In contrast to the procedure-related risks that are generally captured due to uniform reporting requirements mandated by policy, the long-term consequences of living kidney donation have been much less thoroughly studied. This is in part due to the perception that living donors are healthy prior to donation and return to a healthy lifestyle following recovery from the surgical procedure. Practical issues also confound efforts to track the health of kidney donors over long periods of time. Many donors live relatively long distances from the transplant center that performed their surgery, making it difficult to return to the transplant center for routine health assessments following kidney donation. Second, a significant fraction of living donors do not have health insurance. As funds are not set aside to cover the long-term medical expenses (including routine healthcare maintenance) of former living donors, there are significant financial impediments for both the donors and the transplant centers with respect to conducting comprehensive, long-term follow-up of living kidney donors. Lastly, living kidney donors frequently view themselves as being healthy, as do their physicians, and do not see the value in the time spent in routine health assessments following kidney donation. Consistent with this gestalt since 1996, only 280 prior living kidney donors have been listed for a kidney transplant. In view of their former living donor status, these rare individuals receive priority for transplantation. At the time of listing they are awarded four additional points, placing them ahead of the vast majority of recipients, excluding zero HLA-mismatched recipients and recipients of extrarenal organs. While the barriers to monitoring the long-term health of living kidney donors are formidable, there is a rapidly growing consensus that society and the transplant community are responsible for ensuring that information about the long-term consequences of living kidney donation are collected and disseminated. The need for studying the long-term consequences of living kidney donation is made even more pressing by the changing demographics and increasing medical complexity of living kidney donors in the 2000s. As discussed, the trend is for living kidney donors to be older, more racially and ethnically diverse, and less closely related to their recipients than in times past. An increasing number of living donors also have, or are at risk for, health conditions such as hypertension, obesity, and abnormalities of lipid and glucose homeostasis, each of which increases their risk of cardiovascular and renal disease [56].

Despite concerns about the inadequacy of existing data to inform potential living kidney donors about the associated risks, numerous studies do provide useful information. A study of 62 veterans who underwent unilateral nephrectomy for trauma during the Second World War failed to reveal an increase in mortality or hypertension relative to servicemen of the same age who had not undergone nephrectomy [57]. Kidney disease among deceased subjects or dysfunction among living individuals was attributed by the authors to causes other than nephrectomy, suggesting that uninephrectomy in young males had few major adverse sequella over the 45-year follow-up period. One of the earliest efforts to define the effects of kidney donation on the long-term health of donors examined 57 donors followed for a minimum of 20 years after donation [58]. In comparison to 65 siblings, there was no difference in serum creatinine, blood urea and nitrogen, creatinine clearance, mean blood pressure, or the frequency of hypertension or proteinuria treatment. A subsequent study of a significantly larger number of former kidney donors from the same institution confirmed the relative safety of living kidney donation [59]. In this second study, the authors determined the vital status and risk of ESRD in 3698 individuals who donated kidneys between 1963 and 2007. They also performed specific measurements of renal function, renal injury, hypertension, general health status, and quality of life in a subset of 255 patients who donated between 2003 and 2007. Their results indicate that the survival of living donors was comparable to that of control individuals matched for age, sex, race, and ethnicity. Similarly, there was no significant difference in the risk of ESRD for donors as compared to the general population. The quality of life and general health status of living kidney donors was not distinguishable from that of individuals obtained from the National Health and Nutrition Examination Survey (NHANES) who were matched for important variables. Based upon these findings, the authors concluded that the development of significant health issues among living kidney donors was similar to that observed in the general population. While reassuring, it is uncertain to what degree these findings from the study of primarily Caucasian donors, many of whom donated in the 1970s and 1980s, can be extrapolated to the more racially and ethnically diverse donors of today who may have different health risks given the increasing prevalence of obesity and its related health problems. In order to address the impact of changing donor demographics and the general health status of individuals in the US, in recent times a second group compared national registry data for 80 347 living donors who underwent nephrectomy between 1994 and 2009 to 9364 participants in NHANES III, in which those having contraindications to kidney donation were excluded [60]. While the duration of follow-up was obviously

shorter (just over 6 years), the mortality rate of living donors was no different from that of age-, sex-, and race-matched participants in NHANES III. A third recent report directly compared the effect of race on health following living donation [61]. This group examined the medical records of 4650 individuals who were kidney donors between 1987 and 2007 and were insured by a single company at some point between 2000 and 2007. The health status of these living kidney donors was compared to participants in NHANES. This analysis demonstrated that the risk of developing hypertension, diabetes mellitus, or CKD was increased in black and Hispanic living kidney donors relative to white kidney donors. However, these risks were not increased relative to demographically-matched control individuals from NHANES, indicating that race and ethnicity affect the risk of hypertension, diabetes, and CKD but that living kidney donation does not further impact these differential risks. The finding that ESRD, although rare following living kidney donation, is more common in African–Americans warrants further study. One possible contributing factor is the recent description of two mutations in the gene encoding APOL1. These mutations termed *G1* and *G2* are quite common, occurring in nearly one-third of all African–Americans without known kidney disease and two-thirds of those with kidney disease. While the presence of a single at-risk allele, either *G1* or *G2*, conferred protection against the *Trypanosoma* parasite responsible for "sleeping sickness," two copies of the at-risk alleles more than doubled the risk of ESRD. This has caused some to implement screening of African–American potential kidney donors for the presence of the at-risk alleles of APOL1 [62]. While this is relatively inexpensive, in the absence of data about the impact of these mutations on living kidney donors, it may serve to further disadvantage African–Americans with respect to access to living donor kidney transplantation.

When taken together, these and other studies provide some reassurance that living kidney donation is not prohibitively risky from either the standpoint of operative risk or long-term consequences of having a single kidney. However, nearly all of the studies performed to date suffer from the lack of a control population that truly reflects the excellent health status of living kidney donors. In contrast to the exhaustive testing performed on living kidney donor candidates, most studies out of necessity have used control groups comprised of patients who identify themselves as healthy based on medical conditions currently known to them or at best limited testing of small numbers of patients. Attempts to address this issue by using approved living kidney donors who for one reason or another did not undergo living donor nephrectomy have proven difficult in that many of these medically suitable donors who ultimately did not complete donation are not interested in participating in long-term studies of their current and future health for a variety of reasons. Studies defining the life-time risks of living kidney donation are further complicated by the infrequent occurrence of serious, donation-related adverse events and their potential/probable occurrence at time points remote from donation. The impact of these observations on study design requires that in order to be informative, a study would need to follow a large number of living donors for a prolonged period of time. This has obvious financial implications in that there are currently limited funding options to offset the costs of this additional effort. In an attempt to address these limitations and concerns, the National Institutes of Health has sponsored two studies of living donor outcomes. ALTOLD (Assessing Long-term Outcomes of Living Kidney Donation) is a multicenter, 3-year study of 200 living kidney donors and 200 matched controls for the development of renal, cardiovascular, bone, and mineral disease. This study is limited in that it is not designed to detect rare, but serious, adverse events or those that occur more than 3 years after donation. RELIVE (Renal and Lung Living Donors Evaluation) is a study that aims to examine national databases to determine the vital status and occurrence of ESRD in 8951 prior living donors. Subsets of this large population will be selected to undergo additional testing to determine the incidence of renal dysfunction, cardiovascular disease, and changes in quality of life. Several additional multicenter, federally funded studies are currently ongoing, including the Kidney Donor Outcomes Cohort (KDOC) study (ClinicalTrials.gov identifier NCT01427452), the Long-term Effects of Becoming a Living Kidney Donor Study (ClinicalTrials.gov identifier NCT00936078), and the Live Kidney Donor Study – Cross-Sectional and Historical Cohort Study (ClinicalTrials.gov identifier NCT00951977). Despite these initiatives and the widespread opinion of transplant professionals, patients, representatives of payer organizations, and the federal government that these types of studies are critical to inform potential donors about the risks of living donation [63], it is unlikely that optimally designed studies will be undertaken until appropriate financial support is available to offset the disincentives of participating in a long-term study for which there is no apparent medical benefit.

Summary

The past two decades have seen tremendous changes in living kidney donation and transplantation. Technical innovations such as laparoscopic donor nephrectomy, robotic donor nephrectomy, and laparoendoscopic single-site nephrectomy offer prospective donors the realistic expectation of less postoperative pain and a more rapid recovery. Protocols to effectively desensitize recipients together with paired donor exchange programs are extending the benefits of living donor kidney transplantation to an increasing number of sensitized recipients. Changes in donor demographics combined with the willingness of transplant centers to consider more medically and surgically complex individuals for living kidney donation have also contributed to a nearly three-fold growth of living kidney donation in the last 20 years. While the preponderance of existing data suggest that living kidney donation is associated with acceptable short- and long-term risks, the changes in the practice of living kidney donation described above challenge the field to design and implement strategies to accurately monitor the long-term outcomes of living kidney donors so as to adequately inform future donors of the associated risks.

CHAPTER 24

Techniques for Living Donor Liver Procurement

Koji Hashimoto, Cristiano Quintini, and Charles M. Miller

Cleveland Clinic Lerner College of Medicine, Case Western Reserve University; Liver Transplant Program, Digestive Disease Institute, Cleveland Clinic, Cleveland, OH, USA

Introduction

Faced with an ever-increasing donor shortage, surgeons caring for patients with end-stage liver disease have been forced to expand utilization beyond whole organ liver grafts from standard criteria brain dead donors. One important option is the use of partial grafts from living donors. The goal of living donor liver transplantation (LDLT) is to create a partial functional liver graft for recipients, leaving enough remnant liver mass to maintain the donor's health with normal liver function. However, the practical application of LDLT is mitigated to some extent by the ethical principle of "primum non nocere"; first do no harm. Living organ donation is one of the only fields in medicine in which a healthy person undergoes a major surgical procedure without a pathological condition. In full cognizance of this concern, the initial era of LDLT involved only adults donating a small portion of their liver to small pediatric recipients.

In 1988, the first attempt was made for a small child with her mother as a living donor. The patient died 6 days after the transplant due to severe hemolysis and renal failure [1]. The first successful LDLT was performed for a pediatric patient in Australia in 1989 with a left lateral segment graft [2]. Left lateral segmentectomy removes only 20–25% of the donor liver and is well tolerated by adult donors. Adult-to-pediatric LDLT gained wide acceptance as both relatively safe for the donor and highly efficacious for the child.

With this success, the indications for LDLT were slowly broadened to adult recipients. Makuuchi performed the first successful adult-to-adult LDLT in 1993. A left lobe graft was utilized [3]. Unfortunately, the early experiences of adult-to-adult LDLT did not yield results equivalent to those demonstrated in pediatric recipients. The results were hamstrung by the theoretical and actual amount of liver mass needed by the recipient. To overcome this limitation, surgeons began to use the larger right lobe. In 1996, the first adult-to-adult LDLT using a right lobe graft was performed in Hong Kong [4] and this technique then rapidly became the most common procedure in adult-to-adult LDLT [5].

The use of the right lobe graft lead to the rapid increase of LDLT in both eastern and western countries. While this lead to significant improvement in recipient outcomes, it was also fraught with an increasing incidence of morbidity and mortality for the donors [6–9]. There is now sound consensus that donation of the right lobe is associated with an increased risk of donor morbidity and mortality compared to the left-sided graft [10]. In 2002, the combination of a well-publicized donor death and the change to the Model for End-stage Liver Disease (MELD) era of deceased donor allocation, the demand and popularity of adult-to-adult LDLT diminished dramatically in the US and Europe. In contrast, the demand and need for LDLT in eastern countries with poorly developed deceased donation systems has continued to rise. In 2010, while LDLT accounted only for 4.5% of liver transplantations performed in the US [11], it accounted for >90% of liver transplantations in Asia.

Thus today, while LDLT remains safe and effective in children, the aggressive application of adult-to-adult LDLT is still controversial, especially in parts of the world where there are well-developed organ procurement systems and the need for its application in adults is relative. Although several centers, mostly in Asia, utilize LDLT for critically ill patients with high MELD scores, in the west it is generally reserved for patients with low-to-moderate MELD scores [12,13]. In the US, right lobe adult-to-adult LDLT has demonstrated a significant survival advantage when compared in an intent-to-treat analysis to those who must wait for a deceased donor [14,15]. This advantage is sustained even in those with a MELD score of <15, a group that generally does not benefit from deceased donor liver transplantation [16]. Therefore, as new technologies that maximize donor safety evolve, the practice of LDLT has a potential to be revitalized.

In this chapter, we will start with a review of the donor evaluation and graft selection in LDLT. Surgical aspects of living donor hepatectomy will be reviewed, including conventional open techniques as well as laparoscopic donor hepatectomy. Finally, we will outline perioperative donor management and donor complications. Specifics of the recipient procedure for LDLT are covered in the companion Chapter 57. Technical aspects of deceased donor liver procurement from donation after brain death or donation after circulatory death can be found in Chapters 21 and 22, respectively.

Donor evaluation

Donor safety is paramount; there can be no exception to this rule. To prevent unnecessary morbidity, vigilant evaluation of potential donors is crucial. Ideally, the evaluation of the donor should be conducted by a designated donor advocacy team, which independently assesses donor candidacy to avoid a conflict of interest [17]. The aim of the donor evaluation is to assess whether the donor is suitable for living donation medically, surgically, emotionally,

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

psychologically, and financially. Equally important is the need to identify anatomical variants that could increase donor risks and jeopardize the recovery of either the donor or recipient. A variety of criteria may make potential donors unsuitable for living donation (Table 24.1).

The donor must be fully informed. A thorough assessment must be made to ensure that there is no coercion. The donor must make the decision voluntarily, without any direct or indirect financial gain deriving from the donation. During the evaluation, the donor is educated regarding the risks of the procedure. This includes discussion of the morbidity and mortality rates reported in the medical literature, as well as outcomes of the center that will perform the operation [18]. Particular effort is needed in the psychosocial evaluation of potential donors. In this process, a psychiatrist and social worker conduct a thorough evaluation on an individual basis. Significant psychiatric and emotional disorders are a contraindication for donation. Although ambivalence is common in living donors, the majority of them can go through the evaluation process and donor operation with a careful team support [19]. The donor has the right to withdraw his/her willingness to donate up to the time of surgery. The reader is referred to Chapter 138 for a more extensive discussion of the ethics of living donation.

Table 24.1. Possible exclusion criteria for living liver donation

- Age <18 years or >55 years (>60 years in case a recipient needs a left lateral segment)
- Unable to make an informed consent due to mental or psychiatric disorders
- Morbid obesity
- Poorly controlled medical conditions (e.g. hypertension, diabetes)
- History of coagulation disorder (e.g. Factor V Leiden)
- History of bleeding disorder
- Significant cardiac history (coronary artery disease, valvular disease)
- Peripheral vascular disease
- Chronic pulmonary disease
- Recent history of malignancy with long time to recurrence (e.g. breast cancer)
- History of melanoma
- Active infection
- History of recurrent infection
- History of liver disease including hepatitis
- Fatty liver
- Asymptomatic ZZ alpha-1 antitrypsin genotype
- Significant donor/recipient size mismatch (donor < recipient)
- Donor future liver remnant <30% (generally, 35% is considered as a safety margin)
- Vascular or biliary anomaly unsuitable for living donation

The first step of the evaluation begins with a thorough medical history and physical examination. Generally, potential donors should be completely healthy and between 18 and 55 years of age. When the recipient needs a left lateral segment, donors up to the age of 60 years can be considered. The donor and recipient should be blood group identical or compatible. ABO-incompatible blood groups can be accepted in extreme situations where deceased donation is extremely scarce. It is preferable for the donor to have a clear and established relationship with the recipient; however, volunteers who are physically and mentally healthy can, on occasion, be Good Samaritan donors. The donor must not have significant co-morbidities. However, medical conditions such as mild hypertension can be considered to be acceptable if they are medically well controlled. In female donor candidates, oral contraceptives must be discontinued. The past medical history of a hypercoagulable state is a contraindication for living donation due to the risk of fatal thromboembolic events. Active smokers and drinkers should not be considered for donation. If a potential donor's body mass index (BMI) is $>30\,kg/m^2$, a liver biopsy should be performed to rule out the presence of fatty liver, which can negatively affect donor safety as well as recipient outcome.

The next step of the evaluation includes extensive lab profiling and serologic testing. The donor should have normal liver function. Systematic screening for coagulation disorders is important to identify hidden thrombophilic states [20]. A lipid profile is also important; there is a close relationship between hyperlipidemia and fatty liver disease [21].

If the donor is deemed to be a good candidate from a medical and psychosocial perspective, then the next step is to assess the anatomical and surgical aspects. In the assessment of the anatomy, invasive studies should be avoided. In the early eras of LDLT, donors were routinely evaluated with angiography and endoscopic retrograde cholangiography. However, these invasive procedures carried a certain risk that could not be justified as part of a routine evaluation of a healthy donor. Recent advances in the three-dimensional reconstruction of the liver using multiphase computed tomography (CT) scans have contributed to a precise, non-invasive mapping of the important vascular structures, allowing for a preoperative simulation of the graft procurement (Figure 24.1a). This enables surgeons not only to visualize detailed liver anatomy but

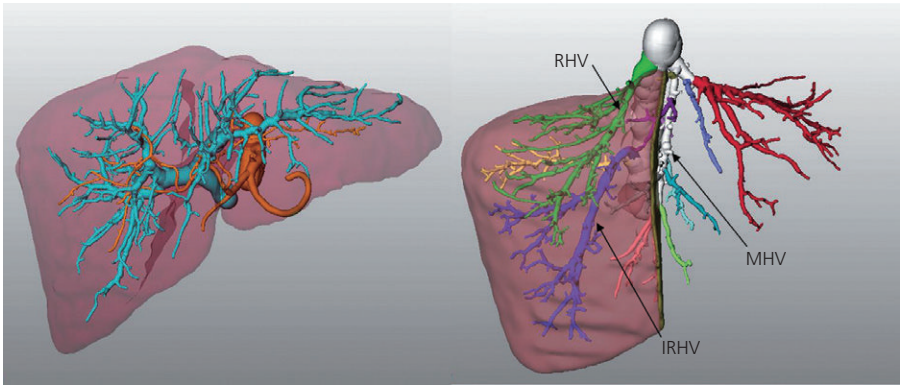

Figure 24.1. Three-dimensional reconstruction of the (A) hepatic artery and portal vein and (B) estimated right lobe graft without middle hepatic vein using multiphase CT scan. RHV, right hepatic vein; MHV, middle hepatic vein; IRHV, inferior right hepatic vein.

also to estimate graft and remnant liver volumes (Figure 24.1b). Biliary imaging can be performed with magnetic resonance (MR) cholangiography or CT cholangiography to exclude significant anatomical variants that jeopardize candidacy (see Anatomical variants below). At the end of the evaluation process, only 30–40% of aspiring donors will be considered good candidates for living donation.

Graft selection

In order to understand the type of grafts used in LDLT, it is important to define two concepts: the future liver remnant (FLR) and the graft-to-recipient body weight ratio (GRWR). The FLR is the proportion of the donor liver that is estimated to remain after the donation. An FLR of 30–35% is considered a safe and acceptable lower limit under which donation takes on a higher risk of the development of postoperative liver failure [22]. The GRWR is the ratio between the donor graft weight and the recipient body weight. The lower limit of graft acceptability in adult-to-adult LDLT is considered to be approximately 0.6–0.8%, which is equivalent to 30–40% of recipient standard liver volume [22]. However, many centers prefer a GRWR of at least 1% to give a safety margin to the recipient in case of certain specific technical complexities. A GRWR below 0.6–0.8% increases the chance of developing graft dysfunction, known as small-for-size syndrome (SFSS). The ideal graft is one that leaves a donor with a FLR of >35% and at the same time provides an adequate liver mass with respect to the recipient.

There are essentially three types of grafts that are commonly used in LDLT (Figure 24.2); the left lateral segment (segment 2–3); the left lobe with middle hepatic vein (segment 1–4); and the right lobe without middle hepatic vein (segment 5–8). The smallest conventional graft is represented by the left lateral segment, which usually provides 20–25% of the total liver volume. This graft is usually reserved for pediatric recipients. The left lobe, which represents 30–40% of the total liver volume, is usually offered to teenagers or small adults. Finally, the right lobe, which represents 60–70% of the total liver volume, is reserved for the remainder of the adult population. This is the largest graft and offers the most consistent results in adult recipients. However, it is also the one that is associated with the highest morbidity and mortality in the donor [10]. The left lobe usually has a single venous outflow (common channel of left and middle hepatic veins), single left branch of the portal vein, and single left hepatic duct. However, the left lobe graft often requires two small anastomoses of hepatic arteries [23]. In contrast, the right lobe graft usually has a single right hepatic artery, but frequently requires multiple and complex reconstructions of the venous outflow and the bile ducts [24].

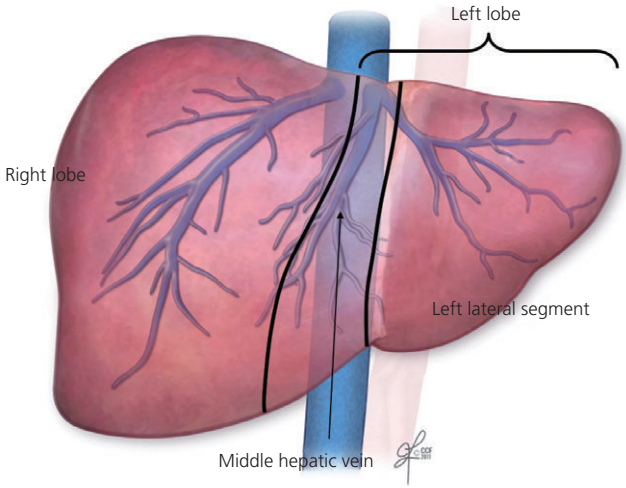

Figure 24.2. Graft types commonly used in living donor liver transplantation.

Graft selection is generally guided by three important factors: liver anatomy; donor–recipient size matching; and severity of recipient liver disease. In determining whether a donor liver can provide sufficient liver function to the recipient, it is important to estimate the functional capacity of the graft. This estimate is known as the "functional graft size," which is a composite function of actual graft size modified by the severity of the recipient's condition, the degree of portal hypertension, and the degree to which a graft outflow might be impaired [5]. The larger graft (right lobe) is more likely to provide enough liver mass to meet the recipient's metabolic demands and withstand the hyperdynamic splanchnic flow commonly seen in adult cirrhotics. However, the right lobe often needs complex venous reconstruction to ensure optimal graft outflow. In using the left lobe graft, actual graft size may not always exceed the 0.8% of GRWR or the 40% of standard liver volume threshold. Even in such cases, the left lobe graft has excellent venous outflow and can provide adequate functional liver mass if the recipient's portal hypertension is limited. If small left lobe grafts are used for patients with high MELD scores or severe portal hypertension, the risk of graft failure is very high.

Several centers routinely use the extended right lobe grafts including the middle hepatic vein [25]. This graft provides a larger liver mass and better venous drainage for the recipient, but donor safety is of increased concern compared to the other graft variants. Right posterior segment (segment 6–7) grafts have been used in some rare instances. This graft requires complex surgical techniques and is considered only when the donor has a disproportionately small left lobe with a rare anatomical variant of the portal vein [26,27]. Mono-segment grafts are used for small infants (body weight of <10 kg) to prevent a large-for-size graft failure [28,29]. In general, when the left lateral segment is too large for such small infants, lateral and caudal portions are removed to down-size the graft. These three grafts are technically more challenging, but can provide excellent outcomes in experienced centers.

Anatomical variants

Hepatic artery

Hepatic artery reconstruction remains one of the most important and challenging steps in LDLT. Preoperative evaluation of hepatic arterial anatomy is mandatory both in the donor and recipient. Arterial variants are commonly encountered in living liver donors (about 50%). Identification of the origin of the middle hepatic artery (A4) is important. When the A4 arises from the right hepatic artery, the left lobe graft has two separate hepatic arteries that need to be reconstructed. If there are intrahepatic arterial collaterals, a smaller branch can be sacrificed [30]. The risk of biliary complications can be reduced, however, by reconstructing both branches [23]. The presence of separate branches of segment 2 and 3 requires anastomosis of each branch with a smaller caliber (1–2 mm) and further increases the risk of thrombosis in the left-sided graft.

Portal vein

Anatomical variants of the portal vein that would require multiple anastomoses or be a contraindication for donation occur less frequently than those of the hepatic artery or hepatic vein [31]. Portal vein variants occur in about 20% of the general population, with trifurcation the most common variant [32]. The right anterior branch can arise from the left portal vein. However, this branch can be identified in the hilar area and is not an absolute contraindication despite its increased complexity; it requires the reconstruction of two separate branches in right lobe LDLT. When a branch of the right lobe arises from the umbilical portion of the left portal vein, the origin of this portal branch can be difficult to dissect and reconstruct.

Hepatic veins

Ensuring perfect venous outflow is a key in partial grafting because venous drainage is a very important determinant of graft function and, accordingly, of functional graft size [5]. Foreknowledge of hepatic venous anatomy enables preoperative determination of surgical plans for optimal venous reconstruction. Since the left hepatic vein is almost always (92%) dominant for the left lobe, a standard left lobe graft retaining both the left and middle hepatic veins usually promises optimal outflow [33]. In contrast, various anatomical variants of right and middle hepatic vein anatomy can create the need for demanding technical reconstructions when using right lobe grafts [34]. Modern three-dimensional CT technology can provide fine estimates of the volume of potentially congested segments. As a general rule, the right anterior segment (segments 5 and 8) is predominantly drained by the middle hepatic vein. In donor right lobectomy without the middle hepatic vein, ligation of segment 5 and 8 veins (V5 and V8) can cause severe venous congestion. This causes two problems: (1) the congested area does not fully function, reducing the functional graft volume; and (2) the right anterior portal vein becomes an outflow tract that can cause portal hyperperfusion of the right posterior segment. This combination can cause serious graft dysfunction and SFSS. When a significant volume of graft congestion is predicted on imaging, major branches of the middle hepatic vein should be reconstructed.

A significant inferior right hepatic vein (>5 mm) exists in approximately 20–40% of donors [35,36]. In these cases, the vein should be preserved for subsequent reconstruction in recipients. An inferior right hepatic vein of <4 mm might also be significant and independently responsible for venous drainage of segment 6. Therefore, it is worthwhile to temporarily clamp the vein to assess whether the corresponding segment becomes congested before it is sacrificed [22]. When an estimated congestion area is minimal, there is minimal portal hypertension, or the GRWR is large, a standard right lobe graft without complex venous reconstruction suffices. In contrast, when a significant volume of graft congestion is anticipated, reconstruction of the inferior right hepatic vein is strongly recommended.

Bile duct

Biliary complications are the most common surgical complications, accounting for complication rates of up to 25% in donors [8,37,38] and 40% in recipients [5,12,39]. Abnormal or non-standard biliary anatomy poses significant technical challenges in LDLT. Surgical challenges are greater when multiple ducts are present and bile duct caliber is very small. MR or CT cholangiography is useful for preoperative evaluation of bile duct anatomy [40], but intraoperative cholangiography is still important to rule out anatomical variants not demonstrated on preoperative imaging.

The biliary anatomy can be classified into two major categories with respect to the presence of the main right hepatic duct [41,42]. The presence of the main right hepatic duct makes the donor suitable for either left or right lobectomy, leaving a single hepatic duct to be reconstructed. In the absence of the main right hepatic duct, the anterior and posterior branches take off separately from the left hepatic duct and/or common hepatic duct. Trifurcation of the left, right anterior, and right posterior branches (12%) is included in this variant. In the absence of the main right hepatic duct, two separate hepatic ducts are identified in right lobe grafts, necessitating complex biliary reconstruction. The left lobe graft almost always presents with a single duct [24]. The biliary transection plane for the left lateral segment graft is in the umbilical fissure and may be distal to the left duct's bifurcation into segmental ducts.

Special attention should be paid to rule out critical variations of the bile duct anatomy. For example, it is best to be aware prior to cholecystectomy and division of the cystic duct of an aberrant right hepatic duct that arises from the cystic duct 2–3% of the time [43]. Accessory left (1–2%) or right hepatic ducts (2%) may also preclude donor hepatectomy.

Surgical techniques: conventional open procedures

Left lateral segment graft (Figure 24.3a)

The laparotomy is performed through an upper midline incision with or without a short right lateral extension. The falciform ligament is divided up to the suprahepatic vena cava. After a brief evaluation of the abdominal organs, the left triangular and coronary ligaments are divided. The gastrohepatic ligament is divided to open the lesser sac, but if a left hepatic artery arises from the left gastric artery, it must be preserved. The base of the left hepatic vein is dissected, but it is unnecessary to encircle it at this point.

Surgical sponges are placed behind the right lobe of the liver to mobilize the liver medially. There is no need to surgically mobilize the right lobe. At the hepatic hilum, the left hepatic artery is dissected free. The left portal vein is identified posterior to the left hepatic artery. This is also dissected free. The caudate branch of the portal vein is tied and divided to free the entire left portal vein. The left hepatic duct is encircled and divided sharply in the plane of the umbilical fissure. Bleeding from small periductal arteries is controlled with fine sutures.

The transection line is marked with electrocautery at 0.5 cm to the right of the falciform ligament. The transection of the liver parenchyma can be performed by a variety of methods [e.g. cavitron ultrasonic surgical aspirator (CUSA), clamp-crushing technique, water-jet, bipolar coagulator); the choice depends on operator experience and confidence, but should be with the aim of minimizing blood loss and maximizing anatomical precision. The parenchyma is divided until the left hepatic vein is reached. By dividing the cranial end of the arantius ligament, access to the left hepatic vein becomes easier.

After administrating 3000 U of heparin intravenously, the left hepatic artery is ligated and transected. The left portal vein is also ligated and transected. The left hepatic vein–middle hepatic vein junction is controlled with a vascular clamp and the left hepatic vein is transected. The graft is immediately removed to the back table and flushed with cold preservation solution. While the

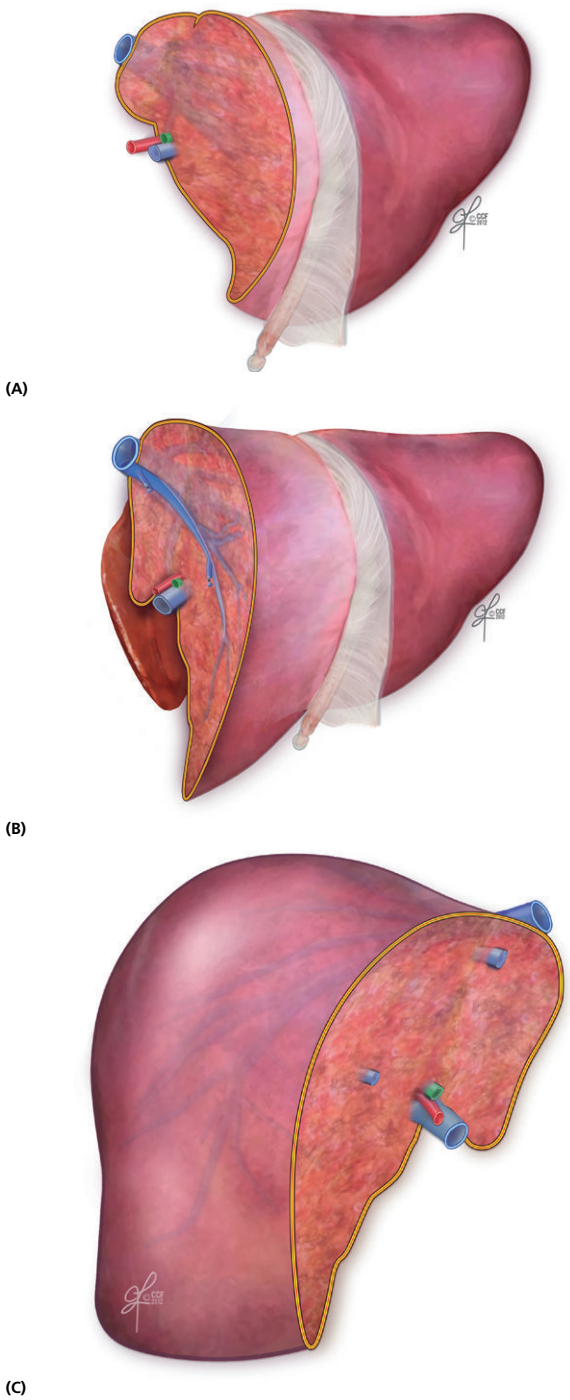

Figure 24.3. (A) Left lateral segment graft, (B) left lobe graft, and (C) right lobe graft.

back-table team perfuses the graft, the stump of the hepatic vein is oversewn with monofilament suture.

Left lobe graft (Figure 24.3b)

An upper midline incision with a right lateral extension is made for optimal exposure. A left lateral extension is usually unnecessary. The left lobe is mobilized as described in the left lateral segmentectomy. The falciform ligament tissue should be preserved on the liver side so that it can be used to fix the graft to the recipient's abdominal wall to prevent graft malposition into the right subphrenic space. The caudate lobe is retracted up to expose the retrohepatic vena cava by dividing the retroperitoneum.

A cholecystectomy is performed and the cystic duct is cannulated to perform a cholangiogram. Special attention must be paid to rule out anatomical variants that were not identified in preoperative imaging studies.

During the hilar dissection, unnecessary dissection must be avoided in the right-sided structures. The left hepatic artery is identified at the level of the bifurcation and dissected free. If the segment 4 hepatic artery arises from the right hepatic artery, arterial dissection is extended toward the right side of the bifurcation. The left portal vein is then identified posterior to the left hepatic artery and dissected free. An effort is made to preserve a small caudate branch to ensure its blood supply.

