 to include liver, lung, heart, and pancreas transplantation. In a randomized, double-blind, placebo control study in liver transplant patients comparing patients receiving CMV-IGIV (n = 69) with control (n = 72), the incidence of serious CMV disease was significantly reduced from 27% to 12% in those treated with CMV-IGIV [95]. Of note, the reduction of serious CMV disease in liver transplant patients at high risk for CMV was less than in transplant with other donor and recipient serologic statuses. In a follow-up study in liver transplant patients comparing the control patients to those receiving CMV-IGIVI, the one year survival was 72% versus 86% respectively ($P = 0.03$) [96].

Additional studies have suggested that combined CMV prophylaxis with CMV-IGIV and ganciclovir may reduce the incidence of serious CMV associated disease in patients at high risk for CMV disease, below that expected from one drug alone. One such study conducted in solid organ transplant patients, including 14 high risk CMV kidney-pancreas transplant patients, reported reduced incidence of serious CMV disease with combined therapy, as compared to previous experience with single drug prophylaxis [92]. Another study in cardiothoracic transplantation compared prophylaxis with CMV-IGIV in combination with intravenous ganciclovir versus ganciclovir alone [97]. In CMV high risk heart transplant patients, the actuarial incidence of CMV disease was reduced from 55% in the ganciclovir group (n = 16) to 46% in the combined therapy group (n = 16). Additionally, there was a statistically significant increase in patient survival from 61% to 94% ($P \leq 0.001$). In heart-lung or lung alone transplant patients at high risk for CMV, the incidence of CMV disease was decreased from 85% in ganciclovir alone to 36% in combined therapy. Survival also improved from 60% to 80% respectively ($P \leq 0.01$). As a result of these studies, CMV-IGIV received an expanded indication to include kidney, pancreas, liver, lung, and heart transplant recipients.

Summary

Drug approval is a complex and highly regulated process in most countries, and knowledge of the approval process is necessary to not only to facilitate drug trial design, but also to have some practical cognizance of the manner in which dosing recommendations are established and associated with a particular drug. This drugs that have been formally approved for use in transplantation have clear evidence of relative safety and efficacy that refers back to the standard of care at the time of the drug's approval. While these drugs form the foundation on which modern immune management of transplant recipients is built, their use migrates over time based on emerging knowledge, introduction of additional adjuvant therapies, and clinician experience. It is reasonable to say that all transplant patients receive some combination of approved and off-label therapy during their post-transplant course. This chapter and Chapter 101 similarly will provide the reader with a good foundation on which to understand modern immune management, while understanding that clinical practice varies considerably.

CHAPTER 99

Infectious Disease Prophylaxis after Organ Transplantation

G. Marshall Lyon, III
Emory University School of Medicine, Atlanta, GA, USA

Introduction

"An ounce of prevention is worth a pound of cure." This saying is often attributed to Benjamin Franklin. However, the origins of the saying are much older than Franklin. The first written account dates to the thirteenth century in a manuscript by Henry de Bracton. Despite the sayings origins, it is very appropriate in the transplant setting. It is often much easier to prevent an infection than to try and cure the infection once established. For transplant patients and providers this prevention may take many forms — medications, immunizations, or disease avoidance through hygiene or avoiding sick contacts.

Preventive measures in the transplant recipient may not always avoid disease or infection altogether. They may mitigate disease making infectious episodes less severe. Or, they may delay the onset of disease until later in the post-transplant period. Delaying the onset of an infection may have benefits. In the current era, where more potent immune suppression induction is more often being used, delaying the onset of an infection until the immune system has recovered from induction may be desirable. Similarly, pretransplant vaccination may not prevent disease post-transplant altogether but may lessen the severity and duration of disease. This appears to be the case of an experimental cytomegalovirus (CMV) vaccine where vaccine recipients needed fewer days of antiviral therapy when compared to placebo recipients. When considering infections in solid organ transplantation, opportunistic infections most often present between 1 and 6 months (see Figure 94.1 in Chapter 94). However, in the presence of effective prophylactic medications, this time frame may be shifted to between 6 and 12 months.

In this chapter we will discuss effective prevention measures used in solid organ transplantation. The chapter complements specific chapters (Chapters 92, 93 and 94) on the diagnosis and management of donor-derived, perioperative and postoperative infections diseases respectively.

Prevention in kidney, pancreas, and kidney/pancreas transplant

Table 99.1 has a summary of recommended antimicrobial dosages and durations for kidney, pancreas and kidney/pancreas recipients.

Bacterial prevention

Surgical prophylaxis

Kidney transplantation is considered a clean surgical wound, although can be a clean contaminated wound if the bladder is colonized. In either case, there is low risk of developing a surgical-site infection (SSI), generally less than 2%. The bacteria that typically cause SSIs are *Staphylococcus* sp. Kidney transplantation is typical of clean surgery. As such, the antibiotics that can and should be used for surgical prophylaxis are those which have activity against Staphylococci. These include the antistaphylococcal penicillins and first generation cephalosporins. It is preferable to administer the prophylactic antibiotic within 30 minutes prior to skin incision [1]. Antibiotics may be continued for up to 24 hours postoperatively, but longer durations have not been shown to reduce rates of SSIs. For patients who are allergic to penicillins the primary alternative is vancomycin [1]. Because vancomycin is typically administered as a prolonged infusion, the dose of vancomycin should be started 60 minutes prior to skin incision. Vancomycin is also acceptable to use in patients who have documentation of colonization with methicillin-resistant *Staphylococcus aureus* (MRSA). Second generation cephalosporins are also acceptable for patients without a penicillin or cephalosporin allergy.

Pancreatic transplantation is considered a clean-contaminated wound. This is because the duodenum is opened during the surgical procedure (see earlier chapter for detail). Therefore, in addition to *Staphylocccoci*, the microorganisms typically involved in SSI related to pancreas transplant are those that colonize the duodenum. These include *Enterococcus, Klebsiella* sp., *Escherechia coli, Enterobacter*, anaerobic gram-negative rods, and *Candida* sp. Despite a wider variety of organisms causing surgical site infections in pancreas transplantation, cefazolin is still an effective prophylactic agent. This is because it has good activity against most aerobic gram-negative rods. Like in kidney transplant, if the patient has a penicillin or cephalosporin allergy, then vancomycin may be used [1]. However, it should be combined with either gentamicin or levofloxacin in order to protect against gram-negative organisms. Some centers choose to add fluconazole for prophylaxis against *Candida* sp. though there are no strong data to support this practice [2]. If used, fluconazole is often continued for 5–14 days after transplantation. Many centers culture the perfusate of abdominal organs and target therapy against any potential pathogens that may grow.

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Table 99.1. General prevention measure recommendations for kidney or kidney/pancreas transplant recipients

	Preferred prevention measure	Alternative prevention measures
Surgical prophylaxis	Cefazolin 1 g iv 0–30 minutes before skin incision	Vancomycin 1 g iv 60 minutes before skin incision
CMV	Valganciclovir, acyclovir, and valacyclovir requiring dosage adjustment for renal dysfunction	
D+/R−*	Valganciclovir 450–900 mg daily for 3–6 months	Pre-emptive monitoring
Any R+†	Valganciclovir 450–900 mg daily for 3 months	Pre-emptive monitoring
D−R−‡		Acyclovir 400–800 mg TID§ or valacyclovir 500 mg BID for 3–6 months
Fungal		
Candida	Fluconazole 200 mg daily up to 14 days	
PCP**	Smx/tmp 1DS†† thrice weekly	Atovaquone 1500 mg daily Dapsone 100 mg daily Inhaled pentamidine Clindamycin + pyrimethamine

* Donor seropositive/recipient seronegative; † recipient seropositive; ‡ donor seronegative/recipient seronegative; § thrice daily (every 8 hours), twice daily (every 12 hours); ** *Pneumocystis* pneumonia; †† Double strength (sulfamethoxazole 800 mg — trimethoprim 160 mg).

Dental prophylaxis

There are few data to support the use of routine antibiotic prophylaxis for transplant recipients prior to undergoing dental procedures. However, most centers recommend that patients take antibiotics before dental procedures whether invasive or not [3]. If used, most transplant centers use regimens recommended by the American Heart Association endocarditis prevention guidelines [3,4].

Treatment of asymptomatic bacteriuria

The Infectious Diseases Society of America (IDSA) guidelines recommend against the treatment of asymptomatic bacteriuria [5]. However, these guidelines make exceptions for patients who have just had genitourinary surgery. Many centers leave ureteral stents in until about 90 days post-transplant. If asymptomatic bacteriuria is detected while the stents remain in place most centers will treat. This is because more severe infections, such as sepsis or pyelonephritis, are associated with asymptomatic bacteriuria in the early post-transplant period [6]. The choice of antimicrobial should be guided by susceptibility testing, and although not well defined, the duration should likely be 7 to 10 days.

Infection with *Mycobacterium tuberculosis* is relatively uncommon in the US. However, patients who attend a dialysis center are at a 30-times risk of being latently infected with *M. tuberculosis* as compared to the general population [7]. It is recommended that all potential transplant recipients be screened for latent tuberculosis (TB) prior to transplantation [8]. However, the timing of treatment for latent TB infection can be done either prior to or immediately following transplantation. A Korean study evaluated performing an interferon-γ release assay (IGRA) for latent TB infection at the time of transplant [9]. All four patients who eventually developed TB post-transplant were IGRA positive. Additionally, all patients who were skin test positive for latent TB infection were treated with 9 months of isoniazid (INH) post-transplant [9]. None of these patients (n = 24) developed active TB [9]. This study suggests that even if all treatment for latent TB is given post-transplantation it is still effective at reducing the risk of active TB. It is also positive to screen only patients who proceed to transplant with an IGRA as opposed to screening all potential recipients. However, the sensitivity of IGRA testing post-transplantation has not been assessed. Therefore it is important that some form of latent TB screening be performed prior to transplantation.

Fungal prevention

Except as mentioned above in regards to pancreas transplantation, specific antifungal prophylaxis is generally not warranted in kidney, pancreas, or kidney/pancreas transplantation. Kidney and pancreas transplant recipients are at risk for developing cryptococcosis post-transplant. Current IDSA guidelines recommend a minimum of 6 months of fluconazole maintenance, then after stopping fluconazole following the serum cryptococcal antigen (CrAg) [10]. If the serum CrAg rises after cessation of therapy and there are no signs of active disease, most transplant infectious diseases experts would restart fluconazole and continue indefinitely.

Pneumocystis jirovecii (formerly *P. carinii*) has been reclassified from a parasite to a fungus. All transplant recipients receive some sort of prophylaxis against developing *Pndeumocystis* pneumonia (PCP). Sulfamethoxazole/trimethoprim (smx/tmp) is the preferred agent for preventing PCP. Many patients have a stated allergy to smx/tmp. Because smx/tmp is markedly better at preventing PCP than second-line agents, it should be elicited what kind of adverse reaction the patient had. Many people have a photosensitivity reaction while taking smx/tmp. This can be avoided by limiting sun exposure while taking smx/tmp. The duration of PCP prophylaxis is typically 6 months after transplant. However, if patient receives antilymphocyte antibodies to treat an episode of rejection consideration should be given to reinstituting smx/tmp for three to 6 months. Also, some centers that use antithymocyte immunoglobulin for induction of immunosuppression extend the length of PCP prophylaxis to at least two years and some even keep patients on PCP prophylaxis for life.

Alternatives to smx/tmp include dapsone, atovaquone, inhaled pentamidine and clindamycin+pyrimethamine [11]. Dapsone has a sulfa moiety. Thus, patients with a true sulfa allergy should not be given dapsone. Dapsone also has been associated with hemolytic anemia in lung transplant patients [12]. While dapsone is cleared through the kidneys, there are no specific recommendations for adjustment for renal function. In the study of lung recipients on dapsone who developed hemolytic anemia, there was an association between peak creatinine and the eventual development of hemolytic anemia [12]. This suggests that patients with diminished renal function post-transplant (e.g. delayed graft function) should have either a reduced dose of dapsone or use atovaquone for PCP prophylaxis. Atovaquone is generally well tolerated from a medical standpoint. Atovaquone comes as a liquid and can be mixed with any drink. However, many patients do not like the taste of atovaquone

nor having to drink the large volume of liquid needed to disguise the taste.

Parasitic prevention

In the US, parasites are usually not a major problem for most transplant recipients. Additionally, smx/tmp, dapsone, and atovaquone, which are given for PCP prevention, also have activity against *Toxoplasma gondii*, the most common parasitic infection in transplant recipients. Even though toxoplasmosis is not a major issue across the transplant population, patients should still be counseled not to scoop cat-litter boxes or eat under-cooked game meat.

With an increasing proportion of immigrants from Latin America representing both donor and recipient populations, *Trypanosoma cruzi* is becoming more concerning. Recently conducted surveillance in the US shows a seroprevalence of 0.026% overall. However, in donors born in Mexico the prevalence was 0.3% and those born in Central American the rate was 0.5% [13]. Chagas' disease (American trypanosomiasis) is concerning because currently there are no FDA-approved medications available in the US to treat Chagas' disease. While heart transplantation has been performed successfully for Chagas' heart disease, the outcomes are less than favorable as early mortality is 18% [14]. Although Chagas' disease did not develop in any of the non-heart organs from two Chagas'-positive donors, using a kidney or pancreas from a *T. cruzi* seropositive donor should probably only be done in the setting of a life-saving transplant. If a potential transplant recipient tests positive for previous Chagas' disease then it is wise to treat prior to transplantation. Benznidazole or nifurtimox both have some activity against *T. cruzi*. However, cure is generally not possible. If an organ from a *T. cruzi* seropositive donor is being used then consideration should be given to treating the recipient. The duration of treatment should be 30–60 days using benznidazole [15].

Viral prevention

Apart from CMV, respiratory viruses (influenza, parainfluenza, respiratory syncytial virus, etc.) are the most common viral infections seen in transplant recipients. Currently, an annual influenza immunization is the best measure to reduce respiratory viral infection. Recommended vaccines will be discussed later in the chapter. Although there are concerns of influenza immunization eliciting alloantibodies [16–18], it appears that routine influenza immunization is safe. In a large study examining Medicare claims between 2000 and 2006, Hurst et al. found that influenza immunization in the first year was not associated with acute rejection [19]. However, influenza immunization was associated with a reduced risk of graft loss (adjusted hazard ratio (HR) = 0.77: 95% confidence interval (CI); 0.69–0.85, $P < 0.001$) and death (HR = 0.82: 95% CI; 0.76–0.89, $P < 0.001$) [19]. Because of limitations in the detail of the data, the authors were not able to associated timing of immunization with rejection episodes. Nor were they able to evaluate timing of influenza illness with rejection [19]. Multiple other studies have looked at surrogate end points of neutralizing antibodies against neuraminidase and hemagglutinin as well as adverse effects (fever, pain at injection site, change in creatinine). All of these studies have concluded that influenza immunization appears safe and effective at generating antibodies in renal transplant recipients [20–23].

CMV has been the viral infection most associated with transplantation. CMV is capable of infecting many organ systems including the gastrointestinal tract, the liver, the bone marrow, the central nervous system, and the eye. Untreated CMV disease can have disastrous consequences including permanent brain damage, blindness, and death. In 1989, Balfour and colleagues evaluated the use of acyclovir in preventing CMV disease after kidney transplant. Patients took acyclovir or placebo, based on randomization, for 12 weeks after transplant. The rate of symptomatic CMV disease was 7.5% in the acyclovir group compared to 29% in the placebo group, $P = 0.002$ [24]. Thus, many centers adopted using acyclovir for primary prophylaxis of CMV disease in high-risk patients, such as, those that are donor positive, recipient negative for CMV(D+/R−). However, in vitro acyclovir has poor activity against CMV. Ganciclovir was developed as an antiviral against CMV. Flechner et al. evaluated 3 months of either oral ganciclovir or oral acyclovir in a randomized fashion. In addition to CMV disease they performed routine blood cultures for CMV. By 6 months post-transplant CMV viremia occurred in 2.5% of ganciclovir-treated patients and 36% of acyclovir-treated patients, $P = 0.0001$. The highest benefit of ganciclovir over acyclovir was seen in the D+/R− patients, 54% vs. 0% ($P = 0.0008$). Thus, many centers converted to ganciclovir for routine prophylaxis against CMV in transplant recipients.

However, as diagnostic technology advanced and as ganciclovir-associated toxicities emerged, many transplant centers sought alternatives to universal prophylaxis with antiviral medications. The pre-emptive approach to treating CMV emerged. Improved diagnostic technology meant that CMV could be detected well before the development of symptoms. These assays included pp65 detection and CMV nucleic acid detection. The pp65 assay uses direct fluorescent antibodies against pp65, a surface protein on CMV. The test can be positive up to 1 week before the onset of symptoms. Nucleic acid amplification assays are usually more sensitive and can detect the presence of CMV in serum or plasma 7–14 days before symptoms. The pre-emptive principal relies on very sensitive assays and frequent monitoring of patients. The benefits of the pre-emptive approach are less exposure to antivirals, which may lead to less toxicity, potentially less ganciclovir resistance, and less cost to the patient. The drawbacks are higher costs to the transplant center, potential more severe disease especially if patients are non-adherent to the frequent testing regimen or if transplant center staff miss a positive result. When compared directly, universal prophylaxis and pre-emptive approaches appear to be equal at preventing CMV disease.