The left hepatic duct is identified within the hepatic hilar plate. A marker clamp is placed approximately 0.5 cm to the left of the bifurcation of the left and right ducts and a repeat cholangiogram is obtained. It is imperative that if a right posterior duct originates from the left duct, the eventual transection point is to the left of the take-off of that duct. The duct and entire hilar plate are then transected.

The short hepatic veins between the caudate lobe and the vena cava are either tied and divided or transected with a sealing devise such as the Ligasure or harmonic scalpel. There is usually a dominant caudate vein >5 mm and it can be preserved with a small vena caval patch so that it can be reconstructed in the recipient surgery to prevent venous congestion of the caudate lobe [44].

The confluence of the left and middle hepatic vein is dissected to its base at the entrance to the vena cava. This requires the ligation and transection of the left phrenic vein and careful mobilization of the confluence from the diaphragmatic attachments. A tape is then passed from the groove between the middle and right hepatic veins, and passed behind the hilar structures, to isolate the liver parenchyma from the vena cava and the hilar structures. This allows for the liver hanging maneuver, which can facilitate exposure, minimize blood loss, and guide the direction of parenchymal transection [45].

An intraoperative ultrasound is performed to delineate the anatomy of the middle hepatic vein. The location of the middle hepatic vein tributaries is also confirmed. Because the transection line is determined based on the anatomy of the middle hepatic vein and the gallbladder fossa, it is unnecessary to confirm the demarcation line by a temporary hemihepatic inflow occlusion. The line is marked with electrocautery on the right side of the middle hepatic vein coming caudad to the gallbladder fossa and down the undersurface of the liver on the left of the gallbladder fossa to the point of biliary transection. Parenchymal transection then proceeds with the surgeon's technique and tool of choice. Once the middle hepatic vein is identified, the parenchymal transection line is best at 1–2 mm to the right of the middle hepatic vein with a thin layer of liver parenchyma between the dissection plane and the vein proper. This can prevent bothersome bleeding from small branches of the middle hepatic vein. During the final parts of the parenchymal transection, both ends of the umbilical tape are pulled gently to give upward traction. The transection is then completed and hemostasis is completely obtained.

After administrating heparin, the left hepatic artery and left portal vein are both tied and transected. Subsequently, a staple

device is applied to the base of the left and middle hepatic vein, and the vein is transected on the graft side. The liver graft is immediately removed and flushed on the back table with cold preservation solution.

After the stump of the left hepatic duct is oversewn, a final cholangiogram is performed through the cystic duct to ensure the integrity of the remaining bile duct.

On the back table, the left lobe graft usually needs a venoplasty to optimize venous outflow. A septum between the left and middle hepatic veins is cut vertically and removed. The defect of intima is closed with a monofilament suture. This technique also helps enlarge the diameter of a venous orifice [46].

Right lobe graft (Figure 24.3c)

An upper midline incision with a right lateral extension is made. The round ligament is divided and then the falciform ligament is divided all the way up to the suprahepatic vena cava. After an evaluation of the abdominal viscera, the right triangular and coronary ligaments are divided. The left lobe should not be mobilized because unnecessary mobilization increases the risk of malposition of the remnant liver and can cause postoperative liver insufficiency in donors. The right lobe is rotated medially to mobilize it until the retrohepatic vena cava appears.

A cholecystectomy is performed and followed by a cholangiogram through the cystic duct. Hilar dissection is started at the right lateral aspect of the hilum. This allows dissection of the bifurcation of the hepatic artery without touching it to ensure an unperturbed blood supply to the common hepatic duct [47]. The right hepatic artery is dissected free. The right portal vein is then dissected. The caudate branch is tied and divided to ensure the necessary length for placing a vascular clamp when the liver graft is removed. The right hepatic duct is encircled with the hepatic hilar plate. After localization cholangiogram, the duct and hilar plate are transected sharply 0.5 cm from the bifurcation.

Attention is then returned to the caval dissection. The caval ligament is carefully isolated and divided. The short hepatic veins are divided on the right side of the vena cava. The groove between the middle and right hepatic veins is dissected and tunneled. The right hepatic vein is isolated and an umbilical tape is brought through this groove for the liver hanging maneuver (Figure 24.4a) [48]. The caudal end of the umbilical tape is passed behind the hilar structures to isolate the liver parenchyma from the vena cava and the hilar structures (Figure 24.4b).

The transection line is determined as for the left lobe graft. The parenchymal transection then proceeds in an identical fashion to that of the left lobectomy (see above). The only difference is that the significant V5 and V8 draining into the middle hepatic vein from the anterior segment needs to be preserved (see Anatomical variants above). These veins are tied on the remnant side and clipped on the right lobe side.

After the transection is complete and full hemostasis achieved, intravenous heparin is administered. The right hepatic artery is then tied and transected, as is the right portal vein. The right hepatic vein is then stapled vertically along the edge of the vena cava and sharply divided on the graft side. The liver graft is immediately removed and flushed with cold preservation solution.

The stump(s) of the right hepatic duct(s) are oversewn with monofilament suture. A final cholangiogram is performed through the cystic duct to confirm the integrity of the remnant bile duct.

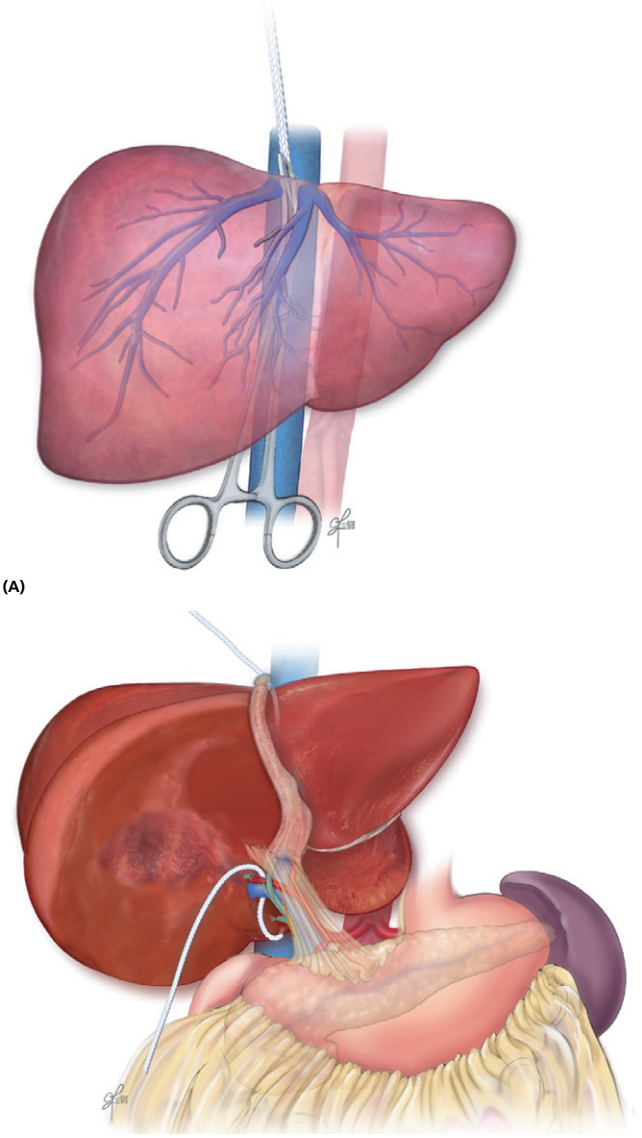

Figure 24.4. Liver hanging maneuver to facilitate parenchymal transection.

On the back table, the V5 and V8 are reconstructed if necessary. This technique provides a functional liver mass comparable to an extended right lobe graft with middle hepatic vein. A vascular graft is necessary for reconstructing the V5 and V8. Unused fresh iliac artery and vein grafts in deceased donor liver transplantation are a good source of vascular grafts. Autologous grafts such as the intrahepatic portal vein of a recipient native liver, inferior mesenteric vein, gonadal vein, and recannalized umbilical vein can be used with good patency [49]. If these are not available, cryopreserved vascular grafts from cadaveric donors are another alternative [50]. Excellent outcomes have been reported using expanded polytetrafluoroethylene (ePTFE) grafts for the V5 and V8 reconstruction [51]. In that series, the patency of ePTFE grafts was 80% at 1 month and 40% at 4 months. Recipients with early obstruction of the ePTFE graft had significant congestion in the anterior

segment, but those with late obstruction were asymptomatic. Patient and graft survival rates were as good as those of the extended right lobe graft (with middle hepatic vein). As long as early patency is achieved, late venous graft obstruction seems to have no impact on congestion in the anterior segment or survival. Because there is no limit to the availability of artificial vascular grafts, they may be a useful alternative for anterior segment drainage.

Laparoscopic donor hepatectomy

Minimally invasive techniques have been successfully applied for living donor renal procurements, and their deployment has made the procedure more appealing to many potential donors. In general, minimally invasive surgery promises better pain control, shorter length of hospital stay, quicker functional recovery, improved cosmesis, and lower risk of surgical complications. In fact, since the introduction of laparoscopic donor nephrectomy [52], the benefits of the laparoscopic procedure (described in Chapter 23) have been widely conceived and this technique has rapidly become the standard for living donor kidney transplantation worldwide [53,54]. It has been proven to be relatively safe, although there have been reports of sporadic donor deaths from faulty clip application to the renal artery [55]. In attempts to follow in the footsteps of minimally invasive renal procurement, some centers began performing laparoscopic-assisted living donor hepatectomies. These techniques include laparoscopic and hand-assisted laparoscopic surgery.

With respect to laparoscopic liver surgery, many reports have suggested its safety and feasibility for resection of benign and malignant liver tumors. With the development of laparoscopic liver surgery, its application for living donor hepatectomy has been raised and the first attempt was made for a left lateral segmentectomy in France [56]. This report was followed by a successful series of 16 donors [57]. More recently, a Korean group reported 11 donors who underwent a laparoscopic left lateral segmentectomy; they achieved shorter hospital stay and earlier oral diet without surgical complications when compared to those with conventional open donor hepatectomy [58].

The first laparoscopic-assisted donor right hepatectomy was reported from Northwestern University in 2006 [59]. Four donors successfully underwent a laparoscopic-assisted procedure without complications. Another Korean group reported nine laparoscopic right donor hepatectomies with the only major surgical complication being an intra-abdominal abscess in one patient [60]. Further, a Japanese group reported 13 successful laparoscopic hemiliver procurements, including three right hepatectomies. They used a gasless abdominal wall-lifting technique rather than pneumoperitoneum to reduce the risk of air embolism [61].

With regard to the surgical technique, pure laparoscopic donor hepatectomy is rarely performed. Instead, the "hybrid" technique is commonly used. This technique consists of a hand-assisted laparoscopic mobilization of the liver followed by an open technique to perform hilar dissection, parenchymal transection, and graft retrieval. In addition to small port incisions, this technique requires a 10–12-cm long epigastric midline incision for a hand port and graft extraction. By avoiding a subcostal incision, the hybrid technique may reduce donor pain and morbidity and shorten the recovery time.

Despite the recent reports of these techniques, surgical stress on living donors seems to be dependent on the amount of liver volume removed. In addition, there remains concern over the ability to rapidly control inadvertent hemorrhage through a small incision if it should occur. Therefore, it appears that routine application of this approach is still controversial. The combination of extensive experience both in laparoscopic surgery and conventional donor hepatectomy is essential to the successful application of this approach. Further careful assessment and discussion will be needed to reach a general consensus [62,63].

Perioperative donor management

On the day prior to planned surgery, the transplant team meets to go through a final checklist to assure the evaluation is complete and nothing has been overlooked. A "huddle" should be performed routinely just prior to the induction of anesthesia to make sure the entire team is fully ready and all equipment is available. If deficiencies are found at either meeting, further evaluations should be performed and the procedure postponed or aborted.

Living liver donors should receive intensive care immediately and for about 24 h after the surgery. Close monitoring of vital signs is essential and laboratory data should be periodically checked. After thorough assessment by the transplant team, the donor is allowed to be transferred to the regular transplant nursing floor where the medical staff is familiar with the care of liver resection and liver transplant patients. These teams should be familiar with common complications associated with donor surgery such as intra-abdominal bleeding, wound infection, acute renal failure, gastric distension, electrolyte imbalance and deep venous thrombosis. Both the intensive care unit and regular nursing floor should have appropriate monitoring in place to detect these complications before they cause significant problems. Donors with unexpected changes in vital signs and laboratory data require immediate evaluation.

A multidisciplinary team lead by an attending transplant surgeon examines and assesses the donor on a daily basis until the day of discharge. Pain management is a major issue that needs to be addressed. Epidural anesthesia can provide good pain management, but there is a risk of complications such as acute spinal compression secondary to a hematoma [64–66] and a case of paraplegia has been reported. Instead of epidural analgesia, intravenous patient-controlled analgesia is a choice in the early postoperative days. Some centers, including our own, prefer to use a very short course of narcotics (24 h) followed by ketorolac (Toradol). Since prolonged use of narcotics increases the risk of complications, early switching to non-narcotics is strongly recommended.

The transplant surgeon should perform outpatient follow-up to check wound healing, signs of infection, and recovery of liver function. Any abnormalities in the physical examination and laboratory data should be further evaluated. Liver function tests should be monitored at least until they normalize. The donor should have some sort of imaging study to confirm adequate liver regeneration and to rule out any surgical complications, including bile leak, biliary stricture, thrombosis, and fluid collection. Without clinical indications, imaging studies do not need to be repeated.

Comprehensive and accurate follow-up data on living donors are critical to ensuring their safety. Currently, the United Network for Organ Sharing (UNOS) requires transplant centers to submit information about the status of each living donor for a minimum of 2 years after donation [67]. Follow-up protocols may vary among

programs, but most centers continue to follow donors annually unless they have any complications.

Donor complications

Despite donor safety being of paramount importance, finite morbidity and mortality rates have been reported worldwide. While the systematic utilization of right lobe grafts allowed for the rapid expansion of adult-to-adult LDLT with good outcomes in recipients, it soon became clear that there was far more morbidity and mortality in right lobe donors compared to left lobe donors. The reported rates of donor complications after left lateral segment, left lobe, and right lobe donation are approximately 15%, 25%, and 35–40% [8,9,37,68,69]. The estimated donor mortality rate is 0.1% for left lobe and 0.5% for right lobe donation [10]. The difference in morbidity and mortality between left lobe and right lobe donation can be attributed to two factors: (1) leaving a larger functional liver remnant after left lobectomy and (2) the commonly encountered multiple bile ducts after right lobectomy. The advantage of a single bile duct should not be overlooked because morbidity in right lobe recipients is often caused by complications associated with multiple bile ducts.

It is important to report these complications according to the Clavien system, which scores them according to five categories of severity (Table 24.2) [70]. Despite this, reported complications vary significantly among different programs, possibly due to different experience or reporting methodology.

Biliary complications represent the most common morbidity occurring in living liver donors. Wound infection is the second most common complication. Vascular complications are less common, but are accompanied by significant morbidity and mortality. Gastric stasis is rare (3%), but severely compromises quality of life in the left lobe donor [9]. Complications associated with anesthesia and postoperative recovery (deep vein thrombosis, pulmonary embolism, etc.) have been reported. These risks must be discussed in detail with donors and their families when considering LDLT and during the consent process. Some donors require social and psychological supports either in the early or late stage after donation [71,72]. Social workers and psychiatrists play an important role in supporting and treating them. Medical treatment may need to be considered in donors with significant problems. Close communication between the transplant team and the donor's primary care physicians is also important in taking best care of these issues.

Table 24.2. Classification of complications according to the Clavien system

Grade 1	Any deviation from the normal postoperative course without the need for pharmacological treatment or surgical, endoscopic, and radiological interventions. Allowed therapeutic regimens are drugs such as antiemetics, antipyretics, analgesics, diuretics, electrolytes, and physiotherapy. This grade also includes wound infections opened at the bedside
Grade 2	Complications requiring pharmacological treatment with drugs other than those allowed for grade 1 complications. Blood transfusions and total parenteral nutrition are also included
Grade 3	Complications requiring surgical, endoscopic, or radiological intervention
Grade 3a	Intervention not under general anesthesia
Grade 3b	Intervention under general anesthesia
Grade 4	Life-threatening complications (including central nervous system complications) requiring intensive care unit stay
Grade 4a	Single organ dysfunction (including dialysis)
Grade 4b	Multiorgan dysfunction
Grade 5	Death of the patient

Summary

Living donor liver transplantation has evolved to become a viable, albeit ethically and technically complex, option for patients with end-stage liver disease. The primary factors driving its successful implementation are proper donor selection and exquisite attention to the anatomical details of the procedure. Careful consideration of the impact of the hepatectomy on the donor and its adequacy for the recipient must be made well in advance of the procedure, with continued assessment intraoperatively. The ideal graft provides the donor with a future liver remnant exceeding 35% and the recipient with a graft-to-recipient weight ratio of >0.8%, simultaneously. In general, living donation remains an open procedure, although laparoscopic approaches are being explored. Perioperative management by a multidisciplinary team is important, and the practice of LDLT should be limited to dedicated, properly trained and resourced teams. Its implementation in the near term will be governed by the availability of such teams and the shortage of deceased donor organs.

CHAPTER 25

Abdominal Organ Preservation and Resuscitation

Henri G.D. Leuvenink[1] and Rutger J. Ploeg[1,2]

Introduction

Modern organ transplantation, particularly deceased donor transplantation, is dependent on methods to maintain the viability of explanted organs until their ultimate revascularization in the recipient. Indeed, the quality of preservation is a major factor dictating subsequent graft function, and almost all of the innovations in organ allocation are made possible by the ability to preserve organs for significant periods of time. This chapter will introduce the prevailing concepts that have emerged as important in organ preservation, and highlight clinical data supporting the preferred methods of abdominal organ preservation and transport. It complements Chapter 26, which covers similar concepts adapted to the unique requirements of thoracic organs. Both of these chapters introduce the emerging concepts involved in organ resuscitation: the maneuvers used to improve the quality and function of an organ while it is ex vivo. Indeed, this later concept represents the future, in that the expectations that organs can merely be preserved in their previous state are giving way to a realization that organs can in fact be improved over time and made more suitable for transplantation through ex-vivo manipulation.

Factors shaping the development of modern organ preservation

In the early days of clinical transplantation, donor and recipient were within the same hospital and in the majority of cases in adjacent operating theatres. This allowed the direct transfer of the organ to be transplanted and hence no method of preservation was necessary beyond the flush-out of blood. As programs have developed into national and even international schemes, the preservation period has become longer to facilitate transportation of the organ from the donor to the recipient as well as HLA tissue matching to reduce the chance of graft failure due to rejection. Adequate preservation during this period is essential to ensure that a functional organ with life-sustaining potential is implanted at time of transplantation. A simple method was therefore adopted to bridge the organ from donor explant to recipient transplant: that of rapidly cooling and storing the organ on ice. However, this hypothermic and hypoxic preservation is not without its harmful side-effects, and preservation methods have been designed to counteract these mechanisms of tissue damage. In addition, in the past decade the type and condition of organ donors have significantly changed, with for example more older, hemodynamically unstable and even non-heart beating donors.

Maintaining organ viability during preservation is an important prerequisite for successful outcome after transplantation. Currently, most centers use static cold storage to preserve organs. This preservation method, however, was developed in an era characterized by the availability of younger and higher quality donor organs [1]. The increasing gap between those who need organ transplantation due to end-stage organ failure and the number of high quality organs available from deceased donation after brain death (DBD) forced the transplant community to accept organs from alternative sources. For kidney transplantation, the living donor program has partially bridged this gap in many countries. For other organs, this type of donation is either impossible or with carries a substantial risk for the donor.

Given the lower availability of high quality donors and the persistent need for transplantable organs, acceptance criteria have been continuously extended. These extended criteria donor (ECD; covered in depth in Chapter 53) organs are DBD transplants and the average recipient survival, graft survival, and organ function are inferior when compared to transplant of standard criteria DBD organs. A DBD kidney is considered to be an ECD organ if the estimated adjusted relative risk of graft failure is $\geq$1.70. The donor characteristics of an ECD kidney include age >60 years, or age 50–59 years plus two of the following features: cerebrovascular accident as the cause of death, pre-existing hypertension, or terminal serum creatinine >1.5 mg/dL. The characteristics of an ECD liver are age >60 years, cold storage time >12 h, extent of steatosis as measured histologically, and use of vasopressors.

The increased use of these types of donors in kidney transplantation resulted in an increased incidence of delayed graft failure (DGF) from 15% in the late 1980s to >25% in the latest reports from the Organ Procurement and Transplantation Network (OPTN). DGF has been shown to negatively affect graft survival with a relative risk of 1.7, leading to 15% reduction in survival compared to standard criteria donors (SCDs) after 1 year.

In an attempt to further increase the donor pool, especially in recent years, the use of donation after circulatory death (DCD;

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

discussed in Chapter 22) has increased. DCD donors are categorized according to the Maastricht criteria. Whilst in most countries only Maastricht category 3 donors or controlled DCD are used, some countries introduced the concept of uncontrolled DCD (categories 1 and 2). The controlled DCD donors are patients with extensive irreversible brain injury where further medical treatment is futile, however, they do not meet the criteria for brain death. As a consequence of withdrawal of ventilation support, the patient will die due to cessation of circulation with cardiac arrest. After a period of "no touch," organs can be retrieved and preserved.

Uncontrolled donors do not suffer from brain injury but die after unsuccessful resuscitation after their primary cardiac arrest. In both controlled and uncontrolled situations, there are substantial warm ischemic periods that lead to injury of the potential graft.

Kidneys from DCD donors have a higher risk of primary nonfunction (PNF) and suffer from DGF. Interestingly, despite the higher incidence of poor function after transplantation, long-term graft survival is equivalent or only slightly lower than that for kidneys derived from DBD donors, which could be due to selection.

The use of DCD donors is less accepted in renal transplantation than in renal transplantation due to inferior outcomes and frequent biliary complications leading to retransplantation. Some centers, however, have equivalent outcomes for DBD and DCD liver transplantation, indicating that with proper donor management and adequate preservation techniques these donors can be a good source to reduce mortality on the waitlists.

Principles of cold preservation

After circulatory arrest, tissue metabolism continues for some time; however, the absence of oxygen and nutrients rapidly leads to major metabolic problems within renal cells. The suppression of metabolism is therefore essential to maintain organ viability during the preservation period.

The reduction in metabolic rate in biological systems as well as chemical reactions is dependent on the reduction in temperature. The Q10 temperature co-efficient is a measure of the rate of change of a biological or chemical system as a consequence of decreasing the temperature by 10 °C [2]. Applying this to organ preservation, this means that reduction of the core temperature of an organ to 4 °C will reduce the metabolism to approximately 10% in the majority of cells and will diminish enzyme activity (Figure 25.1). Calne et al. showed that simply cooling of kidneys in ice water preserved renal function for 12 h [3]. The development of preservation solutions that targeted harmful pathways during cold preservation enabled longer storage times and preservation quality improved [4]. Despite the beneficial concept of hypothermia, unwanted side-effects in the

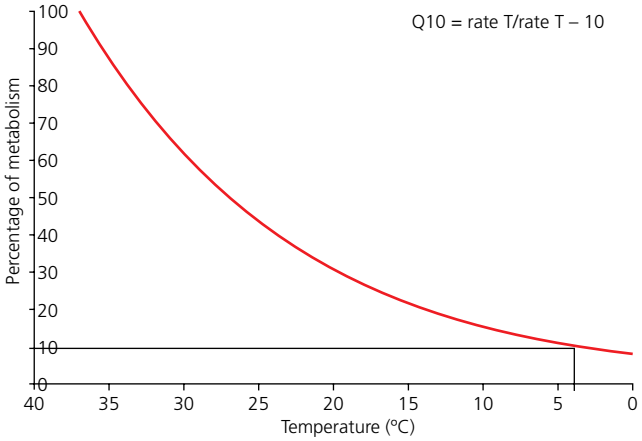

Figure 25.1. Relationship between temperature and metabolic activity.

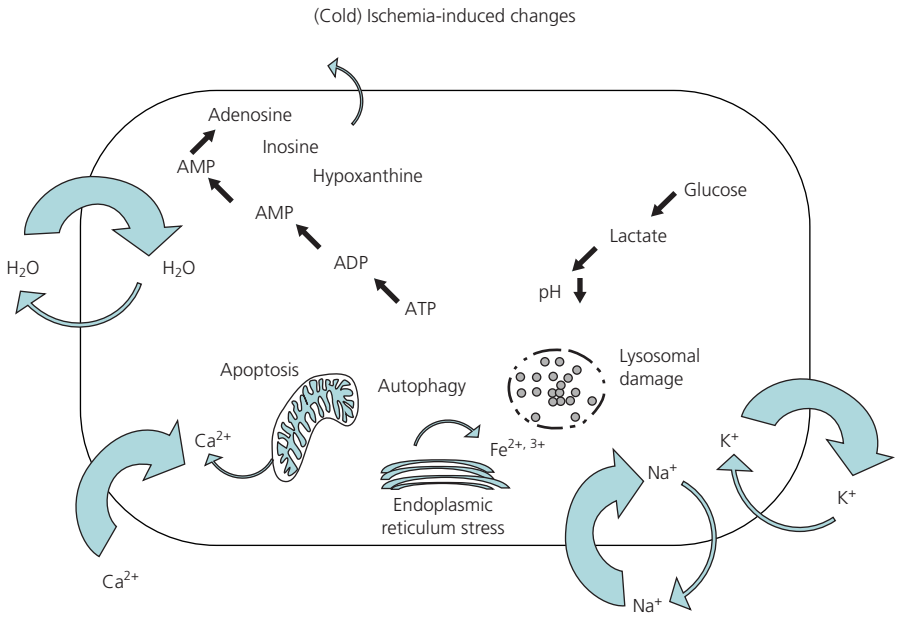

Figure 25.2. Negative effects of cold ischemia: breakdown of ATP, acidosis, release of lysosomal enzymes, endoplasmic reticulum stress, increased Na^+ and Ca^{2+} influx into the cell, and subsequent cell swelling.

preserved organ still occur (Figure 25.2). These effects can only be partly be counteracted by preservation solutions.

Energy and acidosis

Tissue hypoxia during organ preservation results in a rapid fall in intracellular adenosine triphosphate (ATP) levels. Even at temperatures as low as 0–4 °C, cellular ATP content is rapidly depleted and cells switch to anaerobic metabolism to support cellular processes. This leads to a much less efficient production of ATP, but also to the production of lactic acid and acidosis [5,6]. The contribution of acidosis to ischemic injury is pH dependent. Severe acidosis activates phospholipases and proteases, causing lysosomal damage and eventually cell death [7–9]. Mild acidosis (pH 6.9–7.0), however, has been suggested to have a protective effect by inhibiting phosphofructokinase, the rate-limiting step in glycolysis [7,8]. Adequate control of pH is therefore an important function of preservation solutions.

Cell swelling

The changes in cellular structures observed during preservation are cell swelling and formation of protruding pockets [9]. The mechanism underlying these changes is the impaired activity of the Na^+/K^+-ATP-dependent pump. As a result, sodium excretion is reduced and sodium passively enters the cell, attracted by the negative charge of cytoplasmic proteins. This creates a hyperosmolar intracellular environment and subsequently an influx of water. To re-establish the disturbed Donnan equilibrium and to prevent cell swelling, impermeants and colloids are added to preservation solutions.

Effective impermeants are saccharides and non-saccharide anions. Molecular size determines the success of extracellular impermeants in preservation solutions, with larger molecules being the most successful [10–12]. Colloids such as starches are large molecules that are retained in the vascular compartment.

Reactive oxygen species

Reactive oxygen species (ROS) are generated by several processes in ischemic and post-ischemic reperfused organs [13]. An extensively studied generator of ROS is xanthine oxidase, which simultaneously produces hydrogen peroxide (H_2O_2) and the superoxide anion (O^{2-}) [14]. The subsequent reduction of H_2O_2, catalyzed by iron, leads to hydroxyl radical formation (OH^-). ROS react rapidly with other molecules, which results in severe damage to lipids, nucleic acids, and proteins during reperfusion, the ischemia–reperfusion injury (IRI) [15,16]. In addition to xanthine oxidase, which in human renal transplantation may be of minor importance since it is not abundant in human cells, in contrast to rodents [17], several other sources of ROS are important. Infiltration of the graft by leukocytes after reperfusion results in the production of mainly superoxides (known as the respiratory burst).

Mitochondrial malfunctioning resulting from partial reduction of the respiratory chain is an important contributor to ROS formation after reperfusion. The formation of ROS has long been considered to contribute to cellular injury during the reperfusion phase but not during cold preservation) [15,16]. However, some reports suggest that oxygen radicals are formed during reperfusion as well as during cold preservation [18].

Calcium

In normal circumstances a large difference in free Ca^{2+} concentration exists between the intracellular and extracellular space fluids. This difference is maintained by active transport of Ca^{2+} by several ATP-dependent processes, including Ca^{2+}-ATPase and Na^+/Ca^{2+} exchanger [19]. During cold preservation, cellular ATP concentrations fall, leading to increased intracellular Ca^{2+}. Accumulation of Ca^{2+} in the cold phase will lead to activation of calcium-dependent processes, such as calpain activation and protein kinase C signaling. Calpain activation leads to loss of cell structure by breakdown of the cytoskeletal spectrin [20]. Calpain activity has been shown to be increased in cold stored hepatocytes, and further increased during rewarming [21].

Enzymes

Intracellular proteases are involved in the breakdown of proteins during preservation, most likely due to the absence of oxygen. Also, matrix metalloproteinases (MMPs) may be activated during cold preservation, leading to detachment of endothelial cells from the underlying matrix. This phenomenon has been predominantly studied in the liver, but also occurs in renal preservation [22,23]. To reduce this detrimental effect by blocking MMPs (especially MMP 2 and 9), the addition of the often disputed colloid, hydroxyethyl starch (HES), into the University of Wisconsin (UW) solution has been shown to play an important role [23].

Another relevant family of enzymes activated during cold preservation are apoptosis-related caspases [24–26]. During prolonged preservation, free iron is released from cytochrome P450 [27]. The release of free iron will, in combination with hydrogen peroxide, lead to severe production of ROS [28,29]. Recently, changes in autophagy fluxes have been postulated as a possible mechanism of increasing injury with increasing cold ischemia times. Although most studied in the liver [30,31], preclinical work indicates that autophagy may also be important in kidneys [32]. In relation to this, Minor et al. [33,34] have also postulated that endoplasmic reticulum stress might be involved in cold ischemia-induced injury. Peralta and Brenner subsequently confirmed this [35].

As described above, during cold preservation, cellular homeostasis is no longer sustained. Major derangements are shifts in electrolytes, changes in pH, intracellular enzymes and proteins, and increase in intracellular water. Preservation solutions are therefore composed to counteract these processes.

Hypothermic storage

With the establishment of kidney transplant programs, the need for preservation became evident. Belzer and his team thought that continuous cooling of the kidney throughout the preservation period would be the most natural way to do this and showed good results. Due to the hydrostatic pressure and the absence of cellular mechanisms counteracting fluid entrance into the interstitial space and cells, tissue edema was a serious problem. This edema was counteracted by using fluids including oncotic agents. For this purpose, human albumin or cryoprecipitated plasma was used. Belzer and Southard later developed a synthetic machine perfusion (MP) fluid (Belzer MPS) that would eventually also provide the basis for the UW cold storage solution. The complexity of the procedure initiated the search for alternative and easy methods. Many different solutions were tried, varying in complexity and efficacy. With the development of better preservation solutions, most centers now use cold storage as their main preservation methods, although recently hypothermic machine perfusion (HMP) has gained renewed interest as a result of the use of ECD and DCD donors.

Table 25.1. Composition of preservation solutions

		EC	UW	HTK	HOC	Celsior	IGL-1

Composition of clinically used cold storage solutions

Numerous preservation solutions have been evaluated for the static cold storage of kidneys for transplantation [36]. They differ considerably in terms of their chemical composition (Table 25.1). A few examples of the most important solutions in international clinical practice are described below.

Eurocollins solution

The first static cold storage solution was developed by Collins in the late 1960s [37,38]. A minor modification by the Eurotransplant Foundation in 1976, eliminating magnesium, resulted in the Eurocollins (EC) solution that was used mainly in the era before the UW solution had been developed.

EC solution is a simple intracellular-like preservation solution. Phosphate is used for pH buffering and glucose serves as the osmotic agent. As glucose is able to cross the cell membrane, EC solution provides a source for ATP and lactate in an anaerobic environment, reducing its effectiveness against impermeants after a number of hours [39,40]. Most centers have now switched to using the UW solution.

University of Wisconsin solution

Continuous and systematic research by Belzer and Southard in the 1980s led to the development of the UW solution and its clinical introduction in 1987. Metabolically inert substrates such as lactobionate and raffinose serve as osmotic agents (Table 25.1). HES is used as a colloid. The colloids were originally added to hypothermic machine preservation solutions to prevent tissue edema due to hydrostatic pressure. Belzer and Southard used diafiltrated HES in UW solution as they originally aimed at developing one solution suitable for both cold storage and HMP. The feasibility of HES as a colloid in UW solution has been extensively debated. HES prevents interstitial edema and has a beneficial effect on MMPs, but increases viscosity [41,42]. Analyzing the effect of HES on red blood cells (RBC), several authors have shown an increased RBC aggregation when large molecular weight HES is present [41,42]. This effect could partially explain the slower washout of blood and initially patchy reperfusion of organs when UW solution is used [43]. In UW, the compounds allopurinol and glutathione (GSH) are included to prevent formation of ROS. Allopurinol inhibits xanthine oxidase, which improves kidney preservation, while liver or pancreas preservation are almost unaffected [44,45].

GSH is a tripeptide that has free radical trapping properties. This important antioxidant is oxidized to glutathione disulfide together with converting peroxides. Experimental studies have shown the importance of GSH in models of both renal tubular injury and isolated perfused liver [44,46]. In the absence of GSH, less ATP was generated and more lactate dehydrogenase (LDH) was released [44,46]. Subsequent studies have shown the benefit of GSH after kidney transplantation and that GSH is especially important in long-term liver preservation [46].

To date, UW solution is considered the gold standard preservation solution for the kidney, liver, pancreas, and small bowel [39,47–53].

Histidine–tryptophan–ketoglutarate solution

Histidine–tryptophan–ketoglutarate solution (HTK) was initially introduced as a cardioplegic solution in open heart surgery by Bretschneider in the 1970s [54,55]. The basic design is that of a very potent buffer: histidine combined with two amino acids (Table 25.1). Tryptophan serves as a membrane stabilizer and antioxidant, through its oxidative metabolites in the kyunerine pathway, such as 5-hydroxy-tryptophan [56,57], while ketoglutarate acts as a substrate for anaerobic metabolism during preservation [58]. Tryptophan protects the organs against ROS-mediated damage. Mannitol

is a slightly larger monosaccharide than glucose, but unlike glucose it cannot be metabolized and does not pass through the cell membrane easily. Furthermore, it is added for its beneficial effect as a free-radical scavenger. . In a cultured rat hepatocyte experiment, the amount of thiobarbituric acid reactive substances (TBARS) as a marker for ROS-mediated injury was measured. After 24-h preservation TBARS were significantly higher in HTK solution compared to UW solution preserved hepatocytes, suggesting superior antioxidant capacity of UW solution due to the combination of GSH and allopurinol [59].

HTK solution has a low viscosity and to achieve complete tissue equilibration according to Bretschneider, high volumes (~15 L) have to be rinsed through the organs at low flow rates.

Hyperosmolar citrate solution

Hyperosmolar citrate (HOC, also known as Marshall's solution) is used for renal transplantation primarily in the UK and Australia [60,61]. HOC solution is a citrate/$NaHCO_3$-buffered solution with mannitol as the impermeant. Due to its composition as a hypertonic solution, HOC solution prevents the entry of fluid into cells [62] and has been shown to be effective in experimental kidney preservation [38].

Celsior solution

Celsior solution was developed initially for cardiac preservation in the early 1990s. It is similar to UW solution in composition and it has since proven to be of use in the preservation of kidneys, liver, and pancreas [40,48,63–73]. Unlike UW, it has a high sodium content (100 mM) and low potassium content (15 mM), and is relatively low in viscosity, as it does not contain HES. It combines the inert osmotic agent philosophy of UW solution together with the strong buffering capacity of HTK solution. Furthermore, Celsior solution contains lactobionate and mannitol as impermeants, along with reduced glutathione as an antioxidant.

Institut-Georges-Lopez-1 (IGL-1) solution

The HES controversy initiated a search for other colloids, e.g. dextran and polyethylene glycol (PEG) [71,72,74–77]. The high viscosity associated with HES, as well as its tendency to cause red cell aggregation in animal experimental models [42,64] and in vitro [41,65,72,78], justified the search for alternatives such as PEG. PEG is a neutral, water-soluble, non-toxic polymer. Although chemically not a true colloid, it acts like a colloid by the binding water. In addition, PEG can bind to cell membranes and create layers of "structured water." This induces a type of immune camouflage by interfering with the identification of the graft as foreign by cells of the immune system [79,80]. PEG prevents the activation of reperfusion-induced inflammation, which can have a long-term effect on graft outcome, particularly through interference with danger signal production. Several studies, both experimental and clinical, have now confirmed the efficacy of PEG for liver [55,81,82], kidney [83,84], pancreas [85], small bowel [86], and heart preservation [87].

Clinical use of hypothermic preservation

It is difficult to answer the question as to which solution provides the best preservation method using cold storage. The use of a preservation solution is a matter of availability, cost, and "couleur locale." Even in kidney transplantation, only a limited number of high-quality randomized controlled trials (RCTs) have been performed [36].

This following section describes preservation methods for the different organs.

Renal preservation

Nowadays, static cold preservation is the most prevalent storage methods irrespective of the donor type. With the exception of the US, where approximately 20% of kidneys from deceased donors are pumped, most countries primarily use cold storage. While the preservation solution is almost exclusively Belzer MPS for CS, more variation is seen for pump perfusion, with HTK and UW solutions being most commonly used. Since the early 1990s, UW solution has been the gold standard in kidney preservation, replacing EC solution in Europe as the preferred solution. This was the result of a RCT comparing EC solution with UW solution and showing that DGF was significantly lower in the UW group (23% vs. 33%). Also, 1-year graft survival was found to be significantly higher in the UW group [63,88]. Shortly following this trial, another RCT in the same Eurotransplant region showed that HTK solution was superior to EC solution in reducing DGF, but without an effect on graft survival. In the same study, no difference were found between HTK and UW solutions. Registry analysis, however, indicates that UW solution is associated with a lower incidence of PNF and risk of graft loss, particularly when storage times are >18 h..

A multicenter randomized prospective trial comparing UW versus HTK solution in kidney preservation showed equal results in terms of the incidence of DGF (33% vs. 33%) [49,74]. For prolonged cold storage times with HTK solution (>24 h), however, little data are available. One single-center study reported a significantly higher incidence of DGF with HTK solution than UW solution (50% vs. 24%) when cold ischemia time was >24 h [86,89]. The opposite was reported in a more recent study, with much a higher DGF rate associated with HTK solution than with UW solution (56% vs. 16%) [87,90]. Direct comparison of these conflicting findings is impossible due to the different definition of DGF in each of the studies.

Other solutions that were tested against UW solution are Celsior solution and IGL-1 solution, which both can be considered "look-alikes" of UW. Celsior solution was shown in relatively small studies to be comparable to UW solution in terms of DGF and graft survival [40,64,91]. In a small cohort study comparing IGL-1 and UW solutions, no differences were found in DGF or graft survival. Postoperative serum creatinine levels, however, were lower in IGL-1 solution stored kidneys, possibly related to the presence of PEG in that solution [84].

A recent systematic analysis in the UK of preservation solutions used in clinical practice revealed no major differences in transplant outcome between HOC and UW solution or HOC and Celsior solutions [92], although recent work by Kay et al. in experimental transplantation showed more edema in kidneys flushed with HOC solution compared to UW solution [93].

With the increasing use of more marginal kidneys from ECD and DCD donors, a re-emergence of interest in hypothermic machine perfusion (HMP) has been seen. Retrospective data from UNOS showed it had a beneficial effect in reducing DGF, especially in high-risk groups [73]. A large meta-analysis from Wight et al. concluded that HMP results in a 20% decrease in DGF. Retrospective analysis from the US registry also showed it improved DGF rates

and graft survival [75]. Although indicative only, recent Level A evidence became from the Machine Perfusion (MP) trial, was executed in the Eurotransplant region, showed that HMP is beneficial for SCDs, ECDs, and DCDs; the rate of DGF was lower and 1-year and 3-year survival were better [76,77]. Interestingly, the impact of DGF on graft survival seemed to be lower in MP stored kidneys. In an extension of the MP trial, Treckman et al. reported reduced risk of DGF and improved 1-year graft survival and function in ECD kidneys [78].

Jochmans et al. concentrated on DCD donors (all Maastricht category 3) and showed that HMP was associated with a reduced risk of DGF and better early graft function up to 1 month after transplantation. DGF rates decreased from 70% to 54% and graft survivals were identical [80]. In contrast to this study Watson et al. in a study in the UK were unable to show any effect of MP on outcome of DCD kidneys [94]. A likely explanation for the differences observed in the UK and the Eurotransplant region is that in the UK study kidneys were cold stored prior to pumping. In the UK study, similar DGF rates were found in both arms (56% vs. 58%), rates that are comparable to the those found in the Eurotransplant trial. In a study by Hosgood et al., renal resistance of kidneys that were pumped immediately following their retrieval was lower than the resistance of kidneys that were put on the machine after hours of cold storage [95]. The relationship between renal resistance (RR) and DGF has been noted by many centers pumping kidneys and is frequently given as a reason to discard kidneys. In the MP trial where researchers were blinded for RR, the relationship between RR and DGF was confirmed with a high odds ratio; however, predictive value was poor and the authors therefore concluded that RR as a stand-alone quality assessment tool cannot be used to predict outcome with sufficient precision [96,97].

Another potential interesting application of MP is in the use of perfusate biomarkers for selection or predictive value of outcome. The most used and measured biomarker is glutathione-S-transferase (GST), an enzyme localized in the renal tubules. It is involved in deconjugation of waste products and excreted into the urine [97]. Total GST has been shown to reliably reflect renal tubular injury and correlates with warm ischemia time [98,99] and with DGF [97]. In the latter study, NAG and H-FABP were independent predictors of delayed graft function, but not of primary non-function and graft survival. Other potential biomarkers, like lactate dehydrogenase, aspartate aminotransferase, and alanine-aminopeptidase, have no independent prognostic potential for any of the endpoints. Perfusate biomarker concentrations had no relevant correlation with cold ischemic time or renal vascular resistance on the pump [97].

Liver preservation

Similar to renal preservation, cold storage became the preferred preservation method for the liver. The solutions used are also similar to those used for kidney preservation, and for a long time UW solution has been used by most centers, although HTK and Celsior solutions are increasingly used [100]. It was shown that with the preservation capacity of UW solution was equal to that of HTK solution or Marshall's solution, even with longer preservation periods [101–103]. Graft survival and immediate function were improved and UW solution quickly became the preservation solution of choice. In liver transplantation, no high quality studies are available comparing preservation solutions; many of those that have been published have <100 cases in one arm and thus are likely to be underpowered. Most studies have found similar outcomes when comparing HTK and UW solutions, although some studies suggest that HTK solution is more effective for biliary tract flush and prevention of biliary complications [53,104–108]. Retrospective analysis from the UNOS database and a number of recent single-center reports, however, indicate that HTK solution is associated with a higher risk of graft loss, in particular with cold ischemia times longer than 8 h and in DCD donors [109].

The indication that UW solution might be less efficient in preserving the biliary tree can be attributed to the higher potassium content in UW, which results in vasospasm. Alternatively, the type of colloid may also be of relevance. HES has been shown to form aggregates with red blood cells of up to 5 μm^2 in size, which is large enough to block small capillaries [41]. In IGl-1 solution, potassium levels are low and HES is substituted for PEG. In a controlled trial in France, however, comparable results to the standard of care were found, although no report on bile flow or bile composition was given [81].

Comparisons between Celsior and UW solutions showed no differences in PNF rate or graft survival at 1 and 3 years [48,64,70,91,110]. Recently, Garcia-Gil et al. reported a reduced incidence of post-reperfusion syndrome, defined as a decrease in the mean arterial pressure of $>30\%$ of the baseline value for more than 1 min during the first 5 min after graft reperfusion, from 21.6% in the UW solution preserved group to 5.9% in the Celsior solution preserved group [40]. In the same study, no effect on 5-year graft survival was seen. In the same study, HTK and Celsior solutions were compared and showed similar outcomes [40].

Following the developments in MP with kidneys, there also has been renewed interest in the MP of livers. As elegantly summarized by Monbaliu et al., liver perfusion is more complex than kidney perfusion [111]. Factors like hepatic and portal flow competition, exclusive arterial supply to the biliary tree, susceptibility of hepatic sinusoidal endothelial cells, and high metabolic rate of the liver are complicating issues in MP of the liver [33]. Several groups, building on the legacy of Starzl, Belzer, and Bretschneider in the 1960s, are developing new concepts applicable to liver perfusion [112–115], and novel systems that show efficacy in MP in preclinical studies are on the edge of entering the clinical arena. The first and only recently published clinical study using hypothermic liver preservation was performed by Guarera et al. with a home-built MP set-up in 20 patients; the results are encouraging. Peak serum injury markers were lower in the HMP preserved livers and early allograft dysfunction was reduced from 25% in cold stored livers to 5% in HMP stored livers ($P = 0.08$) [116].

Larger studies, however, will be needed to show the benefit of HMP in liver preservation, especially in ECD and DCD donors. Remaining questions about flow rates and perfusion pressures, rate of oxygenation, single or dual vessel, composition of the perfusion fluid, and, probably most debated, perfusion temperature are still under investigation.

Pancreas preservation

Preservation of the pancreas can be divided into two parts, i.e. preservation of the whole pancreas and preservation of islet cells. In clinical practice a pancreas considered unsuitable for whole pancreas transplantation is used for the isolation of islets (details of islet production and preservation are covered in Chapter 61). For both whole pancreas transplantation and isolated cell transplantation (ICT), static cold storage is the predominant method of preservation. Whole organ preservation of the pancreas has almost

exclusively been performed with UW solution since it was developed by Southard and Belzer and proven to be a successful preservative even before it was applied in other organs [117]. Recently, reports have suggested that other preservation solutions may be effective alternatives to UW.

Comparisons between HTK and UW solutions are mostly retrospective and/or single center observations. The only somewhat larger RCT performed by Schneeberger et al. reported equivalent outcome in graft survival and graft function [118]. In a registry data analysis of 4392 pancreas transplantations, it was found that use of HTK solution was an independent risk factor for graft loss (hazard ratio 1.30; $P = 0.014$), especially with cold ischemia times of >12 h (hazard ratio 1.42; $P = 0.017$). Some authors also report higher rates of graft pancreatitis, possibly due to high volume use of HTK solution leading to edema [119,120].

The first prospective RCT comparing UW solution (n = 50) with Celsior solution (n = 50) for clinical pancreas transplants demonstrated that Celsior and UW solutions had similar safety profiles for pancreas preservation. A smaller RCT from Brazil of only 30 transplants found no differences [65]. A retrospective analysis from Italy indicated that EC solution is comparable to UW solution in respect to surgical complications [121]. Another study comparing Celsior solution (n = 28) with UW solution (n = 44) for pancreas preservation demonstrated that 2-year recipient survival rates, 2-year graft survival rates, pancreas leakage rates, and clinical graft pancreatitis rates were similar in both groups [67].

Preservation of pancreatic tissue with the aim to isolate islets is mostly performed using UW solution, although other methods and solutions are available. A meta-analysis by Kaddis et al. from 2010 revealed that storage in UW solution improves outcome [122]. A recent report from the University of Illinois at Chicago indicated that HTK and UW solutions produce a similar islet yield [123]. Likewise, a report from Geneva retrospectively analyzing 376 islet isolations from pancreases flushed and transported with IGL-1 solution (n = 95), UW solution (n = 204), or cold storage (n = 77) showed no differences in islet graft function [124].

Report of HMP of the pancreas is limited to that by Leeser et al. Four human pancreata were procured from deceased donors and HMP was compared with cold storage using UW. This pilot study indicated that low-flow pulsatile MP of the pancreas with prolonged cold ischemia time could result in excellent yield, viability, and function. Experimental studies in pigs also indicate improved preservation and yield with MP [125].

The two-layer method (TLM) is almost exclusively used in pancreas preservation. In the TLM, the pancreas is directly oxygenated by perflurocarbon during reservation and this maintains a high level of adenosine triphosphate (ATP) in tissues, which is thought to be due to the maintenance of cellular integrity and retention of parenchymal and non-parenchymal viability [20,59,126,127]. Most studies report a beneficial effect of TLM, although two recent large-scale studies showed no beneficial effect of TLM or storage on human islet isolation and transplantation [126,128].

Small bowel preservation

Preservation of intestinal grafts is adequate but most likely not optimal [129]. Preservation of the intestine is difficult since the mucosa is extremely sensitive to ischemia [130]. Disruption of the intestinal barrier leads to post-transplant bacterial translocation [131]. To prevent post-transplant complications, cold ischemia times must be kept to a minimum.

As it is with other abdominal organs, UW solution is most commonly used in small bowel preservation [132]. The only clinical report comparing in retrospect UW and HTK solutions found no difference in function or acute rejection [133]. Experimental studies with human intestine by de Roover et al. indicated that UW and Celsior solutions are equal in preservation potential [134].

Experimental models comparing different solutions demonstrate potential improvements with the addition of nutrients [68,135] and luminal preservation [136–138]. Also, the addition of oxygen is suggested to be beneficial [139–141].

Resuscitation protocols

In-situ perfusion of DCD donors

Given the availability of potential DCD Maastricht category 1 and 2 donors, use of organs from this source would shorten the waitlist [142,143]. In 2006, the US Institute of Medicine recommended the transplant community to undertake active efforts to increase donation from Maastricht category 2 DCD donors in particular, estimating that this group could expand the donor pool by 22 000 per year. However, due to the unknown extent of ischemic injury, assessment of organ quality is difficult and risk of poor function is considerable. In Spain especially, where organ donation per million inhabitants is the highest in the world, organs from DCD donors are used extensively. Using strict selection criteria, one center in Madrid, Spain, has successfully transplanted kidneys from Maastricht category 1, 2, and 4 donors [144–146]. Following irreversible cardiac arrest in suitable donors, a femoral arterial and venous catheter is inserted, allowing the maintenance of grafts by extracorporeal membrane oxygenation (ECMO). ECMO systems are widely used to support patients with cardiorespiratory failure on intensive care units. In the setting of organ donation, a double balloon is inflated immediately above the diaphragm and used to prevent recirculation through the brain or heart. This allows continued circulation of warm, oxygenated blood through the abdominal organs after cardiac arrest.

This method has demonstrated good results, with 1- and 5-year graft survivals comparable to those for DBD kidneys at the same institution during the same time period [146]. Category 2 kidneys undergo a variable amount of warm ischemia of up to 2 h, and the discard rate for retrieved kidneys is therefore high at approximately 33%. Even after acceptance, the DGF (68–80%) and PNF rates (6%) are substantial [144,145]. In a small series of category 2 and 4 donors in Barcelona, Spain, normothermic ECMO was compared with hypothermic ECMO and with in-situ cold perfusion by EC solution, where the incidence of DGF and PNF was significantly lower in kidneys perfused with normothermic ECMO [147]. A series of kidneys from Maastricht category 1 and 2 DCD donors in Paris, France, with a longer warm ischemic time of up to 150 min, demonstrated higher discard (43%) and DGF rates (92%), but a lower PNF rate (2%) [148]. Graft survival was 89% at 6 months. The normothermic ECMO group had lower rates of DGF compared to the other groups and less PNF than the in-situ group.

Whilst ECMO is used for uncontrolled DCD, it has not been widely tested in controlled DCD. ECMO provides a possible method by which the acidosis and low venous oxygen levels present after the withdrawal of life-supporting treatment could be reversed in controlled DCD. Following a decision to withdraw treatment on the ICU, family consent for donation is sought, and if agreed to, a femoral catheter is inserted and supportive treatment withdrawn. Five minutes after cardiac arrest, the aortic occlusion balloon is

inflated and ECMO is initiated. In a case series from Michigan, USA, this method has provided low rates of DGF (8%) and PNF (0%) for Maastricht category 3 DCD donors [149]. Another group from North Carolina, USA, transplanted a series of kidneys following sub-normothermic (22 °C) ECMO after controlled DCD [150]. DGF rates were higher in this study (57%) and 1-year graft survival was 87%. A large case series from Taipei, Taiwan, demonstrated that ECMO for kidneys from Maastricht category 1, 2, and 4 donors could result in excellent 5-year graft survival rates of approximately 88% [151]. This survival rate is comparable to that for live donor kidneys (89%) and DBD kidneys (83%) transplanted at the same institution during the same time period.

For livers, the ECMO technique is used only for uncontrolled donors. Fondevila et al. and the Barcelona group reported the first case–control study of ECMO for uncontrolled DCD liver preservation [152]. The group required strict criteria to accept and transplant organs, resulting in only 10 transplants from 40 donors. Livers were rejected if macroscopically steatotic on inspection, or on the grounds of elevated transaminases or poor perfusion. Donors with prolonged warm ischemia time were also excluded. Patient and graft survivals were comparable to matched DBD livers transplanted at the same unit, with an average of 23 months of follow-up.

Another case–control series from Spain examined the results of uncontrolled DCD liver allografts [113,153]. Jimenez-Galanes et al. and the Madrid group have strict criteria for accepting these organs: donors must be younger than 50 years old, have an arrest time of $<$15 min, and have a warm ischemia time of $<$50 min. Maximum acceptable ECMO time is 270 min. Twenty liver allografts were transplanted from 43 potential donors. The 1-year graft survival was 80% and was comparable to that for matched DBD livers transplanted at the same unit. PNF rates were also comparable in this small series (10% vs. 5%). Retransplantation rate, however, was higher for the uncontrolled DCD group (15% vs. 0%) as were the peak aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels.

Oxygenated machine perfusion at different temperatures

Future developments in kidney preservation will aim to repair damaged organs by providing mechanisms to support metabolism and remove waste products, counteracting the effects of ischemia–reperfusion injury (IRI). New preservation fluids may allow static storage at normothermic or sub-normothermic temperatures, as has been demonstrated in animal studies. AQIX, a non–phosphate-buffered solution, has been used for short-term, sub-normothermic, static preservation in a porcine experimental model [154]. Improved outcomes following static cold preservation may also be possible with the development of new solutions. Polysol, a low-viscosity solution, has been tested in porcine autotransplant models, showing improved renal blood flow and tissue oxygenation compared to UW solution [155] and improved creatinine clearance compared to HTK solution [155,156].

Delivery of oxygen to the graft during the preservation period has been the focus of several studies and various methods, other than the delivery of oxygenated whole blood, have proven to be promising in animal and experimental studies. Persufflation of gaseous oxygen directly through the vasculature of the kidney has been tested as a rescue therapy for ischemically damaged kidneys. Filtered and humidified gaseous oxygen can be administered through the renal vein and allowed to escape from the surface of the kidney through fine pin-pricks made with a microvascular needle. In animal studies, autotransplanted kidneys displayed better creatinine clearance following oxygen persufflation as compared with cold static or perfusion preservation alone [157,158]. The Groningen and Poitiers groups in collaboration have tested an oxygenated perfusate to preserve kidneys during HMP, and this has been tested in animal models of DCD and in autotransplant models [159,160]. Membrane oxygenators within MP systems have been shown to promote ATP synthesis even following 30 min of warm ischemia [161]. Oxygenation of machine perfusates with 100% oxygen to achieve very high oxygen partial pressure has also been tested as an adjunct to MP, and shown to be able to recondition kidneys previously stored for 18 h by SCS [162]. On reperfusion, kidneys previously recirculated with oxygenated perfusate showed improved urine production and creatinine clearance. Oxygen could also be delivered to tissues via soluble oxygen carriers. The respiratory pigment Hemarina-M101, a large hemoglobin molecule derived from marine invertebrates, has been used to supplement standard preservation fluids in a static cold preservation animal study [163]. Hemarina-M101 improved metabolic activity of preserved cell lines, increased ATP levels, improved creatinine clearance, and reduced graft fibrosis following transplantation of preserved whole organs [163].

The next logical step would seem to be the combination of normothermic preservation with continuous or pulsatile perfusion to remove metabolites and maintain constant intravascular conditions. Synthetic fluids could possibly be combined with normothermic perfusion. Lifor, a solution incorporating a non-protein oxygen carrier, has been tested for short-term in-situ normothermic preservation [164] and in a porcine model of sub-normothermic renal perfusion [165]. Lifor demonstrated a better preservation of renal function [164] and reduced renal resistance compared to UW solution [165]. A hemoglobin-supplemented fluid allowed the resuscitation of kidneys despite 2 h of warm ischemia, providing life-sustaining function [166]. Another option would be to use blood itself and in an animal study, normothermic perfusion with heparinized whole blood been shown to preserve renal function during 6 h of perfusion, despite a prior 40 min of warm ischemia [167].

It is possible that a period of normothermia and oxygenation may be beneficial at the beginning or end of a cold preservation phase. Theoretically it would offer some degree of ischemic preconditioning at the beginning of the preservation period, or allow cytoprotective mechanisms to aid the recovery of the organ. Two hours of normothermic reperfusion with autologous blood after 16 h of SCS was shown to improve renal blood flow to the level of kidneys statically stored for only 2 h [168]. This technique was at least equivalent to HMP for 18 h [91,168]. Extracorporeal normothermic perfusion has recently been tested in human renal transplantation [169]. The first published case was that of an ECD declined by six UK centers before being accepted in Leicester. One kidney was perfused at normothermic temperatures with plasma-free, RBC-based solution for 35 min prior to transplantation, while the other kidney was stored by static cold preservation alone. Both kidneys had acute tubular necrosis (ATN) and rejection on protocol biopsy at 1 week; however, the recipient of the reperfused kidney had primary function, while the recipient of the static cold preserved kidney required dialysis for a further 4 weeks. The Leicester group has used this method of preimplantation normothermic recirculation in a case series of 16 transplants, with promising results so far [170].

One option in the prevention of IRI may be "immune camouflage," whereby selected polymers interact with allograft cell membranes to reduce immune cell invasion of the graft. Polyethylene glycol (PEG), a constituent of the IGL-1 solution, is one such polymer. Animal studies have suggested that plasma with PEG may have better static preservation effects than IGL-1 or UW solutions, with less immune cell infiltration and improved graft survival [171].

HMP of the liver as a resuscitation modality for previously untransplantable livers has now entered preclinical testing. Guarera et al. preserved 10 discarded human livers with pulsatile perfusion for up to 10 h to test the viability of the technique [114]. Alongside this study, the same group preserved porcine livers modeling DCD and completed three transplantations from livers preserved by HMP. All recipients showed initial graft function with reduction in serum enzymes [116]. Vekemans et al. also tested HMP for the rescue of discarded human livers in an experimental model of ischemia–reperfusion [172]. HMP was used for 4 h after a period of SCS, and was compared to SCS alone. During normothermic reperfusion with blood after the cold preservation, HMP was associated with reduced AST and lactate dehydrogenase (LDH) release, and reduced mitogen-activated protein kinase (MAPK) levels. Histological examination of liver biopsies from both preservation modalities was similar [172].

The potential for HMP to act as a resuscitation therapy for DCD livers may be further extended by the oxygenation of the perfusate during the perfusion period [hypothermic oxygenated perfusion (HOPE)]. This has been tested in animal models of DCD, with HOPE used at the end of a period of SCS to precondition the organs [115,173]. Preconditioning with oxygenated perfusate resulted in reduced cellular damage compared to SCS alone, with reduced necrosis and lipid peroxidation and increased cellular ATP recovery and bile flow. HOPE-treated livers also had improved graft survival, although experimental animals did not survive beyond 18 h whether HOPE was used or not [173]. The use of oxygenated machine perfusate has been further tested using a sanguineous fluid at both normothermic and hypothermic temperatures [115]. HOPE in this form also reversed the microscopic and macroscopic damage present in these livers, reducing AST release, increasing bile flow after reperfusion, reducing serum lactate, and improving recipient survival [115]. In this study, all experimental animals died within 24 h if the liver had suffered 120 min of warm ischemia [115].

Future developments in liver preservation will have to address the demands of the transplant waitlist by making previously untransplantable organs viable. It is speculated that the addition of oxygen to preservation modalities may make this possible through maintaining metabolism. Similarly to kidneys, various methods have been tested to deliver increased oxygen concentrations to livers ex vivo. Minor et al. have tested gaseous oxygen persufflation in a pig transplant model. Following 10 h of SCS, oxygen bubbles are passed into the vena cava for 2 h prior to implantation [174]. Livers receiving oxygen persufflation had greatly improved 1-week graft survival of 83% (in the control group it was 0%). Histological studies at autopsy showed preserved liver architecture in the study group. Serum liver enzymes and clotting parameters were also all within normal ranges. Post-conditioning with persufflated gaseous oxygen has also been tested in a small series of human livers that were otherwise rejected due to previous warm ischemic damage [175]. This resuscitation permitted the transplantation of five livers, and all patients were alive and well at 2 years' follow-up, without retransplantation. There was a significant increase in cellular ATP levels after oxygen persufflation. Persufflation has also shown positive results as a rescue therapy in experimental models following long periods of SCS (18 h), reducing serum liver enzymes, LDH, and tumor necrosis factor (TNF)-alpha, and increasing bile production [162]. The first RCT of resuscitative oxygen persufflation is currently recruiting [176]. When compared with oxygenated HMP, oxygen persufflation has shown slightly more promising results in terms of hepatic enzyme release and bile production in an animal model of DCD [177]. Further adaptations to HMP have included the use of a hyperbaric oxygen chamber to enclose the pump and increase the partial pressure of oxygen within the tissues. In a small experimental series, this technique has shown the benefit of increased cellular ATP and bile production and reduced ALT release after reperfusion [178]. The two-layer method, which was developed initially for pancreas preservation (see above) has also been tested in liver preservation. A continuously oxygenated perfluorocarbon layer lies underneath and in direct contact with the preservation fluid (typically HTK or UW solution). In liver experimental studies, this method improved cellular ATP levels but not cellular morphology [179].

Normothermic reperfusion

Normothermic machine perfusion (NMP) provides an intuitive and possibly better alternative to HMP, but has associated complexities and technological challenges. Provision of a physiological environment for continued metabolism allows assessment of function and recovery of the organ ex vivo. Schön and the Berlin group were the first to demonstrate, in an animal model, that 4 h of ex-vivo normothermic preservation of the liver was safe prior to transplantation [180]. Compared to SCS, this technique also seemed to have increased benefit when following a period of warm ischemia [180]. Friend and the Oxford group followed on from this work to show that porcine livers could be preserved for much longer periods of time (72 h) by NMP with oxygenation of the perfusate [181]. Further development of these experimental models allowed testing of liver synthetic function during a simulated reperfusion phase. This group then compared SCS in UW solution to NMP with oxygenation of the perfusate. NMP resulted in increased bile and glucose production, and galactose clearance, with reduced release of hepatic enzymes and histological damage [182]. The same group used a model of DCD liver preservation (60-min warm ischemia time) to show that NMP could recover function; in comparison, SCS showed no evidence of viability, with no bile production or substrate utilization [183]. In animal transplantation experiments mimicking both DBD and DCD, NMP has shown the potential to reduce hepatic enzyme release, increase patient survival, and improve hepatic histology. This benefit was consistent only if the preservation period was long (20 h) [184]. Currently, the Oxford group in close collaboration with King's College and Birmingham have finalised a first-in-man pilot study applying NMP and using a novel device in 20 liver transplants including both DBD, DCD and ECD. First results appear to be very promising (personal communication). The Barcelona group, in collaboration with the Groningen group, has performed experiments with NMP in animal models of uncontrolled DCD, with long warm ischemia time (90 min). In this study, NMP after a period of ECMO showed the potential to further improve upon the results obtained with ECMO followed by SCS [185]. Improvements were seen in function, and macroscopic and histological appearances of the livers [185]. Tolboom et al. used animal transplantation studies with long warm ischemia time (60 min) to show

that ischemically damaged livers preserved with NMP could be transplanted with excellent (92%) 4-week survival [186]. This is comparable to the survival in controls receiving healthy livers preserved by SCS or NMP [186]. Animals receiving ischemically damaged livers preserved by SCS alone all died within 12 h of transplantation. The same group moved on to examine sub-NMP, again following 60 min of warm ischemia time [187]. Machine perfusion at both 20 and 30 °C recovered ischemically damaged livers, and all animals survived beyond 1 month [187]. Steatotic livers are particularly susceptible to IRI, and given that they make up an increasing proportion of the donor pool, their preservation and resuscitation is of increasing importance. NMP has the potential to reduce the level of evident hepatic injury in these livers, which SCS does not [188].

Hibernation strategies

During preservation, donor organs are cooled to 4 °C after procurement to prevent injury. However, deceased donor organs cannot be maintained at 4 °C indefinitely. In kidneys, the risk of DGF increases progressively as cold ischemia time increases [189]. For every 6-h increment of cold ischemia, the risk of DGF increases by 23% and prolonged cold ischemia time is negatively associated with graft survival (Figure 25.3).

Tubular cell death during human kidney transplantation is apoptotic during cold preservation [32] . During warm ischemia–reperfusion at implantation, both apoptotic and necrotic cell death occur [18,190]. A number of investigators have suggested that hibernation represents a unique natural model of organ preservation and transplantation [191–193], where torpor can be viewed as a natural equivalent of donor kidney storage at 4 °C, whereas arousal is a natural equivalent of the warm reperfusion that occurs during implantation of a graft. Mammalian hibernators undergo extreme reductions in core body temperature (CBT) every winter. During torpor CBT can fall for several days from 38 °C to as low as −3 °C in arctic hibernators or 2–10 °C in temperate-zone hibernators [194] and hibernators undergo physiological changes, reducing their heart rate from a summertime level of 200–300 bpm to 3–5 bpm and their respiratory rate from 100–200 breaths/min to 4–6 breaths/min [194]. Interestingly, during hibernation animals are less susceptible to IRI, possibly related to a reduced activation of the immune system [195,196]. The recent discovery that hydrogen sulfide induces a torpor-like state, referred to as suspended animation in mice by Blackstone et al. [197], lead to the idea that hydrogen sulfide might be protective in IRI [198,199]. Application of non-toxic dosages of hydrogen sulfide gas results in physiological changes similar to those observed during natural hibernation [197,200]. In experimental models it was shown that hydrogen sulfide application results in a reduction of IRI in kidneys and livers [201]. Translation of hibernation strategies to the clinical situation is however complicated since experiments in pigs did not show clear protection [202,203].

Summary

After an initial innovative and active period in the 1960s when organ preservation methods became established, further developments in this important field for transplantation fell almost silent until the late 1980s. Centers had a clear clinical preference for cold storage of organs submerged in a preservation solution. Simple static cold storage appeared to be sufficient to allow recovery after preservation and adequate function using standard criteria donors.

Figure 25.3. Impact of cold ischemia time on (A) delayed graft failure and (B) graft survival. (Data from UNOS/OPTN.)