A prodrug of ganciclovir, valganciclovir, was developed and approved by the FDA in the early 2000s. Valganciclovir has improved bioavailability, which allows for comparable plasma levels to intravenous ganciclovir. A large, randomized clinical study evaluated oral valganciclovir at a dose of 900 mg daily versus oral ganciclovir 1000 mg three times per day for preventing CMV disease in D+/R− transplant recipients [25]. The study enrolled all organ transplant patients. Of the 364 evaluable patient enrolled, 120 (33%) were kidney transplants. Patient received study drug for 3 months post-transplant. At 6 and 12 months post-transplant the number of patients treated for CMV was comparable between the groups, 23% and 30.5% respectively for valgancicovir and 21.6% and 28.0% for oral ganciclovir [25]. The study met non-inferiority criteria and valganciclovir was rapidly adopted by most centers as the preferred agent for prevention against CMV. However, when the FDA approved valganciclovir there was not an indication for CMV prophylaxis in liver transplant recipients. This decision was based on a higher occurrence of tissue-invasive disease in liver transplant recipients who received valganciclovir (see the next section on prevention in liver transplant for more details).

Table 99.2. General prevention measures recommendations in liver transplantation

	Preferred prevention measure	Alternative prevention measures
Surgical prophylaxis	Ampicillin or vancomycin AND 3rd generation cephalosporin or carbapenem or fluoroquinolone or aminoglycoside AND Fluconazole (high-risk patients only)	Ampicillin/sulbactam or Piperacillin/tazobactam or carbapenem
CMV	Valganciclovir, acyclovir, and valacyclovir requiring dosage adjustment for renal dysfunction	
D+/R−*	Pre-emptive monitoring	Valganciclovir 900 mg daily for 3 months
Any R+†	Pre-emptive monitoring	Valganciclovir 900 mg daily for 3 months
D−R−‡		Acyclovir 400–800 mg TID§ or valacyclovir 500 mg BID for 3–6 months
Fungal		
Candida	Fluconazole 200 mg daily up to 70 days	
PCP**	Smx/tmp 1DS†† thrice weekly	Atovaquone 1500 mg daily Dapsone 100 mg daily Inhaled pentamidine Clindamycin+pyrimethamine
Hepatitis B	Lamivudine + hepatitis B immunolobulin	Lamivudine + entecavir or Emtricitabine + tenofovir or Lamivudine + tenofovir

* Donor seropositive/recipient seronegative; † recipient seropositive; ‡ donor seronegative/recipient seronegative; § thrice daily (every 8 hours), twice daily (every 12 hours); ** *Pneumocystis* pneumonia; †† Double strength (sulfamethoxazole 800 mg — trimethoprim 160 amg).

Subsequent studies on the use of valganciclovir prophylaxis in kidney transplant recipients have further refined its role. Initially, studies were published demonstrating that in kidney transplant patients 450 mg orally daily resulted in blood levels which were adequate to prevent CMV. Then, a study by Humar et al. showed that prolonging valganciclovir 900 mg/day prophylaxis from 100 to 200 days resulted in significantly less CMV disease by 2 years post-transplant, 38.7% versus 21.3%, $P < 0.001$ [26]. There was no difference between graft rejection or patient survival [26]. A consensus guideline [27] published prior to the study by Humar et al. recommends using 900 mg/day of valganciclovir for three to 6 months in D+/R− patients and for 3 months in R+ patients. Prophylaxis against herpes simplex and varicella zoster viruses should be considered for patients who are D−R− for CMV [27].

Primarily because there is a lack of effective antivirals, routine prophylaxis for other viruses cannot be general recommended except for some very specific scenarios. Most patients with end-stage renal disease (ESRD) should be vaccinated against hepatitis B virus (HBV). However, if the recipient did not mount an effective antibody response to the vaccination and they eventually receive a kidney from a HBV-infected donor (HBV cAb+, HBV sAg+, or HBV DNA+) then the recipient should probably receive HBV immunoglobulin and/or be started on antiviral prophylaxis. Antiviral agents that are active against HBV include lamivudine, tenofovir, emtricitabine, and entecavir. In addition to antivirals, patients should have surveillance for infection with HBV. This would include testing for HBV sAg and HBV DNA at 1, 3, 6, and 12 months post-transplant. If either of these becomes positive, then the patient should remain on antiviral treatment until the patient develops a detectable HBV sAb. If a patient receives an organ from a donor acutely infected with influenza, then consider giving the recipient oseltamivir for 5–10 days post-transplant. Although this is a soft recommendation as there have not been documented transmission of influenza through kidney transplantation.

Prevention in liver transplantation

See Table 99.2 for a summary of recommended prevention strategies in liver transplantation.

Bacterial prevention

Bacterial infections are common following surgery for liver transplantation. According to CDC surveillance, surgical site infections occur in up to 20% of liver transplant surgeries [28]. These infections range from superficial wound infections to deep, organ space infections. Superficial and deep wound infections are typically with skin organisms just as in any surgical procedure. However, deep, organ-space infections are usually related to flora of either the biliary tract or the bowel, depending on the surgical procedure performed. During the author's training, Robert H. Rubin, considered one of the early leaders in transplant infectious diseases, once said, "The risk for infection in transplantation is directly related to the skill of the surgeon." A corollary and likely more accurate way to state this principle is that the more complicated a surgery the more likely to have an infectious complication. This is illustrated by the experience at Mayo Jacksonville where the authors reviewed 370 liver transplants over a 2 year period [29]. After multivariate analysis there were only 2 factors which remained significantly associated with the risk of infection — a prolonged operative time (>6 hours) or a low liver graft weight to recipient BMI ratio (<0.01) [29]. In addition, in this study a surgical site infection was significantly associated with an increased risk of graft loss or death. Those with a surgical site infection had a 12 month cumulative graft loss or death percentage over 20% as compared to about 8% for those without a surgical site infection [29]. Thus, it is important to choose an antibiotic for surgical prophylaxis that has good activity against the flora of the duodenum and the biliary tree.

A Spanish transplant group, which covers all transplant centers in Spain, reviewed their cohort of liver transplants over a 2 year period to see if antibiotic choice impacted the rate of surgical

infections. There were 1222 liver transplants in the cohort. The cumulative 12 month surgical site infection rate was 8.8%. Most of these (42%) were incision infections with only 26% being deep abscesses [30]. In univariate analysis the use of cefazolin was associated with an increased risk of surgical site infection. However, this association dropped out on multivariate analysis because of high use of cefazolin at a single center. There were several risk factors for developing a surgical site infection following multivariate analysis. These included: choledochojejunostomy (OR = 4.2: 95% CI; 1.6–10.7, $P = 0.003$), previous liver or kidney transplant (OR = 2.6: 95% CI; 1.1–6.3, $P = 0.029$), or red cell transfusion >4 units (OR = 2.0: 95% CI; 1.1–3.4) [30]. Of note, high-volume transfusion has also been found to increased risk for *Candida* infection [31]. Together all of these studies reinforce the principle stated by Dr. Rubin, if a surgery is complicated for whatever reason then there is an increased risk for infection.

However, how do these studies inform decisions about choosing surgical antibiotic prophylaxis? The Spanish study found that *Enterococcus* species were responsible for all infections in their cohort. Thus, it is important to choose an antibiotic regimen that has activity against *Enterococcus*. The authors of the Spanish study suggest that a second or third generation cephalosporin with or without ampicillin may be adequate. Their data would suggest that a glycopeptide plus a fluoroqinolone would also be an acceptable choice (OR = 1.2: 95% CI; 0.01–13.4, univariate analysis) [30]. This would also be an acceptable regimen in either a patient with a stated penicillin/cephalosporin allergy or in a patient who is known to be colonized with MRSA. These regimens are supported by older guidelines currently undergoing revision [1]. Despite the antibiotic choices, it is important that antibiotics be re-dosed if it has been 6 hours since initial or last dose, or if there is large-volume blood loss. Continuing antibiotics for 48 hours postoperatively is generally recommended [1], antibiotics are often continued for longer following complicated surgeries.

Outside of surgical prophylaxis routine antibacterial prophylaxis is generally not needed. Clearly, if bacteria are isolated from fluid collections postoperatively, then using antibiotics in this setting would now be considered therapy rather than prophylaxis.

Fungal prevention

Candida infections are the most common fungal infections following liver transplantation [32]. Routine use of fluconazole for 70 days post-transplant was shown to significantly reduce the rate of *Candida* infections in liver transplant [33]. However, the rate of *Candida* infections in the fluconazole arm of this randomized, placebo-controlled study was higher than the rate encountered in most centers [32,33]. Therefore, many centers use fluconazole in patients at high-risk for developing a fungal infection. Criteria used to determine high-risk are: known *Candida* colonization (urine, wound, or respiratory), a choledochojejunostomy biliary anastomosis, retransplantation, intraoperative administration of >40 units of cellular blood products (red blood cells or platelets), preoperative creatinine ≥2.0 mg/dL, or return to the operating room repair of viscous leak or bleeding complication [34]. If a patient has two or more of these criteria then they are considered at high risk for a fungal infection and antifungal prophylaxis perioperatively is warranted [34,35]. However, patients who do not have two or more of the above criteria do not need routine antifungal prophylaxis [36].

Pneumocystis prophylaxis is recommended for all transplant recipients, including liver transplant, for the first 6–12 months post-transplant [11]. Antibiotic choices are the same as those for kidney recipients and include sulfamethsoxazole/trimethoprim, dapsone, atovaquone, inhaled pentamidine and clindamycin+pyramethamine [11]. For sulfa-allergic patients atovaquone or pentamidine are acceptable alternatives. Pentamidine has the convenience of being administered monthly. However, pentamidine aerosol administration requires specialized equipment and experienced personnel for effective administration [11].

While aspergillosis and cryptococcosis occur post liver transplantation, these are typically late infections with a low rate and routine antifungal prophylaxis is not warranted. Although, there may specific instances where disease is detected in the donor and the use of prophylaxis to prevent a disease transmission is acceptable.

Parasitic prevention

As for kidney transplant recipients, some agents used for PCP prophylaxis are effective against *T. gondi*. However, toxoplasmosis prevention usually is not needed in liver transplantation. Also similar when found in kidney transplantation, Chagas' disease in liver transplantation might be a consideration in a recipient born in rural areas of Latin America. If identified and time permits, patients should be treated prior to transplantation. Alternatively, recipients may be treated for recurrences post-transplant.

Viral prevention

CMV

Like with kidney transplantation CMV is the most common viral infection encountered after liver transplantation. However, unlike in kidney recipients, routine CMV chemoprophylaxis cannot be recommended. Valganciclovir was shown to be non-inferior to oral ganciclovir in preventing CMV disease in D+/R− recipients. However, when the FDA analyzed the data they found that tissue-invasive CMV disease was higher in liver transplant recipients receiving valganciclovir as compared to oral ganciclovir [37]. Therefore, valganciclovir did not receive an indication for prevention of CMV disease in liver transplant. The studied, and approved dose, of 900 mg po daily appears to be associated with an increased risk of toxicity when compared to 450 mg po daily. In a yet unpublished abstract, Kalil et al. found that the higher dose of valganciclovir was associated with a higher risk of leukopenia (OR = 5.24: 95% CI; 2.09–13.15, $P < 0.001$) [38].

If CMV prophylaxis is not used, then consideration should be given to preventing herpes simplex virus (HSV) and varicella zoster by using valacyclovir or acyclovir [39,40]. HSV typically occurs in the first month post-transplant.

Hepatitis B

Patients who are unimmunized against hepatitis B prior to transplantation should receive the immunization series. This may be given on accelerated schedule if needed. Patients with chronic hepatitis B who undergo liver transplant should be instituted on therapy prior to transplantation. Therapy usually consists of combination therapy because of high rates of failure with lamivudine monotherapy [41]. Lamivudine is well tolerated and has an excellent safety profile. It is usually combined with either tenofovir or adefovir. Lamivudine in combination with chronic hepatitis B

Table 99.3. General prevention measures recommendations lung transplantation

	Preferred prevention measure	Alternative prevention measures
Surgical prophylaxis	Ampicillin or vancomycin AND 3rd generation cephalosporin or carbapenem or fluoroquinolone	Piperacillin/tazobactam or carbapenem OR Clindamycin+ Ceftazidime or fluoroquinolone
CMV	Valganciclovir, acyclovir, and valacyclovir requiring dosage adjustment for renal dysfunction	
D+/R−*	Valganciclovir 900 mg daily for 12 months	Pre-emptive monitoring
Any R+†	Valganciclovir 900 mg daily for 12 months	Pre-emptive monitoring
D−R−†		Acyclovir 400–800 mg TID§ or valacyclovir 500 mg BID for 3–6 months
Fungal		
Mold	Voriconazole 200 mg twice daily for ≥4 months	Itraconazole 200–400 mg po daily — BID
PCP**	Smx/tmp 1DS†† thrice weekly	Atovaquone 1500 mg daily Dapsone 100 mg daily Inhaled pentamidine Clindamycin + pyrimethamine

* Donor seropositive/recipient seronegative; † recipient seropositive; † donor seronegative/recipient seronegative; § thrice daily (every 8 hours), twice daily (every 12 hours); ** *Pneumocystis* pneumonia; †† Double strength (sulfamethoxazole 800 mg — trimethoprim 160 mg).

immunoglobulin is also effective in preventing recurrences post-transplant [42].

Hepatitis C

As of yet there are no specific agents that are used to prevent a hepatitis C recurrence post-transplant. However, many centers use approaches to minimize the risk of post-transplant hepatitis C recurrence. This is accomplished by: rapid taper of steroids, minimizing rejection risk by slow steroid taper or avoiding CMV [43].

Respiratory viruses

Routine season influenza immunization is the most effective means of preventing influenza in liver transplantation [44,45]. Recipients who are exposed to influenza post-transplant can receive oseltamivir for 10 days [46,47].

Prevention in lung transplantation

See Table 99.3 for general prevention recommendations in lung transplantation.

Bacterial and fungal prevention

Lung transplantation is similar to other surgical procedures in that patients are at risk for developing superficial wound infections most likely from skin flora. However, unlike other surgical procedures, lung transplantation involves cutting into the respiratory tree. Therefore, the choice of surgical prophylaxis must also account for bacteria, which may be present in this body site. This includes both the donor and recipient airways. Many centers and organ procurement organizations routinely obtain cultures of the airways. Then antibiotics are chosen which target whatever organisms grow. This practice is primarily based on observational studies showing bacterial pneumonias were the most common infections following lung transplantation [48]. Guidelines from the American Society of Health-Systems Pharmacist suggest cefazolin, cefuroxime or vancomycin for penicillin allergic patients. However, these guidelines are based on no data and therefore default to prophylactic regimens used for non-transplant cardiothoracic surgery [1]. These guidelines do state that therapy should be adjusted based on the results of donor cultures. For empiric perioperative prophylaxis, many centers choose antibiotics which are likely to cover ventilator-associated or aspiration pneumonia which may be present or developing in the donor at the time of procurement. At our center the empiric regimen is vancomycin and ceftazidime. This covers oral flora, possible MRSA and *Pseudomonas*. However, a carbapenem, anti-*Pseudomonal* penicillin, or an anti-*Pseudomonal* cephalosporin +/− ampicillin or vancomycin would also be reasonable coverage. For patients with septic lung disease, e.g. cystic fibrosis or bronchiectasis, the perioperative regimen is often designed based on the most recent cultures in the recipient. This regimen should include antimicrobials active against gram-positive oral flora. Or, if MRSA is a problem locally, vancomycin should also be included in the antibiotic regimen. Of course, the timing of antibiotic administration should follow existing guidelines from the Healthcare Infection Control Practices Advisory Committee [49], or more recent data demonstrating that except for vancomycin and fluoroquinolones, which should be dosed within 1 hour of skin incision, antibiotics should be administered between 0 and 30 minutes before skin incision [50].

While pneumonias are an important post-transplant complication, the bronchial anastomosis is a critical site for infection. Because the bronchial anastomosis takes 6–12 weeks to heal, it is susceptible to infection with both pathogenic and saprophytic organisms. This is especially true for fungi where *Candida* and *Penicillium* have been shown to cause anastamotic infections possibly leading to breakdown of the anastomosis [51]. Additionally, apart from small bowel transplants, lung transplant recipients are at highest risk for invasive fungal infections, especially aspergillosis. By 12 months post-transplant 8.6% of lung transplant patients will have developed an invasive fungal infection, and 64% of these cases will be aspergillosis or an unspecified mold [32]. Therefore, preventing fungal infections potentially has high favorable impact in lung transplantation. However, the most effective antifungal agent is not well defined. Most centers use universal prophylaxis with voriconazole with or without inhaled amphotericin B [52]. However, some centers use only an inhaled amphotericin B product, and lipid complex amphotericin B has been shown to be tolerable with only intermittent dosing — once per week after first 2 weeks [53]. While this study by Drew et al. was not powered for efficacy, there were 14.3% prophylaxis failures in the inhaled amphotericin B arm and 11.8% failures in the inhaled lipid complex amphotericin B arm [53]. These rates compare favorably to a retrospective analysis from the University of Pittsburgh where previously universal prophylaxis with fluconazole for 3 months

was used. However, if patients were found to be colonized with an *Aspergillus* species, then targeted intervention with systemic itraconazole combined with inhaled amphotericin B was used [54]. Employing this approach they experienced 23% invasive aspergillosis at one year. However, after switching to a universal prophylaxis approach using voriconazole 200 mg twice daily for 4 months minimum post-transplant, they reduced their invasive aspergillosis rate to 1.5% [54]. Thus, it is clear that universal inhaled amphotericin B — deoxycholate or lipid complex — is better than fluconazole, but universal prophylaxis with voriconazole appears to be better than inhaled amphotericin B, 1.5% versus 11–15% respectively. Although, these have never been compared head-to-head. Unfortunately, voriconazole is not without issues. Studies have linked voriconazole use in lung transplant recipients with increased rates of skin cancers [55–57]. While skin cancers are clearly problematic, this risk must be weighed against the high risk of developing invasive aspergillosis and the high associated mortality. Fortunately, there may be other options in posaconazole, itraconazole, or a currently investigational agent, isavuconazole. Of these, only itraconazole has been shown to be effective when employed in a universal prophylaxis manner [58]. However, itraconazole has poor bioavailability and many centers follow blood levels to ensure levels are adequate. Posaconazole is effective in preventing fungal infections in patients with acute myelogenous leukemia or myelodysplastic syndrome [59,60]. So it may be reasonable to presume posaconazole would be effective in lung transplant prophylaxis, but this has not been demonstrated.