The current challenges due to the changes in donor type, including the use of older and high-risk donors, has now propelled perfusion and preservation into a new period of development and investigation of exciting novel strategies. The use of continuous HMP, normothermic reperfusion in situ, and ex-vivo resuscitation using miniaturized technology and incorporating biochemical strategies is proof of the fact that we are entering a new phase of development. The prior goal to bridge from donor to recipient with only minimal injury and loss of function has given way to a concept of organ improvement during storage and transport. This may be achievable as more sophisticated technologies to reduce injury and initiate repair become available. To unravel some of the clinically relevant questions in preservation recently the Consortium on Organ Preservation in Europe (COPE) was established and supported by the European Commission to focus on three clinical trials in liver and kidney preservation using novel technology and oxygenated

hypothermic or continuous normothermic perfusion. Preservation technology will continue to be crucial in reducing the organ shortage and minimizing organ discard, whilst allowing previously untransplantable organs to be transplanted.

Introduction

Significant advances in lung preservation have been made since the first successful clinical lung transplant was reported in 1983. Lung preservation has evolved from needing adjacent operating rooms for both donor and recipient operations in that era, to cold static immersion for transport, to today's clinical standard: hypothermic flushed inflated preservation (hypothermic, aerobic, static preservation). However, the ideal preservation strategy for donor lungs during the obligate, yet unnatural, phase spent outside of a body remains to be identified. Historically, the central tenet to organ preservation was to "slow the death" of the organ until reimplantation into the recipient could occur. Today, the concept of "maintaining life" of the organ during preservation is emerging and novel technologies and strategies are being developed towards that end. This opens the door to move beyond just preservation of the organ into the era of "personalized medicine for the organ," where an opportunity for diagnosis and targeted treatment of donor lungs can occur. In this chapter, we will review current lung preservation strategies and discuss potential future approaches to lung preservation and resuscitation.

Though lung preservation is often considered the time spent outside of the donor body, preservation strategies in fact must be employed from the time a donor is identified until well into the post-transplant period. As such, this chapter naturally bridges content in Chapters 21, 22, 58, and 59, which deal specifically with organ procurement from deceased donors and donors after circulatory death, and the thoracic transplant procedures themselves, respectively. Prior to organ retrieval and the onset of ischemia, active donor management has helped increase organ recovery and has been shown to improve lung oxygenation from the time of initial brain death to the time of organ retrieval, resulting in improved lung and cardiac recovery rates [1–3].

Lung preservation

In the preretrieval phase

During the preretrieval phase, particular attention should be paid towards maintaining a euvolemic state. This helps avoid aggravating neurogenic pulmonary edema and the development of hypervolemic edema, particularly in the context of brain death physiology [4]. Therefore, potential donors should have central venous pressure (CVP) monitoring to maintain the CVP between 4 and 10 mmHg [5] and a pulmonary artery catheter should also be considered for wedge pressure measurements when left heart dysfunction is suspected. If needed, dopamine (<10 μg/kg/min) and vasopressin (<2.4 U/h) have been shown to be the vasopressors of first and second choice, respectively [6], as norepinephrine and epinephrine have been associated with lung dysfunction [7,8]. In addition, vasopressin infusion has the added benefit of improving hypotension not only due to its vasopressor action, but also due to its antidiuretic hormone action when diabetes insipidus is present [9–11]. It should be titrated to a systemic vascular resistance (SVR) of 800–1200 dyn·s/cm^5 when a pulmonary artery catheter is present [12].

Another principle of donor lung protection is to avoid barotrauma. Generally, protective lung ventilation strategies similar to the ARDSnet strategy [tidal volume, 6–8 mL/kg; positive end-expiratory pressure (PEEP), 5 cm H_2O; fractional inspired oxygen, <0.5] have been employed for ventilation of the donor [13]. However, a recent randomized controlled trial by Mascia et al. has demonstrated an increase in the number of lungs utilized from donors who were ventilated at a tidal volume of 6–8 mL/kg of predicted body weight and PEEP of 8–10 cmH_2O [14]. Lungs are also particularly susceptible to atelectasis and pneumonia. Frequent turning and suctioning for pulmonary toilet is important. Regular recruitment maneuvers should be performed to avoid atelectasis and bronchoscopy for the removal of mucous plugs and bronchoalveolar lavage (BAL) specimens should also be routine. Serial chest radiographs are obtained to monitor for the development of edema or any possible infiltrates [1,6,12].

A methylprednisolone bolus at 15 mg/kg has been shown to improve lung function and post-transplant outcomes even if given hours after brain death [3,15]. However, it is currently unclear whether this is a result of its anti-inflammatory effect or of steroid replacement in the setting of adrenocorticotropic hormone (ACTH) deficiency following brain death. The effect of other hormone replacement therapies, such as triiodothyronine and L-thyroxine have been explored in the literature, but no definite benefit has yet been shown in lung transplantation [3]. The use of beta$_2$-adrenergic agents has been shown to speed up alveolar fluid clearance in ex-vivo perfused human and rat lungs [16]. This finding formed the basis of the Beta-agonists for Oxygenation in Lung Donors (BOLD) study, a randomized, placebo-controlled clinical trial of nebulized albuterol versus placebo in 500 organ donors [17]. Interestingly,

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

treatment with high dose inhaled albuterol did not lead to better donor oxygenation or increased lung utilization, and the routine use of beta$_2$-adrenergic agents cannot be recommended at this time [18].

Angel et al. have used retrospective data to show the impact of a standardized donor management protocol on the resuscitation of poor quality donors [2]. In the 4-year period following initiation of their protocol, of 254 donors initially classified as "poor," 135 were able to be reclassified as "extended" or "ideal" at the end of donor management. Ultimately, 21% of donors originally classified as "poor" were actually used for lung transplantation. In comparison, prior to the initiation of the standardized donor protocol, only 10% of lungs were used from donors originally classified as "poor." Gabbay et al. have also had success with improving the Pao_2/Fio_2 (P/F) ratio with a donor management strategy [1]. Of 140 consecutive transplants, 20 donors who originally would have been rejected were used successfully without impact on 30-day and 3-year survival. Others have also shown increased yield with aggressive donor management [3,19,20].

At retrieval

In the current paradigm of lung transplantation, the decision to utilize an organ for transplantation is made at the time of donor surgery. Once the decision to utilize a donor lung is made, the lungs are procured from the donor and the obligate ex-vivo phase begins. Most often, the recipient operation will begin in parallel with the decision to utilize the lung; thus, minimizing injury to the organ during the ex-vivo phase is important.

At the time of procurement, many strategies are employed in an attempt to better preserve the donor lung [21]. As in the preprocurement phase, a lung protective strategy similar to ARDSnet is utilized for ventilation to avoid injury from barotrauma. Full anticoagulation of the donor (300 U of heparin/kg) is given to minimize the risk of intravascular clot formation during the retrieval. Once the assessment of the donor is complete, a dose of 500 μg of prostaglandin E_1 (PGE_1) is given into the pulmonary artery to lower the pulmonary vascular resistance (PVR) by dilating the pulmonary vasculature. This facilitates the subsequent homogenous flushing of the pulmonary vasculature. PGE_1 has also been found to also downregulate proinflammatory cytokine expression, which may further help to reduce primary graft dysfunction (PGD) [22]. Response to PGE_1 can be recognized by a subsequent fall in the systemic blood pressure due to pulmonary vasodilation. With this fall, aortic crossclamp of the donor is commenced. The heart is cardiopleged and organ recovery can begin. The vasculature of the lung is flushed to cool the lung tissue and to remove blood from the pulmonary vasculature, further minimizing the potential for clot formation and allowing for the removal of inflammatory and immune cells. Early in the experience of lung transplantation, the use of an extracellular-type (i.e. low potassium) solution was found to be beneficial to lung preservation as opposed to the intracellular-type solutions used in other organs [23]. The intracellular type solutions led to significant arterial vasoconstriction, limiting the effectiveness of the flush. Dextran 40 was also found to be a key ingredient in the lung flush solution and serves two purposes [24]. First, it acts as an oncotic agent to help keep fluid within the intravascular space. Second, it has the ability to reduce the aggregation of erythrocytes, neutrophils, and thrombocytes. This can help preserve flow through the microvasculature after reperfusion, particularly in the bronchial microcirculation, and may play a role in reducing bronchial anastomotic complications. Another key ingredient in the flush solution is glucose. Because the lungs are stored inflated with oxygen, a unique situation arises during storage where the lungs are ischemic but not hypoxic. Glucose helps support aerobic metabolism in the lung during preservation. Multiple retrospective studies have demonstrated the superiority of low potassium dextran glucose (LPDG) solution to intracellular-type solutions [25–29].

The flush solution is first administered anterograde into the pulmonary artery, and then retrograde into each of the main pulmonary veins. This additional retrograde flush can help remove embolic clot from the pulmonary arteries and also helps to perfuse bronchial vessels via the bronchopulmonary shunt [30]. Furthermore, retrograde flush will possibly better flush areas of the lung affected by hypoxic pulmonary artery vasoconstriction [31]. Approximately 50–60 mL/kg of perfusate is utilized for the anterograde flush and 1 L for the retrograde flush. The desired flush pressure is a balance between too high a pressure leading to injury of the pulmonary vasculature and too low a pressure leading to inhomogeneous flushing. In practice, the flush solution is hung 30 cm above the patient and driven by gravity. Following the flush, the lungs are removed, inflated at an airway pressure of 20 cmH_2O with 50% oxygen, and stored on ice. Inflation of the lungs serves two purposes. First, it provides oxygen to the lung parenchyma for aerobic metabolism and second, it preserves the alveolar structure and surfactant during storage. Accordingly, van Raemdonck et al. have shown that inflation, even with nitrogen, is superior to atelectatic storage [32]. An airway pressure of 20 cmH_2O has been found to be ideal. In the case of donor lung transport by air, extra care should be taken to not overinflate the lungs as the low atmospheric pressure in flight, despite pressurized cabins, will result in gas expansion and may cause barotrauma to the lung during transport.

Once the lungs have been removed from the body, reduction of the metabolic rate by cooling of the lungs remains the cornerstone strategy for lung preservation today. Kayano et al. have shown in a rat model that the optimal temperature for lung preservation is approximately 10 °C [33,34]. However, to simplify transport logistics, 4 °C, the temperature of ice, is most commonly used. Once removed from the body, transplantation into the recipient is generally performed as soon as possible. PGD and 30-day mortality have been reported to increase with cold ischemic times longer than 8 h [35]. While lungs with 10–12 h cold ischemic times have been transplanted with success, these selected lungs have typically had fewer donor and recipient risk factors.

At Transplantation

Throughout the entire procurement process, warm ischemia is carefully avoided. However, during implantation, this is largely unavoidable. Date et al. showed that a significant increase in temperature occurs during implantation and that use of a cooling jacket to surround the lung during implantation can greatly reduce this warming [36]. Though Stammberger et al. showed that 2 h of warm ischemia made no difference to post-transplant outcomes in a pig model of lung transplantation, these lungs were not injured at baseline and the follow-up time was short [37]. Use of a cooling jacket during implantation is largely unobstructive and has potential benefit; therefore, we routinely utilize a cooling jacket during implantation.

Reperfusion is a crucial part of lung transplantation where additional injury could occur and thus should be performed with particular care. Gradual reinstitution of pulmonary arterial blood flow over a period of 10 min by the slow release of the pulmonary artery

clamp after implantation has been shown to improve post-transplant outcomes [38]. Some have advocated the use of a special perfusion solution to perfuse the lung just prior to release of the pulmonary artery clamp; however, this is not standard practice in most centers [39]. Once reperfusion is commenced, ventilation of the new lung is performed with a low fraction of inspired oxygen (usually FiO_2 21%) to avoid oxygen-related lung injury. For patients transplanted on cardiopulmonary bypass, it is important to leave some pulmonary artery ejection/pulsatility (PAP 10–15 mmHg) to reperfuse the already transplanted lung during implantation of the second lung. An extension of this strategy of gradual, protected reperfusion has been described by the Vienna group: Aigner et al described the use of extracorporeal membrane oxygenation (ECMO) support rather than cardiopulmonary bypass during lung transplantation for all patients experiencing hemodynamic or respiratory instability during transplantation [40]. Of 130 patients who underwent intraoperative ECMO support, 51 patients had their ECMO extended into the perioperative period, allowing for a very gradual increase of pulmonary artery flow over hours or days rather than minutes.

Post-transplantation

Following reperfusion, we routinely utilize heparin (100 U/h) and Rheomacrodex (10% dextran 40, 500 mL/24 h) as an intravenous infusion for 7 days to improve the pulmonary and bronchial microcirculation [41,42].

In donation after circulatory death

The use of controlled donation after circulatory death (DCD) lungs (Maastricht category III or IV) is now well described in the literature, with equivalent or near-equivalent outcomes to conventional donor lungs in international case series and demonstrating promise to increase lung transplant activity [43–48]. However, the use of DCD lungs creates new challenges in lung preservation due to the additional warm ischemic time accrued between cardiac arrest and cold flush. Fortunately, lungs have been shown to tolerate a relatively long period of warm ischemia and this is likely due to the low metabolic demand of the lung combined with the presence of oxygen in the lungs [49,50]. Indeed, Miyoshi et al. recently demonstrated the importance of oxygen in the alveoli in a porcine model [51]. In their study, hypoventilation rather than circulatory arrest contributed most to poor post-transplant outcomes. Clinically, a warm ischemic time of less than 1 h has been considered to be acceptable for transplantation [49,52–55]. In general, this 1-h timeframe is adequate for the retrieval of donor organs in controlled DCD. However, the Lund group has reintroduced the concept of topical in-situ cooling in an attempt to better preserve DCD organs [56]. Two chest tubes are placed and then cold Perfadex® is used to cool the lungs to 18 °C. In animal models and case reports, topical cooling has been shown to safely prolong DCD lung preservation in situ for up to an additional 6 h after 1 h of warm ischemia time. However, the practical need for such a strategy is probably best suited to uncontrolled DCD lungs (Maastricht category I or II).

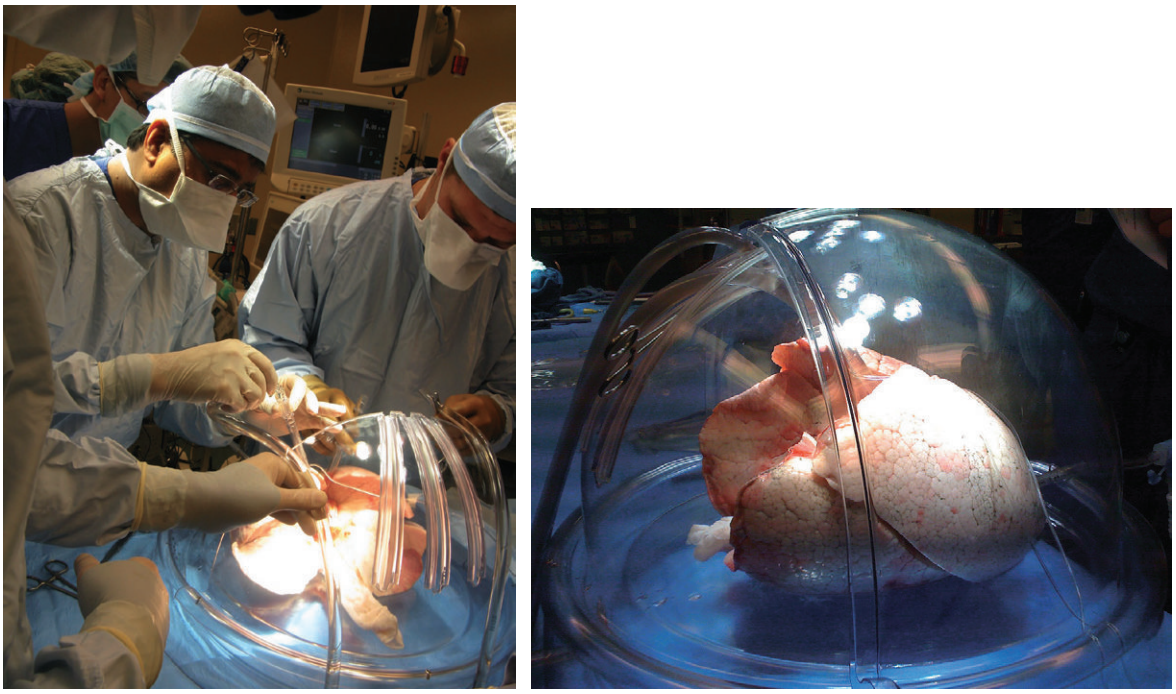
The use of full heparinization prior to circulatory arrest and cold flush in the brain dead donor is well established. However, the use of heparin in DCD may not always be possible due to potential ethical issues, as it is an intervention aimed solely at organ preservation and is given prior to donor death. To circumvent this, post-arrest heparinization given by injection into the pulmonary artery and followed by a few beats of cardiac massage to help distribution is included in most DCD retrieval protocols. Okazaki et al. have shown in a canine lung transplant model that post-mortem heparinization can be beneficial, supporting this approach [57]. Clinical data are also now emerging demonstrating that no difference in outcomes are seen in donors who received preretrieval heparinization versus those who did not [58]. Retrograde flush, however, remains a particularly important strategy to remove embolized or in-situ clot in the pulmonary artery in DCD lungs.

Normothermic lung preservation

While the current cornerstone of clinical lung preservation is to limit the metabolic rate by hypothermia, this strategy best serves lungs meeting ideal acceptance criteria. With the current donor organ shortage, most programs now utilize increasing numbers of extended criteria organs where lung function is not as assured as in ideal lungs. Ideally, further evaluation and even resuscitation of the lungs would be possible during the ex-vivo phase of the organ before transplantation into the recipient. As limitation of the metabolic rate by hypothermic preservation precludes the possibility of meaningful lung evaluation and recovery, preservation of donor organs would need to occur at normothermic or near-normothermic conditions to achieve these goals. One such strategy has been that of ex-vivo lung perfusion (EVLP; Figure 26.1). This strategy attempts to simulate the in-vivo situation by ventilation and perfusion of the donor lung graft. Originally proposed as early as 1938 by Carrel for organs in general and then in 1970 by Jirsch et al. for the evaluation and preservation of lungs in cases of distant procurement, attempts in those eras failed due to an inability to maintain the air–fluid barrier within the lung, leading to the development of edema and increased PVR in the donor lung during EVLP [59,60].

Driven by the objective of better evaluation of DCD lungs, Steen et al. in Lund, Sweden developed a modern ex-vivo perfusion system with the intent of short-term evaluation of lung function of this population of lungs ex vivo [61]. In doing so, they developed a buffered, extracellular solution with an optimal colloid osmotic pressure to act as the lung perfusate (Steen Solution™, Vitrolife). This solution helps hold fluid within the intravascular space during perfusion and provides nutrients needed to maintain lung viability. The composition of Steen solution is quite similar to the current clinically utilized preservation solution of LPDG (Perfadex®, Vitrolife), with human albumin as the major additional constituent. This protein is meant to maintain a higher oncotic pressure to reduce the development of pulmonary edema during perfusion. Steen et al. utilized this solution mixed with red blood cells in combination with their circuit and were able to successfully perfuse and evaluate lungs in a large animal model for 1 h without the development of pulmonary edema; subsequent transplantation was successful [61]. Following their work in large animals, Steen's group was the first in 2007 to publish a case report of successful transplantation of a non-acceptable lung following a brief period of EVLP [62]. Subsequently, Steen's group has published a case series of six cases using short-term perfusion to evaluate rejected donor lungs [63].

The ultimate goal of Steen's studies was to utilize EVLP as a method for lung evaluation and thus the perfusion times have been short. For the application of EVLP for preservation, improved evaluation, and the goals of lung recovery and repair, much more time is required. Erasmus et al. first attempted to extend the EVLP duration to 6 h; however, circuit-induced injury again became problematic with increased PVR and airway pressures in the lung near the end of 6 h [64]. We first described successful long-term (12 h)



(A) (B)

Figure 26.1. Ex-vivo lung perfusion (EVLP). (A) A lung preparation being placed on an EVLP device. The capacity to actively manipulate the organ, including to perform bronchoscopic lavage, is a significant advantage of EVLP over cold storage. (B) Human lungs undergoing EVLP resuscitation. Ventilation and perfusion can both be maintained during storage.

EVLP using a lung protective strategy for acellular normothermic perfusion and ventilation [65].

To attain stable 12-h perfusion, several key lung protective strategies were employed [65]. First, an acellular perfusate was utilized. We hypothesized that oxygen delivery to the lung could occur via the ventilator rather than via the vasculature. This concept is also supported by Egan's group, where mere ventilation of a donor lung with room air at normothermia was demonstrated to preserve cell viability for 24 h [66,67]. In addition, acellular perfusion is logistically simpler for clinical use and also avoids the problem of limited lifespan of red blood cells within the harsh environment of the perfusion circuit. Second, rather than subject the lungs to perfusion at 100% of cardiac output, maximal flow was limited to 40%. This lower flow aids in the reduction of hydrostatic edema caused by perfusion and, despite lower flows to non-dependent areas of the lung, histology and post-transplant function in EVLP lungs were shown to be normal. Third, we found that maintenance of a positive left atrial pressure of 3–5 mmHg to be important for the success of long-term perfusion. This small, but positive left atrial pressure tents open the capillaries and post-capillary venules and prevents collapse of the microvessels from occurring during increases in airway pressures and decreases of flow at inspiration [68]. Absence of positive left atrial pressures can lead to unstable alveolar geometry and results in decreased lung compliance [69]. Finally, we noted the importance of using a centrifugal pump. With ventilation, distension of the alveoli will place pressure upon the perialveolar vessels, leading to cyclical increases in PVR with every breath. As a consequence of how a centrifugal pump functions, increased afterload to the pump will result in decreased rotation and flow. Thus, the pump will back off during times of increased resistance rather than forcing fluid through, potentially causing injury or edema as a roller pump might do. During perfusion, oxygen is removed and carbon dioxide is supplied via a membrane oxygenator as a simulation of cellular metabolism. Removal of oxygen allows for the measure of lung function by taking the difference between post-lung and pre-lung perfusate Po_2, and addition of carbon dioxide helps maintain the stability of the pH of the perfusate. Using this strategy, reproducible, safe 12-h normothermic ex-vivo perfusion has been demonstrated in porcine and human lungs, and this strategy of EVLP has been shown to interrupt ischemic damage caused by prolonged cold ischemia [65,70,71].

Ex-vivo lung evaluation

Current lung evaluation is a clinical process greatly dependent on the judgment of the surgeon. While some evaluation does occur prior to retrieval, i.e. chest X-rays and intensive care unit (ICU) bronchoscopy, the majority of the evaluation leading to the decision about utilization occurs at a single time point: the time of organ retrieval. Lungs that may be injured but have not yet had time to express that injury in the form of edema and lower P/F ratios may still be utilized, inadvertently. Furthermore, donor physiology during retrieval may not be entirely conducive to accurate lung evaluation as blood pressure is often labile and under-recruitment of the lung parenchyma may give falsely low Pao_2. Injury, as represented by the development of edema during EVLP, is reflected in changes in compliance and airway pressure, which precede the effect on perfusate Po_2 [72]. Thus, during EVLP, these parameters should be monitored carefully and EVLP allowed to proceed over a period of at least a few hours to allow for trends in compliance and airway pressure to be detected. To reduce the effect of atelectasis that might occur during donor lung transport, the baseline time

point should be 1 h after warming the perfusate and after careful recruitment of the lung. All subsequent physiological measurements (compliance, airway pressures, PVR, and perfusate Po_2) can be compared to this time point. A cut-off, or normal value, is often sought for lung evaluation, but compliance and resultant airway pressure are based in part on lung volume and thus can fall within a large range of values. With this strategy, the trend of values becomes more important than the absolute values themselves, e.g. a lung that has a compliance of 80 mL/cmH_2O at the start but 40 mL/cm H_2O after 4 h is more concerning than a lung that starts and ends with a compliance of 40 mL/cm H_2O. When an acellular perfusate is utilized, its effect on Po_2 interpretation also needs to be understood. Because the Po_2–oxygen content curve is linear in the situation of ex-vivo acellular perfusion, mixtures of perfusates of different Po_2, such as in a shunt situation, results in higher measured total Po_2 [72].

Using our EVLP strategy described by Cypel et al. and the evaluation strategy described above, a clinical trial was performed by the Toronto Lung Transplant program using EVLP for the assessment of high-risk lungs that otherwise would not be used [73]. Lungs that originally did not meet acceptance criteria but during EVLP evaluation demonstrated stable or improved PVR, dynamic compliance, and/or peak inspiratory pressure and Po_2/fraction of inspired oxygen >350 mmHg were transplanted and resulted in post-transplant outcomes equivalent to those of contemporary controls.

Commercially available platforms for EVLP are now in various stages of development. Among them are the XPS system by XVIVO Perfusion, the LS1 by Vivoline Medical, and the OCS Lung by Transmedics. Of the three, the XPS system is the most faithful replication of the Toronto strategy and differs only in the addition of various in-line monitors to streamline organ assessment. The LS1 system resembles most closely Steen et al's system for lung evaluation and differs from the Toronto strategy in the use of a roller pump, an open atrium, and a blood-based cellular perfusate. A clinical trial is currently underway in the UK using this device [74]. The OCS Lung device is marketed as a mobile lung preservation system. It provides an additional strategy for lung preservation that Transmedics has termed the "preservation mode," where the perfusate is swept with an oxygenated gas (12% O_2, 5.5% CO_2, 82.5% N_2) and a captive breath is recirculated. This minimizes the amount of gas volume needed and therefore simplifies transport of the system, but the lung is not actively functioning for assessment. The remaining "continuous monitoring" and "sequential monitoring" modes are the more conventional perfusion strategies, where the lung is ventilated with room air and a venous perfusate provided to the pulmonary artery to allow for assessment. Whereas the continuous monitoring mode operates similar to the Toronto and Lund strategies, where the lung oxygenates a continuously deoxygenated perfusate, the "sequential monitoring" mode measures the time needed to oxygenate a preset pool of perfusate at a venous saturation of 73% and arterial saturation of 93% in an automated manner without further deoxygenation. This system also differs from the Toronto strategy in the use of an open atrium, a roller pump, bellows instead of a ventilator, and a blood-based cellular perfusate. Results following OCS lung preservation have been limited to case reports, but this is now the subject of the international INSPIRE trial [75,76]. The predication that cold ischemia is detrimental to the donor lung underlies the development of mobile normothermic perfusion solutions such as the OCS Lung system. However, it remains to be proven whether limited cold ischemia is truly detrimental, particularly when 30 years of clinical experience with short cold ischemia as the sole strategy of lung preservation has shown good outcomes. Even if normothermic preservation is utilized from retrieval to implantation, the need for some cold ischemia is inevitable; cold flush and topical cooling at the time of donor cross-clamp and preimplantation cooling are utilized to protect the lung and minimize warm ischemia during the actual surgical implantation. Compelling experimental and clinical data demonstrating that continuous mobile normothermic perfusion is superior to a combination of short intervals of cold ischemic preservation and normothermic evaluation and treatment will be needed to justify the conversion to this strategy, considering the logistical challenges and the added economic expense needed for mobile normothermic perfusion of lungs, whether for standard or "extended" criteria organs.

Rather than aiming solely at minimizing cold ischemia, normothermic preservation instead demonstrates great promise for resuscitating injured donor lungs. Given that the majority of potential donor lungs are injured by a variety of mechanisms, including brain death, contusion, aspiration, infection, edema, and atelectasis, one could imagine that targeted therapies for each of these injuries could be delivered ex vivo for repair and greatly increase the donor lung pool. The requirements for perfusion for repair compared to perfusion solely for evaluation differ by time. While the majority of lungs can be evaluated within 2–4 h of perfusion, repair will require longer non-injurious stable perfusion while potential treatments are administered. The HELP study by the Toronto Lung Transplant Program perfused 23 initially rejected donor lungs and was able to recover 20 of them for transplantation with equivalent short- and medium-term outcomes. This experience has now been extended to more than 50 clinical lung transplants after EVLP with improved outcomes; the experience continues to grow [77].

Other early studies in the use of EVLP for lung repair have been reported, many still only in abstract form. Each of these studies was targeted at a different form of donor lung injury and it is this breadth of exploration that will ultimately result in an arsenal of ex-vivo lung therapy techniques applicable to each uniquely injured donor lung. Pulmonary edema is a common injury in donor lungs due to brain death physiology and/or ICU fluid management prior to retrieval. Unlike the in-vivo situation, use of terbutiline was found to accelerate the clearance of alveolar fluid during perfusion [78]. Another common mechanism of injury is aspiration. Inci et al. have attempted to improve porcine lungs injured by acid aspiration [79]. By lavaging the donor lung with surfactant during EVLP, they were able to achieve improved graft function when compared with controls. Due to the significant number of lungs rejected for suspicion of infection or pneumonia, delivery of high doses of antibiotics during EVLP is attractive. Both the Newcastle and Toronto groups have early data showing potential reduction in the burden of infection following EVLP antimicrobial therapy [80,81].

EVLP-based gene and cellular therapy have also been explored. We have shown that ex-vivo gene therapy with an adenoviral vector is effective and additionally attractive because of reduced vector-associated inflammation. Furthermore, this strategy can easily fit into the logistical flow of clinical lung transplantation, simplifying adoption [82]. We have demonstrated that EVLP-based interleukin (IL)-10 gene therapy of rejected human donor lungs resulted in improved function and reduced biomarkers of inflammation, suggesting that IL-10 gene therapy could possibly increase the resilience of all donor lungs to reperfusion [71]. Lee et al. have shown that the delivery of mesenchymal stem cells to EVLP lungs can

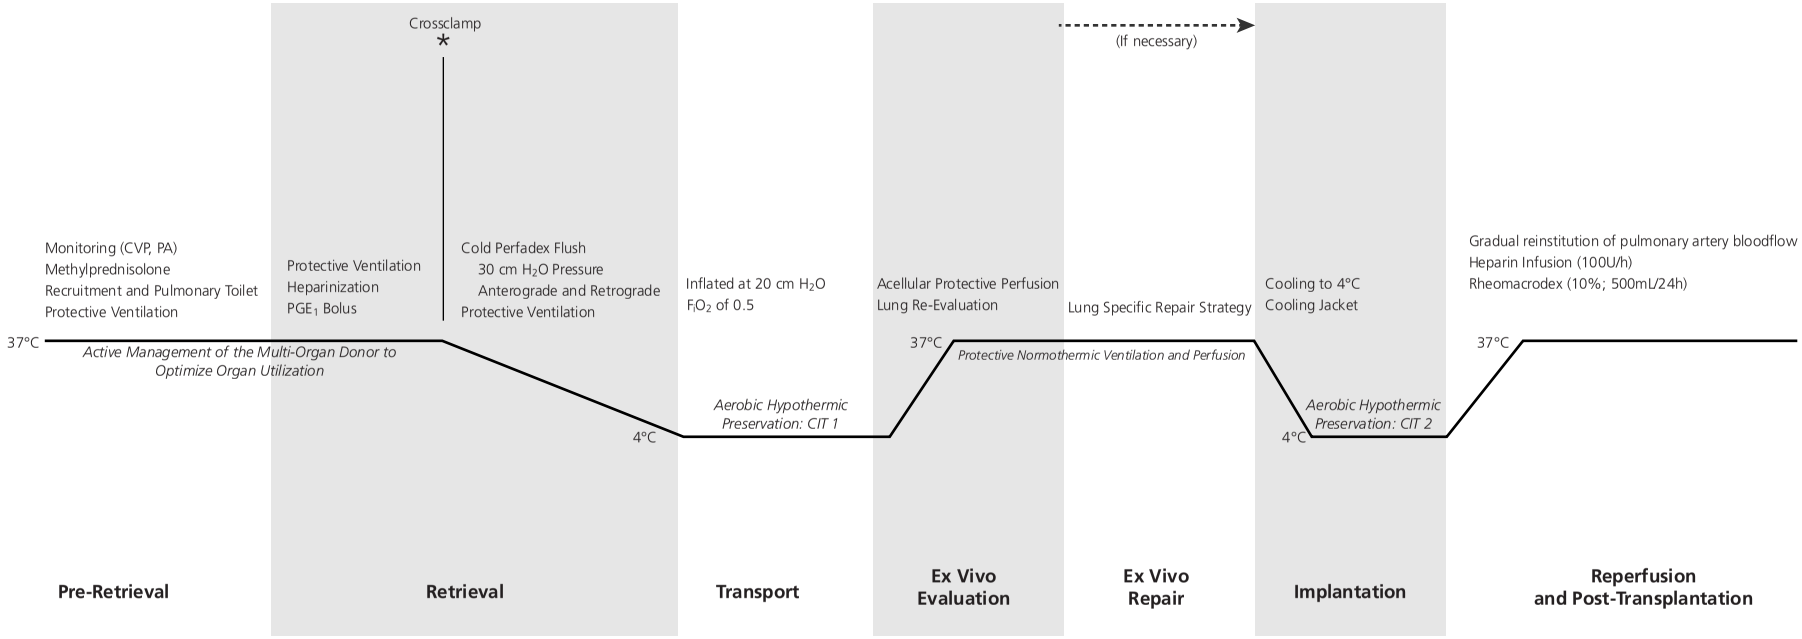


Figure 26.2. Trajectory of contemporary lung preservation techniques. Lung preservation begins in vivo in the multiorgan donor and continues through the ex-vivo phase of aerobic hypothermia and possible aerobic normothermia, finishing with reperfusion in the recipient. At each step there is potential for lung injury and opportunity to prevent or repair the injury. Temperature variation is used as a tool to provide hypothermic static preservation and normothermia for active therapy as needed. CVP, central venous pressure; PA, pulmonary artery.

restore endothelial barrier permeability and alveolar fluid balance after endotoxin-induced lung injury [83].

Heart preservation solutions

A major factor limiting the size of the donor pool is the duration of tolerable ischemic time. The most common method of heart preservation currently is antegrade perfusion with potassium-containing crystalloid solution at 4°C. The organ is then transported on ice and the graft reperfused within 4 h. Prolonging the ischemic time has been a focus of intense investigation. New methods to circumvent ischemic injury include variations in preservation solution and use of warm, heart beating strategies is being tested currently as described next.

Initial experience with cardiac allograft preservation involved use of solutions originally developed for use in abdominal organ transplantation, such UW solution and Euro-Collins solution. The electrolyte composition in these solutions is similar to intracellular fluid with low sodium and high potassium concentrations. Additionally, these solutions contain a number of impermeable molecules that minimize cellular edema. It became evident to heart surgeons that the preservation solution used for cardiac allografts must provide not only myocardial but also endothelial protection. A high potassium concentration in the preservation solution delivered to a warm graft can damage endothelium and predispose to chronic allograft vasculopathy [84–87]. To address this issue, newer solutions such as Histidine-Tryptophan-Ketoglutarate (HTK; Custodiol® or Bretschneider) and Celsior were developed. These solutions were based more on the extracellular milieu with lower potassium concentrations and additional substrates for energy production. Alternatively, some groups advocate the use of blood-based cardioplegic solutions. This requires a significant volume of blood to be withdrawn from the donor, which is not always tolerated. Nevertheless, published results suggest that this strategy provides good endothelial preservation and does not prevent the successful procurement of other organs [88]. Several comparisons have evaluated the merits of the various solutions and the weight of evidence demonstrates relatively equivalent and effective myocardial protection. Many novel preservation solution additives have been investigated, including antifreeze proteins to allow subzero preservation [89], endothelin antagonists to enhance endothelial preservation [90], antioxidants to blunt the deleterious effects of ischemia and reperfusion [91], and agents to maximize vascular smooth muscle relaxation [92], post-ischemic myocardial contractility [93], and preservation of mitochondrial energy stores [93]. While the majority of these modifications are not clinically available, it is likely that enhanced preservation solutions will one day improve graft function or prolong tolerable ischemic time.

Normothermic heart perfusion

Use of continuous oxygenated perfusion may improve graft preservation and ventricular function [93]. It allows for ongoing aerobic metabolism and washout of products of ischemia such as lactate and adenosine [94], thereby producing less substrate for free radical generation [95,96]. Also, since the myocardium tolerates higher temperatures better than lower, normothermic preservation should prevent thermal damage [97]. A preservation technique incorporating these two strategies has demonstrated that myocardial recovery and function after warm, machine perfusion are superior to cold static preservation at 4 h [98]. A practical way to transport a donor heart warm and beating using machine perfusion is being evaluated in the US in the Proceed II trial [99].

Summary

Ever since the development of clinical heart and lung transplantation, transplant clinicians and scientists have sought to reduce injury and maximize safe preservation time during the storage and transport of donor organs. Key advancements in lung preservation in the form of hypothermia, inflated storage, and Perfadex® flush have culminated in the maturation of lung transplantation into a standard of care for end-stage lung disease around the world. The state of cardiac transplantation remains considerably more limited by time. Today, the emphasis in lung preservation is shifting from slowing down organ death to that of facilitating organ recovery and regeneration prior to implantation. This has led to the emergence of normothermic EVLP as a strategy for lung preservation. Though EVLP is effective for lung preservation alone, its true potential lies in facilitating lung recovery and repair. Therefore, the thoughtful manipulation of preservation temperature in the context of the lung transplant process is important; i.e. protective hypothermia for retrieval and implantation and normothermia for recovery and repair (Figure 26.2). The development of ex-vivo lung repair strategies for the broad spectrum of donor lung injury is a burgeoning and important area for research. Development of an ex-vivo treatment arsenal ranging in complexity from pharmacological to gene and cellular therapies will hopefully one day allow for a "personalized medicine approach to the donor organ" – the "personalized" or targeted repair of donor lung injuries specific to each individual lung, finally allowing clinicians to utilize the full potential of the donor organ pool.

CHAPTER 27

Kidney Paired Donation Networks

Adam W. Bingaman[1] and Cathi L. Murphey[2]

[1] Methodist Specialty and Transplant Hospital, San Antonio, TX, USA

[2] Southwest Immunodiagnostics, Inc., San Antonio, TX, USA

Introduction

The waitlist for kidney transplantation continues to grow at a rapid rate across the world. In the (US, the wailist has doubled in the past 10 years with no significant increase in deceased donor organ availability [1]. Approximately 4500 Americans die on the kidney transplant waitlist each year [1]. Thus, the advantage of living donor kidney transplantation has increased over the years, offering patients the chance of receiving a kidney without waiting years on the list. Indeed, a living donor may be the only route to transplant for some older patients who can do well once transplanted but who cannot wait years for a deceased donor organ. Other advantages to living donor transplant include the chance for better immunologic compatibility, and improved early and long-term renal allograft function compared to deceased donor transplantation [2,3]. Furthermore, the transplant operation becomes elective surgery, allowing for optimal patient preparation and the opportunity to perform pre-emptive transplantation prior to the initiation of dialysis.

A significant barrier for many patients to receiving a living donor kidney transplant is that they must be immunologically compatible with their donors. Compatibility testing consists of blood type (ABO) as well as human leukocyte antigen (HLA) testing. It is estimated that there are at least 6000 patients on the kidney transplant waitlist with willing healthy donors who are not compatible [4]. The concept of kidney paired donation (KPD), in which incompatible pairs exchange donors to create compatible combinations, was first proposed in 1986 by Rapaport as a means to achieve compatible living donor transplantation for otherwise incompatible pairs [5]. The concept exchanges two incompatible donor pairs to create two compatible combinations (Figure 27.1a) A three-way exchange (Figure 27.1b) is more complex but allows more possible permutations of matching [6]. More recently, non-directed donors have been utilized to begin "chain transplants" (Figure 27.1c), resulting in large numbers of transplants from a single non-directed donor who is willing to donate a kidney to any recipient in need. While the concept of KPD to expand living donor transplant options had been well received, significant ethical, legal, immunologic, and logistical barriers needed to be overcome for this concept to become a reality. This chapter will cover these issues and describe how they are being successfully dealt with in modern paired exchange programs. The chapter should be considered along with Chapters 28 and 37 that cover the general considerations in accepting a patient for kidney transplantation and the management of patients awaiting kidney transplantation in general, respectively.

Which recipients are most likely to benefit from kidney paired donation?

Segev et al. published computer simulations of a cohort of incompatible donor–recipient pairs in a KPD program to predict matching rates for different subgroups of patients. These data have been an important predictive foundation for which pairs may be most likely to benefit from KPD and which factors predict such a benefit. They found that for recipient candidates with a panel reactive antibody (PRA) of <80%, the likelihood of a match is approximately 50% for most blood types and that there is only a small increase in benefit with a larger cohort size of incompatible pairs. As expected, moderately sensitized candidates with non-O blood types or with blood type O donors are expected to have short waiting times for a match. Not surprisingly, very few pairs with blood type AB donors are ever likely to be matched. In the group with a PRA of >80%, the likelihood of a match is significantly impacted by the cohort size of the incompatible database for almost all blood types. As expected, highly sensitized candidates who are blood group AB or with blood type O donors are more likely to be matched.

The simulations demonstrate that there are two major barriers to more matches. First, a significant imbalance of blood groups develops in KPD programs; the recipient pool becomes enriched with O blood type and the donor pool becomes enriched with non-O blood types. Of course, blood type O donors will usually be attached to highly sensitized recipients if they do not match quickly in a large cohort of incompatible pairs. Second, highly sensitized recipients in the cohort are in competition to find rare donor HLA types who may provide a match. For example, donors who are homozygous at multiple HLA loci will be more likely to match with sensitized patients, but such HLA types are uncommon.

Kidney paired donation matching algorithms

The matching software system should be optimally designed to predict matches with at least one-, two-, and three-way matching algorithms. Statistical modeling has shown that three-way exchanges have the opportunity to make the best use of blood type O donors and help more highly sensitized recipients compared with two–way exchanges [6]. Four-way or greater closed loop exchanges add significant complexity to the logistics of exchanges and add less benefit, and thus are not routinely performed. Utilization of non-directed donors to initiate a non-simultaneous, extended, altruistic

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

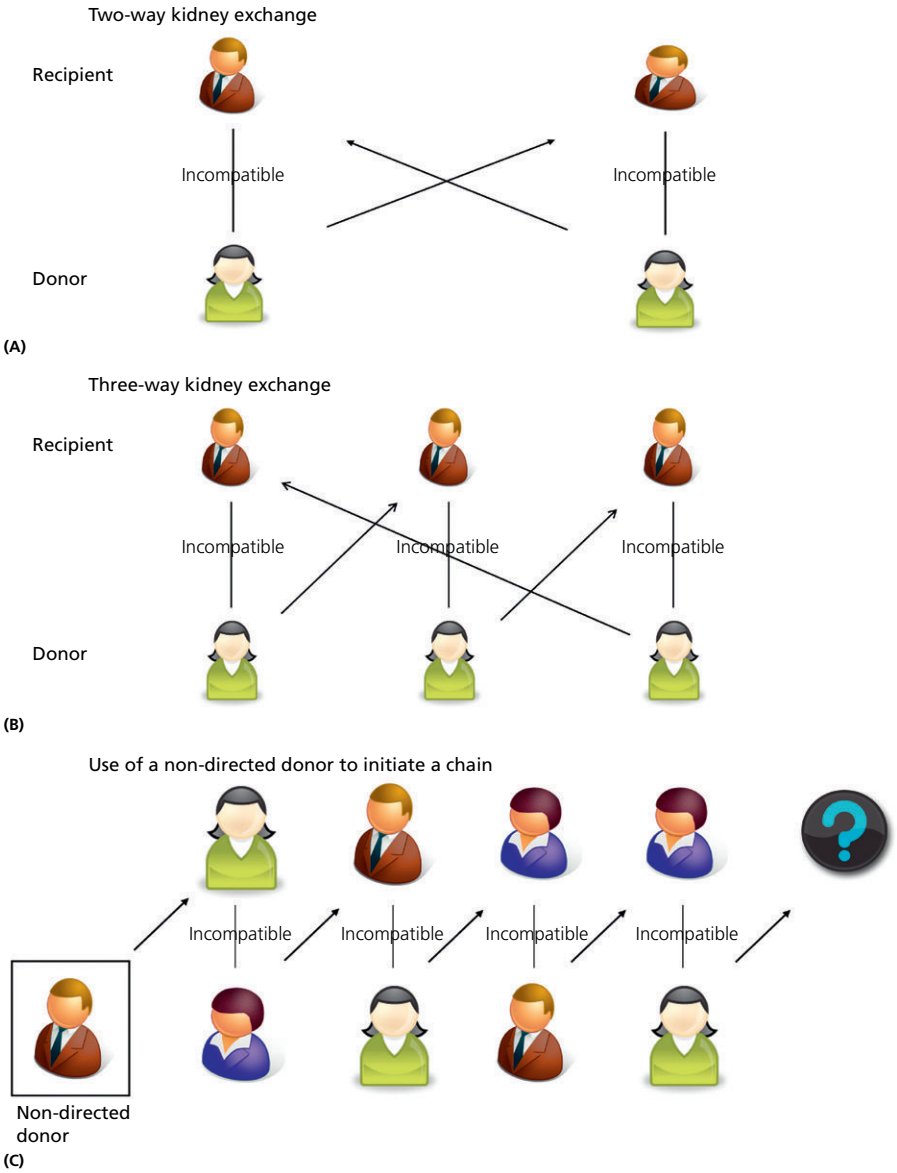

Figure 27.1. Common types of kidney paired donation transplants. (A) A closed loop two-way exchange between incompatible pairs. (B) A three-way closed loop exchange between incompatible pairs. (C) A one-way "chain" exchange started with a non-directed donor and which can terminate in either donation to the deceased donor waitlist or kept as a "bridge donor" to initiate another chain.

donor (NEAD) chain has benefitted large numbers of patients. Rees et al. reported the first NEAD chain in March 2009 in which a single non-directed donor facilitated 10 transplants involving six transplant centers in five different states over a period of 8 months [7]. Subsequent larger chains involving other regional and single-center programs have been reported, including a chain with a total of 46 individuals (23 donors and 23 recipients) at a single center [8,9]. There are two possible ways to end a chain: (1) the last living donor donates directly to the deceased donor waitlist thus ending the chain; and (2) a "bridge donor" is held and thus another chain is started at a later date. It has not been definitively established which method generates the greatest number of transplants. Computer models generated by Gentry et al. show that donating directly to the list generates more transplants over time if the chain length is held to three pairs within a concurrent segment [10]. However, simulations generated by Ashlagi et al. utilizing unrestricted chain lengths demonstrated that using "bridge donors" generates more transplants despite the risk of a donor reneging [11,12]. Clearly, more data and experience with both of these modalities is necessary to determine which chain termination mechanism generates the greatest number of transplants over time.

The kidney paired donation database, software matching program, and use of solid phase antibody testing

A successful KPD program depends upon a large number of incompatible pairs and a sophisticated software program to predict matching. All recipient and donor candidates should be consented for inclusion into a KPD database to maximize the pool size. The critical pool size to generate substantial numbers of matches is not known, but has been estimated to be at least 100 pairs [13]. Early

education about immune compatibility and the option to enroll both donor and recipient candidates in a KPD program are important aspects of KPD programs to maximize enrollment. Inclusion of multiple donors for a single recipient may be encouraged in an effort to enroll more blood type O donors or donors with more favorable HLA types into the program. Many programs, especially regional and national programs, mandate complete evaluation of all donors prior to enrollment into the KPD program, which limits the number of donors who may otherwise participate if not for the cost and time involved in each evaluation process.

The essential elements that are necessary to enter into any KPD system include donor and recipient demographic information, such as age and gender, as well as blood type and histocompatibility information. Both donor and recipient HLA types should be entered to allow for the identification of mismatching between pairs; these data are utilized by many (but not all) KPD programs. Indeed, the US program gives considerable points in the national algorithm to zero mismatch pairs. The majority of candidates in large KPD databases are sensitized and thus difficult to match with a compatible donor. Therefore, the most critical information entered into the KPD database is the assigned unacceptable antigens based upon very sensitive HLA antibody identification assays. These assays are the basis for predicting matched pairs for sensitized candidates and as such have had a profound impact on the development of KPD. Thus, to understand KPD, one must have an understanding of HLA antibody detection techniques (comprehensively reviewed in Chapters 36 and 89).

Role of HLA antibody identification

Advances in immunogenetics such as DNA-based HLA testing, solid phase antibody characterization, and flow cytometry cross-matching have refined the ability to identify acceptable donor–recipient profiles [14,15]. The most widely used technique to determine anti-HLA antibodies in the US uses a solid phase assay in which fluorescent microbeads are coated with individual HLA molecules. Fluorescence detection is then used as a marker for antibody detection. Identification of anti-HLA antibodies in recipient candidates is used in a "virtual cross-match" as the basis to predict actual cross-match results with a given donor [16,17]. In KPD, all sensitized candidates must have these antibodies to "unacceptable antigens" assigned in the database; matching software can then preclude a match with any donor with the "unacceptable antigens." Careful assignment of unacceptable antigens allows for accurate prediction of cross-match results. By contrast, over-assignment of unacceptable antigens, especially in highly sensitized candidates, will limit their transplant options and may prevent a successful transplant combination [18]. Ideally, assignment of unacceptable antigens in a KPD database should be sufficiently stringent to prevent a positive cross-match that would preclude transplantation (and thus interfere with a planned KPD transplant), but not so stringent as to prevent a transplant combination that may be acceptable [19,20]. Indeed, the goal of anti-HLA antibody identification is to lead to *more* successful transplants, and not to prevent transplantation of candidates with acceptable levels of donor-specific antibodies or antibodies that may not be clinically relevant. This is an area in which significant work is left to be done; this work will have a profound impact on the transplantation of highly sensitized patients by KPD. This concept of "unacceptable antigens" is used in the US; however, the European Transplant Program utilizes the reverse system and assigns "acceptable antigens" [21]. While the approach differs in Europe, the concept of utilizing a virtual cross-match to predict actual cross-match results is the same.

Global kidney paired donation experience

KPD has had a global impact on living donor transplantation. Many transplant centers worldwide have adopted this strategy to increase access to transplantation in single-center, regional, or national programs.

The United States experience

In the US, though firm foundation had been laid for lawful living donor transplantation for many decades, a clause in the National Organ Transplant Act (NOTA) of 1984 caused concern for the legality of paired donation. It stated, in part, "it shall be unlawful for any person to knowingly acquire, receive or otherwise transfer any human organ for valuable consideration for use in human transplantation" [22] (see Chapter 138 for a more detailed discussion of the ethics of living donation). There was concern that the kidney exchange process, whereby an incompatible donor gives a kidney to a different recipient in exchange for the kidney from the other incompatible donor, was tantamount to valuable consideration and thus unlawful. In response to lobbying efforts by the transplant community and transplant organizations, the Charlie W. Norwood Living Organ Donation Act was passed in December 2007, which amended the NOTA by adding that the clause regarding valuable consideration "does not apply with respect to human organ paired donation" [23]. Other countries continue to face legal barriers to KPD that have limited its international growth.

In addition to legal obstacles to KPD, ethical issued also needed to be addressed. In 1997, Ross et al. from the University of Chicago published a discussion of the ethics of a paired kidney exchange program [24]. Other subsequent publications have also laid an ethical foundation for paired donation [25,26]. The four overriding biomedical ethical principles that guide the justification of living donor transplantation are beneficence, non-malfeasance, justice, and autonomy [27]. It is felt that "indirect donation," by means of paired donor exchange, does not weaken or change these guiding principles. However, concerns such as the potential for coercion and the maintenance of anonymity have special consideration in paired donation. For example, a reluctant donor may be relieved by an incompatible result, but faced with the option for paired donation, no longer has the incompatible result as a reason for not proceeding with donation. Thus, extra measures and care should be taken with donors enrolled in paired donation to be certain that the decision to donate is purely voluntary. Of course, all participants have a right to withdraw consent at any time, and thus paired donor transplants must proceed in a sequential fashion such that a potential recipient's donor will not donate until the recipient has been transplanted. Thus, it is felt that consents and policies should be in place at all US centers performing KPD to ensure that such special considerations are managed appropriately.

In addition, since two or more pairs are involved in the paired donation process, it is felt in the US that protocols should be established to maintain privacy and confidentiality between pairs. These protocols should encompass clinic visits, all phases of the operation including preoperative, operative, and postoperative care units, and all family waiting rooms. With the legal framework in place and strict adherence to the guiding principles of biomedical ethics and attention to these special considerations, the public has largely come to accept KPD as acceptable in the US.

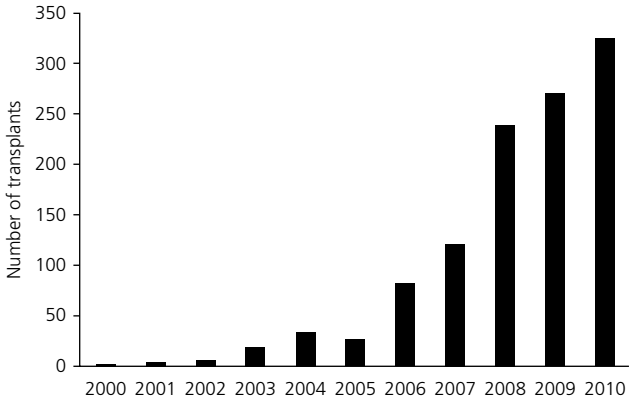

Figure 27.2. Number of reported kidney paired donation transplants performed in the US from 2000 to 2010.

Table 27.1. Scoring system proposed in the United States National KPD program

Match characteristic	Points
Match between a candidate and a potential living donor	200
Zero antigen mismatches between candidate and potential donor	200
Candidate who is a prior living organ donor	150
Highly sensitized candidate with PRA ≥80%	125
Candidates ≤18 years of age	100
Matches between candidates and potential donors at the same center	75
Matches between candidates and potential donors in the same donation service area	50
Matches between candidates and potential donors in the same region	25
Candidates who have participated in previous match runs but were not transplanted	2
Candidates who have one or more antibody assignments against the potential donor	−5

PRA, panel reactive antibody.

KPD in the US has been utilized by single centers, multiregional programs, and more recently by a national program that was initiated in 2010 as a pilot project with four coordinating centers [12,28,29]. Since KPD was initiated in the US, >1000 KPD transplants have been performed (Figure 27.2.) [1,30,31]. Johns Hopkins initiated the first large single-center KPD program in 2000 and reported their 100th KPD transplant in March 2010. The Methodist San Antonio program began in 2008 and has done 250 KPD transplants through December 2013. Each of these single-center experiences has been aided by computerized matching software developed by Inessa Kaplan [32]. Several multiregional programs have also been quite successful, including the Alliance for Paired Donation, New England Program for Kidney Exchange, Paired Donation Network, and National Kidney Registry [7,29,33,34]. Each of these multiregional programs has distinct rules for participation, unique matching algorithms, and differing levels of success and participation. Importantly, the outcomes of KPD transplant recipients have been shown to be comparable to those for non-KPD living donor transplants [35]. In an effort to standardize and hopefully expand KPD in the US, the United Network for Organ Sharing (UNOS) initiated a pilot program in 2010, which has subsequently been approved for utilization by all approved US transplant centers.

The operational guidelines for the US National KPD program were updated in 2011 and set out the rules for participation [36]. All pairs must be consented and fully evaluated and approved for transplant and donation prior to entrance into the KPD program. Unacceptable antigens are identified by the local center according to guidelines that include the use of solid phase, single antigen bead testing. The matching algorithm uses a scoring system to prioritize matches based on a weighted point system (Table 27.1). All cross-match testing is done by the local transplant candidate's participating center. If a center identifies repeated positive cross-matches that preclude an exchange from occurring, the center may be required to submit samples to a referral laboratory for testing in order to participate further in the program. Donor operations should occur simultaneously except in the case of chain operations in which separate rules are employed for the order of operations. Anonymity amongst pairs must be preserved prior to the exchange operations. It is anticipated that most donor kidneys will be shipped to avoid the logistics of travel for donors and to avoid separation of candidates and their donors.

As of December 2011, 86 US transplant centers were participating in the national program and 10 transplants had been performed as part of the national program. Since then, broader participation by more centers, along with the recent addition of chain transplants, have significantly expanded the program.

The Korean experience

The first paired donor transplant in the world was a two-way exchange in Korea in 1991 between recipient pairs who had HLA incompatibility [37,38]. In Korea, deceased donor transplantation is limited, which has enhanced efforts to expand living donor transplantation options. The Korean criteria for acceptable living unrelated (LURD) transplantation require either a two- of four-antigen match at HLA A/B or at least a one-antigen match at HLA DR [39]. The reasons for exchange transplantation in Korea include blood-type incompatibility, unacceptable HLA matching according to policy, or positive cross-match. Anonymity between pairs has not been required. At a single transplant center in Korea, 1090 living donor kidney transplants were reported between 1995 and 2006, including 692 living related transplants (LRD) and 398 LURD transplants [39]. The LURD transplants included 129 exchange recipients and 269 non-exchange recipients. Of the 129 exchange recipients, 84 (65%) were done for blood-type incompatibility, 39 (30%) to conform to HLA matching criteria, and six (5%) for positive cross-match. Sensitization levels of exchange and non-exchange donors have not been reported by the Koreans, but interestingly, the proportion of retransplant patients was significantly lower in the exchange group compared with the non-exchange group. Graft survival and patient survival data were comparable between the exchange and non-exchange groups of LURD recipients. The KPD program increased the overall percentage of living donor transplants by 11.8%. The success of the Korean experience has been driven by large single centers and not a national program, and is expected to continue to increase in the future due to the more recent utilization of more non-directed donors [40,41].

The Romanian experience

Romania also has very limited deceased donor transplantation and thus a strong willingness to pursue alternative strategies for living donor transplantation. There are two active kidney transplant programs, one of which initiated a KPD program in 2001 [42]. Inclusion criteria for the KPD program include an incompatibility due

to ABO or positive cross-match, informed consent, and an emotionally-related living donor. From January 2001 to December 2005, a total of 26 paired donor transplants were performed, including 23 two-way exchanges, two three-way exchanges, and one four-way exchange. Operations were simultaneous for two- and three-way exchanges and on subsequent days for the four-way exchange. All pairs were acquainted preoperatively, as anonymity was felt to be unnecessary and unrealistic. Neither the proportion of ABO or cross-match incompatible pairs transplanted, nor sensitization levels of recipients, were reported. Graft survival rates between the KPD recipients (98.2%) and the direct living donor cohort (97.9%) were very similar and the difference in acute rejection rates between the groups was not statistically significant. This Romanian experience was entirely driven by a single transplant center and thus also highlights the capacity of single-center paired donation.

The Dutch experience

It is clear that the success of KPD is related to the number of pairs in the incompatible pool. To this end, the Netherlands, a country with a population of approximately 16 million, formed a highly successful national program in 2004 in which all seven kidney transplant programs participate [43–49]. An independent organization, The Dutch Transplantation Foundation, was formed and manages the KPD allocation system according to a set of rules agreed upon by all centers. First, all donors are evaluated by a common protocol and pairs are entered into the system four times a year if medically suitable. Second, a computerized matching algorithm is used to select best matches according to present conditions, including: (1) a maximum number of matched pairs; (2) blood type identical before blood type compatible matches; (3) most difficult-to-match (highly sensitized) recipients first; (4) short chains preferred; (5) pairs distributed over multiple centers; and (6) time on dialysis. The program considers that such a relatively simple algorithm that does not account for degree of HLA matching, donor age, gender or size, or other variables is important to the success of the program. Third, all compatibility testing between matched pairs is done at a national HLA reference laboratory, which allows for standardization of cross-matching. Finally, paired donor surgical procedures are done simultaneously and all donors must travel to recipient centers. The matching algorithm originally accommodated only two-way exchanges but was adapted to provide three-way exchanges in 2005 and to include maximum possible chain length in 2007. Between January 2004 and December 2008, 312 pairs were registered, including 54% from ABO incompatible pairs and 46% from cross-match incompatible pairs. Exchanges were identified for 169 pairs and 131 exchange transplants were performed, making the Netherlands' experience the most successful national program to date.

The United Kingdom experience

The legal framework to establish a KPD program in the UK developed in 2004 and is regulated by the Human Tissue Act, which set up the Human Tissue Authority (HTA) to regulate all living donor transplantations. Independent assessors evaluate all living donors and make recommendations to the HTA with regard to suitability. In the case of KPD, donor approval is required from a panel of three HTA members. With this structure to approve KPD donors in place, a matching scheme was developed by UK Transplant and is carried out amongst the 23 kidney transplant centers on a nationwide basis [50]. When ABO and cross-match incompatible pairs are identified, they are fully evaluated and, after approval, are entered into the program. An algorithm was developed to identify all potential two-way and three-way exchanges and then to score the matches based upon four criteria: (1) geographical proximity of donor to recipient; (2) calculated antibody reaction frequency; (3) HLA A, B, and DR mismatch; and (4) donor–donor age difference. Match runs are generated every 3 months and cross-match testing is organized and carried out by the participating centers. Strict anonymity between pairs is a requirement of the program. It is strongly recommended that donor kidneys are shipped and it is required that donor operations are performed simultaneously. Recently, UK Transplant adopted a scheme to allow for altruistic non-directed donation and initiation of chain transplants. Between April 2007 when the initial KPD transplant was performed by UK Transplant and April 2010, a total of 64 KPD transplants have been performed. This initial productivity was less than originally anticipated, but it is hoped the recent initiation of chain paired donation utilizing non-directed donors will further enhance the productivity in the future.

The Australian experience

The Western Australian (WA) KPD program was established in October 2007 as an initiative of a single transplant center in Perth which performs approximately 80 living donor kidney transplants annually [49,51]. Thirteen months after initiation of the program, nine KPD transplants had been done, including one two-way exchange, one three-way exchange, one two recipient chain initiated by a non-directed donor, and one three recipient chain initiated by a non-directed donor. Five of the recipients were sensitized, of whom three had a PRA of >70%. This KPD experience increased living donor transplantation by approximately 10% in Western Australia. The WA KPD experience was the basis for developing a national program, including all 14 Australian transplant centers, to increase access to living donor transplantation in Australia. To ensure equitable matching and allocation for all transplant centers, the National Organ Matching System (NOMS) performs the match runs generated by a computer program that was developed based on the guidelines of the Dutch algorithm. It is anticipated that the national experience will mimic the WA experience in expanding access to living donor transplant by 7–10%, but such national data has not yet been published.

Future expansion

Utilizing compatible pairs

In an effort to expand KPD, it has been suggested that non-HLA identical compatible pairs should be considered for inclusion into KPD programs. The utilization of compatible pairs to facilitate KPD transplants has been termed altruistic unbalanced paired kidney exchange (AUPKE) [52]. Ratner et al. have studied attitudes toward AUPKE and found that many pairs may favor such an arrangement, especially if there is a perceived benefit for the recipient [53,54]. One example of such a perceived benefit would be if the compatible exchange recipient were to receive a kidney from a younger donor. Several groups have utilized compatible pairs in KPD simulations and shown significant benefit [55,56]. Addition of compatible pairs increases the population of blood type O donors with unsensitized recipients, thus addressing the blood type imbalance that exists in the KPD pool. For example, each unsensitized blood type A candidate with a blood type O donor could facilitate a transplant between an incompatible blood type O recipient with a younger blood type

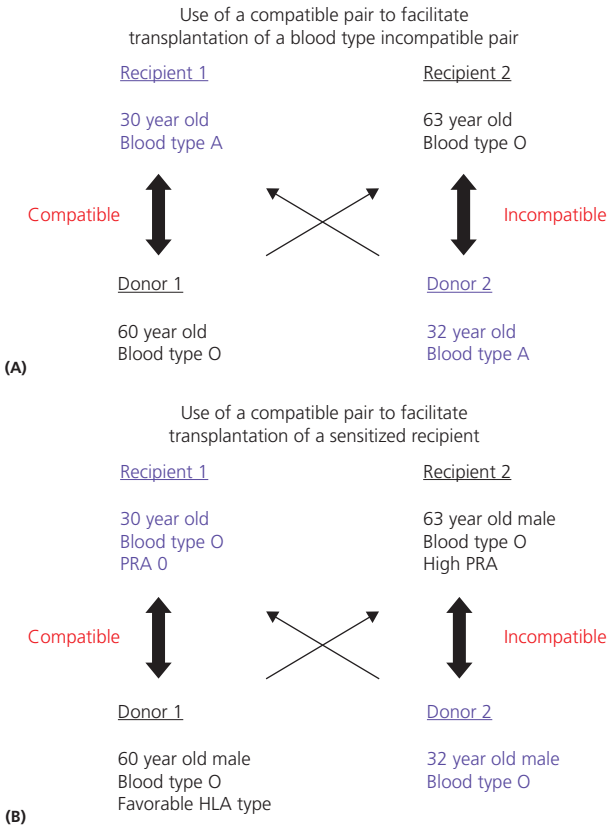

Figure 27.3. Utilization of a compatible pair to facilitate kidney paired donation transplants. (A) Use of a compatible pair to facilitate transplantation of a recipient with a blood-type incompatible donor. (B) Use of a compatible pair to facilitate transplantation of a sensitized recipient with a cross-match incompatible donor.
PRA, panel reactive antibody.

A donor (Figure 27.3a). Additionally, donors with rare, favorable HLA types can be used to match otherwise very difficult-to-match highly sensitized recipients (Figure 27.3b). Inclusion of compatible pairs into large KPD programs may be expected to double the match rate for incompatible pairs and thus may have a dramatic effect on further expansion of KPD. Ethical concerns, however, regarding the use of compatible pairs in KPD are an important consideration and may limit further expansion of such programs; further discussion and research are needed.

Combination of kidney paired donation with desensitization

KPD and desensitization have often been viewed as competing strategies to transplant incompatible pairs, but more recently they have been viewed as complementary [28,57,58]. The subset of candidates who are very highly sensitized (PRA $\leq$90%) or moderately sensitized with non-blood type O donors are very difficult to match with a compatible pair in KPD programs. These candidates may be ideally suited to a combination of KPD with desensitization. For example, a candidate with high antibody reactivity against an original donor may be able to find an exchange donor to whom they have less antibody reactivity that would be amenable to successful desensitization. Such a strategy has been widely employed by the transplant groups at Johns Hopkins, UCLA, and Methodist San Antonio, and is thought to be an important option for the most challenging to match candidates. Results utilizing this strategy have not been published and thus this concept will need to be studied further prior to wide implementation.

Internationalization

The international growth of KPD programs over the past 10 years has resulted in thousands of patients realizing the benefit of living donor kidney transplantation and who would otherwise have waited years to receive a deceased donor kidney transplant. Importantly, each KPD transplant that is performed results in one less candidate on a waitlist, allowing for more rapid transplantation for others who do not have donors. Now that many ethical, legal, and logistical barriers have been overcome, successful programs have now been established in Europe, Asia, Australia, and North America. Several reports have shown that shipment of living donor kidneys over very large distances has not been associated with significant delayed function or poor outcomes [59,60]. It is envisioned that the future may bring international co-operation and thus even larger exchange registries to benefit further highly sensitized patients around the world [61].

Summary

KPD has long been recognized as a potential solution to the shortage of suitable deceased donor kidneys and the factors maintaining patients on deceased donor waitlists for prolonged periods of time. However, it is only recently that the substantial logistical barriers preventing broad implementation of ethically sound KPD programs have been sufficiently addressed to allow for meaningful implementation of broad KPD sharing programs. As these programs emerge in the coming decade, it is likely that they will become increasingly utilized to provide the best option for sensitized patients awaiting transplantation.