Lung transplant recipients are at increased risk for PCP. However, unlike other transplant recipients, this risk is probably elevated for life. Therefore, current guidelines recommend continuing on PCP prophylaxis for life [11]. As with other organ transplant recipients, smx/tmp is the preferred agent. Alternative agents include dapsone, atovaquone, inhaled pentamidine, and clindamycin plus pyrimethamine. However, dapsone should be used with caution in lung transplant recipients as there may be an increased risk of hemolytic anemia without glucose-6 phosphatase deficiency (G6PD), especially if there is accompanying renal failure [12].

Parasitic prevention

As for kidney transplant recipients, some agents used for PCP prophylaxis are effective against *T. gondi*. However, toxoplasmosis prevention usually is not needed in liver transplantation. Also similar when found in kidney transplantation, Chagas' disease in liver transplantation might be a consideration in a recipient born in rural areas of Latin America. If identified and time permits, patients should be treated prior to transplantation. Alternatively, recipients may be treated for recurrences post-transplant.

Viral prevention

Immunization against hepatitis B virus prior to transplantation may help diminish the chance of hepatitis B being transmitted with the organ. However, if lungs known to be procured from an actively infected donor or concerns for recent infection (e.g. HBV cAb IgM positive), then consideration should be given to using lamivudine with HBIG to prevent infection. If a lung transplant recipient does develop chronic, active HBV infection, then treatment with combination therapy with antivirals is warranted.

Vaccination against seasonal influenza is effective at inducing an immune response in lung transplant recipients [61–63]. And, in the general population neutralizing antibodies are correlated with protection against seasonal influenza. Therefore, it is recommended that lung transplant recipients be immunized annually, preferably as soon as vaccine becomes available.

CMV is a major cause of morbidity post-transplant in lung recipients. CMV has been associated with the development of bronchiolitis obliterans syndrome (BOS) [64,65] In the pivotal study by Paya et al. [25] there were an insufficient number of lung transplant recipients enrolled for the FDA to give valganciclovir an indication for CMV prevention in these patients. However, a follow-up study examined whether 12 months versus 3 months of valganciclovir 900 mg daily (adjusted for renal dysfunction) was better following lung transplantation [66]. Patients were randomized to an additional 9 months of therapy or placebo following in initial, standard 3-month prophylaxis period. At one year post transplant, the patients in the extended prophylaxis period had, both statistically and clinically, significantly less CMV disease, 3.6% versus 35% [66]. This benefit was gained without an increase in toxicity as manifest by study withdrawal or the development of ganciclovir resistance. Therefore, it is recommended that lung transplant recipients who are positive for CMV either donor or recipient seropositive, should receive valganciclovir for 12 months post-transplant. It is advisable that some form of monitoring for CMV viremia be undertaken while on prophylaxis to insure there are no breakthroughs.

If CMV prophylaxis is not used, then consideration should be given to preventing herpes simplex and varicella (HSV) zoster by using valacyclovir or acyclovir [39,40]. HSV typically occurs in the first month post-transplant.

Prevention in heart transplantation

See Table 99.4 for general prevention recommendations in heart transplantation.

Bacterial prevention

Surgical site infection rates following heart transplantation are not any higher than coronary artery bypass grafting surgery [28]. Therefore, it is acceptable to use similar perioperative prophylactic antibiotics. Current guidelines [1] recommend either cefazolin or cefuroxime for prophylaxis. For patients with a penicillin or cephalosporin allergy, then vancomycin is an acceptable alternative. The cephalosporin should ideally be given in the 30 minutes prior to skin incision and vancomycin infusion should start 30–60 minutes before skin infusion [49].

Fungal prevention

Like other transplant recipients, all heart transplant recipients should receive PCP prophylaxis. Smx/tmp is the preferred agent for preventing PCP [11]. Also, if a patient receives antilymphocyte antibodies to treat an episode of rejection, consideration should be given to reinstituting smx/tmp for 3 to 6 months. Many patients have a stated allergy to smx/tmp. Alternatives to smx/tmp include dapsone, atovaquone, inhaled pentamidine and clindamycin plus pyrimethamine [11]. Dapsone has a sulfa moiety. Thus, patients with a true sulfa allergy should not be given dapsone. As previously discussed, dapsone has also been associated with hemolytic anemia in lung transplant patients [12]. Therefore, hemolytic anemia should be considered in a heart transplant recipient with anemia on dapsone. This occurs even without G6PD.

Heart transplant recipients have a relatively low risk of developing a fungal infection post-transplant [32]. As such, routine antifungal prophylaxis (other than PCP) is not indicated.

Table 99.4. General prevention measures recommendations in heart transplantation

	Preferred prevention measure	Alternative Prevention Measures
Surgical prophylaxis	Cefazolin 1 g iv 0–30 minutes before skin incision	Vancomycin 1 g iv 60 minutes before skin incision

Parasitic prevention

Heart transplant recipients have the highest risk of significant morbidity from *T. gondi*. Heart transplant recipients also have the highest risk of acquiring *Toxoplasma* from the donor. The risk of toxoplasmosis is highest in seronegative recipients who receive a heart from a seropositive donor. Fortunately, all heart transplant recipients receive PCP prophylaxis, and smx/tmp, atovaquone, and dapsone are all effective prophylaxis against *Toxoplasma*. High risk patients (D+/R−) should remain on prophylaxis for life since relapses do occur after stopping prophylaxis [67]. In addition to chemoprophylaxis, heart transplant recipients should avoid acquiring *Toxoplasma* post-transplant. This means avoiding eating undercooked meat and animal feces, especially cats or other carnivores. Patients should be reminded that animal feces can contaminate soil. So, care should be taken to insure cats do not use gardens and flower beds for defecation.

Chagas' cardiomyopathy is a leading reason for heart transplantation in Brazil [14]. However, the early mortality rate is high, 18%. Treatment with benznidazole is recommended for Chagas' positive patients prior to transplantation. The duration of treatment should be 30–60 days using benznidazole or nifurtimox [15]. While benznidazole and nifurtimox are not FDA-approved in the US, either may be obtained through the CDC's Division of Parasitic Diseases and Malaria (404-718-4745; e-mail chagas@cdc.gov) or outside of regular business hours, call the CDC Emergency Operations Center (770-488-7100) and ask for the person on call for Parasitic Diseases. If treatment cannot be feasibly administered prior to transplant then patients should be closely monitored for the development of symptoms post-transplant and treated if they become symptomatic.

Viral prevention

CMV infection has been associated with post-transplant vasculopathy in heart transplant recipients [68,69]. Based on the study by Paya et al. there is a benefit of heart transplant recipients who are CMV D+/R− receive valganciclovir prophylaxis for 3 months after transplant [25]. There were 56 heart recipients enrolled in this study. By 12 months, patients in the valganciclovir arm had investigator-treated CMV disease 30.5% of the time, which compared favorably to oral ganciclovir (28.0%) [25]. Since oral ganciclovir is no longer available in the US, oral valganciclovir or high-dose valacyclovir are the only feasible prophylactic agents available. Many centers choose to use a pre-emptive approach for CMV in heart transplant recipients. This may result in a higher number of patients being treated for CMV. However, there may be less CMV disease or toxicity from valganciclovir. Although, studies have demonstrated that CMV prophylaxis results in less intimal thickening and presumably less post-transplant vasculopathy [70].

If CMV prophylaxis is not used, then consideration should be given to preventing HSV by using valacyclovir or acyclovir [39,40]. HSV typically occurs in the first month post-transplant.

As with other organs, heart transplant recipients should receive annual influenza immunization as it reduces symptomatic, influenza-like illness [71]. Influenza immunization is also safe post heart transplant. Patients who are on the waiting list for a heart transplant should also receive influenza vaccination. Flu shots have been demonstrated to reduce the occurrence of cardiovascular events and potentially overall mortality [72,73]. This is especially true for patients with ischemic cardiomyopathy. If a post-transplant patient is definitely exposed to someone with influenza, then secondary prophylaxis with oseltamivir can be considered. The usual dose and duration are 75 mg once daily for 10 days.

If the deceased donor of the heart has evidence of recent or active HBV (e.g. HBV cAb IgM positive or positive HBV sAg), then consideration should be given to using lamivudine with HBIG to prevent infection. If the heart transplant recipient does develop chronic, active HBV infection, then treatment with combination therapy with antivirals is warranted.

Prevention in small-bowel and composite vascular allografts (CVA)

Very little quality data has been accumulated to guide prevention strategies in small bowel and CVA transplantation. Even so, the principles outlined above can be empirically applied to these two transplant scenarios. Like liver transplant, small-bowel transplant involves cutting into the intestines. Therefore, surgical antimicrobial prophylaxis should include agents active against small bowel flora. These would include a combination of ampicillin with a third-generation cephalosporin, or a beta-lactam combined with a beta-lactamase inhibitor (ampicillin plus sulbactam or piperacillin plus tazobactam). Antibiotics should be redosed for large-volume blood loss or prolonged operative time. Like other non-viscous surgical procedures, cefazolin or vancomycin should be adequate prophylaxis for CVA limb surgery. However, if the CVA surgical procedure involves the face, then additional Gram-negative coverage should be added to vancomycin, such as, fluoroquinolone, aminoglycoside, or aztreonam.

Based on observational reports, CMV-disease rates are higher in both small-bowel and CVA transplantation. Most experts recommend antiviral prophylaxis with valganciclovir in both of these

Table 99.5. Recommended vaccines for transplant recipients (adults)

Vaccine	Comments
Influenza — trivalent, inactivated	Give annually as soon as available
Tetanus + diphtheria + acellular pertussis (Tdap)	Give once if never received
Tetanus + diphtheria (Td)	Give every 10 years
Human papilloma virus (HPV)	Consider giving pretransplant if potential recipient is <26 years old and unvaccinated. Vaccines are different based on gender.
Hepatitis A	Give series if unvaccinated and non-immune, pre or post-transplant is acceptable.
Hepatitis B	Give series if unvaccinated and non-immune, pre or post-transplant is acceptable though pretransplant is preferable.
Pneumococcal	Give every 5 years
Meningococcal	Give every 5 years if felt at risk
Live virus vaccines — should not be given post-transplant	
Varicella (chicken pox)	Give pretransplant if non-immune
Varicella-zoster (shingles)	Consider pretransplant if potential recipient is >50years
Measles + mumps + rubella	Consider checking rubella titers and immunizing pretransplant if the vaccination history is questionable.
Live attenuated influenza vaccine (intranasal)	Currently (2012) not recommended for transplant recipients or household contacts, or healthcare workers who care for transplant recipients.

patient populations. Three months post-transplant should be a minimum. However, longer courses may be desired.

Immunizations in solid organ transplantation

See Table 99.5 for vaccination recommendations in transplantation.

In general, transplant patients should be immunized similarly to adult or pediatric patients of the same age. The CDC's Advisory Committee on Immunization Practices issues periodic updates for both children and adults [74]. However, there is one important caveat with solid organ transplant recipients — **no live vaccines should be administered to a post-transplant recipient receiving immunosuppression**. Recipients with failed allografts who are on minimal immunosuppression may receive live vaccines. Also, if the benefit of receiving a live vaccine is felt to outweigh the risks of developing a chronic infection with the vaccine strain, then administration of a live vaccination is warranted. Transplant recipients should not change the diaper of an infant who has received either rotavirus vaccine or oral polio vaccine. Also, household contacts should thoroughly wash their hands after changing diapers in order to prevent transmission of the vaccine strain. Of note, oral polio vaccination is no longer routinely done in the US. However, a foreign-born infant may have received oral polio vaccination. Other than these two instances transplant recipients do not routinely need to avoid contact with live-virus vaccine recipients. One caveat to this, if a varicella-vaccine recipient develops a rash, then the transplant recipient should avoid contact until the rash resolves [74].

Summary

The field of transplantation has evolved toward the use of effective strategies to prevent infections when possible, and numerous validated approaches for chemoprophylaxis now exist for use in transplant procedures. A thorough knowledge of the organisms to be anticipated, combined with robust institutional protocols for disease avoidance, combine to lessen the risk of infectious disease, and provide improved outcomes. However, regardless of the prophylactic measures taken, good clinical surveillance and a high index of suspicion should be combined with a collaborative relationship between the clinical transplant team and the infectious disease service to anticipate and if necessary respond to infectious illness.

CHAPTER 100

Metabolic and Endocrine Management of the Organ Transplant Recipient

Naim Issa, Scott A. Reule, and Aleksandra Kukla
Division of Renal Diseases and Hypertension, Department of Medicine, University of Minnesota, Minneapolis, MN, USA

Introduction

Solid organ transplant recipients may develop a number of metabolic and endocrine disorders. These disorders, which arise on a background of pre-existing co-morbid conditions, result from complex interactions among physiological changes related to the transplanted organ, post-transplant lifestyle changes, immunosuppressive medications and genetic susceptibility.

In the immediate post-transplant period, patients require close monitoring for numerous electrolyte abnormalities. Acutely these are related to the operative procedure but quickly these give way to disorders brought on by changes in organ function and the requirement for electrolyte-altering immunosuppressive agents. Specific management of hyperkalemia, hypercalcemia, hypomagnesemia, and hypophosphatemia is frequently required. Acute hyperglycemia is not uncommon, having been observed in as many as 87% of kidney transplant recipients with no history of diabetes mellitus [1]. In the long term, the prevalence of clustered metabolic risk factors, called the metabolic syndrome consisting of diabetes mellitus, hypertension, and dyslipidemia, may reach at least 40–50% in liver and kidney transplants [2,3]. The metabolic syndrome is associated with the development of allograft vasculopathy in heart transplant recipients and an increased risk for cardiovascular disease in kidney transplant recipients [3,4]. New onset diabetes after transplant (NODAT) is associated with graft failure and all-cause mortality after kidney [5,6] and liver transplantation [7].

The successful management of endocrine and metabolic disorders after solid organ transplantation requires careful consideration of co-morbidities, impaired kidney function, and medication interactions. There is some evidence of a genetic predisposition to the toxicity of transplant-related therapies. Single nucleotide polymorphisms (SNPs) have been linked to particular side effects of immunosuppressive agents [8–10]. Identification of genetic factors may shed light on our understanding of etiology behind metabolic and other complications of anti-rejection agents, and create an opportunity for future personalization of immunosuppression. Close collaboration among transplant nephrologists, endocrinologists, and primary care physicians well-versed in the management of post-transplant complications is necessary to optimize co-morbid conditions and minimize the risk of drug-related toxicities. The reader is also referred to Chapter 88, for additional information on long-term management of metabolic issues as they relate to cardiovascular morbidity post-transplantation.

Hyperglycemia and diabetes mellitus after solid organ transplantation

Post-transplant management of hyperglycemia differs depending on the timing and expected duration of elevated blood sugar levels (Figure 100.1). Immediately after transplant, hyperglycemia can occur from the stress of surgery and exposure to immunosuppression. Notably, acute hyperglycemia after transplant is associated with a four-fold increase in the incidence of NODAT [11]. Insulin is a preferred therapy in the perioperative period, as acute hyperglycemia is usually resistant to oral medications, and changes in the daily doses of immunosuppressants (especially corticosteroids) lead to unpredictable blood glucose levels.

In the long term, the incidence of NODAT may be as high as 30% across all transplanted organs, especially in adult solid organ transplant recipients (Table 100.1). While traditional risk factors (older age, obesity, ethnicity) are well-recognized contributors, hepatits C infection and exposure to immunosuppression also increase the risk (Figure 100.2) [3,6,12–18]. The pathophysiology of NODAT is complex and revolves around two important pathways: direct toxicity to the pancreatic β cells and increased insulin resistance (Figure 100.2). Moreover, the kidney play a substantial role in the clearance and degradation of circulating insulin, and therefore restoration of kidney function may "unmask" pre-existing diabetes [19]. An understanding of the etiology behind the diabetogenic action of individual agents may guide clinicians in choosing targeted therapies.