SECTION 4

Pre-operative Management of Transplant Patients

CHAPTER 28

Patient Selection and Indications for Kidney Transplantation

Jeremy Goodman and Robert S. Gaston
Departments of Surgery and Medicine, University of Alabama at Birmingham, Birmingham, AL, USA

Introduction

Though solid organ transplantation originated with kidney isografts and allografts, modern renal transplantation remains distinct due to several key attributes. First, as death was the consequence of irreversible renal failure in the 1950s, and the kidney is a paired organ, living donors enabled the first successful transplants, and remain a major source of transplantable kidneys a half-century later. Second, because there is now an alternative treatment for patients with irreversible kidney failure (maintenance dialysis is successful and widely available throughout the developed world), much of the urgency associated with transplantation of other organs does not apply to kidneys. Accordingly, though as with all solid organs demand far exceeds supply, acceptance of chronic dialysis as a therapeutic modality makes a decision by patient or provider not to pursue transplantation a reasonable one, as death is not the only alternative. Thus, defining indications and contraindications for transplantation and selecting appropriate transplant candidates occur in the context of renal replacement therapy (RRT), a very different scenario from patient selection for other solid organ transplants. This chapter will summarize the common indications that might bring a patient to consider transplantation as their option for renal replacement. The chapter complements information found in Chapter 37, which details waiting list management for patients awaiting transplantation.

Kidney transplantation as renal replacement therapy

End-stage renal disease (ESRD) is the most advanced stage of chronic kidney disease (CKD) (Table 28.1) [1]. CKD risk increases dramatically with age, with the vast majority of patients never progressing beyond Stage 3 due to mortality from associated co-morbidities. Ultimately, there are approximately 120 000 incident cases of ESRD in the US each year [2]. An almost uniformly fatal outcome was the norm until the 1960s, when dialysis and transplantation first became available. Originally, dialysis was thought to be only a temporizing solution, providing support until recovery for a patient with acute kidney failure or a bridge to transplantation for those with irreversible disease. However, due to dismal transplant outcomes and a limited supply of transplantable kidneys, chronic dialysis had by the 1970s become the more common therapy [3]. This paradigm became institutionalized in the US by the Social Security Amendments of 1972, federal legislation that created the Medicare ESRD program, to this day the only organ-specific entitlement in this country [4]. With benefits thought largely related to quality of life, indications for transplantation were limited (the young and healthy being considered the best candidates) and strict patient selection criteria were utilized to distinguish those most likely to benefit and withstand the hazards of chronic immunosuppression. There existed in most centers multidisciplinary selection committees entrusted with decision-making regarding access to dialysis, transplantation, or neither [5]. Selection criteria often included not just health status, but age, rehabilitation potential, and "value" to society [6]. Not surprisingly, the conundrums inherent in such a process led to the abandonment of these committees during the 1980s, though multidisciplinary assessment of "transplantability" persists in most transplant centers [7].

In the 1980s and 1990s, several major advances changed the dynamic of patient selection for transplantation. The availability of cyclosporine in 1983 ushered in the modern era of effective immunosuppression: rejection could be prevented, corticosteroid doses reduced dramatically, complications managed, and overall outcomes improved, particularly for recipients of deceased donor kidneys [8]. Less dependence on HLA matching between donor and recipient meant that transplantation could be offered to a much broader group of patients [9]. Advances in antimicrobial therapy, particularly antifungals and antivirals, allowed effective treatment of the infections that had caused the demise of many hardy and not-so-hardy recipients in earlier days [10]. Co-incidentally, a novel statistical model applied to a maturing Medicare database enabled comparison of outcomes with each modality of RRT [11]. To the surprise of more than a few, regardless of age, ethnicity, or original disease, not to mention the futility of trying to define an individual's value, kidney transplantation offered a substantial survival benefit over any other alternative: projected longevity compared to dialysis was essentially doubled by transplantation. In a more recent analysis designed to better inform allocation of deceased donor kidneys,

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Table 28.1. Chronic kidney disease (CKD) in the US

(a) Clinical stages of CKD according to estimated glomerular filtration rate (eGFR) [1,96]

Stage	Description	eGFR (mL/min/1.73m^2)	Prevalence (% US adults ≥20 years old)
1	Evidence of kidney damage with normal GFR (e.g. proteinuria, hematuria)	>90	5.7
2	Mild	60–89	5.4
3	Moderate	30–59	5.4
4	Severe	15–29	0.4 (Stage 4 or greater)
5	Kidney failure (end-stage renal disease)	<15	

(b) Common causes of end-stage renal disease (ESRD) with associated percentages of incident cases in 2009 [2]

Cause of ESRD	Percentage of incident cases
Diabetes mellitus (types 1 and 2)	44
Hypertension	28
Glomerulonephritis	7
Cystic kidney disease	2
Other or unknown	19

the concept of life years from transplant (LYFT) was developed. LYFT was derived utilizing patient characteristics in the USRDS database: projecting longevity on dialysis for any given patient, projecting longevity for that same patient with a kidney transplant, and subtracting the former from the latter [12]. Regardless of age, gender, ethnicity, original kidney disease, diabetic status, region, or insurance status, receiving a kidney from a deceased donor (with presumption of even greater benefit from a live donor kidney) substantially extends projected lifespan of most ESRD patients. It has also been estimated that a successful kidney transplant may save payers as much as $330 000 [adjusted to 2011 US dollars, including the value of quality-adjusted life years (QALYs)] over the life of the transplant [13]. Because of the life-sustaining and cost-effective nature of kidney transplantation, Medicare mandates assessment of transplant status for each covered ESRD patient. Recent data indicate extreme variability in how this policy is implemented from center to center [14].

In the current era, indications for transplantation in the ESRD population are now quite broad, and the selection process is focused on identifying the presence of a shrinking number of known contraindications. This "transplant evaluation" occurs after a CKD patient is referred to a transplant center by his/her nephrologist or other provider. Ideally, such referrals should occur at the same time as patients are referred for creation of dialysis access: during Stage 4 CKD [estimated glomerular filtration rate (eGFR), 20–29 mL/min), which allows completion of testing and identification of potential living donors early enough for the transplant to occur as primary therapy [15].

The guiding principle of transplant evaluation is determining the best option for each individual patient. Some would inject a competing ethic into the process, that of making the best use of the relatively limited number of kidneys available for transplantation (almost 100 000 candidates are listed, but only approximately 10 000 kidneys are recovered each year), attempting to ascertain the validity of one person's claim over that of another [16]. However, even granting that a provider might be capable of such a judgment, recent evidence suggests that while as many as 20% of those on the current waiting list may receive relatively little benefit from transplantation, the number of patients likely to live substantially longer with a transplant but lingering on dialysis without evaluation and listing may be ten-fold greater [17]. The solution would appear to be not limiting access but finding more transplantable kidneys.

Selecting a donor

As implied above, kidney transplantation, and to some extent all solid organ transplantation, owes its existence to the living donor. The first successful transplants were between twins, who are without important histocompatibility differences [18]. Subsequently, after development of effective immunosuppression, most of the first successful allografts originated in living donors [19]. In the current era, there remains substantial benefit of receiving a kidney from a living donor, including better kidney function and short- and long-term graft survival (61% versus 45% at 10 years) [16]. In addition, living donor transplantation offers elective surgical scheduling and excellent immediate function that may mitigate other risks (e.g. perioperative cardiac events, delayed graft function, acute rejection). With average time to transplant in excess of 3 years nationally (and longer in many locales) for a deceased donor kidney, the biggest advantage of living donor transplantation may be avoidance of prolonged time (and attendant dialysis co-morbidities) awaiting transplantation. For most potential recipients, living donor transplantation offers timely intervention and the best opportunity for a successful outcome, making it the donor option of choice in most situations.

Optimal timing of kidney transplantation

Although not totally without controversy, it is generally accepted that increasing duration of dialysis is associated with increased risk of kidney allograft failure [20,21]. Meier-Kriesche et al. reported in 2002 that time on dialysis was an important variable influencing risk for recipients of both living and deceased donor kidneys, with as little as 6 months of dialysis therapy significantly reducing long-term graft survival [22]. Subsequent work indicates any decrement in outcome is primarily reflective of reduced patient survival, not immunologic graft failure, and varies according to age and ethnicity [23]. A recent study by Schold et al. documented that the impact of time on dialysis could be broken down into time spent before and after wait listing [24]. When examined in this regard, the differential impact on outcome was entirely due to the time between onset of dialysis and wait listing, with the time between wait listing and transplantation having no impact. The authors interpreted the data as indicating pre-evaluation characteristics, including co-morbidities and socioeconomic status, as responsible for delayed referral and major factors contributing to increased mortality risk after transplantation.

Nuances aside, it is generally accepted that optimal timing for transplantation is before maintenance dialysis is initiated (pre-emptive), allowing patients to avoid associated co-morbidities, maintain functional status and employment, and promote optimal outcomes [15]. Given the number of candidates on the waiting list, pre-emptive transplantation typically requires the availability of a living donor, and only 2% of ESRD patients begin RRT with a transplant [16]. It is common among third-party payers and transplant centers to require recipients be at late stage 4 CKD (eGFR ≤20 mL/min) before proceeding with living donor transplantation;

Table 28.2. Medical assessment of the kidney transplant candidate

1 Comprehensive history and physical examination
2 Diagnostic evaluation:
  (a) Electrocardiography
  (b) Chest radiography
  (c) Colonoscopy (over 50 years of age)
  (d) Ultrasound of urinary tract and native kidneys
  (e) Females:
    Pap smear
    Mammography (age over 40 years or family history of breast cancer)
  (f) Cardiac evaluation (see text)
  (g) Urologic evaluation (history of bladder/voiding dysfunction or recurrent urinary tract infections)
  (h) Vascular evaluation: non-contrast pelvic CT (age >50 years or >5 years on dialysis)
3 Laboratory evaluation:
  (a) Routine: CBC with differential and platelet counts, comprehensive metabolic panel, prothrombin time, partial thromboplastin time
  (b) Urinalysis, urine culture
  (c) Serologic tests: HIV, HBV (core and surface antibody, surface antigen), HCV, CMV, EBV, varicella, rapid plasma reagin (RPR)
  (d) Prostate-specific antigen in men over age 50 years
  (e) Immunologic testing:
    ABO blood group
    HLA typing and determination of preformed anti-HLA antibodies
    Cross-matching with potential donors

current United Network for Organ Sharing (UNOS) guidelines require a eGFR of $\leq$20 mL/min to accrue allocation points on the waiting list [25]. There is no indication that pretransplant eGFR exerts any influence on either post-transplant allograft function or graft survival; the benefit of pre-emptive transplantation appears to be related entirely to avoiding dialysis and its attendant co-morbidities [26]. Thus, optimal timing for transplantation would be in a candidate with an eGFR of $\leq$20 mL/min, with little or no uremic symptomatology, and before initiation of chronic dialysis. Again, achieving this goal requires referral for transplantation early enough (eGFR 20–29 mL/min) to allow completion of the pretransplant process in a timely fashion [27].

The transplant evaluation

The transplant evaluation itself is designed to include:

- An educational component in which prospective candidates learn about risks, benefits, measures necessary to promote successful kidney transplantation, and strategies to identify potential living donors.
- Medical testing to identify co-morbidity that either requires therapy or may preclude transplantation (Table 28.2), as well as provide risk stratification for appropriate patient counseling.
- Psychosocial evaluation to assess ability of a potential candidate and his/her support network to understand and follow treatment plans (Table 28.3).
- Financial counseling to ensure access to resources (Medicare, Medicaid, private insurance, personal finances) sufficient to maintain a healthy allograft [28].

At most centers, referral results in triage based on patient history; obvious contraindications preclude further testing. The subsequent evaluation process typically involves a multidisciplinary team consisting of a coordinator, nephrologist, surgeon, mental health professional, social worker, and financial counselor. The medical screening is typically straightforward, with interpretation of results of testing geared toward addressing the issues noted below. A positive screening test (Table 28.2) will generally result in additional testing.

As is common in dealing with chronic diseases, successful transplantation is often accompanied by significant psychologic and socioeconomic concerns. In its early years, psychiatric problems were considered a major contraindication to kidney transplantation. Now, psychiatric illnesses, if appropriately treated, rarely preclude transplantation [29]. Rather, most transplant centers would require that psychiatric disturbances be adequately treated and have a reasonably benign prognosis before proceeding [30]. Initial assessment of a potential transplant candidate must address level of cognitive function [29]. Granting informed consent requires comprehension of risks and benefits of transplantation relative to dialysis. After transplantation, cognitive skills adequate to understand and follow complicated immunosuppressant and follow-up regimens are essential. At times, ESRD is associated with significant organic illness (anemia, vitamin deficiencies, etc.) that can impair cognition and these should be aggressively diagnosed and treated. In some ESRD patients, cognitive deficits may improve after transplantation with more definitive resolution of the uremic state. However, at times, even patients with severe, irreversible cognitive deficits may still benefit from transplantation with availability of a committed caregiver [31,32].

It is well established that non-medical variables (socioeconomic status, ethnicity, educational achievement, geographic distance to transplant center) have a substantial influence on access to transplantation as well as subsequent patient outcomes [33–35]. In the US, with its complex and often confusing system of healthcare financing, socioeconomic assessment is an important part of most pretransplant evaluations [36]. Usually, this task is performed by a social worker familiar with the requirements for post-transplant care, and able to provide counsel on an individual basis and assess the resources each candidate brings to the transplant process. The latter include insurance coverage, ability to travel to and from the transplant center, current employment, and prospects for future employment. For the ESRD patient, transplantation changes the dynamic of access to socioeconomic resources, removing them from the defined benefits associated with chronic dialysis. Terms of insurance coverage often change after transplantation and patients may lose disability benefits. Thorough socioeconomic assessment before transplantation simplifies coping with events afterwards.

Most ESRD patients identified as suitable transplant candidates remain under the care of a practicing nephrologist (not the

transplant center) while awaiting transplantation [27,37]. As time awaiting transplantation grows lengthier, new medical and psychosocial challenges may arise [38]. It is the treating physician's responsibility to ensure that newly emergent problems are addressed promptly and that the transplant center is notified of the change. Likewise, ongoing contact between the candidate and transplant center is increasingly the norm, with annual re-evaluation mandated by some payers and many transplant centers. Up to date knowledge of changes in medical status, cognitive function, insurance coverage or social support systems is crucial in determining whether to proceed with transplantation when an organ becomes available.

Contraindications to kidney transplantation

Any discussion of contraindications to kidney transplantation must be tempered by two considerations. The first is that contraindications evolve over time, due either to changes in standards of care that alter the potential impact of a given variable or specific approaches to a variable that mitigate its risk [39]. In the 1970s, contraindications included diabetes mellitus, age over 55 years and, among others, a history of gastrointestinal bleeding. The first two were jettisoned with changes in practice and the third with availability of effective medical therapy (H_2 blockers, etc.). Second, there is wide variation from center to center in how strictly contraindications are interpreted and implemented. It has been said that a limited projected lifespan may preclude transplantation; however, since for essentially all measurable parameters transplant offers extended longevity compared to dialysis, making such a determination, in the absence of a specific contraindication, is difficult [40]. Thus, medical, psychologic, and socioeconomic evaluation at most centers is designed to disclose contraindications; if none is found, evaluated patients are deemed acceptable candidates [28].

The list of absolute contraindications in 2014 is relatively short (Table 28.4), especially when compared to previous decades. These conditions typically pose significant barriers to one or both necessary and essential components of kidney allotransplantation: an open, subdiaphragmatic, vascular operation and long-term immunosuppression. The operation itself requires suitable vascular anatomy and a mechanism to provide adequate urinary outflow. While the latter is only rarely an issue (with surgical reconstruction of the urinary tract, if necessary, able to provide adequate outflow), the former often poses problems. Standard surgical approaches involve the iliac circulation. With worsening metastatic calcification often the consequence of increasing duration of CKD and dialytic care, it is not uncommon to find significant, circumferential vascular calcification that precludes anastomoses. Likewise, aortobifemoral bypass precludes common approaches to establish adequate circulation to the allograft. In some rare instances, however, creative surgeons may choose to proceed after endarterectomy or at alternate sites. In the case of aortoiliac stent grafting (which is increasing in popularity), detailed knowledge of the extent of distal landing sites of the stent graft is imperative. As waiting times (and resultant time on dialysis) increase, pelvic venous abnormalities may become more important. Candidates with a history of failed thigh arteriovenous grafts or long-term femoral catheters should have evaluation of their iliac veins and inferior vena cava to ensure patency for venous outflow.

Most transplant candidates undergo extensive cardiac testing as part of the evaluation process (see below). A contraindication based on advanced cardiac and/or pulmonary disease reflects significantly increased perioperative risk as well as potential impact on longevity even after a successful operation.

Table 28.4. Contraindications to kidney transplantation at the University of Alabama at Birmingham, 2014

1. Unsuitable vascular anatomy:
   - **(a)** Aortobifemoral bypass or aortoiliac stent grafting extending to both external iliac arteries
   - **(b)** Circumferential calcification of iliac vessels
   - **(c)** Thrombosis of the iliac veins and inferior vena cava
2. Advanced cardiopulmonary disease:
   - **(a)** Ischemic cardiomyopathy with left ventricular ejection fraction (LVEF) $\leq$20%
   - **(b)** Continuous home oxygen therapy
3. Invasive malignancy within 2 years of evaluation, excluding non-melanoma skin cancer and small (<2 cm) renal cell carcinomas
4. Obesity: body mass index (BMI) $\geq$40 kg/m^2
5. Active infection (e.g. tuberculosis, invasive fungal disease, osteomyelitis)
6. Active alcohol or substance abuse (excluding tobacco)
7. Care status: nursing home

Adherence

In the current era, daily ingestion of maintenance immunosuppressants is essential to successful transplantation. The inability to reliably take prescribed medications (for whatever reason) thus must be considered a contraindication. Because of the link between substance abuse and non-adherence to medical therapies, most consider active drug abuse or alcoholism an absolute contraindication to transplantation [28]. A history of non-adherence in the absence of substance abuse may be recognized as a relative contraindication, though interpretation varies widely from center to center [41]. Since the transplant center's exposure to potential candidates is limited, documentation and follow-up with the dialysis unit or nephrologist are essential in assessing and monitoring compliance history. This issue is particularly germane for teenagers being considered for transplantation. This particular topic is addressed in depth in Chapter 120.

Infection and malignancy

Long-term immunosuppression impairs the recipient's ability to deal effectively with infection and malignancy, its two principal complications. Again, while the long-standing tradition is eradication of infection before transplantation, the availability of effective antimicrobials has altered the standard somewhat towards control rather than eradication. Most centers defer transplantation of patients with invasive bacterial, fungal, or mycobacterial disease until an effective therapeutic course is completed. The approach to some viral infections [notably hepatitis C (HCV), hepatitis B (HBV), and human immunodeficiency virus (HIV)] has changed dramatically (see below). For HCV, recognition that patient survival with a transplant even in the presence of viremia exceeds survival on dialysis makes transplantation (in the absence of advanced liver disease or cirrhosis) the preferred therapy [42]. For HBV and HIV, availability of effective antiviral therapy allows control of viral replication despite ongoing maintenance immunosuppression [43,44].

Malignancy poses similar challenges. Non-melanoma skin cancers are common in the general population; even though immu-

Table 28.5. Impact of malignancy on waiting time for transplantation. Potential transplant candidates with a history of significant malignancy may require oncologic evaluation

No waiting time if thought cured at evaluation	
Incidental renal cell carcinoma	
In-situ carcinoma of bladder	
In-situ carcinoma of cervix	
Non-melanoma skin cancers	
Waiting time at least 2 years	
Most invasive tumors (including Wilms', invasive bladder and uterine)	
Waiting time beyond 2 years	
Melanoma*	5 years
Renal cell carcinoma	2 years if <5 cm 5 years if ≥5 cm
Breast carcinoma†	2–5 years
Lymphoma	2–5 years
Colorectal carcinoma	2–5 years
Invasive cervical carcinoma	2–5 years

*In-situ melanoma may require a shorter waiting period of 2 years.
†Early in-situ may only require 2-year wait. Individuals with advanced breast cancer (Stage III or IV) should be advised against transplantation.
Adapted from Pham et al. [28] with permission from John Wiley & Sons.

nosuppression may increase their frequency and severity, they are rarely life threatening and are not considered to preclude transplantation. However, with general acceptance that immunosuppression promotes tumor growth, other solid and hematogenous malignancies remain contraindications [45–48]. For a potential candidate with active cancer, transplantation should be avoided [28]. Traditionally, after appropriate therapy followed by a "waiting period" of variable length (determined by tumor characteristics and risk of recurrence) transplantation could be offered (Table 28.5) [29]. Again, there is some evolution towards shorter waiting periods for many tumors, driven by increased understanding of tumor biology as well as recognition of the survival benefit of transplantation over maintenance dialysis. Thus, the previously accepted waiting period of 5–10 years is now considered inappropriate for many candidates, especially given shorter projected longevity with maintenance dialysis. Where uncertainty exists, informed consent is essential, with oncologic evaluation and explicit acknowledgement that some tumors may recur regardless of waiting time.

Additional issues in patient selection

In the evaluation process, concerns arise that may not preclude transplantation, but require additional testing, treatment, and/or follow-up before transplantation can proceed. These "relative contraindications" are less universally accepted, potentially amenable to intervention, and more likely to lose significance as current therapies and understanding evolve over time. They can be either medical or psychosocial in nature, and though they may threaten the success of a transplant, do not themselves preclude either a surgical operation or long-term immunosuppression. For example, two decades ago (and more recently in some European countries) age (over 55, or 60, or 65, or 70 years) was considered a contraindication to kidney transplantation [49]. Currently, with data supporting a longevity benefit for recipients up to the age of 80 years, older chronologic age, if a consideration at all, is at most a relative contraindication, with greater emphasis on overall health status [17].

Table 28.6. Potential clinical approaches to kidney transplantation in patients with defined native kidney diseases

Native kidney disease	Recurrence rate	Management
Primary focal glomerulosclerosis	Up to 50%	Recurrence rate of up to 80% in those who lose an allograft to recurrent disease may influence retransplantation choices
Antiglomerular basement membrane disease	Low	Anti-GBM antibody in serum associated with increased risk
Wegener's granulomatosis	17%	ANCA presence not associated with risk of recurrence
IgA nephropathy	20–60%	Histologic recurrence common but graft failure rare
HUS/TTP	Up to 75%	Factor H mutation imparts poor prognosis

HUS, hemolytic-uremic syndrome; TTP, thrombocytopenic purpura, ANCA, antineutrophil cytoplasmic antibody.
Data from Golgert et al. [52].

Native kidney glomerulopathies

Recurrent glomerular disease is a common cause of allograft failure, but risk of recurrent disease is rarely a defining issue in the evaluation of transplant candidacy. In the past, diseases such as primary focal glomerulosclerosis were considered to recur with enough frequency that transplantation was discouraged [50–52]. Current data indicate recurrence rates perhaps less than previously thought, with disease recurrence often amenable to clinical management. The most likely native glomerulopathy to recur is primary focal glomerulosclerosis, with up to a 50% risk in young, Caucasian patients undergoing first transplants, and even higher in those undergoing retransplantation after an earlier graft was lost to recurrent disease (Table 28.6). However, the benefits of transplantation versus dialysis are so substantial that the risk of recurrence exerts only a minor impact on candidacy, and even donor selection, in most patients. While recurrent lupus nephritis is rare, most centers require quiescence of disease on minimal immunosuppression before proceeding with transplant; in addition, presence of anticardiolipin antibody (lupus anticoagulant) may require prophylactic anticoagulation.

Polycystic kidney disease

A consideration for patients with polycystic kidney disease (PKD) is the potential need for native nephrectomy either before or during the transplant procedure. While the majority of PKD patients will not require nephrectomy, some may benefit from having their native kidneys removed. Massive polycystic kidneys, extending into the pelvis, may not permit implantation of a transplant; physical examination and abdominal computed tomography (CT), which also allows assessment for malignant changes within native kidneys, enable appropriate assessment. Patients with significant symptoms or complications, including intractable pain, early satiety, recurrent urinary tract infections, and recurrent hematuria should also be considered for native nephrectomy. While this was traditionally performed prior to transplantation, there is increasing successful experience with synchronous bilateral native nephrectomy at the time of renal transplant [53].

Addressing perioperative complications

In general, most surgeons are reluctant to transplant nephrotic patients with ongoing protein loss and severe hypoalbuminemia

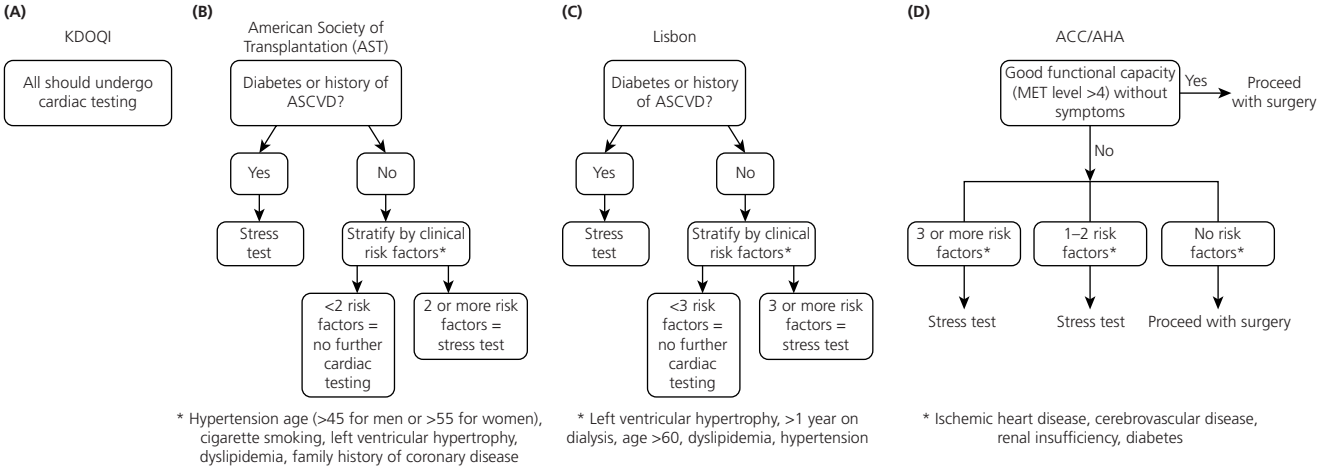

Figure 28.1. Overview of four pretransplant cardiac risk assessment guidelines: (A) Kidney Disease Outcomes Quality Initiative (K/DOQI); (B) American Society of Transplantation (AST); (C) Lisbon Conference on the Care of the Kidney Transplant Recipient (Lisbon); (D) American College of Cardiology/American Heart Association (ACC/AHA). ASCVD, atherosclerotic cardiovascular disease; MET, metabolic equivalent. (Source: Friedman et al. [62]. Reproduced with permission from the American Society of Nephrology.)

due to a perception of increased perioperative risk of complications. In a patient with advanced CKD, medical ablation of renal function with agents such as angiotensin-converting enzyme inhibitors or non-steroidal anti-inflammatory drugs usually controls urinary losses sufficiently to reverse the process, although native nephrectomy may be required in rare instances prior to transplantation. A history of venous or dialysis access thrombosis generally leads to consideration of studies of thrombotic tendencies, including assessment for Factor V Leiden mutations and/or deficiencies of protein C and protein S [54].

Cardiovascular disease

The cardiovascular burden associated with CKD is substantial, accounting for as many as half of patient deaths [2]. Even though transplantation is associated with a lower risk of cardiovascular death than maintenance dialysis, risk remains high compared to the general population [55,56]. It is widely recognized that traditional risk factors for coronary disease (as established in studies like Framingham) do not associate with risk after transplantation [57]. Hypertension, dyslipidemia, and cigarette smoking are relatively minor risk factors compared to pretransplant diabetes, previous coronary events, and post-transplant renal function [58]. In terms of patient selection, screening for cardiovascular disease, with implementation of corrective measures where possible, is an important part of the evaluation process in order to address two major concerns [59]. The first is defining individual risk associated with the transplant operation itself, with as many as 5% of recipients estimated to experience perioperative myocardial infarction. The second is assessing potential longevity of the recipient after a successful transplant; most would consider utilizing a kidney from either a deceased or living donor in a patient with irreversible cardiac dysfunction destined for early mortality as not being efficient use of a scarce resource. Unfortunately, there is no uniform standard applied to either purpose [60]. In fact, a recent provocative article suggested the potential adverse effects of routine screening of asymptomatic patients (needlessly delaying transplantation, risk of radiocontrast nephropathy, surgical bleeding from antiplatelet agents, psychologic burden, morbidity, and mortality associated with angiography and revascularization, and inefficient use of healthcare resources) as significant offsets to any potential benefits [61].

Defining the population to be screened (beyond the thorough history and physical examination, electrocardiography, and chest imaging that are part of every evaluation) is the first major challenge. Virtually all would agree that symptomatic patients (chest pain, dyspnea on exertion, limited exercise capacity, etc.) be studied. Given the extraordinary cardiovascular morbidity in those with advanced CKD even in the absence of symptoms, controversy resides in how asymptomatic patients should be addressed [61,62]. At the extremes are Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines indicating all candidates should undergo non-invasive testing and American College of Cardiology(ACA)/American Heart Association (AHA) recommendations that functional status tempered by risk factor profile should be the only major determinant of testing [63,64]. Intermediate levels of testing result from application of guidelines developed by more kidney-specific stakeholder groups (Figure 28.1) [29,65]. Recent surveys indicate most centers apply some version of the society-based recommendations to their patient population, with age, functional status, and risk factor profile determining level of testing for each individual. In a recent analysis of Medicare data, patients considered at high ischemic heart disease (IHD) risk (defined as diabetes, previous IHD, or >2 cardiac risk factors) had a 3-year post-transplant risk of acute myocardial infarction of 10%, versus 3% in patients not so characterized [58]. The lower-risk patients were substantially more likely to proceed to transplant without cardiac evaluation than the high-risk IHD group (20% versus 65%). Acute myocardial infarction risk was more influenced by IHD characterization than whether or not patients underwent screening, which indicates the influence of risk factor profiling not only on outcomes but also screening practices (Figure 28.2) [59,66]. The absence of a strong evidence base informing such practices supports those who advocate prospective controlled trials of screening protocols.

After deeming cardiovascular screening to be necessary in a transplant candidate, choosing the proper technique is the next challenge. Because non-invasive testing has significantly less pre-

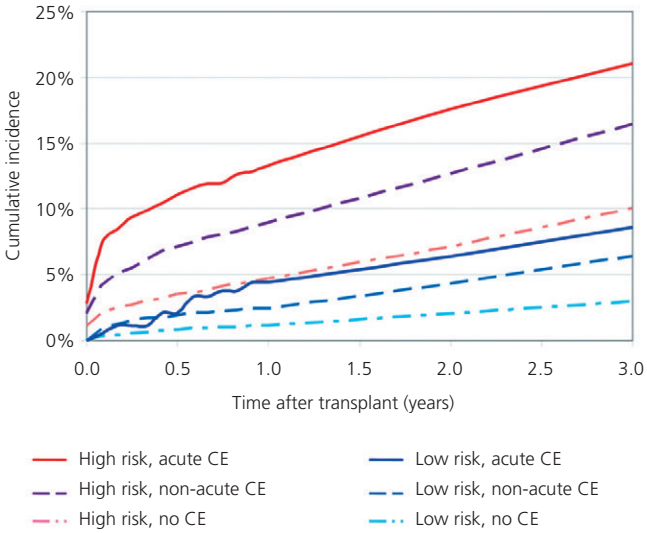

Figure 28.2. Observed incidence (Kaplan–Meier) of acute myocardial infarction after transplant according to clinical ischemic heart disease (IHD) risk group and pretransplant cardiac evaluation status. CE, cardiac evaluation. (Source: Lentine et al. [59]. Reproduced with permission from the American Society of Nephrology)

Table 28.7. Non-invasive tests utilized in assessing cardiac risk during pretransplant evaluation of potential kidney recipients. (Data from Friedman et al. [62])

- Stress echocardiography [using either exercise or pharmacologic stress, such as dobutamine stress echocardiography (DSE)]
- Myocardial perfusion scintigraphy (using either exercise or pharmacologic stress)
- Stress electrocardiography (EST)
- Electron beam computed tomography (EBCT)
- Resting electrocardiography (ECG)
- Conventional echocardiography
- Exercise ventriculography
- Digital subtraction fluorography (DSF)
- Carotid intimal medial thickness (CIMT)
- Cardiopulmonary exercise testing
- Computed tomography (CT) coronary angiography
- Magnetic resonance angiography
- Cardiac magnetic resonance imaging (MRI)

dictive value in the CKD population than the general population, early studies indicated angiography to be the preferred approach. While improvements in non-invasive testing may make these approaches preferable in triaging patients for coronary angiography and defining need for aggressive risk factor modification, there is still little consensus on the best way to risk-stratify transplant candidates. Studies of transplant candidates undergoing non-invasive testing followed by coronary angiography show considerable discordance, with angiographically demonstrable disease present in up to 40% of patients with negative stress tests [67,68]. At least two other observations may also be important. Work from the Mayo Clinic, not yet widely confirmed, indicates that a single measurement of serum troponin T at the time of evaluation (an indicator, perhaps, of subclinical ischemia) is a better predictor of subsequent mortality than other non-invasive testing [69]. Other work indicates that left ventricular dysfunction at evaluation, independent of results of other testing, is most predictive of waiting list mortality [70].

Applicable non-invasive tests are listed in Table 28.7. In general, no specific non-invasive study has been found to be ideal or superior. Given disparate expertise in cardiovascular testing among centers, the traditional recommendation is that whichever test can be performed most efficiently and reliably be utilized at a given center. A recent Cochrane meta-analysis supported such a recommendation, with dobutamine stress echocardiography (DSE) and myocardial perfusion studies (MPS) performing equally well in identifying those with ≥50% stenosis of a major coronary artery in published studies [71].

Positive results of non-invasive testing in most algorithms then leads to coronary angiography and, where indicated, revascularization. In this population, there is a strong preference for revascularization over medical management, based at least partially on studies performed decades ago on small numbers of transplant candidates [60,72]. Critics point to data from large studies in the general population applying modern medical interventions (aspirin, statins, beta-blockers, angiotensin blockade, etc.) with near -equivalent or superior outcomes to revascularization, except in triple vessel disease (or equivalent) [73,74]. Alternatively, recent studies in the CKD population have continued to document compromised therapeutic responses to medical management when compared to the general population [75].

Diabetic patients comprise a group at especially high risk for cardiac events after transplantation [56,76]. The relatively poor negative predictive value of non-invasive screening in this population has led some to advocate for cardiac catheterization as the only diagnostic test predictive of major coronary events in diabetics seeking transplantation.

Which findings at cardiovascular screening preclude transplantation? Again, this is a moving target. Currently, evidence of ongoing ischemia not amenable to revascularization would preclude transplantation at most centers. Likewise, significant left ventricular dysfunction (ejection fraction ≤20–25%) after optimal revascularization of severe coronary disease is associated with high mortality and may preclude transplantation. Alternatively, severe impairment of left ventricular systolic function in the absence of coronary disease is almost considered an indication for transplantation, with many reported cases in the adult and pediatric populations of remarkable improvement after restoration of renal function. Pulmonary hypertension is common in the dialysis population, seeming to worsen with duration of time on dialysis. Recent data have associated severe elevations [right ventricular systolic pressure, (RVSP) ≥50 mmHg] with increased risk of allograft failure and patient death [77]. Although these data have not been widely confirmed, some now see elevated RVSP as a relative contraindication to transplantation. Finally, severe valvular disease (critical aortic stenosis, symptomatic mitral stenosis) should be treated prior to transplantation [78].

Weight

Both severely underweight and overweight transplant candidates experience excess mortality rates on the waiting list and more complications after transplantation, though obesity garners significantly more attention in the evaluation process [79]. Even in the early 1970s, obesity was considered a contraindication to transplantation; at most centers, it remains one [80]. What has changed is the prevalence of obesity in the general and ESRD populations. Obesity increases the risk of CKD; recent National Health and Nutrition Examination Survey (NHANES) data indicate 35% of the US population is obese or morbidly obese [body mass index (BMI) ≥30 kg/m^2], and BMI at initiation of RRT is likewise increasing. Over 20% of kidney recipients have a BMI above 30 kg/m^2 [81].

Evidence indicates that increasing BMI is associated with increased risk of graft failure and mortality after transplantation. Risk is greatest for those with a BMI $\geq$36 kg/m^2, with increased risk for delayed graft function, acute rejection, wound infections, and major coronary events all contributing factors [82–84]. Nonetheless, for an ESRD patient with a BMI over 35 kg/m^2 or even over 40 kg/m^2, mortality and morbidity associated with kidney transplantation is lower than that associated with maintenance dialysis [81]. Thus, some choose to proceed with transplantation even in morbidly obese patients under certain circumstances. Most centers, however, ask patients to lose sufficient weight to result in a BMI of <36–38 kg/m^2, though a provocative study indicated little or no benefit on outcomes for obese patients who actually lose weight as prescribed pretransplant [79]. For the morbidly obese candidate, bariatric surgery may offer some benefit, although the risk and benefit of this operation in the ESRD population is not well established.

Age

Older age, if a concern at all, is at most a relative contraindication to transplantation. As noted above, there is substantial survival benefit of transplantation over dialysis at any age. Risk of complications increases with age and time spent on dialysis awaiting transplantation. In the US expanded criteria donor (ECD), and in some parts of Europe, Eurotransplant "old-for-old", allocation attempt to mitigate time on the list by offering kidneys from older donors preferentially to older candidates [85,86]. ECD kidneys in recipients over the age of 65 years have a 55% 5-year graft survival versus 64% for non-ECD kidneys from deceased donors, indicating relatively slight risk in this population. However, the attraction of this approach is limited by the number of potential candidates for ECD kidneys (35 000), and the number of ECD kidneys available each year (<1500) [16]. It also should be noted that recipients over 65 years demonstrate 77% graft survival at 5 years with kidneys from living donors. Given the length of the waiting list in many areas for both ECD and non-ECD kidneys, some offer transplantation to candidates over 70 years of age only if a suitable living donor can be identified.

HIV infection

Based on a presupposition that patients infected with HIV are already immunosuppressed and would not tolerate transplant protocols, HIV infection a decade ago was considered a contraindication to transplantation [87]. Now, HIV disease is considered a manageable chronic illness with extended survival due to modern antiviral therapy. Since HIV can cause kidney failure, the number of HIV-infected patients with ESRD is increasing. Though immunosuppressant management is challenging, with drug–drug interactions common, ESRD patients with HIV demonstrate better survival with transplantation than dialysis and are now offered transplantation at many centers [44].

Hepatitis B and C

Assessing kidney transplant candidacy in patients with exposure to viral hepatitis has become less demanding in recent years even as HBV infection has become less common and HCV almost epidemic. Ultimately, the goal in both scenarios is to avoid transplantation in patients with advanced hepatic fibrosis or cirrhosis unless the patient is considered a candidate for combined liver/kidney transplantation. Standard recommendations are that patients should undergo liver biopsy as part of the evaluation process if not already done [42]. Such an approach would allow identification of the patient with advanced fibrosis/cirrhosis, and implementation of appropriate therapies for chronic active hepatitis.

Routine liver biopsy is less uniformly practiced than before, for several reasons. First, hepatic fibrosis severe enough to preclude kidney transplantation is likely to be clinically evident based on imaging, physical findings, and laboratory abnormalities. If not, with liver allocation according to Model for End-Stage Liver Disease (MELD) criteria, such patients will be unlikely to receive enough priority to undergo transplantation. Second, therapy for HBV is now standardized, effective, and easily administered in the post-transplant setting, with little or no impact of HBV serostatus on outcomes [43]. Alternatively, therapy for HCV remains toxic and relatively ineffective when administered to patients with advanced CKD, and is contraindicated after transplantation; thus, with current therapies, treatment of HCV is not a major consideration for most transplant candidates. If treatment of HCV is desired, it should be administered before the transplant occurs [88]. Finally, as in other situations, survival of transplanted ESRD patients with either HBV or HCV exceeds their projected survival on dialysis, without evidence of worsening viral illness, again indicating transplantation to be the preferred option. Current practice at the University of Alabama at Birmingham in infected candidates is to monitor viral loads and hepatic enzymes, synthetic function, and serial imaging of the liver for changes indicative of worsening fibrosis or tumor development, and otherwise care for the patient as indicated.

Special considerations

Type 1 diabetes mellitus

Forty years ago, type 1 diabetes mellitus was considered an absolute contraindication to both transplantation and dialysis. Now, diabetes is the most common cause of ESRD, and young type 1 diabetics are a patient group that derives the greatest relative benefit from transplantation versus dialysis [12]. This finding is the consequence not of superior transplant outcomes among diabetic recipients, but of excess dialysis-related mortality in this population. Thus, in the current era, kidney transplantation is the preferred therapy for most type 1 diabetics with kidney failure, with pre-emptive transplantation of particular benefit [15].

A key aspect of evaluating the CKD patient with type 1 diabetes is choosing among approaches to transplantation (also see Chapters 32 and 41, which cover indications for the various types of pancreas transplants and the management of pancreas transplant candidates on the waiting list, respectively). In those undergoing kidney transplantation alone, there is substantial risk of recurrent diabetic nephropathy compromising long-term allograft survival, particularly beyond 10 years [89]. A kidney from a living donor offers at least two benefits over one from a deceased donor: greater average longevity of the allograft (51% vs. 36% 10-year allograft survival) and avoidance of lengthy waits on the list with correspondingly longer time on dialysis [16]. Outcomes with simultaneous pancreas–kidney (SPK) transplantation are excellent, with evidence that a successful pancreas transplant reduces long-term mortality and prevents progression of microvascular complications. However, waiting times of 2–3 years or longer are common for SPK transplantation, and long-term kidney graft survival is only marginally better than for living donor kidney transplantation alone (63% versus 51% at 10 years). For those who choose to undergo a living donor kidney transplant followed by pancreas-after-kidney (PAK)

transplantation, pancreas graft survival is inferior to that following SPK. However, there has been a steady improvement in pancreas graft survival over the past decade, with 55% 5-year survival (compared to 72% after SPK) [90].

How does one choose among these alternatives? In general, the greatest threat to the well-being of a type 1 diabetic with ESRD is time on dialysis. Thus, for the candidate with an identified living donor allowing pre-emptive or early transplantation, this may be the best choice, both for the candidate as well as all others awaiting a suitable organ. PAK transplantation can then be offered to the successful recipient who desires the advantages of a pancreas transplant in terms of glycemic control, often as soon as 2 months after the kidney. Risk factors for poorer outcome in PAK, including GFR <45 mL/min, interval from kidney to pancreas transplant >1 year, history of kidney rejection, and proteinuria, should be considered when planning for the subsequent pancreas transplant [91].

For the candidate with no living donor, SPK is probably the preferred choice: outcomes are better and time on the waiting list perhaps shorter than for a kidney transplant alone. It is not unreasonable, however, for the type 1 diabetic to demur on the living donor possibility in the hope of achieving the benefits of SPK transplantation, assuming he/she recognizes the trade-off of additional time on dialysis. Projected waiting time for SPK at the transplant center must be considered when choosing this option over a living donor kidney.

Patient with multiorgan failure

Kidney failure is accompanied by failure of a second organ in two principal circumstances. The first is that of renal insufficiency occurring against a backdrop of cardiac or hepatic failure in a patient considered a candidate for heart or liver transplantation. In 2009, 444 such transplants occurred (4% of all deceased donor kidneys transplanted), 82% of which were liver/kidney and 10% heart/kidney transplants [16]. The second is development of ESRD in a patient with a functional heart, lung, liver, or intestinal transplant. Such patients accounted for fewer than 1% of waitlisted candidates in 1995, but now comprise over 3% of the waiting list and account for 2% of recipients of deceased donor kidneys [92].

Assessing a patient with cardiorenal or hepatorenal syndromes for dual organ transplantation can be very difficult due to the high frequency of reversible renal dysfunction in severely ill patients. Even patients requiring dialysis may recover substantial function after receiving a healthy heart or liver. Conversely, outcomes of the primary transplant may be threatened by ongoing renal insufficiency. Typically, decision-making is influenced by the severity and longevity of renal dysfunction [93]. A recent consensus conference concluded that combined liver–kidney transplantation was indicated if:

1. ESRD with cirrhosis and symptomatic portal hypertension or hepatic vein wedge pressure gradient ≥ 10 mmHg;
2. liver failure and CKD with GFR ≤ 30 mL/min;
3. acute kidney injury or hepatorenal syndrome with creatinine ≥ 2.0 mg/dL and dialysis ≥ 8 weeks;
4. liver failure and CKD and biopsy demonstrating $>30\%$ glomerulosclerosis or 30% fibrosis [94].

For patients with end-stage cardiac failure, there is no consensus on how to address renal insufficiency. However, a recent analysis of UNOS data indicated that heart transplant candidates with an eGFR of ≤ 30 mL/min fared very poorly without the combined transplant [95].

In the patient with a successful solid organ transplant who subsequently develops ESRD, data indicate substantially poorer survival on maintenance dialysis than with kidney transplantation, perhaps reflecting the challenge of achieving optimal immunosuppression in such patients. Such patients are more likely than others to be listed pre-emptively, and principles of candidate evaluation mirror those in more standard situations.

Summary

Kidney transplantation remains the best option for most patients with ESRD. However, to achieve a result that substantially improves upon that achieved through dialysis, patient selection and preparation are critical. Optimal results are achieved when co-morbidities have been recognized and mollified, the patient has established realistic expectations for the procedure and the requirements for drug adherence, and contraindications have been sought and excluded. As a suitable donor organ remains a limiting resource, proper patient selection remains one of the most critical aspects of the transplant procedure, and a responsibility of all physicians caring for the patient with irreparable kidney failure.

CHAPTER 29

Patient Selection and Indications for Liver Transplantation

Kimberly A. Brown[1] and Marwan Kazimi[1,2]

[1] Division of Gastroenterology, Henry Ford Hospital, Detroit, MI, USA

[2] Division of Transplant Surgery, Transplant Institute, Henry Ford Hospital, Detroit, MI, USA

Introduction

The selection of patients for liver transplantation is guided by the overall medical philosophy of benefit to risk. At the very heart of every determination by the medical team is the weighing of overall benefit of transplantation to the patient while estimating risk to the individual. This often proves to be a challenging task for several reasons. The first is that we have limited data on individual outcomes for particular diseases. We have general data, which may apply to groups of patients with specific diseases but fail to be adequately specific for an individual patient. Second, the data that exist are insufficiently granular to understand the impact of multiple co-morbid conditions, such as is the case with an elderly patient with hepatitis C, renal insufficiency, diabetes, and a history of coronary disease. Although we may have some data with regards to each individual medical issue, their interactions are poorly understood. Lastly, we select patients with our best understanding of their individual benefit-to-risk ratio. However, the supply of organs for transplantation is limited. Therefore, our choice of any individual patient has implications for other patients waiting for or in need of transplantation.

To bring the later issue of population impact into focus, Organ Procurement and Transplantation Network (OPTN) data accessed on December 16, 2011 showed that of 16 148 unique candidates waiting for liver transplantation, only 4734 candidates had received liver transplantation as of that date [1]. In fact, the total number of liver transplants performed on a yearly basis over the last several years has been declining yearly from a peak of 6651 in 2006 to 4734 in December 2011 which was similar to the number performed in 1999. Therefore, when we select individuals who require liver transplantation, we do so with the understanding that the need of all patients in the US for liver transplantation continues to increase while supply appears to be decreasing. Indeed, these issues have become the domain of regulation that should be understood when selecting patients for the waitlist.

This chapter will cover the general indications and regulations at play when considering an adult patient for liver transplantation. Pediatric-specific issues will be covered in more depth in Chapter 114. The current chapter serves as a companion to Chapter 38, which deals with waitlist management prior to liver transplantation.

Indications for liver transplantation

General considerations

Currently, UNOS has seven liver diagnosis categories and 72 listed liver diagnoses as indications for liver transplantation [1]. In general, the beneficial impact of liver transplantation is primarily on the liver. Indeed, many other diseases that complicate the health of humans are made acutely worse by the process of transplantation and the treatment prescribed following the procedure. Exceptions exist, such as renal failure in hepatorenal syndrome; regardless, the procedure is formidable and takes its toll on the recipient. Therefore, we return to the basic assessment of benefit versus risk.

The major indications and contraindications for liver transplantation are listed in Table 29.1. In general, most patients with cirrhosis and acute liver failure (ALF) are deemed to be suitable candidates for evaluation when the risk of death with transplant is less than the risk of death without transplant. For these patients, liver failure is the issue and transplantation replaces liver function and prevents death from liver failure. In other categories, the indications may be more concerned with lifestyle or the prevention of complications from existing liver disease. For these patients, the outcome is based more upon improvement in health or reduction in future risk and less on overall survival probability.

Prior to the current allocation system in the US, the Model for End-stage Liver Disease (MELD) allocation system, livers were allocated based primarily upon the degree of liver dysfunction in combination with the length of time a patient had been waiting. To better understand and clarify listing for transplantation, a national conference was convened by the American Society of Transplant Physicians and the American Association for the Study of Liver Diseases in 1997 [2]. One-year survival in patients undergoing liver transplantation at that time approximated 90%. Therefore, the conference recommended listing a patient for liver transplant when the anticipated 1-year survival without transplant was 90% or less. Decompensated cirrhosis (defined as the presence of jaundice, encephalopathy, variceal bleeding, or ascites) is associated with 1-year survival of 70–75% [3]. With median survival in medically treated cirrhotics decreasing from 6.4 years in Child's A patients to 2 months in Child's C patients [4], the authors recommended listing for transplantation at a Child–Pugh score of $\geq$7. In patients with advanced liver disease and decompensation, the trigger for

Table 29.1. Indications and contraindications for liver transplantation in adults

Indications
Acute liver Failure
• Virus
• Drug/medication
• Ischemia
• Wilson's disease
• Autoimmune
• Idiopathic
Cirrhosis with decompensation
• Hepatitis B or C
• Alcohol
• Non-alcoholic steatohepatitis
• Cholestatic disease (primary biliary cirrhosis, primary sclerosing cholangitis, secondary biliary cirrhosis,vanishing bile duct)
• Autoimmune
• Metabolic (alpha-1 antitrypsin deficiency, hemochromatosis, Wilson's disease)
• Malignancy (hepatocellular carcinoma, cholangiocarcinoma)
• Cryptogenic
Systemic complications of liver disease
• Hepatopulmonary syndrome
Benign liver conditions
• Polycystic liver disease
• Chronic Budd–Chiari
Metabolic conditions with systemic disease
• Primary oxaluria
• Familial amyloidosis
• Urea cycle deficiencies
• Glycogen storage disease
Retransplantation
• Primary non-function
• Recurrent disease with graft dysfunction
• Vascular complications
• Biliary complications
Contraindications
• Extrahepatic malignancy
• Hepatocellular cancer exceeding Milan or UCSF criteria
• Active substance or alcohol abuse
• Severe cardiopulmonary disease
• Inadequate social or financial support
• Poorly controlled psychiatric illness
• Anatomic abnormalities precluding adequate surgical reconstruction
• Poorly controlled HIV
• Non-compliance with medical recommendations

consideration of transplantation becomes risk of death without transplantation.

For patients without progressive liver failure, the need for transplantation may be based more upon risk of, for example, progressive disease (cancer), complications from the intrinsic liver abnormality (hereditary oxalosis, familial amyloid polyneuropathy), or improvement in health and well-being (Budd–Chiari, polycystic liver disease). Regardless of the indication, the evaluation process for each individual is designed to better inform the transplant team as to the potential for benefit as weighed against the overall risk of the procedure and recovery.

Viral hepatitis B

In the early years of liver transplantation, hepatitis B was a relative contraindication to selection for transplant. This was in large part due to the very high risk of recurrent disease, the risk of severe fibrosing cholestatic hepatitis, and increased mortality following transplant in these patients [5,6]. In 1993, a landmark paper from Europe showed that the absence of viral replication at the time of transplant and long-term immunoprophylaxis for hepatitis B virus (HBV) was associated with a reduced risk of recurrent HBV infection and reduced mortality [7].

A large study from Taiwan showed that lamivudine could significantly reduce disease progression in patients with hepatitis B over controls (7.8% vs. 17.7% over 32 months of treatment) [8]. In patients with evidence of hepatic decompensation and HBV replication, both lamivudine and adefovir have been shown to improve liver tests and reverse some clinical signs of liver failure [9–12]. A major concern with long-term lamivudine therapy has been the high rates of resistance (70% after 5 years of treatment) [13] and the potential for virologic breakthrough leading to alanine aminotransferase (ALT) flares and further decompensation [14]. More potent nucleos(t)ide analogs (entecavir and tenofovir) have been Food and Drug Administration (FDA) approved for the treatment of hepatitis B. Shim et al. [15] treated 70 patients with decompensated liver disease due to HBV with entecavir. The authors found that reduction in HBV replication and clearance of e-antigen were similar to those in treated patients with compensated disease and that entecavir improved hepatic reserve in patients with decompensated disease. No evidence of resistance or virologic breakthrough was observed during the study period. These studies and others have led to the recommendation from all three major liver societies to consider antiviral treatment in decompensated cirrhosis regardless of HBV DNA levels [16–18].

It would stand to reason that, given the availability of potent oral antiviral agents for HBV with proven efficacy and the recommendation to treat patients with cirrhosis, fewer patients with hepatitis B and decompensation would be presenting for transplantation. In fact, since 1990 the percentage of patients undergoing transplantation for hepatitis B has fallen from 5.7% to 1.5% [1]. A trend toward decreasing listing for end-stage liver disease (ESLD) and an increase in listing for hepatocellular cancer (HCC) in patients with hepatitis B has been shown [19]. Overall 5-year survival for patients with hepatitis B undergoing liver transplantation has increased from 53% between 1987 and 1991 to 85–94% currently [20,21].

In contrast to earlier years, hepatitis B in association with either liver decompensation or HCC is a clear indication for liver transplantation. Management of these patients both prior to and following transplantation are discussed in Chapters 38, 78, and 82.

Viral hepatitis C

The prevalence of hepatitis C virus (HCV) in the general population is highest in those born between 1945 and 1965 [22]. Due to the slow progressive nature of the disease, some authors project the burden of chronic complications due to HCV, including the need for liver transplantation, will continue to increase in the near future [23]. The earliest studies of the outcome of orthotopic liver transplantation (OLT) for HCV reported post-transplant patient and graft survival similar to those achieved following OLT for other chronic liver diseases. These were usually single-center reports limited by small numbers and relatively short follow-up. Several large registry analyses have recently reported reduced graft and patient survivals in recipients with HCV. Forman et al. [24] reported on the UNOS database which showed 3-year patient survival was 78% in 7459 HCV-positive recipients versus 82% in 20743 HCV-negative recipients ($P = 0.0001$). Likewise, 3- and 5-year graft survivals were significantly reduced in patients undergoing OLT with HCV as compared with non–HCV-infected patients.

Early studies showed approximately 10–15% of patients progressed to cirrhosis within 5 years of OLT. Later studies showed a significant increase in cirrhotic patients at 5 years, up to 40%,

leading many to suggest that HCV in recent years has become more aggressive in transplant recipients. It is hypothesized that HCV appears to be associated with worse results in recent years because of the more routine use of liver biopsies, stronger immunosuppressive agents, rapid steroid withdrawal, and increasing donor age [24]. Berenguer et al. have shown that patients with HCV have experienced a worsening of graft survival over time as compared to patients without HCV in whom graft survivals have consistently improved [25]. These data suggest that our change in practice may have negatively influenced HCV recurrence and/or progression.

Despite the negative impact of HCV on both morbidity and mortality following liver transplantation, it remains the most common indication for liver transplantation once patients have progressed to decompensation.

Alcoholic liver disease

In patients with advanced cirrhosis and decompensation due to alcohol, liver transplantation remains the best option for prolonged survival in appropriate candidates. Alcoholic liver disease is currently the second most common indication for liver transplantation in the US [1]. Survival (1–7 years) appears to be comparable to that in patients with other diagnoses at transplant in the setting of continued abstinence [26,27]. Overall indications for liver transplantation remain the same as in other forms of liver disease. However, the risk of recidivism causes additional concern with respect to patient evaluation.

Despite stringent selection criteria, rates of recidivism have varied widely in this patient group, likely in part due to the definition of relapse (any use vs. binge drinking for example) [28–30]. In one of the few prospective studies on recidivism, return to alcohol use at any level was reported in 22% of patients by 1 year post transplant [30]. Furthermore, at 5 years post transplant, 42% reported some use of alcohol, of whom 26% had a pattern consistent with harmful use.

Therefore, a major focus in the evaluation of patients with alcoholic liver disease remains the prediction of risk for recidivism. Several potential predictors have been studied, including family history, degree of social support, associated psychiatric diagnoses, prior relapse from treatment, and non-alcohol substance abuse. Results from studies have varied widely, making it difficult to use these predictors as absolute guides to selecting patients for transplantation. A meta-analysis of a large number of studies from 2008 showed a poor social support system, family history of alcohol abuse, and pretransplant abstinence of 6 months or less were significant predictors of recidivism [31]. Given the current limitations in the literature and the significant ramifications when patients are not selected, most centers have adopted a standard of abstinence (6 months or greater) as the major defining factor for selection in this patient group.

Metabolic syndrome

Metabolic syndrome has become increasingly prevalent in the US. Although the frequency of non-alcoholic fatty liver disease (NAFLD) and the incidence of cirrhosis in patients with NAFLD is not entirely clear, the frequency of NAFLD as an indication for liver transplantation continues to increase and is currently the third most common in the US [1]. The prevalence of obesity in the US is currently estimated to be 28.7% in men and 34.1% in women, with an increasing number of individuals moving into the most severe obesity categories (BMI 40–50 kg/m^2) [32,33]. These increases are likely to be mirrored by increases in NAFLD and non-alcoholic steatohepatitis (NASH); however, the rate at which these diseases progress to cirrhosis and liver decompensation is not clear. A review of the UNOS database showed that from 1988 to 1996, 16.8% of liver recipients had a BMI of $>30\,kg/m^2$, with 5.3% of these having a BMI of $>35\,kg/m^2$ and 2.1% a BMI of $>40\,kg/m^2$ [34]. Furthermore, from 2001 to 2004, 32.5% of liver recipients were obese with 8.4% of these patients were classified as severely obese and 3.2% as morbidly obese [35].

In a comprehensive analysis of the Scientific Registry of Transplant Recipients (SRTR) database, Charlton et al. [36] found that the frequency of NASH as a primary or secondary indication for liver transplantation is steadily increasing (1.2% in 2001 to 9.7% in 2009). Furthermore, several authors have suggested that the true frequency of NASH as an indication for liver transplantation may be underestimated as steatosis may be absent as cirrhosis develops. Phenotypically, patients with a pretransplant diagnosis of cryptogenic cirrhosis are quite similar to patients with cirrhosis due to NASH, making the classification of these patients suspect [37,38].

In selecting patients with metabolic syndrome or obesity for transplantation, one needs to take into consideration both the potential for recurrence of disease as well as the impact on patient and graft survival. NASH is well documented to recur following liver transplantation [39,40]. However, in the analysis of the SRTR database, Charlton et al. found that 3-year patient and graft survivals for recipients with a primary or secondary indication of NASH were similar to those for recipients with other indications [36]. Several authors have reported recurrent NASH-related cirrhosis and graft loss at 2.5–5%, with overall outcomes reported to be comparable to those for other indications [41,42].

In patients who are obese (BMI 30–35 kg/m^2) with NAFLD, short-term (30-day) mortality may be increased, with longer-term (1- and 3-year) mortality being similar to that in patients without NAFLD [43]. In patients with morbid obesity (BMI $>35\,kg/m^2$), 1- and 2-year mortality and primary non-function are worse as compared with other patients [44]. A review of the UNOS database from 1987 through 2007 found that patients who were very severely obese (BMI $>40\,kg/m^2$) had a higher number of infectious complications and cancer events ($P = 0.02$) leading to death as compared with control patients. In three different eras of liver transplantation, multivariable analysis showed that being severely underweight (BMI $<18.5\,kg/m^2$) or severely obese (BMI $>40\,kg/m^2$) were significant predictors of death [45]. In addition, many of these patients have associated diabetes mellitus, which has been shown to have a significant negative impact on survival in liver transplantation [46]. A case–control study that focused on the impact of diabetes in relation to transplantation found that patients with diabetes were 40% more likely to die within 5 years as compared with non-diabetics [47].

For patients with metabolic syndrome or obesity, both the impact of recurrent disease in the graft as well as the impact of associated co-morbidities on patient survival must be considered when selecting patients for transplantation.

Immune liver disease

Primary biliary cirrhosis

In a relatively recent study looking at trends in transplantation for primary biliary cirrhosis (PBC), the authors found that from 1995 to 2007, the absolute number of transplants that were performed for this diagnosis decreased by an average of 5.4 cases per year despite a steady rise in overall liver transplants [48]. The primary indication for transplantation in PBC remains the development of clinical

features of hepatic decompensation, which occurs in up to 26% of patients within 10 years of diagnosis [49]. The indication for intractable pruritus or debilitating fatigue is perhaps more specific to the cholestatic disorders [50]. Although pruritus is often treated with ursodeoxycholic acid, some studies have failed to show a significant effect in alleviating pruritus in these patients [51]. For those who fail to respond to pharmacologic therapy, transplantation may be the only option to improve their quality of life. Furthermore, chronic fatigue is reported in up to 80% of patients with PBC [52]. Although some patients without frank evidence of decompensation have been transplanted more for quality of life issues such as fatigue, one must be aware that fatigue has not been shown to consistently improve with liver transplantation in these patients [53].

Ideally, one would be able to identify patients as potential candidates on the basis that their 1-year survival with transplant would be higher than their 1-year survival with medical care alone. Traditionally, survival for patients with cholestatic liver disease has been the highest among all groups undergoing liver transplantation [1]. For most patients, the optimal benefit to risk of transplant occurs when they have reached a Child's B score or higher or a MELD score of $\geq$15. Serum bilirubin appears to be predictive of outcome in PBC and some authors have used an absolute value of 5.9 mg/dL or greater as an indication for consideration of liver transplantation [54]. Other authors have used a combination of factors, including bilirubin, albumin, prothrombin time, age, edema, and diuretic use (Mayo risk score), to identify patients with PBC in need of liver transplantation [55]. Centers may opt to use one or more of these tools in identifying those patients who may benefit from transplant.

Despite recurrence in up to a quarter of patients with PBC following liver transplantation, overall patient and graft survivals in this group are excellent [1]

Primary sclerosing cholangitis

Primary sclerosing cholangitis (PSC) typically presents in men under the age of 50 years. Although it may be a slowly progressive disease in many patients, liver transplantation should be a consideration in those patients who progress to decompensation or have complications related to biliary strictures such as recurrent cholangitis. Similar to the Mayo risk score for PBC, prognostic models have been developed to assist in determining timing of transplantation for PSC [56]. The Mayo risk score for PSC is based on age, serum bilirubin, serum albumin, and history of variceal bleeding [56]. MELD score has not been directly assessed against the Mayo risk score for either PBC or PSC, but does appear to remain valid regardless of disease etiology for patients [57].

Unique to PSC is the presence of biliary strictures, which can lead to additional complications, including accelerated jaundice, obstruction, and infection. In addition, patients are at significant increased risk of cholangiocarcinoma (see later) [58]. Patients may suffer from recurrent cholangitis requiring antibiotics and hospitalization. In some patients, this may occur with MELD scores of $<$15. For these patients, submission to a regional review board for additional points would be appropriate given the risk of sepsis and complications in patients with recurrent cholangitis. Although pruritus may be present in patients with disease, the indication for transplantation based upon pruritus alone would require careful consideration.

Although the disease may recur in up to 10–25% of recipients, outcomes for PSC, are excellent and similar to those for PBC [1,59,60].

Autoimmune hepatitis

The primary indication for liver transplantation in autoimmune hepatitis is evidence of hepatic decompensation. Many of these patients are likely to have been exposed to immunosuppression prior to transplantation. Therefore, a careful review of medications prior to transplantation is essential to assess potential risk. Metabolic complications from steroids may be increased in this population and should be reviewed as part of the overall evaluation prior to selection (see Evaluation).

Autoimmune hepatitis has been reported to recur in approximately 23% of patients following liver transplantation [61] and may lead to decompensation requiring retransplantation [62]. Similar to other immune diseases, although recurrence may occur following liver transplantation, outcomes for autoimmune hepatitis are excellent [1,61].

Inherited liver disease

Liver disease due to alpha-1 antitrypsin deficiency may present as cirrhosis in either childhood or adulthood [63]. Approximately 15% of patients with the PiZZ phenotype will develop liver disease and these patients are at increased risk of developing HCC [64]. There is no effective treatment for alpha-1 disease in the liver. In patients with liver involvement who develop evidence of decompensation, liver transplantation is the only therapeutic option. Because of the possible associated pulmonary involvement with the disease, patients considered for liver transplantation should undergo a thorough pulmonary evaluation. Overall survivals in patients who are transplanted for alpha-1 antitrypsin deficiency are excellent, with 1- and 3-year survivals of 88% and 84%, respectively [65].

Although the gene frequency for hemochromatosis is approximately 1 in 200, the need for transplantation in patients with this disorder is relatively uncommon [66]. Early detection and iron depletion can delay/prevent complications of advanced liver disease [67]. Patients with hemochromatosis and cirrhosis have an increased risk of HCC [68]. In patients with cirrhosis and decompensation, liver transplantation remains the only treatment. However, several authors have reported reduced survivals in patients undergoing liver transplantation for hemochromatosis [69,70]. Increased cardiovascular complications, infections, and recurrence of HCC in these patients likely reflect increased iron deposition in organs outside the liver [70]. In patients being considered for transplantation, thorough cardiovascular assessment and consideration of iron depletion should be made as part of the patient evaluation in this disease [71].

Patients with Wilson's disease may present with either cirrhosis and decompensation or ALF as an indication for transplantation. Oral or parenteral therapy to target copper depletion can result in long-term remission of the disease in some patients [72]. In patients with decompensated liver disease due to Wilson's disease or in patients presenting with ALF, liver transplantation is the best option. Following liver transplantation, most associated metabolic changes reverse, with the exception of severe neurologic dysfunction [73]. Despite this, overall survival in these patients appears to be very good [74].

Malignancy

Hepatocellular cancer

During the National Institutes for Health (NIH) consensus development conference in Washington DC in 1982, liver transplantation was accepted as a treatment modality for patients with ESLD

and malignant tumors of the liver. A quarter of a century later, OLT has become the standard of care for all forms of ESLD, including HCC. In patients with cirrhosis and HCC, liver transplantation provides both replacement of hepatic function as well as complete surgical removal of the tumor. While early experience with OLT for cancer resulted in poor patient survival and high recurrence rates, methods of patient selection have been refined and results have improved dramatically [75].