All non-diabetic solid organ transplant recipients should be screened for NODAT. The Kidney Disease: Improving Global Outcomes (KDIGO) Transplant Work Group recommends measurement of fasting blood glucose, an oral glucose tolerance test and/or assessment of HbA1C weekly for 4 weeks, every 3 months for 1 year, and annually thereafter [20].Given that many patients may experience postprandial hyperglycemia related to insulin resistance, the use of fasting blood glucose is limited due to a lack of sensitivity, and use as a screen may under-diagnose up to 25% of patients with NODAT [21]. HbA1C is useful for screening but values may be confounded by uremia, blood transfusions,

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

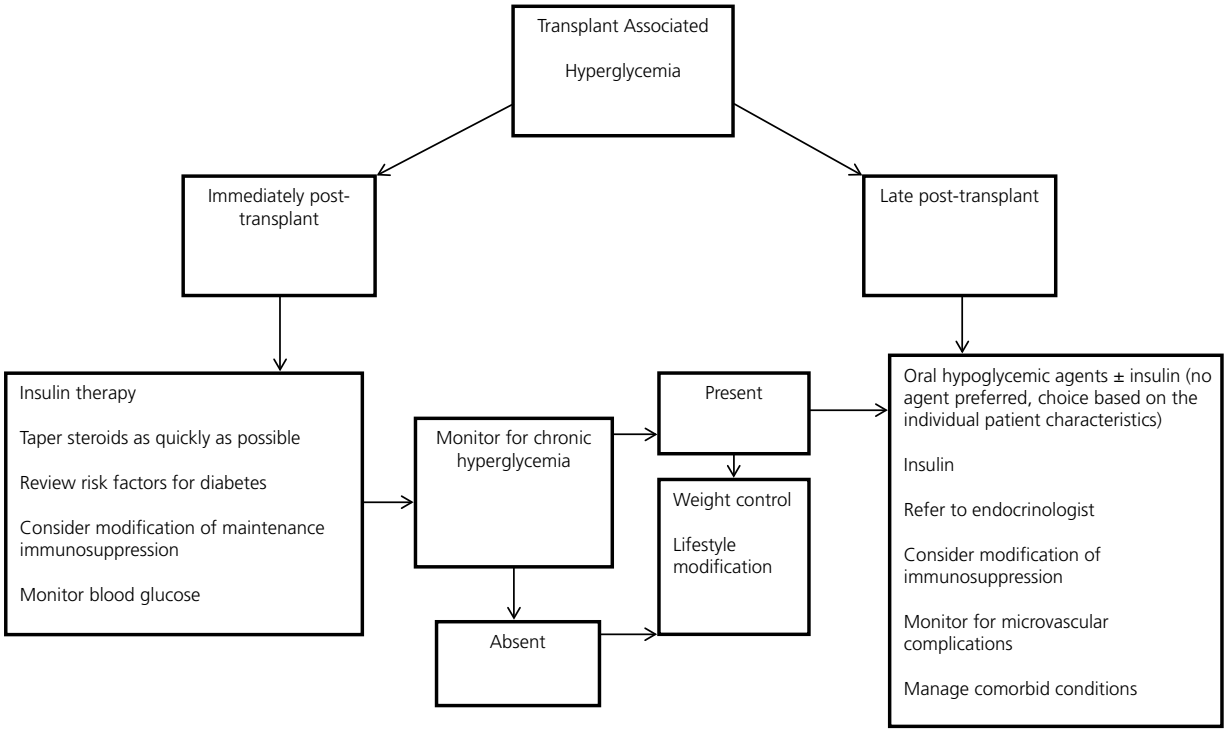

Figure 100.1 Transplant associated hyperglycemia.

erythropoietin administration, and hemolysis (not uncommon early post-transplant). Moreover, when measured in the early post-transplant period, HbA1C may reflect transient hyperglycemia.

The management of glucose disorders following pancreas transplantation is substantially different from that of other organ transplants and is covered in Chapter 77.

Role of immunosuppressive agents

Glucocorticosteroids

Glucocorticosteroids induce NODAT mainly by increasing insulin resistance, which results from increased hepatic gluconeogenesis and weight gain, as well as decreased glycogen synthesis and glucose uptake in muscle. Glucocorticosteroids also exert a direct negative effect on β cell function. Cumulative dose and duration of corticosteroids seem to influence the risk of NODAT [22]. Steroid-sparing protocols, developed to avoid unfavorable metabolic complications, are increasingly common [23]. These protocols have been associated with a decreased incidence of NODAT and may possibly decrease other cardiovascular risk factors including hypertriglyceridemia and weight gain [24–27]. Existing literature on the benefits of steroid-sparing protocols in other organ transplant recipients is limited.

Calcineurin inhibitors

Two calcineurin inhibitors (CNIs), cyclosporine and tacrolimus, form the backbone of maintenance immunosuppression after organ transplantation. Use of these medications, especially tacrolimus, contributes to the development of NODAT [28–30]. CNIs inhibit insulin transcription and synthesis through the disruption of calcineurin/transcription factors of the nuclear factor of activated T cells (NFAT) pathway, an essential regulator of β cell function [31].

Mammalian target of rapamycin inhibitors

Mammalian target of rapamycin inhibitors (mTOR inhibitors) were once considered alternative medications for patients on CNIs who developed NODAT. However, studies failed to demonstrate an improvement in glucose metabolism in kidney transplant recipients who underwent conversion from CNIs to sirolimus. Rather, the conversion was associated with a 30% increase in the incidence of impaired glucose tolerance [32]. The diabetogenic action of sirolimus may be related to impaired insulin-mediated suppression of hepatic glucose production, insulin resistance, and direct β cells toxicity [33–35].

Costimulation blockers

Belatacept is a first-in-class biological agent that selectively inhibits T cell activation by acting on a costimulatory pathway. Belatacept was designed as an alternative drug to CNIs in hopes of prolonging kidney allograft survival by avoiding CNI-related toxicity and minimizing metabolic complications. Two prospective trials compared the rates of metabolic complications in kidney transplant recipients randomized to cyclosporine or belatacept. In a prespecified pooled analysis, use of belatacept was associated with lower incidence of NODAT at 12 months [36]. Longer follow up is necessary to delineate true metabolic benefits of this new agent.

Other immunosuppressive agents

Azathioprine and mycophenolate mofetil have not been shown to have an independent diabetogenic effect, and in fact, were shown to have "protective" effects in one analysis [6]. This relationship needs to be interpreted with caution, as no good explanation exists.

Adjustment of immunosuppression

Given the important role of immunosuppressive agents in the development of NODAT, careful risk assessment in individual

Table 100.1. Incidence of new onset diabetes in solid organ transplant recipients

Study	Organ	Database	n	Time post transplant (months)	Incidence (cumulative) (%)	Increased risk	Risk not increased	Risk reduced
Israni et al [3]	kidney	PORT	1840*	12–60	13	MS 6–12 m post-transplant older age (per 10 years) AA race GFR (per 10) BMI >30 kg/m^2	—	—

*Patients with NODAT in first year were excluded; Tac, tacrolimus; MMF, mycophenolate mofetil; AZA, Azatioprine; mTOR, mammalian target of rapamacin; GFR, glomerular filtration rate; MS, metabolic syndrome, AA, African American; ESLD, end stage liver disease; AHN, acute hepatic necrosis; PSC, primary sclerosis cholangitis; HCV, hepatitis C; AR, acute rejection; CNI, calcineurin inhibitors

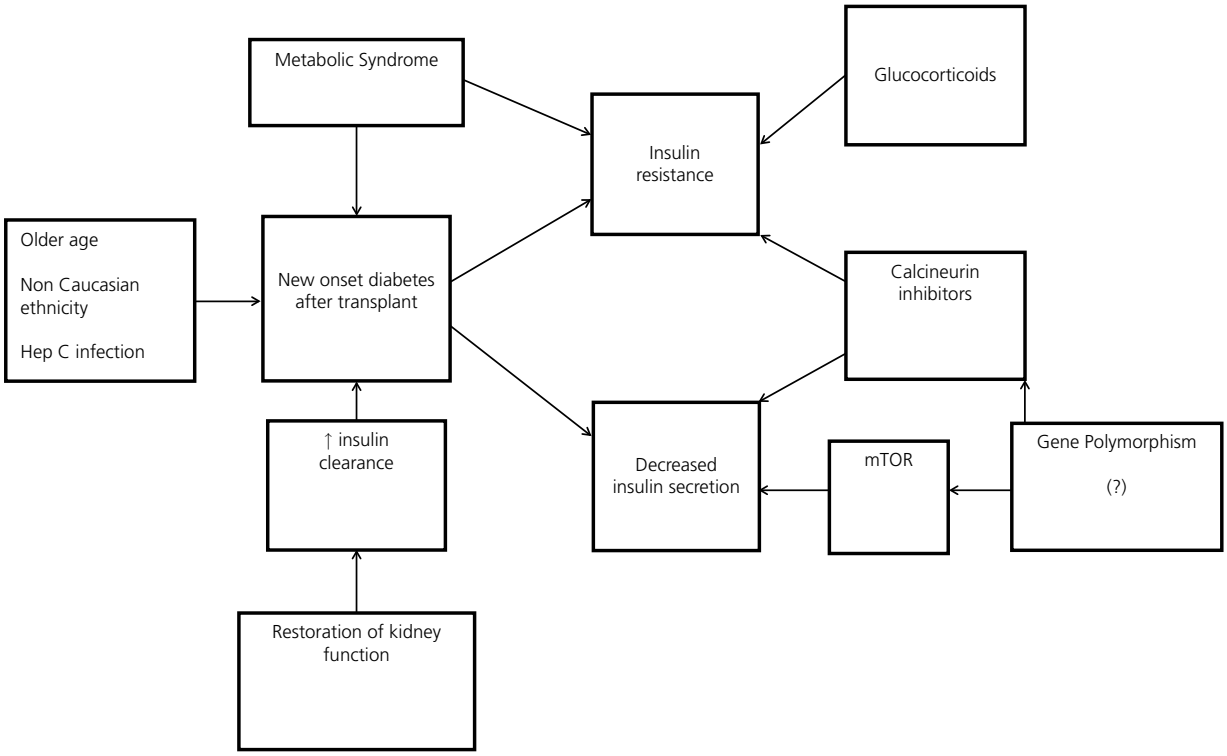

Figure 100.2 Risks factors for new onset diabetes after transplant.

patients may guide the clinician in the choice of maintenance immunosuppression. Certain risk factors are concordant across all solid transplant organs (Table 100.1). Tacrolimus has been repeatedly shown to be more diabetogenic than cyclosporine [37]. Older age, African American ethnicity, hepatitis C infection, and obesity predispose transplant recipients to NODAT and those patients may be best served with cyclosporine, rather than tacrolimus. Similarly, it has been previously shown that recipients with NODAT who are on maintenance tacrolimus may benefit from conversion to cyclosporine [38–40]. Belatacept may be a good option in those with high risk of metabolic complications, however longer follow-up is needed to adequately assess its long-term safety. Corticosteroids-minimization protocols, if deemed safe, should be considered in patients at risk for NODAT. For recipients on maintenance steroids, reduction of the dose to 5 mg/day may result in improvement of glucose metabolism [41].

Treatment of post-transplant diabetes mellitus with oral hypoglycemic Medications: safety profile and side effects (Table 100.2)

Insulin sensitizers

Metformin is recommended as a first-line therapy for non-transplant patients with type 2 diabetes mellitus. It has a favorable effect on weight stabilization, or even weight loss, and a limited side-effect profile (mainly gastrointestinal intolerance). Metformin monotherapy reduces HbA1C levels by 1.5%, and does not typically induce hypoglycemia [42]. The use of metformin has been limited in patients with renal disease because of the perceived risk of lactic acidosis; however, it was shown to be safe in patients with chronic kidney disease (CKD) stage 1–3, without severe co-morbidities [43,44]. Incidence of lactic acidosis in patients on metformin is very rare (4.3 cases per 100 000 patient years) and comparable to that in patients on non-metformin therapy (5.4 cases per 100 000 patient years) [45]. Risk for lactic acidosis increases with severe co-morbidities like hepatic dysfunction, kidney failure, heart failure, and hypoxia. Although data are limited, metformin has been shown to be a safe option in kidney transplant recipients with preserved kidney function [46]. In the non-transplant population, metformin use reduces the risk of metabolic syndrome and improves cardiovascular outcomes [44,47]. More research is needed to confirm these benefits in solid organ transplant recipients.

Insulin secretagogues

Sulfonylureas and glinides directly stimulate insulin secretion and may be especially beneficial in patients with CNI-induced insulin hyposecretion. Sulfonylureas and repaglinide lower hemoglobin A1C by 1.5%, while nateglinide is less effective when used as monotherapy [42]. The main side effect of these agents is prolonged hypoglycemia, which is more common in elderly patients.

Glyburide and its active metabolite are renally cleared and thus accumulate in patients with renal insufficiency, leading to frequent and prolonged hypoglycemic episodes [48]. In animal studies the hypoglycemic action of glyburide was inhibited by cyclosporine [49]. In contrast, glipizide is extensively metabolized in the liver to inactive metabolites. Glipizide does not interact with cyclosporine and causes hypoglycemia less frequently [48,50]. Clearance of glipizide is prolonged in patients with liver disease and therefore should be avoided in patients with significant liver impairment. Repaglinide and nateglinide are also hepatically metabolized and should be avoided in patients with liver failure, but do not need dose adjustment for kidney dysfunction. While repaglinide was shown to be a safe and effective option in kidney transplant recipients [51], it is metabolized through hepatic cytochrome p450 isoenzyme CYP 3A4. This isoenzyme is inhibited by CNIs,

Table 100.2. Oral hypoglycemic medications

Agent	Action	Metabolism/elimination	Benefits	Risks, precautions and contraindications
Insulin sensitizers				
metformin, buformin, phenformin	Decrease glucose production, increase glucose uptake by skeletal muscle	Major: renal tubular secretion	Low risk of hypoglycemia Weight neutral of weight reduction	GI intolerance Contraindicated in patients with renal disease and hepatic disease Increased risk of lactic acidosis with renal and liver disease
Insulin secretagogues				
the sulfonylureas glipizide, glyburide, glimepiride;	Increase pancreatic insulin secretion	Major: hepatic Glyburide is renally excreted	Rapid onset of glycemic effect	Hypoglycemia (highest risk with glyburide) Weight gain Adjust dose or avoid in patients with renal disease or liver failure
the meglitinides repaglinide, nateglinide		Major: CYP2C8 And 3A4	Rapid onset of glycemic effect	Hypoglycemia Weight gain Adjust dose or avoid in patients with liver failure Watch for immunosuppressive drug interactions
Others with different actions				
the thiazolidinedione derivatives pioglitazone, rosiglitazone;	Bind to peroxisome proliferator-activated receptors (PPARs) and stimulate insulin sensitive genes	Major: CYP2C8 Minor: CYP3A4	Low risk of hypoglycemia Improved lipid profile No adjustment needed for kidney disease	Weight gain Peripheral edema Heart failure Bone fractures Contraindicated in those with established NYHA class III and IV heart failure Avoid in patients with liver disease
the glucagon-like peptide-1 analogs exenatide, liraglutide;	Increase pancreatic insulin secretion	Major: renal	Low risk of hypoglycemia Weight loss ? β cells preservations	GI intolerance Not recommended in patients with history of pancreatitis Do not use (exenatide) or use with caution (liraglutide) in patients with advanced kidney disease
the dipeptidyl peptidase-4 inhibitors sitagliptin, saxagliptin	Increase endogenous incretins	Major: renal Minor: CYP3A4 2C8	Low risk of hypoglycemia Weight neutral May improve lipid profile	Reduce dose in moderate or severe kidney disease Watch for immunosuppressive drug interactions

therefore patients on calcineurin inhibitors may be at risk for hypoglycemia [52].

Thiazolidinediones

Thiazolidinediones (TZDs) increase the sensitivity of muscle, adipose tissue, and liver to endogenous and exogenous insulin. Monotherapy with TZDs lowers HbA1C by 0.5–1.4%, but their effect is more durable compared to sulphonylureas [53]. They typically require 3–6 weeks of therapy to show an effect. Main side effects are weight gain and peripheral edema; their use is also associated with a two-fold increased risk of heart failure [54]. While TZDs exert a positive effect on the lipid profile, their effect on the incidence of cardiovascular events remains controversial [55].There is also evidence of accelerated bone loss and higher risk of fracture in patients on TZDs, likely resulting from activation of peroxisome proliferator-activated receptor gamma (PPARγ), inhibiting bone formation and enhancing bone resorption [56]. TZD use in kidney transplant recipients was shown to be well tolerated without significant interactions with immunosuppressive medications in the short term [57]. Nonetheless, they should be used with caution in transplant recipients, many of whom are already predisposed to bone fractures. Additionally, the lack of positive effects on cardiovascular outcomes makes this class of drug less desirable in solid organ transplant recipients.

Glucagon-like peptide-1 analogs

The incretins, natural hormones produced by the small intestines, are secreted in response to carbohydrate ingestion, which potentiates glucose-stimulated insulin secretion. Incretin hormone-based treatments, including glucagon-like peptide 1 (GLP-1) agonists and dipeptide peptidase IV (DDP-4) inhibitors, are promising new therapeutic options for patients with type 2 diabetes mellitus. GLP-1 agonists bind to GLP-1 receptors and increase GLP-1 activity, leading to glucose-dependent insulin secretion, decreased glucagon secretion, and hepatic glucose production. Exenatide lowers HbA1C by 0.5–1% mainly by lowering postprandial glucose levels. Main side effects include gastrointestinal disturbances such as nausea, vomiting, and diarrhea. Exanetide promotes weight loss by inducing satiety and slowing gastric motility, and therefore is not recommended in patients with severe gastroparesis. Exanatide should not be used in patients with GFR <30 mL/min. Similarly, liraglutide should be avoided in patients with severe kidney dysfunction [42,58].

The DPP-4 inhibitors prevent endogenous GLP-1 and gastric inhibitory polypeptide enzymatic inactivation, leading to prolonged availability of physiological levels of endogenous GLP-1. They reduce HbA1C by 0.5–0.8%. Similar to GLP-1 agonists, the DPP-4 inhibitors exert a positive effect on weight loss and do not cause hypoglycemia. Dose adjustment is necessary for kidney

dysfunction. Overall, the use of this class of drugs in transplant recipients should be done with caution due to lack of data on safety and efficacy, as well as potential drug interactions [42,58].

Management of post-transplant diabetes mellitus

The target HbA1C has not been established in solid organ transplant recipients, but a goal of <7% is often extrapolated from guidelines for treatment of type 2 diabetes mellitus in the general population [42]. Analogous to the non-transplant population, lifestyle and dietary modifications play an important role in NODAT management, but patients with persistent hyperglycemia require pharmacological therapy.

The literature is lacking adequate studies addressing the safety and efficacy of oral hypoglycemic agents versus insulin in long-term management of diabetes after transplant. Despite increasing understanding of the pathophysiology of NODAT, a thorough assessment of insulin resistance versus decreased insulin secretion is not done routinely in clinical practice.

While no single oral hypoglycemic agent is preferred, the risks and benefits of each drug should be carefully examined for potential interactions with immunosuppressive agents in solid organ transplant recipients. Metformin appears to be a good option for patients with insulin resistance and stable kidney function. Metformin should be discontinued if a patient experiences acute changes in renal function, acute illnesses such as gastrointestinal disturbances, severe infections, or conditions that can cause hypoxia including either cardiac or respiratory failure. Metformin should be used cautiously in kidney transplant recipients, especially during the first six months post-transplant when the incidence of rejection, and therefore graft dysfunction, is greatest.

Insulin secretagogues can be used in the transplant population, especially if the predominant mechanism is suspected to be decreased insulin secretion. However, the particular hypoglycemic agent should be chosen based on pharmacokinetics in the context of an individual patient's co-morbidities. TZDs should be used with caution because they have a propensity to cause edema, heart failure, and bone fractures. Incretin-based therapies are a new, promising class of drugs, but their safety and efficacy in transplant patients has not been adequately studied. Combination therapy of oral hypoglycemic agents from different classes may be necessary based on the severity of hyperglycemia and initial response to therapy.

Hyperlipidemia after solid organ transplantation

Hyperlipidemia is common in solid organ transplantation and may affect over half of the liver, kidney and heart transplant recipients [59–61]. Contributing factors include genetic predisposition, obesity, nephrotic syndrome, hypothyroidism, diabetes mellitus, and medication use — including immunosuppressive agents.

Role of immunosuppressive agents

Corticosteroids

Corticosteroids have many deleterious effects on cholesterol metabolism. A correlation between high cholesterol levels and the cumulative dose of corticosteroids has been described. Their prolonged use induces insulin resistance and hyperinsulinism, thereby causing an increase in triglycerides (TG), total cholesterol (TC), and very low-density lipoprotein (VLDL) levels, and a decrease in high-density lipoprotein (HDL) levels. Other lipogenic mechanisms include up-regulation of the activity of acetyl-coenzyme A carboxylase and free fatty acid synthetase, an increase in the activity of HMG-CoA reductase, inhibition of lipoprotein lipase, and down-regulation of LDL receptor activity [62–65].

CNIs

The mechanisms of cyclosporine-induced hyperlipidemia include decreased synthesis of bile acids from cholesterol via inhibition of the enzyme 26-hydroxylase and the down-regulation of LDL receptors [66]. This effect is independent of concurrent corticosteroid use; withdrawing corticosteroids has a limited and modest effect on dyslipidemia [67]. A trial of late cyclosporine reduction in kidney transplant recipients, who were treated with both mycophenolate mofetil and corticosteroids, showed a dose-responsiveness reduction of lipid levels [68]. Kidney and liver transplant recipients treated with tacrolimus had a lower incidence of dyslipidemia than those treated with cyclosporine [69,70]. Some studies showed both de novo use and conversion from cyclosporine to tacrolimus had favorable effects on dyslipidemia [71,72].

mTOR inhibitors

Use of mTOR inhibitors significantly increases cholesterol and TG levels in a dose-dependent pattern. The mechanisms of adverse lipidemic effects of sirolimus are not known and may be multifactorial, including blockage of insulin-stimulated lipoprotein lipase, increased hepatic production of TG and lipoproteins, decreased plasma clearance and cellular transport, and decreased catabolism of apoB100-containing lipoproteins [73–78]. Conversion from CNIs to sirolimus is associated with a higher prevalence of hypertriglyceridemia and hypercholesterolemia [79]. Combination therapy of sirolimus with CNIs is associated with a significant increase of total cholesterol and TG levels [80–82].

Other immunosuppressive agents

There are no data suggesting that either azathioprine or mycophenolic mofetil causes dyslipidemia. Use of the costimulation blocker belatacept was associated with a 25–50% reduced increase in non-HDL and total cholesterol compared with cyclosporine, and a reduction in post-transplantation concentrations of TG [36,83].

Treatment with anti-dyslipidemic agents: safety profile and side effects (Table 100.3)

Hypolipidemic agents for clinical use include statins, ezetimibe, nicotinic acid, fibrates and fish oil. Statins are the most commonly prescribed agents, with potent LDL-lowering properties, excellent tolerability, and a proven ability to reduce cardiovascular events [84]. The major difference in the treatment of dyslipidemia of solid organ transplant recipients versus the general population stems from drug interactions between immunosuppressive agents and lipid-lowering medications.

Statins

Statins are HMG-CoA reductase inhibitors (the rate-limiting step in cholesterol biosynthesis) and the most powerful drugs for lowering LDL-cholesterol; reductions of 20–60% have been documented [85–87]. They also exhibit pleiotropic effects including inhibition of inflammatory activity and cytokine activation, attenuation of endothelial dysfunction, and attenuation of vascular hypercoagulability, adding to their cardiovascular benefits [88–91]. Randomized clinical trials have shown that pravastatin and simvastatin improve survival and reduce the incidence of acute rejection and transplant

Table 100.3. Pharmacotherapy of lipid-lowering agents

	Usual daily dosing in general population	Dosing Instructions	Metabolism	Selected Drug-Interaction	Side Effects
HMG CoA Reductase Inhibitors (Statins)					
Pravastatin	10–80 mg/day	Should be taken at bedtime	50% renally cleared as unchanged drug. Smaller amounts are cleared by biliary excretion or undergo non-CYP and CYP 3A4 hepatic transformation.	Cyclosporine: increased risk of myopathy due to additive toxicity and elevation of statin serum level by competitive inhibition of CYP 3A4.Pravastatin and fluvastatin are less likely than other statins to interact significantly with cyclosporine. mTOR inhibitors (sirolimus, everolimus): increased serum levels of sirolimus and everolimus in combination with atorvastatin The FDA recommends avoiding doses higher than 20 mg of simvastatin in patients receiving amlodipine	Transaminitis, GI intolerance, CPK elevations, muscle toxicity, rhabdomyolysis (rare), Close monitoring of transaminases may provide early evidence of elevated statin levels and toxicity.
Fluvastatin	20–80 mg/day	Regular release should be taken at bedtime	75% undergoes hepatic transformation by CYP 2C9 and 20% by CYP 3A4.		FDA warning of increased myopathy risk about the use of high dose of simvastatin (80 mg/day)
Atorvastain	10–80 mg/day	May be taken at any time of the day	Undergoes extensive CYP 3A4 transformation to active metabolites.		
Resuvastatin	5–40 mg/day	May be taken any time of the day	Cleared as unchanged drug. 10% undergoes CYP 2C9 transformation to a partially active metabolite.		
Simvastatin	10–80 mg/day (FDA warning for doses >40 mg/day)	Should be taken at bedtime	Undergoes extensive CYP 3A4 transformation to active and inactive metabolites.		
Cholesterol Absorption Inhibitors					
Ezetimibe	10 mg once daily	May be taken any time of the day	Undergoes glucuronide conjugation in liver and in small intestines to form active metabolite. Cleared by enterohepatic recycling and fecal excretion.	Statins: added LDL lowering in combination with a statin or as single agent if statin not tolerated. Fibrate: increased serum level of ezetimibe. Cyclosporine: increased serum level of ezetimibe and possible alteration of cyclosporine level. 50% dose reduction to 5 mg of ezetimibe daily in combination with cyclosporine.	Increased transaminases in combination with statins
Fibrates					
Gemfibrozil	600 mg twice daily	30 to 60 minutes before meals	Undergoes non CYP transformation by glucuronide conjugation with small amount of CYP 3A4 transformation. Gemfibrozil inhibits other drugs metabolized by CYP 2C8, 2C9 and 2C19	Cyclosporine: potentially nephrotoxic in cyclosporine treated patients. Statins: increased risks of hepatotoxicity, myopathy, and rhabdomyolysis Avoid combining gemfibrozil with statins. Statins: increased risk of myopathy and rhabdomyolysis.	Skin rash, gastrointestinal intolerance (bloating, cramping, nausea), cholelithiasis, myalgia, muscle toxicity, rhabdomyolysis
Fenofibrate	Dose varies, depending on preparation	Not recommended with renal dysfunction (especially in patients with GFR < 30 mL/min).	Metabolized to active intermediary by plasma and tissue esterases. Undergoes non CYP metabolism by glucuronide conjugation.	Cyclosporine: additive risk of nephrotoxicity	

(*Continued*)

Table 100.3. (*Continued*)

	Usual daily dosing in general population	Dosing Instructions	Metabolism	Selected Drug-Interaction	Side Effects
Bile Acid Sequestrants					
Cholestyramine	4–24 g/day	Should be taken within 30 minutes of a meal.	Not well-absorbed from the gut into the bloodstream. Thus, bile acid sequestrants, along with any bile acids bound to the drug, are excreted via the feces after passage through the GI tract	Affects other medications' absorption, bind and decrease absorption of fat-soluble vitamins, such as vitamin A, vitamin D, vitamin E, and vitamin K, digoxin, warfarin, thyroxine and phenobarbital.	Nausea, bloating, cramping and constipation, transaminitis
Colesevalem	3.75 g/day	Should be taken with meals daily			
Colespitol	5–30 g/day	Should be taken within 30 minutes of a meal.			
Miscellaneous					
Nicotinic acid	1–2 g/day (avoid higher doses)	Should be taken with meals daily TID. Start with low dose and titrate up.	Not absorbed from the gut into the bloodstream.	Bile Acid Sequestrants: May decrease the absorption of Niacin. Statin: niacin may enhance their toxic effect especially with niacin doses of 1 g or greater daily.	Skin flushing, headache, warm sensation and pruritus, nausea, vomiting, diarrhea, angina pectoris, and myositis
Omega-3-acid ethyl esters (Fish oil)	1–2 grams twice per day	May be taken at any time of the day	Not defined	No CYP mediated interactions with immunosuppressive agents, statins, fibrates or ezetimibe based on in vitro data	Dyspepsia, eructation, fishy breath and taste, modest increase in LDL, modest increase in bleeding time

vasculopathy in heart transplant recipients [92–94]. The effects of fluvastatin on cardiovascular outcomes in kidney transplant recipients were examined in the ALERT trial [95]. Indeed, this trial serves as an exemplary specimen of clinical trial design in Chapter 134. Although the initial results did not show a significant difference, extension of the trial demonstrated a 21% reduction of major cardiovascular events with fluvastatin use [96].

Statins vary in their potency, metabolism, and drug interactions (Table 100.3). Atorvastatin and rosuvastatin are the most potent, reducing LDL-cholesterol levels by approximately 60% at doses of 80 and 40 mg/day, respectively [97]. An additional benefit of atorvastatin and rosuvastatin is an improvement in triglyceride levels and modest elevation in HDL-cholesterol levels [98,99].

Most statins, including lovastatin, simvastatin, and atorvastatin, are metabolized by the hepatic isoenzyme CYP3A4. Systemic exposure to statins may be increased 3- to 20-fold when co-administered with CNIs due to its inhibitory effect on the CYP3A4 or CYP2C9 isoenzymes. This is especially seen in patients taking cyclosporine [100–103]. Cyclosporine also inhibits other transport proteins, like P-glycoprotein organic anion transport polypeptide (OATP1B1), which may explain elevated levels of non-CYP3A4-dependent statins such as pravastatin, fluvastatin, and rosuvastatin [104].

Greater exposure to statins increases the risk of statin-induced myopathy, ranging from muscle pain and weakness to the potentially fatal complication, rhabdomyolysis. In a retrospective analysis of 20 366 kidney transplant recipients in the US Renal Data System (USRDS) database, the incidence of rhabdomyolysis was 1.4 (95% CI, 1.1–1.8) per 1000 person years and was significantly more likely to occur with cyclosporine than with tacrolimus or sirolimus [105]. Statin-induced myopathy was found to be dose dependent in non-transplant population [106], leading to a Food and Drug Administration (FDA) warning regarding the use of high dose of simvastatin (80 mg/day).

Table 100.4. Inhibitors of cytochrome P450 isoenzymes that potentiate HMG-CoA reductase inhibitors levels*

Agent	P450 Isoenzyme**
Cyclosporine	3A4
Macrolides (erythromycin, clarithromycin)	3A4
Azole antifungals (ketoconazole, fluconazole, itraconazole, voriconazole)	mainly 3A4 and 2C9
Non-dihydropyridine calcium blockers (diltiazem, verapamil)	3A4
Amlodipine	3A4 (mainly with high dose simvastatin)
Gemfibrozil	3A4
Amiodarone	3A4 and 2C9
Omeprazole	2C9
Trimethoprim/sulfamethoxazole	2C9
Protease inhibitors	3A4

*Typically induces between less than twofold increase to more than twofold increase in the area under the curve plasma concentration of the statin; **P450 indicates the subfamily of P450 hepatic oxygenase enzyme.

In transplant recipients on CNIs, the maximum dose of statins metabolized by cytochrome P450 should be reduced to 50% of the maximal dose for the general population. Co-administration of medications inhibiting the hepatic cytochrome P450 enzymes should be avoided or managed with extreme caution [107]. An example of this interaction involves the use of amlodipine, which is commonly administered for hypertension, and requires further statin dose reduction because amlodipine is a weak inhibitor of the CYP3A4 isoenzyme [108]. Similar concerns exist regarding other agents sharing the same metabolic pathway (Table 100.4).

Statin use is associated with elevations in liver transaminases in up to 3% of treated patients. This occurs in a dose-dependent fashion, with spontaneous resolution occurring in the majority of cases. Statins rarely lead to serious drug-induced liver injury,

chronic liver disease, or acute liver failure. Liver function should be monitored shortly after initiating statins and with any dose increase. If liver transaminases are higher than three times the upper limit of normal, statin use should be discontinued or reduced in dose.

Ezetimibe

Ezetimibe is a selective cholesterol absorption inhibitor that effectively blocks intestinal absorption of dietary and biliary cholesterol. In kidney transplant recipients, ezetimibe can effectively decrease total cholesterol and TG levels with a good safety profile [109,110]. A review of available randomized trials in the non-transplant population indicates that addition of ezetimibe to statin therapy does not increase the risk of myalgias, creatine kinase level increases, rhabdomyolysis, transaminase increases, gastrointestinal adverse events, or discontinuations because of an adverse event [111]; therefore, ezetimibe may be considered in solid organ transplant recipients to avoid statin dose escalation. However, there is no convincing evidence that its addition improves clinical outcomes beyond treatment with statin alone.

Nicotinic acid

Nicotinic acid can reduce the level of triglycerides, small, dense LDL particles and raise the level of HDL. Nicotinic acid, in combination with statins, has been shown to be effective in reducing the progression of atherosclerosis in patients with hypertriglyceridemia who are at risk for premature coronary artery disease [112]. Possible side effects include flushing, dizziness and nausea, which often limit the use of this agent in clinical practice.

Fibrates

Fibrates are peroxisome proliferator-activated receptor-α (PPARα) agonists and are effective in decreasing TG levels. The risk of fibrate-induced myositis and rhabdomyolysis, especially seen with gemfibrozil, is higher in patients with renal dysfunction and when used concomitantly with statins. Fenofibrates have been associated with kidney function decline in kidney transplant recipients, and dose adjustments are necessary for renal dysfunction [113–115]. In the action to control cardiovascular risk in diabetes (ACCORD) trial, the rate of fatal cardiovascular events, non-fatal myocardial infarction, or non-fatal stroke did not significantly differ in patients with type 2 diabetes who were treated with a combination of fenofibrate and simvastatin as compared to patients receiving simvastatin alone [116]. Given their unproven benefits and potential for drug interactions, fibrates should be avoided in solid organ transplant recipients.

Fish oil

The advantages of fish oil include good tolerance with minor adverse effects and no drug interactions.

A meta-analysis of data from randomized controlled trials in kidney transplant recipients showed a decrease in triglyceride levels and increase in HDL levels in patients on fish oil therapy, but no effect on patient survival, graft survival, acute rejection, and CNI toxicity [117]. It may be used as an adjunct therapy to statins.

Management of dyslipidemia

The KDIGO Transplant Work Group recommends measuring fasting serum, total cholesterol, LDL, HDL and TG 2–3 months post-transplant, 2–3 months after a change in treatment of other conditions known to cause dyslipidemia, and annually thereafter [20].

Lifestyle modifications such as weight loss, a low-fat diet, increased physical activity, and treatment of diabetes mellitus are always recommended, however, pharmacological therapy is usually necessary to achieve the target LDL goal (Table 100.5). Current target lipid levels in transplant recipients have been extrapolated from the general population. In kidney transplant recipients, LDL levels greater than 100 mg/dL (>2.6 mmol/L) should be treated to a goal of less than 100 mg/dL (<2.6 mmol/L). Some experts now recommend a lower goal of less than 70 mg/dL (1.8 mmol/L) for

Table 100.5. Management of dyslipidemia in transplant recipients (Adapted from KDIGO 2009 guidelines [11])

Risk Category	Goal	First line therapy	Preferred agent(s)	Additional therapy	Alternative*	Special considerations
Fasting TG ≥500 mg/dL	TG <500 mg/dL	lifestyle modifications +/− niacin	Nicotinic acid	Statin	Fibrates (preferably gemfibrosil)	TG ≥500 mg/dL increases risks of acute pancreatitis Fibrates are generally not recommended in patients with renal failure especially with GFR <15 mL/min/1.73 m^2; Dose reduction by 50% in patients with GFR <60 mL/min/1.73 m^2
LDL 100–129 mg/dL	LDL <100 mg/dL	lifestyle modifications +/− statin	Atorvastatin (more potent) fluvastatin or pravastatin	Statin	Nicotinic acid alone	Statin dose need to be reduced by approximately 50% in patients treated with cyclosporine and also probably with tacrolimus
LDL ≥130 mg/dL	LDL <100 mg/dL	lifestyle modifications + statin	Atorvastatin (more potent) fluvastatin or pravastatin	Ezetimibe	Nicotinic acid alone	Cases refractory to pharmacological therapy may require decreasing the dose or discontinuation of the immunosuppressive agent and switching to another immunosuppressant agent
LDL <100 mg/dL Fasting TG ≥200 mg/dL non-HDL-C ≥130 mg/dL	Non-HDL-C <130 mg/dL	lifestyle modifications + statin	Atorvastatin (more potent) fluvastatin or pravastatin	Ezetimibe	Nicotinic acid alone	Relatively small number of patients who have normal or low LDL, increased TG and high non-HDL-C considered to have high levels of atherogenic lipoprotein remnants Treatment for these patients is similar to treatment for patients with high LDL

TG, triglycerides; LDL, low-density lipoproteins; HDL, high-density lipoproteins; non-HDL-C, non-high-density lipoproteins cholesterol; GFR, glomerular filtration rate.* Alternative therapy: in the case when first line therapy is not tolerate.

secondary prevention of coronary heart disease among the general population. These more aggressive guidelines may also be applicable for solid organ transplant recipients, given that such patients are considered a high-risk equivalent. However, the risks of more aggressive therapy may outweigh the benefits, and these recommendations have not been adopted by the 2009 KDIGO guidelines. Treatment of hyperlipidemia in liver, heart, and lung transplant recipients is similar, with no formal guidelines.

Triglyceride levels >500 mg/dL

Among patients with TG levels >500 mg/dL lifestyle modifications are recommended as first line, unless severe hypertriglyceridemia is present. If levels are not adequate after 2–3 months, therapy with nicotinic acid could be initiated [112]. Fish oil has few side effects and should be considered as an alternative agent.

LDL ≥100 mg/dL

Among patients with LDL ≥100 mg/dL, lifestyle modifications are recommended along with statin therapy. In heart transplant recipients, the benefits of statins extend beyond the cholesterol treatment and should be used regardless of cholesterol level [93]. The safest statins are fluvastatin and pravastatin because they are not metabolized by cytochrome P450 3A4 and have little or no muscle toxicity. These statins have lower potency than others, however, and should therefore be selected for patients with mild LDL elevations. In most solid organ transplant recipients, a more potent statin such as atorvastatin may be a more appropriate choice, given its well documented effectiveness in decreasing cardiovascular events in the general population and excellent tolerability in combination with tacrolimus [104].

If a statin alone fails to adequately lower LDL-cholesterol levels, ezetimibe can be an additional agent. If adverse effects develop with statins, reducing the dose or switching to a different statin can be considered. Ezetimibe or nicotinic acid alone can be used for patients who are not able to tolerate statins. In severe cases of dyslipidemia refractory to pharmacological therapy, decreasing the dose of or discontinuing the patient's current immunosuppressive agent and switching to another may be necessary. Such adjustments should always be done under the guidance of a transplant specialist.

Bone and mineral disorders after solid organ transplantation

Bone and mineral disorders are common in solid organ transplant recipients. Contributing factors include advanced age, pre-existing osteodystrophy, underlying disease leading to end stage organ failure, vitamin D deficiency, smoking, diabetes and transplantation-specific therapies, in particular the immunosuppressive agents [118].

Bone loss is especially rapid within the first 6 to 12 months post solid organ transplantation and range from 0–24% at the spine and 2–11% at the hip [119]. In the later post-transplant period, rates of bone loss decrease, likely due to lower doses of immunosuppressive agents and improvement in metabolic/endocrine abnormalities, and there may be some recovery of bone mineral density (BMD), particularly seen at the spine [120]. Increase in glucocorticoid doses for treatment of rejection or other reasons may lead to accelerated bone loss. Accordingly, the frequency of bone fractures ranges from 6–45% for kidney transplant recipients to 22–42% for heart, lung, and liver transplant recipients [119–125].

Kidney transplant recipients are unique in having pre-existing chronic kidney disease (CKD), which affects many aspects of mineral metabolism including phosphate retention, hypocalcemia, and decreased vitamin D activation. These effects stimulate the parathyroid glands, leading to secondary hyperparathyroidism. If not appropriately treated, these metabolic disturbances can lead to parathyroid cell hyperplasia and tertiary hyperparathyroidism. Successful kidney transplantation reverses many of these abnormalities in mineral and bone metabolism, however, the degree of improvement is frequently incomplete [126–131]. Persistent hypercalcemia can have adverse effects on renal allografts including graft microcalcifications and dysfunction, renal failure from afferent arteriole vasoconstriction, bone demineralization and loss, soft tissue and vascular calcifications, and increased fracture rate [132–136].

Persistent hyperparathyroidism and hypercalcemia

The incidence of persistent hyperparathyroidism after kidney transplantation may be as high as 50% [132,137–144]. The magnitude of pretransplant hyperparathyroidism and renal function determine long-term post-transplant parathyroid function [133]. Although the parathyroid glands involute after transplantation, this process takes a few months to several years to complete [129,130,137,138].

Within the first 3 months after transplant, up to 41% of recipients will develop transient hypercalcemia [145]. After the first year, up to 20% of patients will have persistent hypercalcemia with elevated parathyroid hormone (PTH) levels [146,147]. The development of hypercalcemia correlates with duration of pretransplant dialysis, degree of parathyroid hyperplasia, and gland size; thus, spontaneous resolution of hypercalcemia after 1 year is uncommon [139]. While persistent hyperparathyroidism is the main cause of post kidney transplant hypercalcemia, other factors may contribute such as enhanced tubular calcium reabsorption in the new renal allograft and normalization of calcitriol production, which enhances the PTH effect on bone and also increases intestinal calcium absorption [132,148].

Therapeutic considerations for tertiary hyperparathyroidism

There are no universal recommendations for the indications, timing, and modality of therapy of tertiary hyperparathyroidism. Vitamin D analogs typically have a negative biofeedback effect on the parathyroid glands, but their use may be limited in patients with hypercalcemia. Calcimimetics may be promising therapy in those with persistent hyperparathyroidism and hypercalcemia, as their use effectively lowers calcium levels, but decrease in PTH levels has not been demonstrated consistently [149–154]. An interaction between cinacalcet and tacrolimus leading to a moderate, but significant decrease in systemic exposure of tacrolimus has been described in renal transplant recipients, while cyclosporine and mycophenolate mofetil pharmacokinetics are not affected [155]. Although an improvement in BMD was shown in a small number of kidney transplant recipients treated with cinacalcet for 12 months, further studies and longer follow-up is needed to better elucidate the efficacy/safety profile of calcimimetics, particularly with regard to long-term bone histology and renal outcomes [156].

Parathyroidectomy is thought to be a definitive therapy for tertiary hyperparathyroidism after kidney transplantation. Some studies have demonstrated resolution of hypercalcemia and an increase in bone mineral density, along with improved blood pressure and lipid control, following parathyroidectomy [157–161]. There are two major indications for parathyroidectomy in renal transplant

patients: severe symptomatic hypercalcemia, usually occurring in the early post-transplant period, and persistent, marked hypercalcemia despite medical therapy. There is no consensus regarding the optimal timing for parathyroidectomy. Given the lack of evidence-based guidelines, a conservative approach of waiting for at least 12 months before considering parathyroidectomy in patients with tertiary hyperparathyroidism has been advocated. The use of cinacalcet along with careful monitoring of tacrolimus trough levels and calcium levels may be an alternative to parathyroidectomy, although it is not FDA approved for use in renal transplant recipients. Further studies are needed to determine the relative risk and benefits to surgical therapy of tertiary hyperparathyroidism after renal transplantation.

Vitamin D deficiency is an important contributor to elevated PTH in chronic kidney disease patients and often persists even after kidney transplantation [162,163]. No guidelines exist for vitamin D replacement in transplant recipients; therefore, in the absence of hypercalcemia, it is advised to maintain a 25-OH-vitamin D concentration greater than 30 ng/mL based on the recommendations of the National Kidney Foundation in the non-transplant population. Treatment with vitamin D requires a minimum 1000–2000 IU of vitamin D3 daily [164].

Table 100.6. Immunosuppression medications and bone disease

Immunosuppressive agent	Mechanism(s) of bone mineral density loss
Corticosteroids	Impair osteoblast bone formation by direct toxicity Decrease calcium gastrointestinal absorption Increase calcium urinary excretion Reduce gonadal hormone production (estrogen, testosterone, adrenal androgen) Reduce insulin-like growth factor–1 production Decrease sensitivity to PTH Increase receptor activator of NF-κ β ligand Increase osteoclastogenesis
Cyclosporine	Conflicting reports ? Increases osteoclast number and bone turnover ? Suppresses osteoblasts ? Decreases mineral apposition and bone formation rates
Tacrolimus	? similar effects as cyclosporine vs. less toxic
Mycophenolate	No evidence of adverse bone effects
Azathioprine	No evidence of adverse bone effects
Sirolimus	No human data to date; animal data: interferes with proliferation and differentiation of osteoblasts
Everolimus	No human data to date; animal data: decreases osteoclast-mediated bone resorption

Hypophosphatemia

Hypophosphatemia can develop in up to 93% of patients during the first few months after kidney transplantation [165], and very rarely after transplantation of other solid organs. The condition typically resolves within 1 to 3 months post-transplant but may persist for up to 10 years [165]. In general, encouragement to resume food rich in phosphorous is a sufficient therapy that is usually welcomed by the patient.

Persistent hypophosphatemia is primarily induced by renal phosphate wasting due to hyperparathyroidism, relative calcitriol deficiency, and the use of glucocorticoids and other immunosuppressants (mTor inhibitors and cyclosporine more than tacrolimus) [165–169]. In the early post-transplant period phosphaturic fibroblast growth factor-23 (FGF-23), which accumulates in patients with CKD, is a major contributor [165,170–173]. Yet, persistent hyperparathyroidism, but not increased FGF-23, appears to underlie the phosphate wasting that persists beyond one year [143].

Most patients with low phosphorus levels are asymptomatic. Plasma phosphate levels below 1.5 mg/dL can cause generalized muscle weakness. Severe hypophosphatemia, although generally rare post-transplantation, can be associated with acute respiratory failure, muscle weakness, hemolytic anemia, rhabdomyolysis, and altered mental status. The net effect of hypophosphatemia on bone density and risk for fracture is not well known; however, prolonged and severe hypophosphatemia could lead to osteomalacia and ricketts.

Most post-transplant hypophosphatemia will resolve spontaneously. Without knowledge about factors predictive of persistent or symptomatic hypophosphatemia, it is unclear which patients might benefit from pharmacological therapy. Phosphate supplementation (intravenous and/or oral) has been supported by some studies [174], but there is concern that phosphate replacement might create bursts of high phosphorus levels that would trigger more PTH production and thereby delay the resolution of secondary hyperparathyroidism. Others advocate that phosphorus replacement is unlikely to have any more significant an impact than watchful waiting and resumption of normal diet. A more rational approach may be to supplement with calcitriol, which increases tubular Na+/phosphate co-transporter activity and thereby enhances phosphate reabsorption [175]. Lowering PTH levels by treating tertiary hyperparathyroidism (whether medically or surgically), as discussed earlier, would also help treat hypophosphatemia by inhibiting PTH-induced phosphate renal wasting.

Role of immunosuppressive agents (Table 100.6)

The largest influence on early post-transplant bone loss appears to be the use of corticosteroids. Steroids impair bone formation by direct osteoblast toxicity and increased osteoclast activity and promote a negative calcium balance (by decreasing gastrointestinal absorption and increasing urinary excretion). They also reduce the production of gonadal hormone and insulin-like growth factor-1, decrease sensitivity to PTH, increase receptor activator of NF-κ β ligand, and increase osteoclastogenesis [176,177]. Steroid dose positively correlates with the amount of bone loss. Even small doses of steroids can result in significant bone loss [178].

The data on cyclosporine's influence on bone loss are conflicting. There are reports of cyclosporine being utilized in a corticosteroid-free regimen with no significant bone loss [179,180]. However, other data suggest that cyclosporine may contribute to bone loss by increasing osteoclast number and bone turnover, as evidenced by increased osteocalcin [181,182]. Cyclosporine appears to have more negative effect on bone than does tacrolimus [180,183,184].

Epidemiologic studies could not establish an association between CNIs and fracture risk [125,185]. There are no available data regarding the effects of mycophenolate and azathioprine on bone. A recent in-vitro study suggests that sirolimus might interfere with the proliferation and differentiation of osteoblasts in mice [186]; while a study of ovariectomized rats found that everolimus might reduce trabecular bone loss by decreasing osteoclast-mediated bone resorption [187].

Treatment with anti-resorptive agents: safety profile and side effects (Table 100.7)

Calcium and vitamin D analogs

Calcium supplementation of at least 1000 mg daily should be considered in non-hypercalcemic patients, since glucocorticoid therapy

Table 100.7. Pharmacological agents used for the management of mineral and bone disorders in solid organ transplant recipients

Drug family (brand names)	Effects on serum calcium and phosphorus	Effects on Serum PTH	Notes/evidence
Bisphosphonates			
Alendronate (Fosamax)	Decrease	Decrease	Increase bone mineral density, particularly at the lumbar spine.
Pamidronate (APD, Aredia)	Decrease	Decrease	May cause low turnover bone disease.
Zoledronate (Zometa, Aclasta)	Decrease	Decrease	Unclear whether they really reduces the risk of fractures.
Risedronate (Actonel)	Decrease	Decrease	Uniform use is not recommended.
Ibandronate (Boniva)	Decrease	Decrease	Contra-indicated when GFR <30 mL/min.
Etidronate (Didronel)	Decrease	Decrease	
Clodronate (Bonefos, Loron)	Decrease	Decrease	
Vitamin D			
Ergocalciferol (Drisdol)	Increase	Decrease	Improve bone mineral density.
Cholecalciferol (Calciol, vitamin D3)	Increase	Decrease	May cause hypercalcemia.
25(OH)D (calcidiol, calcifediol)	Increase	Decrease	
Vitamin D receptor activators			
1-Alfa-calcidiol (One-alpha)	Increase	Decrease	Improve bone mineral density.
Doxercalciferol (Hectoral)	Increase	Decrease	May cause hypercalcemia.
Calcitriol (Calcijex, Rocaltrol)	Increase	Decrease	
Vitamin D mimetics			
Paricalcitol (Zemplar)	No change or Increase	Decrease	Improve bone mineral density.
Calcimimetics			
Cinacalcet (Sensipar)	Decrease	Decrease	Not FDA approved for use in renal transplant recipients for secondary/tertiary hyperparathyroidism. May improve bone mineral density May interact with tacrolimus (tacrolimus levels should be carefully monitored)
Miscellaneous Agents			
Teriparatide (Forteo)	Calcium: Increase Phosphorus: Decrease	Increase	No proven benefit in transplant patients. Not recommended post-transplantation.
Calcitonin (Miacalcin, Fortical, Calcimar)	Decrease	Decrease	No proven benefit in transplant patients.

reduces intestinal calcium absorption. There is a high incidence of vitamin D deficiency in the transplant population and treatment with both 25-hydroxy- and 1,25-hydroxy-vitamin D is associated with improved bone mineral density as compared with no treatment [188–190]. Careful monitoring for hypercalcemia is necessary in recipients on vitamin D therapy.

Bisphosphonates

In the non-transplant population, bisphosphonates are used to prevent bone mass loss and to treat osteoporosis. Several clinical interventional trials confirmed the efficacy of bisphosphonates in the prevention and treatment of bone loss after transplantation in liver, heart, lung and kidney transplant recipients [191–196]. Notably, a majority of the studies have had inadequate statistical power to detect differences in fracture among treated and untreated patients. Results of meta-analysis of trials involving the treatment with bisphosphonates or active vitamin D analogs in patients with kidney, liver, heart, or lung transplants in the first 12 months post-transplant suggest a reduction in the number of subjects with fractures, vertebral fractures and improvement in bone mineral density in patients on bisphosphonates or vitamin D therapy [197]. When bisphosphonate trials were analyzed separately, there was a reduction in number of subjects with fractures, but no improvement in vertebral fractures.

Bisphosphonates should be used with caution in certain populations. Kidney transplant recipients treated with biphosphonates may be at risk for low turn over bone disease due to pre-exsting renal osteodystrophy, although bone biopsy studies showed conflicting results [193,198].

Similarly, biphosphonates should be avoided in patients with advanced CKD (stage 4–5), since renal excretion is the only route of elimination. Bisphosphonates accumulate in bone, with a half-life of more than 10 years, and gradually are released back into the circulation and taken up again or excreted [199]. Long-term use of bisphosphonates may lead to over suppression of bone formation, therefore bone biopsy should be considered in patients with CKD to exclude low-bone-turnover disease before starting therapy.

Teriparatide

Teriparatide is an amino-terminal parathyroid hormone with full physiological activity. It increases bone mineral density and decreases fracture risk in post menopausal women and in patients on steroid therapy [200,201]. In transplant recipients, no benefit of teriparatide use has been demonstrated to date [202]. Until further studies are conducted, its use is not recommended post-transplantation.

Calcitonin and other therapies

Another potential therapeutic agent is calcitonin, but it has no effect on mortality, graft loss, and risk of fracture in patients after kidney transplantation [203,204]. Regular exercise and hormone replacement therapy were shown to reduce bone loss and risk of fracture in lung and heart transplant recipients, but they have not yet been examined in kidney transplant recipients [205,206]. Early stages of osteonecrosis are generally managed conservatively or with decompression accompanied by bone grafting.

Management of bone disease

Prevention and management of bone disease in solid organ transplant recipients should focus on correcting any metabolic derangements which can affect bone metabolism and life style modifications to increase physical activity level. Formal guidelines for bone disease prevention and therapy are only available for kidney transplant recipients. The National Kidney Foundation Disease Outcomes Quality Initiative (KDOQI) guidelines recommend obtaining a DEXA (dual-energy X-ray absorptiometry) scan at the time of transplant, then at 1-year and 2-years post-transplant. If the T-score

is equal to or less than −2 at the time of the transplant or at subsequent evaluations, consideration should be given to therapy with bisphosphonates [207]. The KDIGO guidelines suggest that, in patients with low bone mineral density and GFRs greater than approximately 30 mL/min per 1.73 mm^2, treatment with vitamin D, calcitriol, or bisphosphonates should be considered [208]. The choice of these agents is determined by abnormal calcium, phosphate, PTH, alkaline phosphate, and 25-hydroxy Vitamin D levels. In non-renal solid organ transplant recipients, data from clinical trials suggest that bisphosphonates and vitamin D analogs are safe and effective agents for the prevention and treatment of post-transplantation osteoporosis and fractures [119,197].

Management of solid organ transplant recipients with low bone mineral density and a GFR less than 30 mL/min per 1.72 mm^2 should include dietary phosphate restriction and replacement of vitamin D stores. Biphosphonates should be used with caution in patients with advanced CKD and bone biopsy should be ideally done prior to the initiation of therapy [209].

Steroid withdrawal or avoidance immunosuppression protocols have been developed and found to retain a higher bone mineral density than that observed with standard steroid immunosuppression protocols. The greatest differences were seen in the lumbar spine. However, randomized controlled trials showed that late steroid withdrawal (when done several weeks to months post-transplant) is associated with an increased risk of acute rejection in kidney transplantation [210,211]. Therefore, current KDIGO guidelines do not recommend steroid withdrawal and avoidance for the sole purpose of treating bone disease.

Hyperuricemia and gout after solid organ transplantation

Hyperuricemia is common after solid organ transplantation. The etiology is complex and related to decreased uric acid excretion with reduced GFR, older age at transplant, obesity, metabolic syndrome, the presence of pretransplant hyperuricemia, and the use of diuretics and immunosuppressive agents. The prevalence of hyperuricemia in kidney transplant recipients may be as high as 80%, especially in recipients taking cyclosporine and close to 50% in liver transplant recipients [212,213]. The incidence of gout is much lower (6–7%) [213,214].

Elevations in serum levels of uric acid are associated with an increased risk for both cardiovascular and all-cause mortality in men in the general population [215]. Hyperuricemia has also been associated with insulin resistance and the development of metabolic syndrome [216]. The question of whether uric acid plays a causative role in the development of disease versus merely serving as a surrogate for co-morbid disease remains unclear.

The impact of asymptomatic hyperuricemia on morbidity and mortality in solid organ transplant recipients is unknown. Similarly, data are conflicting regarding the impact of hyperuricemia on allograft function in kidney transplant patients. One study demonstrated an association of hyperuricemia with decreased allograft function in 405 kidney transplant recipients over 3 years [217], whereas the results from a much larger prospective trial did not find an association [212].

Role of immunosuppressive agents

Calcineurin inhibitors

Cyclosporine induces a decrease in GFR and a net increase in tubular resorption of the filtered urate, leading to hyperuricemia [218,219]. Tacrolimus shares many of the same hemodynamic and toxic effects as cyclosporine, but the incidence of hyperuricemia appears to be lower in tacrolimus-based regimens [220]. Dose reduction strategies of CNIs have been employed as part of immunosuppression management to address hyperuricemia and gout. One report documented a decrease in uric acid after conversion from cyclosporine to tacrolimus, but the data are limited [221].

Other immunosuppressive agents

Long-term use of glucocorticoids is associated with the development of insulin resistance and the metabolic syndrome. Hyperuricemia has also been associated with the metabolic syndrome, although there are no definitive studies linking glucocorticoid use and hyperuricemia [216,222].

Azathioprine, mycophenolate mofetil and sirolimus have not been shown to significantly influence uric acid.

Role of diuretics

Treatment with loop and thiazide diuretics leads to an increased risk of gout and hyperuricemia. Diuretic therapy has a dose-dependent association with increases in serum uric acid. This is due to an induced relative hypovolemia, leading to an increase in tubular urate reabsorption and a decrease in urate excretion [223].

Therapeutic considerations for hyperuricemia and gout

Non-steroidal anti-inflammatory drugs

Non-steroidal anti-inflammatory drugs (NSAIDs) act through the non-selective inhibition of cyclooxygenase enzymes, resulting in decreased synthesis of prostaglandin and various mediators of inflammation. While effective for the treatment of acute gouty attacks in the non-transplant population, the high prevalence of decreased kidney function in the transplant population and use of CNIs limit their use. Short-term therapy with NSAIDS may be used in transplant patients with normal kidney function.

Glucocorticoids

The anti-inflammatory effects of glucocorticoids are mediated through decreased peripheral migration of leukocytes into the area of inflammation. In a randomized control trial, therapy with systemic oral corticosteroids (35 mg of oral prednisolone for 5 days) was compared to naproxen in 120 non-transplant patients during an acute gout flare. The safety and efficacy of prednisolone was comparable to naproxen [224]. While similar studies in transplant recipients have not been conducted, a short course of corticosteroids is considered to be effective. Intra-articular preparations may be reasonable options for therapy in the setting of monoarticular disease.

Colchicine

Colchicine is commonly used in the non-transplant population for both acute gout flare and prophylaxis. It provides rapid pain relief (within 48 hours), but its significant side effect profile may limit its use in transplant recipients. Colchicine-induced myopathy is especially seen in the context of renal function impairment; accordingly, alternative treatment should be considered in patients with chronic kidney disease stage 3–5 [225]. Myotoxicity related to colchicine has been reported in both kidney and heart transplant recipients [226,227]. Cyclosporine co-administration increases colchicine toxicity by a dual mechanism: cyclosporine inhibits P-glycoprotein, which leads to increased intracellular colchicine concentrations and

decreased hepatic and renal excretion of the drug and cyclosporine interacts with CYP3A4, which decreases the hepatic elimination of colchicine [228,229]. Concomitant statin use increases the risk of muscle injury. Myelosuppression, not uncommon in kidney transplant recipients, may also be caused by colchicine.

Allopurinol

Allopurinol is a purine analog and inhibitor of the enzyme xanthine oxidase, which is necessary for production of uric acid [228]. Allopurinol is often the first choice of therapy for long-term treatment of hyperuricemia and gout. Co-administration with azathioprine may lead to severe myelosuppression due to inhibition of metabolism of its active metabolite, mercaptopurine; thus, alternative therapy should be considered. If that is not possible, the azathioprine dose should be reduced by 50–75% and a reduced dose of allopurinol should be used [230]. Despite dose adjustment, pancytopenia can be seen after months or even years of therapy [231]. Dose adjustment is necessary for CKD.

Febuxostat

Febuxostat is a non-purine inhibitor of xanthine oxidase, shown to be more effective in reducing uric acid than allopurinol in clinical trials [232]. While no dose reduction is required for patients with CKD stage 3, data are insufficient for patients with more advanced kidney disease [225]. The risk for myelosuppression is increased with co-administration of azathioprine.

Uricosuric agents

Probenecid lowers uric acid by increasing renal excretion. It is ineffective in patients with decreased renal function. Moreover, it may lead to deposition of uric acid crystals in the kidney, resulting in urate nephropathy and/or uric acid stones. A more potent uricosuric agent, benzbramorone, is effective in patients with kidney disease and has been shown to be effective in kidney transplant recipients, but hepatoxicity is a significant concern [230,233].

Losartan has been shown to have modest uricosuric effects along with its antihypertensive activity, an effect not demonstrated with other angiotensin receptor blockers [234].

Pegloticase

Peglioticase, mammalian recombinant uricase, allows for metabolism of uric acid to its solube metabolite, allantoin, and has effectively lowered uric acid in patients with gout who are intolerant to allopurinol or refractory to treatment [235]. It has not been thoroughly studied in patients with chronic kidney disease and solid organ transplant recipients.

Management of gout

The evidence outlining treatment goals for patients with asymptomatic hyperuricemia is conflicting and generally not recommended in transplant recipients because of insufficient data and the high potential of side effects. Treatment is necessary, however, for symptomatic hyperuricemia such as gout and uric acid stones. Therapeutic strategies target both the acute inflammatory response associated with gouty flares and hyperuricemia. Dietary modifications, such as decreased consumption of alcohol, seafood, and red meat, are important lifestyle components. Foods containing fructose are of concern because their consumption prompts a rapid increase in serum uric acid [222].

The risks and benefits of anti-gout therapeutic agents need to be carefully examined in the context of other co-morbidities and their treatment. Hypertension and hyperlipidemia are common in the transplant population, and agents for their treatment may affect uric acid levels or potentiate toxicity. Diuretics should be avoided, if possible, and alternative agents may need to be used for treatment of hypertension.

For the acute gout flare, short-term corticosteroids can be administered. Short therapy with NSAIDS may also be used in patients with normal kidney function. Prolonged use of colchicine should be avoided in patients with eGFR $<60\,mL/min/1.73\,m^2$. If absolutely necessary, colchicine can be used at reduced doses for <1 week in patients with eGFR $>10\,mL/min/1.73\,m^2$ and not requiring dialysis [20].

Long term, agent-lowering uric acid may need to be started. Allopurinol is commonly used, but adjustment of immunosuppression may be necessary and dose reduction is needed in kidney disease. Newer hypouricemic agents, like febuxostat or pegloticase, may prove to be useful in transplant recipients, but more studies are needed.

Electrolyte disturbances after solid organ transplantation

Hyperkalemia

Hyperkalemia is the most frequent electrolyte disturbance encountered after solid organ transplantation, especially in the first few weeks. Its cause is almost always multifactorial, including increased dietary intake, redistribution and decreased renal excretion. Medications commonly used in transplant recipients, such as trimethoprim and CNIs, increase the risk of hyperkalemia. Trimethoprim induces hyperkalemia by inhibiting potassium elimination in the distal nephron, and this effect is especially seen in patients with impaired kidney function [236]. CNIs impair aldosterone production, renal response to aldosterone, and inhibit potassium secretion in the collecting duct [237,238].

Acute treatment of hyperkalemia in solid organ transplant recipients follows general therapy in the non-transplant population. Options include intravenous calcium gluconate, glucose followed by insulin injection, sodium bicarbonate, or even hemodialysis (when other therapies fail). Treatment is guided by the degree of renal function, presence or absence of EKG changes, and the absolute level of potassium. Replacement of certain drugs such as trimethoprim may be necessary; in most cases it is sufficient to decrease serum potassium levels. Chronic management of hyperkalemia includes optimization of renal function, use of potassium-wasting agents such as resin binders and mineralocorticoids (e.g. fludrocortisone) and, in severe cases, minimization or withdrawal of calcineurin inhibitors.

Hypomagnesemia

Hypomagnesemia is very common in solid organ transplant recipients treated with CNIs. It typically manifests in the first few weeks and may persist with the chronic use of CNIs. Approximately 80% of serum magnesium is freely filtered in the glomerulus and more than 95% is reabsorbed throughout the tubules. CNIs have direct magnesiuric tubular effects; they decrease magnesium reabsorption and increase urinary magnesium wasting, thereby causing hypomagnesemia [239].

Serum magnesium levels are associated with a faster rate of decline in kidney allograft function and increased rates of graft loss in renal transplant recipients treated with cyclosporine [239]. Severe hypomagnesemia may be associated with arrhythmias and

seizures. Hypomagnesemia is also an independent predictor of new onset post-transplant diabetes mellitus in kidney transplant recipients [240]. Oral magnesium-oxide supplementation may be chronically needed when dietary supplementation fails to maintain the magnesium level, especially in patients treated with CNIs.

Metabolic acidosis

Metabolic acidosis after solid organ transplant can be caused by decreased kidney function and CNIs. In animal studies, CNIs were shown to induce metabolic acidosis through dysregulation of major acid-base transporters in the proximal tubule and the distal nephron [241]. Post-transplant recipients on CNIs may present with hyperkalemic metabolic acidosis (type IV renal tubular acidosis), resulting from inhibition of potassium secretion in the collecting duct [237]. Treatment to correct the acidosis and hyperkalemia should be promptly initiated. Pancreas transplant recipients with bladder-drained pancreata may present with metabolic acidosis due to bicarbonate loss in the urine from pancreas secretions. Due to this major side effect of pancreas bladder drainage, along with chronic volume depletion, enteric-drained pancreas transplantation has gained popularity. Moreover, enteric drainage conversion leads to correction of metabolic acidosis in most of the cases [242]. Oral sodium bicarbonate supplementation has been shown to preserve renal function in non-transplant chronic kidney disease patients, but data on post-transplant kidney outcomes are lacking [243].

Summary

Disorders of metabolic pathways and mineral homeostasis are common in solid organ transplant recipients. In the early postoperative period, electrolyte abnormalities like hyperkalemia, hypercalcemia, hypomagnesemia, and hypophosphatemia are frequently seen. In the long term, recipients require close monitoring and management of co-morbidities like diabetes, hyperlipidemia, bone disease and gout. Treatment is especially challenging due to potential interactions with the transplant medications and variations in renal and hepatic function. In this chapter we review the therapeutic options available for treating metabolic and electrolyte disorders post-transplant with a particular focus on the potential side effects and drug interactions of commonly used medications.

CHAPTER 101

Off-Label Use of Immunosuppressive Agents in Solid Organ Transplantation

Jill C. Krisl, Rita R. Alloway, and E. Steve Woodle
University of Cincinnati, Cincinnati, OH, USA

Introduction

The Food and Drug Administration (FDA) is charged by statute with maintaining public safety for food and drugs, which is assured through a stringent regulatory drug approval process. In order for a drug to be approved by the FDA, the sponsor must provide satisfactory evidence regarding the safety and efficacy of a drug in a specific patient population and a defined clinical condition. Inherent to the drug approval process is the creation and definition of the product label, which includes dosing, administration, intended patient population and clinical condition. Use of the drug outside of these aspects of the label is generally considered off-label use. In theory, the FDA has regulations regarding off-label drug use and promotion by manufacturers but in practice this regulation is limited [1].

In the US it is legal, and common practice, for physicians to choose to use FDA approved drugs outside the defined label [2,3]. Off-label use may differ from labeled uses in one or more of the following aspects, including: clinical indications, patient populations, dosing, or route of administration. The term "unlabeled" is preferred to "unapproved" as the FDA has recognized that these unlabeled uses may be appropriate and accepted and supported by evidence in medical journals [4]. While the term "off-label" derives from the US FDA, the concept of drug use expanding beyond the specific drug indication is commonplace worldwide, and as such, this chapter's applicability extends well beyond national borders. Indeed, within solid organ transplantation, off-label use has become so common it is regarded as "standard of care" for most immunosuppressive regimens, and is supported by a substantial evidence base provided by numerous randomized trials (Table 101.1). This chapter will cover the concept and practice of off-label drug use, and in doing so, serve as a complement to Chapter 98, which deals with drugs formally indicated for transplant use. Detailed mechanistic information regarding many of the agents listed in this chapter can be found in Chapters 17 and 18.

Off-label use in transplantation

The extent of off-label drug use in modern medicine is significant, and especially common in the practice of transplantation. It has been estimated that off-label drug use represents 20% of the 750 million prescriptions per year in the US [2]. Transplantation and oncology are two medical specialties where off-label drug use has become common practice. It is estimated that 50% or more of the drugs use in oncology are off-label [5,6]. A primary reason for this has been the large number of individual cancers and that anticancer agents are generally approved initially for a specific cancer. The recent advent of molecular profiling in oncology has led to the recognition of shared gene mutations among a large number of cancers; therefore a drug that targets a specific gene mutation may enjoy substantial off-label use in other cancer types with similar gene mutations.

In transplantation, the extent of off-label use varies considerably between individual drugs and across various organ types. A highly visible example of off-label use in transplantation is the combination of tacrolimus and mycophenolate for the prevention of rejection in kidney transplant recipients. Tacrolimus was approved in 1994, shortly prior to FDA approval of mycophenolate. Studies for both tacrolimus and mycophenolate were ongoing simultaneously, but independently and therefore were not conducted with these agents in combination. When first approved, mycophenolate mofetil (MMF) was labeled for use with cyclosporine, as no data existed regarding its safety and efficacy with tacrolimus. Almost immediately after MMF approval, studies were initiated evaluating the tacrolimus/MMF combination, as many centers considered tacrolimus the preferred calcineurin inhibitor (CNI) over cyclosporine. Tacrolimus is widely considered a more potent immunosuppressive agent and is associated with better renal function [7]. Large multicenter randomized trials were conducted with the tacrolimus/MMF combination that confirmed the efficacy and safety of the regimen [8,9]. Today, tacrolimus is the most commonly utilized CNI in kidney transplant with approximately 80% of kidney transplant recipients discharged on tacrolimus. Similarly, the tacrolimus/MMF combination is the most commonly prescribed regimen, with over 70% of kidney transplant recipients receiving the combination at the time of hospital discharge from kidney transplantation operation [7,10].

Although the tacrolimus/MMF combination was the most frequently used immunosuppressive regimen in kidney transplant recipients for several years, it was regarded as off-label until 2009 [11]. In 2006, a supplemental New Drug Application (sNDA) was submitted by Astellas, the manufacturer of brand Prograf™ (tacrolimus), to seek FDA approval for the tacrolimus/MMF regimen for rejection prophylaxis in kidney transplantation. In a novel regulatory action for the solid organ transplant field, the FDA granted

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

approval for the tacrolimus/MMF combination based on submission of a large number of multicenter, randomized trials that demonstrated efficacy and safety in lieu of prospectively conducted phase 3 registration trials. This action by the FDA set a precedent in the transplant field by accepting a large evidence base from non-registration randomized trials as a basis for approval.

The FDA has traditionally required the use of FDA approved immunosuppressive drug combination as the control arm in registration trials. Prior to the approval of the tacrolimus/MMF combination, this policy required control arms consisting of an interleukin-2 receptor antagonist (IL-2RA) for induction therapy with cyclosporine, MMF, and steroids as maintenance therapy [7]. The perception of therapeutic inferiority of this cyclosporine-based regimen as a control group substantially limited patient enrollment in registration trials, thereby creating a substantial burden for sponsors. This FDA policy, therefore resulted in sponsors avoiding drug development in the transplant field, and led to a shift in immunosuppressive drugs being developed in autoimmune diseases rather than transplantation. This trend has continued to the present day, to the disadvantage of transplant patients.

At the same time, endpoints historically considered acceptable to the FDA and practical in terms of drug development by sponsors were undergoing substantial change. As patient and graft survival rates continued to improve with advances in immunosuppression, the number of patients required to achieve statistical power exceeded budgetary limits for sponsors. Similarly, biopsy-proven acute rejection (BPAR), which is associated with significant morbidity and is considered a traditional endpoint for registration trials, had fallen to such a low rate that it also became an unfeasible endpoint due to the large numbers of patients required to achieve statistical power [12,13]. As a result, composite or surrogate endpoints (e.g. change in renal function) allow for more reasonable sample sizes, and have been more recently accepted by the FDA for registration trials. Clinical investigators largely consider the FDA approval of the tacrolimus/MMF regimen paramount in creating the ability to use the regimen as the control arm in future registration trials.

The problem of clinically inferior FDA labeled regimens being required as control group therapies has also complicated registration trials for rabbit anti-thymocyte globulin (rATG, Thymoglobulin™, Sanofi) for induction in kidney transplantation. Currently, rATG is only FDA approved for the treatment of rejection in kidney transplantation, and is not FDA approved for induction therapy following the transplant procedure, which is a greater volume of use. Compared to other available agents for induction therapy in kidney transplantation, rATG is the most commonly used agent, and is considered by most transplant programs the induction agent of choice for patients at high immunologic risk, delayed graft function, and corticosteroid avoidance or minimization protocols. These considerations made induction trials in kidney transplantation unfeasible because of anticipated negative effects on enrollment without rATG as an induction agent in the control group. An approach similar to that used for the tacrolimus/MMF combination has been suggested for the concerns related to rATG as the comparator for registration trials of induction agents in kidney transplantation. Investigators with substantial experience in drug development within the transplant field have vocalized this observation:

> I think it is important for transplant professionals (through their societies) to engage the FDA on regulatory matters for drugs used off label where it's clear either because of patent expiration or unwillingness of the transplant community to have a placebo arm such as depleting antibodies in high immunologic risk patients to approve them when there is enough data from registry and multicenter trials. As in the case of TAC-MMF combo, it's time to proceed with the approval of thymoglobulin for induction in high-risk patients. We have demonstrated that a respectful yet determined advocacy can yield results. [Personal Communication, Flavio Vincenti, MD] [14]

FDA regulatory process for new drug approval

In order to obtain FDA approval, a drug company must file a New Drug Application (NDA) or Biologic License Application (BLA), which provides data from registration trials that support a proposed indication for drugs proving efficacy and safety [15]. A sNDA is filed whenever a company wants to expand the labeled indication of a drug (e.g. the process through which the tacrolimus/mycophenolate combination was approved). An Investigational New Drug (IND) Application is filed when a company would like to gain approval for a new or novel clinical indication [15].

Orphan drug designation provides an alternative approach for FDA approval under specific conditions. Orphan drug designation can be sought for drugs used for treatment, prevention or diagnosis of rare diseases and conditions that affect fewer than 200 000 people in the US [15]. Orphan drug designation can also be given to drugs used in rare disease affecting more than 200 000 but which the market will never help to recover the cost of development. With approximately 16 000 kidney transplants performed in the US in 2009, and even fewer among other solid organs, all transplants would qualify as rare conditions [10].

Medicare reimbursement approval process for off-label drug use

Over the past several years, payor reimbursement has become the greatest barrier to off-label use of immunosuppressive agents (ISA). Private health insurance carriers and managed care providers have become increasingly resistant to reimburse drugs (particularly expensive drugs) when used outside the FDA approved indication. This issue often precludes off-label use of drugs as immunosuppressive agents.

The Office of Inspector General (OIG) of the Department of Health and Human Services (HHS) issues a yearly policy statement regarding prescription drug coverage that provides the basis for drug coverage by the Centers for Medicare and Medicaid Services (CMS), health insurance coverage for ISA use in transplant recipients. This provides the basis by which other insurance payors develop coverage policies. The fiscal year 2012 OIG policy stated that:

> . . . for prescription drugs to be covered, Federal law generally requires that they are prescribed according to the medically accepted indications, such as those approved by the FDA or supported in one or more of the authoritative drug compendia identified by the Secretary of HHS [16].

This policy thereby dictates that off-label use of drugs is covered if drug compendia report sufficient evidence that the drug is safe and effective for that clinical disease or condition.

Historically, the Social Security Act (Section 1861(t)(2)(B)(ii)(I)) recognized three compendia as acceptable sources for medically accepted drug indications for off label use. These three compendia included the Medical Association Drug Evaluations (AMA-DE),

United States Pharmacopoeia-Drug Information (USP-DI) or its successor publication [amended in Section 6001 (f)(1) of the DRA] and American Hospital Formulary Service-Drug Information (AFHS-DI). Current Medicare-recognized compendia have included American Hospital Formulary Service Drug Information (AHFS-DI), Clinical Pharmacology and DrugDex [16]. For anticancer drugs, the National Comprehensive Cancer Network (NCCN) Drugs and Biologics Compendium is utilized. Other insurance carriers may utilize the same or different compendia.

Thomson Reuters, maintains the DrugDex compendia (a database within the larger Micromedex resource) that has long been dedicated to including information regarding off-label drug use [17]. Off-label indications are monitored through ongoing evaluation of primary literature and influential sources of drug information, such as the FDA, National Institute of Health (NIH), and the Center for Disease Control and Prevention (CDC). Additionally, the database accepts requests for additions to off-label indications. For every drug, all FDA approved indications are included, as well as various off-label indications. Each indication is evaluated similarly with a rating for strength of efficacy, strength of evidence, and strength of recommendation (Table 101.2) [17]. Efficacy is given a Class I, IIa, IIb, or III designation based on whether or not available evidence favored efficacy. Class I is considered the highest level of effectiveness. The strength of evidence is given a category A, B, C or "no evidence." Category A evidence is based on meta-analysis and/or randomized, controlled trials. The overall strength of recommendation takes in to account the efficacy and evidence rating. Class I, IIa, or IIb are considered acceptable for use, Class III rating is not recommended [17].

American Hospital Formulary Service – Drug Information (AHFS-DI), another HHS-recognized drug compendium, is a resource that aims to provide information on the safe and effective use of drugs based on available evidence. A vital part of the drug resource's mission is to evaluate evidence for the off-label use of drugs. Off-label drug use recommendations are provided by AHFS-DI by the presence of supportive narrative. AHFS-DI data is also available through the Lexicomp drug resource [18].

The Medicare benefit policy states that an off-label drug use may be covered if supportive text is provided in AHFS-DI or Clinical Pharmacology; or is given Class I, IIa or IIb recommendation in DrugDex [19]. However, coverage decision processes are complicated by inconsistencies by the various drug compendia resources in their support and evidence for off-label ISA use. The support of off-label drug use by AHFS-DI is based on whether the use is discussed and whether the narrative present is supportive or not supportive (Table 101.2). However, the extent of this narrative is extremely limited. The majority of the ISA listed in Table 101.1 have no narrative within AHFS-DI regarding the off-label use and therefore no support for its use. In contrast, DrugDex provides a rating for whether the off-label use is acceptable or not. The compendium goes on to provide ratings for strength of evidence and efficacy.

Discrepancies exist between AHFS-DI and DrugDex compendia complicate coverage decisions regarding off-label ISA use. For example, the use of sirolimus to prevent rejection in heart transplant is rated III (unacceptable for off-label use) yet available evidence was found to favor efficacy. Given these facts, the basis for a rating of unacceptable is unclear. Interestingly, AHFS-DI did not provide a narrative for the same off-label use.

Significant discrepancies exist between AHFS-DI and DrugDex in supporting rATG use outside the labeled indication of treatment of renal allograft rejection (current FDA approved indication). Within AHFS-DI, off-label use listed for transplantation consists only for prevention of renal allograft rejection. Specifically, AHFS-DI does not mention rATG for treatment or prevention of rejection in heart or pancreas transplantation, and does not include narrative text supporting this use. In contrast, DrugDex supports the use of rATG for the treatment and prevention of rejection in heart transplant recipients, and is assigned a Class IIb recommendation, which is often considered satisfactory for OIG approval of off-label use.

The shortcomings of compendia for determination of coverage for ISA may be best represented by the DrugDex assignment for rATG use as induction therapy in kidney transplantation. DrugDex assigned rATG a Class III (i.e. not recommended) for prevention of rejection in renal allografts despite providing a supporting rating for efficacy and strength of evidence.

The lack of support for this off-label use of rATG for induction in renal transplantation is difficult to justify given the state of clinical use and the existing evidence base. According to the Scientific Registry of Transplant Recipients (SRTR), rATG was the most commonly used induction agent in 2009, nearly 48% of kidney transplant recipients received rATG, and the agent is largely considered standard of care across US transplant centers [10]. Additionally, this off-label use of rATG for induction therapy is extensively supported by scientific literature [20–24]. This discrepancy between the drug compendia, clinical practice, and available scientific evidence provides a cogent reason for a rational re-evaluation of the current state of compendia. The issue presents considerable challenges for transplant providers in providing optimal care for their patients. One approach for dealing with the problems presented by compendia would be for the major professional transplant societies (American Society of Transplant Surgeons and the American Society of Transplantation) to become engaged in developing and providing the scientific evidence base that is used in developing compendia-based classifications and narratives.

An additional reimbursement option of off-label ISA is providing source documentation of therapeutic efficacy in peer-reviewed journal articles. The use of off-label drugs may be considered acceptable if validated by authoritative medical literature or standard of care practices. For the off-label use of anticancer drugs and biologics, OIG and Medicare have provided specific details for how medical literature will be evaluated and accepted [19]. This policy provides a list of acceptable literature sources, specific to investigation of anticancer drugs. In terms of biologics in transplantation, the major solid organ transplantation academic journals are not included in the list of approved medical literature, thereby seriously complicating the issue of Medicare coverage for off-label ISA use. This situation offers an opportunity for major professional societies in the transplant field to engage and influence established approaches.

Off-label drug use within the oncology patient population has been well recognized and addressed through policies by OIG. However, OIG has not applied a similar degree of effort and rigor for off-label ISA use in transplantation. The lack of OIG policies regarding off-label drug use in transplantation is further complicated by the presence of more significant time constraints within transplantation — transplants are often performed on an urgent basis and acute rejection therapy must be instituted on an emergency basis. These observations provide a cogent rationale for a greater concentration of effort with respect to federal policy development and regulatory application of policy.

Drug	FDA approved indication	Off-label clinical uses in transplant and drug compendia recommendation				
			AHFS-DI	DrugDex©		
				Overall	Evidence	Efficacy
Tacrolimus	• Heart: Prevention of rejection	Heart: Treatment of rejection	NN	None	None	None
	• Liver: Prevention of rejection	Liver: Treatment of rejection	NN	IIb	B	Favors, IIa
	• Kidney: Prevention of rejection	Kidney: Treatment of rejection	Supportive	IIa	B	Favors, IIa
		Lung Transplant	NN	IIb	C	Favors, IIa
		Kidney/pancreas: Prevention of rejection	NN	IIa	C	Favors, IIa
		Pancreas: Treatment of rejection	NN	IIa	B	Favors, IIa
Cyclosporine	• Heart: Prevention of rejection	Lung: Prevention of rejection	NN	IIa	B	Favors, IIa
	• Heart: Treatment of rejection	Lung: Treatment of rejection	NN	IIa	B	Favors, IIa
	• Liver: Prevention of rejection	Pancreas: Prevention of rejection	NN	None	None	None
	• Liver: Treatment of rejection	Pancreas: Treatment of rejection	NN	None	None	None
	• Kidney: Prevention of rejection					
	• Kidney: Treatment of rejection					
Sirolimus	• Kidney: Prevention of rejection (low, moderate, high immunologic risk)	Heart: Prevention of rejection	NN	III	B	Favors, IIa
		Kidney: Treatment of rejection	NN	IIb	B	Favors, IIa
		Liver: Prevention of rejection	Not Supportive	III	B	Inconclusive
Everolimus	• Kidney: Prevention of rejection	Heart: Prevention of rejection	NN	III	B	Favors, IIa
		Kidney: Treatment of rejection	NN	None	None	None
Belatacept	• Kidney: Prevention of rejection in when used in combination with basiliximab induction in EBV seropositive recipients	Kidney: Prevention of rejection when used in combination with anti-thymocyte globulin induction	NN	None	None	None
Mycophenolate mofetil	• Heart: Prevention of rejection	Kidney: Treatment of rejection	NN	IIb	B	Favors, IIa
	• Liver: Prevention of rejection	Kidney: Alternative regimen	NN	IIb	B	Favors, IIa
	• Kidney: Prevention of rejection					
Mycophenolic acid	• Kidney: Prevention of rejection	Kidney: Treatment of rejection	NN	None	None	None
Azathioprine	• Kidney: Adjunct therapy for prevention of rejection	Liver: Prevention of rejection	NN	IIb	B	Favors, IIa
		Pancreas: Prevention of rejection	NN	IIb	B	Favors, IIa
Basiliximab	• Kidney: Prevention of rejection in combination with cyclosporine and corticosteroids	Liver: Prevention of rejection	NN	IIb	B	Favors, IIa
Rabbit anti-thymocyte Globulin	• Kidney: Treatment of rejection, in conjunction with concomitant immunosuppression	Heart: Prevention of rejection	NN	IIb	B	Favors, IIa
		Heart: Treatment of rejection	NN	IIb	B	Favors, IIa
		Liver: Prevention of rejection	NN	IIb	C	Favors, IIa
		Kidney: Prevention of rejection	Supportive	III	B	Favors, IIa
		Lung: Prevention of rejection	NN	IIb	C	Favors, IIa
		Pancreas: Prevention of rejection	NN	IIb	B	Favors, IIa
		Pancreas: Treatment of rejection	NN	IIb	B	Favors, IIa
Horse anti-thymocyte globulin	• Kidney: Prevention of rejection	Alternative to rabbit anti-thymocyte globulin in non-renal organs	Supportive	None	None	None
	• Kidney: Treatment of rejection					
Alemtuzumab	• B-cell chronic lymphoid leukemia	Kidney: Prevention of rejection	NN	IIb	B	Favors, IIa
Rituximab	• Rheumatoid arthritis (moderate to severe)	Treatment of PTLD	NN	IIb	B	Favors, IIa
	• CD20-positive chronic lymphoid leukemia	Desensitization regimens	NN	None	None	None
	• CD20-postiive non-Hodgkin's lymphoma	Treatment of antibody-mediated rejection	NN	None	None	None
Bortezomib	• Multiple myeloma	Desensitization regimen in combination with plasmapheresis	NN	None	None	None
	• Mantle cell lymphoma					
		Treatment of antibody-mediated rejection	NN	None	None	None

Off-label use of immunosuppressive drugs in transplantation

Over the past several years, three drugs with FDA indications for oncology have seen used off-label as immunosuppressants in transplantation: alemtuzumab, rituximab, and bortezomib. The following sections detail the published clinical use of these oncologic agents in transplantation, and how they have become standard practice at a number of transplant centers.

Alemtuzumab

Alemtuzumab (Campath-1H™) is a monoclonal antibody specific for the CD52 antigen expressed on T and B lymphoctyes, monocytes, macrophages and eosinophils [25,26]. Alemtuzumab was originally FDA approved for treatment of B-cell chronic lymphocyte leukemia (CLL). This cytoloytic agent, which causes rapid and sustained lymphocyte depletion, has been extensively studied in solid organ transplant as induction therapy. Alemtuzumab was approved for use in the US in 2001 for CLL, but was used prior to this outside the US. In 1998, a study in the UK investigated the use of alemtuzumab as induction therapy in 13 kidney transplant recipients [26]. A 5-year follow-up study of a larger group of patients was published in 2005 [27]. Alemtuzumab, in combination with low-dose cyclosporine, was found to be safe and effective when compared to standard therapy with respect to patient and graft survival [27]. Another study conducted in three centers in Asia, suggested alemtuzumab was an effective induction agent in steroid-free regimens [28].

Randomized studies comparing alemtuzumab to rATG and IL-2RAs (daclizumab or basiliximab) have provided a substantial evidence base supporting the off-label use of alemtuzumab as induction therapy in kidney transplantation. Cianco et al. published findings at 15 months of patients randomized to alemtuzumab,

Table 101.2. Definition of recommendations and ratings in drug compendia. Adapted from: Micromedex [Internet database]

Drug Compendia			
AHFS-DI	Narrative text is ***supportive*** — considered acceptable off-label drug use Narrative text is ***non-supportive*** — considered unacceptable off-label drug use ***No narrative (NN)*** in supportive text		
DrugDex©	Acceptable off-label drug use	Class I	Recommended. Treatment has been proven to be useful and should administered
		Class IIa	Recommended, in most cases. Treatment is generally considered to be useful, and indicated in most cases
		Class IIb	Recommended, in some cases. Treatment may be useful, and is indicated in some, but not most, cases
	Unacceptable off-label drug use	Class III	Not recommended. Treatment is not useful, and should be avoided
	Strength of Evidence	Category A	Evidence is based on data derived from: meta-analysis of randomized controlled trials with homogeneity with regard to the directions and degrees of results between individual studies. Multiple, well-done randomized clinical trials involving large numbers of patients
		Category B	Evidence is derived from: meta-analysis of randomized controlled trials with conflicting conclusions with regard to directions and degrees of results between individual studies. Randomized controlled trials that involved small numbers of patients or had significant methodological flaws (e.g. bias, drop-out-rate, flawed analysis, etc.). Nonrandomized studies (e.g., cohort studies, case-control studies, observational studies)
		Category C	Evidence is based on data derived from: expert opinion or consensus, case reports or case series
		No Evidence	
	Efficacy	Class I	Effective. Evidence and/or expert opinion suggests that a given drug treatment for a specific indication is effective
		Class IIa	Evidence favors efficacy. Evidence and/or expert opinion is conflicting as to whether a given drug treatment for a specific indication is effective, but the weight of evidence and/or expert opinion favors efficacy
		Class IIb	Evidence and/or expert opinion is conflicting as to whether a given drug treatment for a specific indication is effective, but the weight of evidence and/or expert opinion argues against efficacy