The so-called Milan criteria were borne of a 1996 study by Mazzaferro et al., which reviewed radiologic and histologic results of patients with ESLD and HCC who received liver transplants [76]. They reported that in patients with a solitary tumor of $\leq$5 cm or no more than three tumors, each no larger than 3 cm, overall and recurrence-free survivals after transplant were 85% and 92%, respectively. Overall HCC recurrence was 8% at 4 years' follow-up. Patients who exceeded the criteria showed an actuarial survival of 50% and only 59% of surviving patients were free of recurrence. The Milan criteria are currently the standard by which the UNOS and Medicare guide selection of patients for cadaveric OLT in the US, with some variation established by regional review boards.

During the past decade, several studies have challenged the Milan criteria, reporting comparable outcomes after transplantation for more advanced stages of HCC. Yao et al. showed a 5-year survival of 70.2% in patients with HCC fulfilling so-called University of California, San Francisco (UCSF) criteria [77]. These criteria, based on explant pathology, allowed inclusion of patients with single tumors of $\leq$6.5 cm, or a maximum of three tumors of $\leq$4.5 cm, and a cumulative tumor size of $\leq$8 cm.

The Barcelona Clinic Liver Center has developed a system for treatment of HCC with OLT, based on tumor stage, liver function, physical status, and cancer-related symptoms [78]. Its emphasis is on dropout rates and intention-to-treat analyses, and its expanded criteria include one tumor of $<$7 cm, three tumors of $<$5 cm each, or five tumors of $<$3 cm each, or down-staging to conventional Milan criteria with pretransplant adjuvant therapies. Using this expanded approach, the Barcelona group has achieved 5-year post-transplant survival in excess of 50%, versus 20% for palliative treatment alone.

Studies that followed appear to support the UCSF and the Barcelona group criteria, and such observations led to the description of the so-called "metro ticket paradigm" by Mazzaferro et al. [76] using a decision analysis model. This model follows the concept that larger tumor diameter and/or increased number of tumors is related to a "higher price" in terms of HCC recurrence. Although this model has not been widely adopted, transplant physicians and surgeons recognize that both tumor size and number of tumors relate to recurrence and outcomes, and the decision to select patients for transplant in large part depends on these factors.

Cholangiocarcinoma

Today, available therapies for hilar cholangiocarcinomas (CCAs) are not satisfactory. These tumors are rare, but they bear high death rates in afflicted patients, rivaling those for pancreatic cancer. Surgical resection offers the only current hope for long-term survival, averaging only 20% in major series [79]. The reality is such that for the majority of patients, CCA is a diagnosis of despair.

Although surgery has offered the only hope of cure, one of the major limiting factors in achieving long-term survival following surgical resection of CCA is the technical ability to achieve negative resection margins. The presence of malignant cells at the surgical margins following resection is a major prognostic factor predicting recurrence and death [80]. Theoretically, the likelihood of achieving negative margins can be increased with total hepatectomy and OLT. Previous experience with OLT performed in isolation for hilar CCAs has shown that this practice has met with various success. However, a protocol developed at the Mayo Clinic demonstrated that long-term survival can occur in carefully selected patients by combining the benefits of radiotherapy, chemosensitization, and OLT [81]. With this strategy, patient survival rates of 92%, 82%, and 82% at 1, 3, and 5 years after transplantation, respectively, have been achieved.

Selection criteria used in consideration of liver transplantation for hilar CCA that is not amenable to surgical resection require accurate assessment of potential extrahepatic disease, including lymphatic spread. Contrast computed tomography (CT) is sensitive for detecting intrahepatic bile duct tumors, the level of biliary obstruction, and the presence of liver atrophy. In addition, CT may also permit visualization of the pertinent nodal basins [82], and dynamic CT may provide more information regarding resectability than magnetic resonance imaging (MRI). While both imaging methods have similar abilities to show tumor enhancement and biliary ductal dilatation, the relationship of the tumor to the vessels and surrounding organs is more easily evaluated using CT.

A significant number of patients have peritoneal implants or locoregional lymph node involvement that are not easily detected on preoperative imaging studies. At centers with expertise, endoscopic ultrasound may be useful to determine the local extent of the tumor and to detect local lymphatic involvement, especially for distal lesions. In addition, diagnostic laparoscopy helps identify many of these patients before committing them to a laparotomy [83]. A study that examined the role of laparoscopy in the staging of hepatobiliary and pancreatic neoplasms detected unknown metastases in 30% of patients [84]. In addition, laparoscopy offers the opportunity for intraoperative hepatic ultrasound, which may be useful for the detection of occult intrahepatic metastases. Ultimately, however, true resectability and/or candidacy for transplant cannot be determined until a complete abdominal exploration has been performed.

Liver transplantation for CCA is controversial and, because of the high recurrence rate published by most authors, many centers have abandoned this as an indication for liver transplantation. The most recent review of 207 patients who underwent liver transplantation for CCA reported 1-, 2-, and 5-year survival rates of 72%, 48%, and 23%, respectively, but $>$50% of patients had recurrence within 2 years [85]. A second review, with a 30% 3-year survival rate, reported that small tumor size and a single tumor focus are positive prognostic indicators [86].

Given these data, the use of liver transplantation for the treatment of CCA should be reserved for very select patients as a part of research protocols. As more effective adjuvant and neoadjuvant protocols are developed, transplantation may be a more useful treatment for this disease. This is suggested by the results from De Vreede et al. in which highly selected patients with stage I and II hilar CCA underwent neoadjuvant external beam radiation, systemic 5-fluorouracil (FU) therapy, and brachytherapy prior to liver transplantation [81]. Survival times of $>$36 months were reported for seven of 11 transplanted patients, and eight of 11 patients had no tumor recurrence with a median follow-up of 44 months. A similar study using neoadjuvant chemoradiation therapy for highly selected patients with stage I–IIIa hilar CCA reported a 45% survival rate (5 of 11) at a median follow-up of 7.5 years, but two patients died from tumor recurrence [87]. These studies

demonstrate that early-stage CCA may be an indication for liver transplantation as part of a research protocol.

Benign liver conditions

Not all patients presenting for liver transplantation will have hepatic dysfunction. In patients with benign conditions (those that are neither malignant or the result of chronic disease), the decision to consider liver transplantation depends on the probability that patient symptoms will be improved with transplant.

Budd–Chiari syndrome (BCS) results from obstruction of the hepatic venous outflow. This results in centrilobular congestion, necrosis, and fibrosis, and may result in cirrhosis [88]. The degree of liver damage and dysfunction in large part drives the decision regarding transplantation. Patients with acute BCS may have severe hepatic necrosis from which the liver may not recover. In addition, the chronic outflow obstruction may lead to fibrosis and cirrhosis and in these individuals with hepatic insufficiency liver transplantation may be considered [89]. The underlying etiology of thrombosis is rarely reversed with transplantation and long-term anticoagulation is required following transplant. Myeloproliferative disorders have been found to be a frequent cause of BCS in the US [90]. Consideration of patient candidacy for long-term anticoagulation would be an essential part of the selection of candidates with BCS for liver transplantation [91]. The 1-, 3-, and 5-year graft and patient survivals appear to be comparable in BCS patients and non-BCS patients undergoing OLT [92]. Therefore, liver transplantation should be considered in patients with BCS in whom alternate therapies, including medical, surgical and radiologic, have failed or in whom liver decompensation has occurred.

Liver transplantation remains the only curative therapeutic option for patients with polycystic liver disease (PCD). Indications for transplantation in this group depend primarily on symptoms [93]. In patients in whom pain, poor nutrition, dyspnea, fatigue, or recurrent cystic infection occurs, liver transplantation may be considered to improve overall function of the patient and quality of life [94]. Survival in this group of patients is excellent, with 5-year survival of approximately 92%. Consideration of combining liver transplantation with kidney transplantation should be made on the basis of overall symptoms related to liver size. Not all patients considered for kidney transplant will have liver involvement and only a select few of those with liver involvement will be symptomatic and expected to benefit from combined kidney and liver transplant [95].

Acute liver failure

Altered mental status (hepatic encephalopathy) and coagulopathy in the setting of acute hepatic decompensation without evidence of prior hepatic disease define ALF. The term "fulminant hepatic failure" (FHF) is generally applied to patients in whom hepatic encephalopathy develops within 8 weeks of the onset of illness, whereas "subfulminant hepatic failure" is used to describe a minority of patients in whom hepatic encephalopathy develops after a longer illness of up to 26 weeks in duration (also called late-onset hepatic failure) [96]. ALF is used as the designation to encompass all of these clinical presentations. It is a potentially devastating syndrome that may manifest with increasing cerebral edema, hemodynamic instability, renal failure, profound metabolic disturbances, and a particular susceptibility to fungal and bacterial infections, as well as coagulopathy.

ALF is uncommon but not rare; approximately 2000 cases occur annually in the US, with a mortality approaching 80%. It accounts for approximately 6% of transplants in the US [97].. In most instances, massive necrosis of hepatocytes occurs; however, hepatocellular failure without necrosis is characteristic of fatty liver of pregnancy and Reye's syndrome, suggesting that the actual death of cells is not a universal or essential feature. Regardless of the inciting event, the typical pathologic picture is that of coagulative necrosis throughout the hepatic lobule.

Viral hepatitis was previously reported to be the most common cause of ALF in the US, but acetaminophen overdose and idiosyncratic drug reactions have emerged as the most frequent causes in recent studies [96]. Malignancy is an uncommon cause of ALF, and thus imaging studies may not be useful in this setting, but liver biopsy may be beneficial in selected cases. Other less common causes of FHF include drug reactions (e.g. certain antibiotics and antiretroviral agents), autoimmune hepatitis, pregnancy-related disorders such as acute fatty liver of pregnancy, the HELLP (hemolysis, elevated liver enzymes, and low platelet) syndrome, BCS, Wilson's disease, and ingestion of certain toxins such as *Bacillus cereus* toxin or *Aminita phalloides* poisoning.

Liver transplantation has emerged as a life-saving procedure leading to marked improvement in survival rates. Although select patients with ALF may recover spontaneously, those with subfulminant hepatic failure have 100% mortality without transplantation [96]. Improved surgical techniques, immunosuppression, and comprehensive care have led to an overall 1-, 5- and 10-year survival rate of approximately 65%, 59%, and 54%, respectively, with liver transplant [1].. Those patients who survive beyond the first 3 months follow a survival curve comparable to that seen after elective OLT for cirrhosis [97]. Appropriate selection of FHF patients, determining which patients may or may not survive with medical support alone, remains perhaps the most daunting aspect of caring for this subpopulation of potential liver transplant patients. Further refinement of selection criteria, intensive care support, and perioperative care will hopefully continue to improve clinical results. An emerging technology for this condition is the use of hepatic assist devices. This is covered in Chapter 47.

Previous graft failure

Patients undergoing liver transplantation may have graft failure due to technical complications, primary non-function of the graft, or recurrent disease leading to decompensation. Approximately 10% of liver transplants are performed in the USs for this indication. Consideration of retransplantation must take into account the significant reduction in both patient and graft survival as compared with first transplant [1]. Recurrent disease due to hepatitis C or severe autoimmune disease may be an additional risk in patients being considered for repeat transplantation for these diagnoses [98]. Poor prognosis appears to be related to serum bilirubin, creatinine, Child–Pugh score of 10 or more, or MELD score of >25 [99,100].

Evaluation

The evaluation process for liver transplantation is designed to gather additional information regarding patients such that overall morbidity and mortality risk versus benefit may be estimated. This ensures that selected patients can be expected to have overall benefit from the procedure. The following are considered as part of the evaluation: lack of or failed alternative treatment for the underlying condition, anticipated survival following transplant equivalent to or better than in the current literature, and acceptable rate of recurrent

Table 29.2. Evaluation

Medical/surgical
Consultations
• Hepatology
• Transplant surgery
Laboratory
• Complete blood count with platelet
• Biochemical profile including electrolytes, blood urea nitrogen (BUN), creatinine and liver profile
• Prothrombin time (PT), partial thromboplastin time (PTT), and international normalized ratio (INR)
• Tumor markers alpha-fetoprotein (AFP) and carcinoembryonic antigen (CEA) (CA19-9 when appropriate)
• Anti-human immunodeficiency virus (HIV)1/HIV2
• Venereal Disease Research Laboratory (VDRL) test
• Viral serologies including anti-hepatitis C virus (HCV) antibody, HBs antigen, anti-HBc antibody, anti-HBs antibody, anti-hepatitis A virus (HAV) IgG, anti-herpes simplex virus (HSV) IgG, anti-cytomegalovirus (CMV) IgG, anti-Epstein–Barr virus nuclear antigen IgG, antitoxoplasma IgG, antiherpes zoster IgG (and as appropriate in patients with acute liver failure)
• Prostate-specific antigen (PSA) in men
• Iron, total iron-binding capacity (TIBC), ferritin
• Antinuclear antibodies (ANA), anti-mitochondrial antibodies (AMA), anti-smooth muscle antibodies (ASMA)
• Serum protein electrophoresis (SPEP)
• Ceruloplasm
• Alpha-1 antitrypsin
Radiologic
• Doppler ultrasound of the liver
• Computed tomography (CT) or magnetic resonance imaging (MRI) of the liver
• Chest X-ray, posteroanterior and lateral
Cardiopulmonary
• Cardiology consultation
• Dobutamine echocardiography or other non-invasive cardiac stress test
• Arterial blood cas
• Electrocardiogram (ECG)
• Pulmonary consultation in select patients
Additional testing
• Mammogram in women
• Tuberculosis skin test (PPD)
• Colonoscopy (patients aged 50 years or older or with increased risk of colon cancer)
• Pulmonary function tests (in patients with a history of smoking, symptomatic patients, or those with increased risk of pulmonary disease)
• Bone density
• Coronary angiogram in select patients
Psychosocial
• Social worker evaluation
• Chemical dependency evaluation (in patients with a prior history of substance abuse)
• Psychological screening and evaluation
Financial
• Determination of benefit coverage for transplantation and medications, as well as financial resources of patients when coverage is less than adequate

disease in the graft [101]. Evaluation of patients requires a detailed assessment of the patient's liver disease, overall medical and psychological health, infectious risk, social support, and financial resources through a series of testing and evaluations by the transplant multidisciplinary team. The components for evaluation are listed in Table 29.2.

The evaluation process is designed to answer three simple questions:

1 Is the liver disease bad enough to consider transplantation as an option? In other words, in the absence of alternative treatments for the patient's liver disease, does the benefit of transplantation outweigh the risk of transplantation? The evaluation process in part is designed to better estimate the overall risk of death with transplantation as compared with the risk of death with continued medical and symptomatic support for the patient.
2 Is the patient a suitable candidate? The transplant community recognizes that there are numerous aspects of a patient's medical and social health to be weighed when determining his/her suitability for transplantation. Excess mortality risk or decreased anticipated benefit may be present depending on patient co-morbidities. Lack of social or financial support or the inability of patients to comply with medical recommendations will likely decrease the overall success of the transplant. These findings influence the overall assessment of risk versus benefit.
3 Is the atient and family willing to accept the risk if the transplant team recommends transplant as the best option? Patients can always refuse transplantation if recommended, but they cannot demand transplant if the transplant team determines the risk to outweigh the benefit.

The evaluation process involves consultation with transplant hepatology and surgery, testing for and assessment of co-morbidities, and a thorough psychosocial evaluation (see Table 29.2). Patients undergo a battery of tests designed primarily to identify significant co-morbidities that may affect outcome. The evaluation of insurance and prescription coverage is essential to inform both patients and caregivers of the resources available to the patient. Finally, patients and families are asked to participate in a family meeting, which serves to identify social support and resources, as well as to further educate the patient and caregivers on the demands and requirements of transplantation.

Cardiopulmonary evaluation

Evolutionary improvement in the outcomes of liver transplant over the past two decades has permitted an increased willingness to accept higher risk patients, and reflects the increased experience in anesthetic, operative, and critical care of liver transplant recipients. Previous "absolute" contraindications such as severe cardiovascular or pulmonary disease have become relative contraindications. Transplant centers have established basic criteria for pretransplant evaluation of patients with cardiac and pulmonary disease in the hope of maximizing opportunity for transplantation while minimizing the risk of untoward outcomes.

Preliver transplant assessment breaks down into two main objectives: (1) individual evaluation and stratification of the associated perioperative risk in patients with co-morbidities, and (2) estimation of the long-term prognosis considering other potential extrahepatic disorders in the hope of establishing a realistic risk-to-benefit ratio. For potential living liver donor recipients, a third objective is the assessment of the added risk of the donor operation in relation to the recipient's quality of life and estimated reasonable waiting period for cadaveric liver transplant. The inherent risk of liver transplantation and the shortage of donors mandate the selection of patients who are likely to obtain a significant survival benefit from transplantation.

Cardiac evaluation

Liver transplant recipients today are older and present with more co-morbidities than 20 or 30 years ago [102]. Early studies in liver transplant recipients seemed to suggest that ESLD somehow protected patients from coronary artery disease (CAD). However, recent data point to equal, if not increased, prevalence of CAD in these patients when compared to other surgical candidates [103,104]. Some evidence points to the possibility of a cardiomy-

opathy specific to cirrhosis, of any etiology, potentially related to severe cardiovascular events in this population [105].

Estimates of cardiac events around the time of liver transplant vary between 25% and 70% [106,107], and such events can significantly alter patient and graft survival. If recurrent disease and de-novo malignancies are excluded, cardiovascular disease represents the most common cause of death in long-term liver transplant survivors [108]. Thus, the cardiac preoperative risk assessment of candidates for liver transplant has garnered much scrutiny, and is an increasingly important clinical requirement, with significant impact on postoperative outcomes. The evaluation itself is complex and details are often center specific.

The liver transplant operation, compared to other transplant as well as abdominal surgeries, can provoke severe hemodynamic changes that may unmask CAD. Although cardiac morbidity and mortality have improved compared to older studies, due to improvements in selection and management of CAD as well as in perioperative management of liver transplants, they continue to be higher than in patients without CAD.

The optimal screening strategy for liver transplant candidates is a topic of debate due to conflicting data available for non-invasive stress testing and different algorithms used in several centers. Preoperative work-up must include a careful cardiovascular history to detect symptoms and risk factors. The limited functional capacity characteristic of the ESLD population may prevent common symptoms of CAD, such as chest pain or shortness of breath that are usually provoked by exercise. Thus, nearly all CAD patients with ESLD are asymptomatic, making it necessary to detect silent heart disease in many cases.

Recommendations from the American Heart Association/American College of Cardiology for perioperative evaluation for non-cardiac surgery are generally used and adapted to preliver tranplantation cardiac evaluation strategies [109]. The use of non-invasive stress testing in a set of selected patients (criteria differ by institution) is a general first step. Unfortunately, previous studies have failed to identify a clear risk factor profile in ESLD patients, and there is no optimal risk stratification strategy [110]. In a retrospective cohort analysis of liver transplantation candidates aged over 45 years without known CAD, coronary angiography showed a 26% prevalence of moderate-to-severe CAD [111]. A diagnosis of NASH independently increases the risk of CAD [112].

Dobutamine stress echocardiography (DSE) and myocardial perfusion scintigraphy (MPS) are the two most commonly used screening methods to detect CAD in patients being evaluated for transplantation. A positive test mandates further investigation with coronary angiography or, in some centers, cardiac CT or magnetic resonance angiography (MRA) to evaluate for CAD. While abnormalities seen on DSE and MPS testing correlate well with the presence of CAD in the general population [109], the reported sensitivities and specificities in patients with ESLD are more variable, ranging from 12–100% and 57–100%, respectively [101]. DSE is the preferred test in most liver transplant centers both because it seems to be more specific than MPS and also because it provides additional information regarding overall left ventricular function and valvular disease. In both screening methods, however, care must be taken to consider specific patient population concerns, such as the frequent use of beta-blockers in cirrhotics, as well as the overall vasodilated state, which may affect response to chronotropic agents such as dobutamine, or dilating agents such as adenosine or dipyridamole [113,114].

Recent advances in cardiac CT for the detection and quantification of coronary artery calcification have improved cardiovascular risk prediction in a general population; McAvoy et al. in a recent study demonstrated a strong relationship between coronary artery calcium score and a number of known cardiovascular risk factors in the setting of liver transplantation [115]. Although the utility of using calcium scores in predicting cardiovascular events around the time of liver transplantation requires further prospective evaluation, it seems to hold promise based on results in other surgical cohorts.

If significant obstructive CAD has been identified in a pretransplant candidate, management opinions vary widely among centers. Liver transplantation must be delayed to allow revascularization or percutaneous coronary intervention, and/or the titration of appropriate medical therapy such as statins or beta-blockers [116,117]. However, it is not clear whether revascularization influences outcome relative to transplantation status. In the general population, prophylactic revascularization in the absence of significant ischemia or symptoms has not been proven superior to conventional medical therapy [118]. On the other hand, this specific population undergoing liver transplantation has the aforementioned characteristics that frequently prevent or mask the manifestation of cardiac disease, and the transplant operation itself can be considerably more stressful than is modeled by either DSE or MPS. As always, individual patients and the overall picture of physical health, co-morbidities, and data obtained by various testing methods need to be carefully considered.

Pulmonary evaluation

While cardiac testing of liver transplant candidates generally receives more attention, pre-existing pulmonary disease also has a significant impact on perioperative risk. Chronic obstructive pulmonary disease (COPD) and emphysema due to smoking or other etiologies, primary or portopulmonary hypertension, hepatopulmonary syndrome, or hepatic hydrothorax, which may be identified in cirrhotic patients, can present multiple challenges in perioperative pulmonary management. In the liver transplantation context, it is critical to establish not only the diagnosis, but also the prognosis of the potential pulmonary co-existing disease. This section discusses the most common pulmonary problems observed in ESLD patients that may impact recipient selection.

COPD is common in cirrhotic patients who undergo transplant, and it is estimated that 18% of liver transplant candidates have COPD [119,120]. Although there are no consistent data, it seems plausible that COPD patients may have diminished long-term survival after liver transplant [121]. Postoperative intensive care unit and hospital length of stay, ventilator dependence, the need for post-discharge rehabilitation, and infectious risk all may be affected in patients with COPD. In addition, continuation or resumption of smoking post liver transplant may increase the risk of de-novo malignancy [122].

Forced expiratory volume in 1 s (FEV_1) is often used to grade the severity of COPD. The BODE (body mass index, airflow obstruction, dyspnea, and exercise capacity) index, a multidimensional grading system, is superior to simple pulmonary function testing at predicting the risk of death from any cause and from respiratory causes among patients with COPD [123,124]. Accurate respiratory evaluation, including walk tests, should be mandatory in liver transplant candidates with moderate-to-severe COPD.

Ascites and pleural effusions are common in cirrhosis, and can affect oxygenation and ventilation. Hepatic hydrothorax is defined

as the presence of pleural effusion in patients with cirrhosis in the absence of primary cardiopulmonary disease [125]. It manifests in 5–12% of patients with ascites. Ascites can cause increased intra-abdominal pressure with diaphragmatic rise and resulting decrease in lung volume and chest wall compliance. Pleural effusions in ESLD patients may be exacerbated by hypoalbuminemia and azygos vein hypertension [126].

Formation of hydrothoraces has been shown to be due to passage of ascitic fluid through defects in the diaphragm directly into the pleural space. Hepatic hydrothorax will accumulate when the peritoneal fluid accumulating in the pleural cavity exceeds the pleural space's absorptive capacity. For poorly understood reasons, this accumulation of fluid is much more common in the right hemithorax. Interestingly, up to 20% of cases of hepatic hydrothorax may occur in the absence of clinically detectable abdominal ascites [126].

Liver transplant candidates who present with hepatic hydrothorax require a work-up that includes chest X-ray and CT scan of the chest with contrast, to rule out any primary pulmonary pathology that would account for the pleural effusion. It is important to evaluate the absence of mediastinal lymphadenopathy that would signal the possibility of malignant effusion. Work-up usually also includes a diagnostic thoracentesis, to confirm a sterile transudate with low protein level and cell counts. Cultures and fungal and Gram stains, as well as acid-fast bacilli stains, should also be assessed, and cytology examined to rule out malignancy. Cases in which infection or malignancy must be absolutely ruled out may require thoracoscopy with pleural biopsy. Finally, patients with ascites should also undergo diagnostic paracentesis [127].

Hepatopulmonary syndrome defines a syndrome consisting of dyspnea, hypoxia, and increased pulmonary shunting in the presence of chronic liver disease. Several reports have suggested resolution of the syndrome following liver transplant [128]. Therefore, although it is important to diagnose and manage it prior to liver transplant, hepatopulmonary syndrome should not exclude patients from selection.

Pulmonary hypertension may be present in patients with cirrhosis and may first be diagnosed at the time of transplant evaluation due to lack of symptoms. Patients with increased pulmonary pressures have increased mortality as compared with cirrhotic patients with normal pulmonary pressures. In addition, perioperative mortality is significantly increased in patients with pulmonary hypertension and would be considered a contraindication to transplant [129,130]. Patients who respond to intravenous prostaglandins may be considered candidates for liver transplant [131] as their pulmonary pressures may reduce to normal following transplantation [132].

Psychosocial evaluation

Patients considered for liver transplant require extensive psychosocial evaluation in addition to a thorough medical evaluation to best determine the relative risk and benefit of transplantation. However, there are relatively few evidence-based guidelines for pretransplant psychological and social screening [133,134]. Although formal evaluation by both psychiatrists and social workers is common in most transplant centers, observation of adherence to medications and recommendations in the pretransplant phase is a strong predictor of 1-year outcomes following liver transplant [135]. Neroticism and limited social support may negatively impact on outcomes following liver transplant, whereas active coping skills may work to improve them [136].

For patients with a history of alcohol, the "6-month" rule has become a standard approach when evaluating patients for liver transplant [137]. A meta-analysis identified 6-month abstinence as one of three pretransplant predictors of alcohol relapse following transplantation [138], although the exact time period required for abstinence has been somewhat controversial [139]. The goal of evaluation is toward identifying patients likely to maintain abstinence following transplantation. This requires evaluation by an addictive disorders specialist [140].

Patients should be screened for depression and patients with a history of past depression should be further evaluated by a clinical psychologist or psychiatrist. Mental health issues are common among patients with advanced liver disease [141] and depression may affect post-transplant psychiatric morbidity and possibly adherence [142,143]. Patients would be considered for transplant if they were found to have a stable condition that was not anticipated to interfere with their recovery. Recommendations for psychiatric follow-up during the waiting period or following transplantation would be patient specific.

Although ongoing use of addictive drugs is considered a contraindication to liver transplant in the majority of transplant centers [144], a recent survey of transplant centers found that 56% of the responding programs accepted patients in methadone maintenance programs [145]. However, the same survey found 32% of programs required discontinuation of methadone prior to listing. Several studies have found that patients on methadone replacement can undergo successful liver transplant with similar outcomes to those patients not on methadone replacement for prior addiction [146]. Therefore, it is imperative that centers develop policies regarding the selection of patients with prior addiction.

Infectious disease evaluation

The pretransplant infectious disease evaluation of potential liver transplant candidates should include immunization history, history of prior peritonitis or cholangitis, and travel history.

Recommended studies include testing for tuberculosis, hepatitis, and prior exposure to certain viruses and other pathogens (see Table 29.2). This allows for appropriate vaccination prior to transplantation and identifies "at-risk" patients such that prophylaxis strategies may be employed.

Schaffner outlined four important aims of screening potential recipients of liver transplants [147]:

1. To determine the immune status of the recipient against common pathogens that can be transmitted through transplantation.
2. To permit the allocation of organs from donors infected with a certain pathogen to recipients who are already carriers of the pathogen.
3. To recognize and treat infections that can be expected to exacerbate or reactivate after immunosuppression.
4. To avoid transplantation in patients with a poor prognosis after transplantation.

Recommended screening laboratories reflect these aims and inform our selection and prophylaxis of patients before and following transplantation.

Selection of patients with acute liver failure

Selection criteria for OLT in the setting of FHF are not currently standardized. Work-up for transplant encompasses the same general requirements as that for patients with chronic liver disease who need transplantation, performed urgently. The most widely applied criteria were formulated at King's College Hospital in

Table 29.3. King's College criteria for acute liver failure

Acetaminophen overdose
Arterial pH <7.3 or all three of the following:
- Prothrombin time >100 s
- Creatinine >300 μmol/L
- Grade 3 or 4 encephalopathy

Non-acetaminophen cause
Prothrombin time >100 s or international normalized ratio (INR) >6.7 or any three of the following:
- Unfavorable cause (non-A, non-B hepatitis, halothane hepatitis, drug-induced hepatitis)
- Jaundice >7 days before encephalopathy
- Age <10 or >40 years
- Prothrombin time >50 s or INR >4
- Serum bilirubin >300 μmol/L

London based on a retrospective, multivariate analysis of possible prognostic factors in 588 patients treated medically between 1973 and 1985 [148] (Table 29.3). Other centers have noted that, while fulfillment of these criteria carries a poor prognosis for spontaneous survival, lack of fulfillment carries a less favorable outlook than originally suggested [149,150].

More recent analyses aim to consider which other factors currently not included in the King's College criteria have prognostic relevance. Several have been reviewed, including white blood cell count, hyperkalemia [150], and lactate levels [151]. Unfortunately, most additional risk factors for failure to recover without OLT occur late in the clinical course, and thus are of limited utility in determining timing or necessity of listing for transplant.

Liver transplantation has emerged as a life-saving procedure leading to marked improvement in survival rates. Improved surgical techniques, immunosuppression, and comprehensive care have led to an overall 1-, 5-, and 10-year survival rate of approximately 65%, 59%, and 54%, respectively, with liver transplant [1]. Those patients who survive beyond the first 3 months follow a survival curve comparable to that seen after elective OLT for cirrhosis. Appropriate selection of FHF patients, determining which patients may or may not survive with medical support alone, remains perhaps the most daunting aspect of caring for this subpopulation of potential liver transplant patients. Further refinement of selection criteria, intensive care support, and perioperative care will hopefully continue to improve clinical results.

Selection of patients with hepatocellular carcinoma

In the largest prospectively collected single-institution study of HCC in OLT to date, from the University of California, Los Angeles (UCLA), factors that predicted poor survival included increased tumor number, presence of lymphovascular invasion, and poor tumor differentiation. These findings echo the results of prior series and underscore the key principle that tumor biology, more than size or number, determines outcome after OLT for HCC [152]. This has led several researchers to surmise that tumors that on radiologic images are seen to respond favorably to pretransplant therapy, be it transcatheter arterial chemoembolization (TACE) or radiofrequency ablation (RFA), possess a more favorable biologic profile. More study needs to be done to elucidate this theory, especially with regard to the best means of assessing tumor biology pre transplant, be it by serologic or radiologic testing.

Within the framework of persistent organ shortage and high waitlist dropout rates due to HCC growth, pretransplant patient selection has become the determining factor in treating HCC in patients with ESLD, and pretransplant adjuvant therapies are a routine component of this process. Controlling tumor growth during the waitlist time may have several advantages, including preventing dropout, influencing HCC recurrence rates post transplant, and overall survival for this subgroup of patient.

While single treatment modalities are effective in slowing tumor progression in many patients with HCC, multimodality treatment may allow for increased rates of complete tumor necrosis, and thus better post-transplant recurrence-free survival. Several centers, and most notably that at UCSF, have shown in uncontrolled studies that multimodality approaches can offer a low dropout rate during the waiting time, favorable survival rates, and a low recurrence rate after transplantation [77]. Also, Freeman et al. showed similar results in a retrospective review of the SRTR data on liver transplantation in the US from 1997 to 2006 [153]. They observed a significant survival advantage at 3 years post transplant in patients with HCC exemptions and local ablative therapies during the waiting time.

Based on these findings, Duffy et al. from UCLA proposed that preoperative tumor staging is best accomplished with a CT or MRI scan within 6 months of the time of OLT, as well as liver biopsies to assess histologic grade and the absence or presence of lymphovascular invasion [154] . Because there are real concerns about liver biopsies in cirrhotic patients and the risks of sampling error, bleeding, or tumor dissemination, others have recommended using tumor biopsies only in cases of large tumors that approach 3 cm or more, or tumors that do not respond well to locoregional therapy.

Selection committee

Once patients have completed their medical, surgical, and psychosocial/financial evaluation, they may be discussed at the selection committee. This committee generally consists of members representing transplant hepatology and surgery, transplant nursing, psychiatry, chemical dependency, financial services, diet, and social work. During patient review, relevant problems can be identified, which may result in recommendations for further consultation or testing. This discussion allows full review of all data acquired during the evaluation such that relative risk-to-benefit can be determined and final recommendations regarding listing or monitoring can be made.

Summary

Patients should be evaluated and considered for liver transplantation when the overall benefit of transplant exceeds the risk. Consideration of overall medical and surgical risk, psychosocial support, and financial means should be made during the process of evaluation. Decisions regarding candidacy will necessitate the co-operative review of the transplant team, taking into account all aspects of the patient work-up. For patients with progressive liver failure, the need for transplantation may be influenced by the health consequences and mortality risk of the complications. For patients with liver cancer, the benefit of transplantation may be in the reduction of recurrent disease. For others, the overall need/benefit may be based on quality of life improvement. Regardless of the indication, the evaluation process for each individual is designed to better inform the transplant team as to the potential for benefit as weighed against the overall risk of the procedure and recovery.

CHAPTER 30

Patient Selection and Indications for Heart Transplantation

Andrew L. Smith[1] and Daniel B. Sims[2]

[1] Division of Cardiology, Emory University School of Medicine, Atlanta, GA, USA
[2] Montefiore Medical Center, Albert Einstein College of Medicine, Bronx, NY, USA

Introduction

Heart transplantation is performed in 2300 patients in the US each year, of whom approximately 1950 are adults over age 18. Despite broadening criteria for acceptable donors, this number has been constant over the past decade. It is estimated that 5000 heart transplants are performed each year worldwide [1]. The prevalence of heart failure is increasing, resulting in a widening gap between the numbers of patients listed versus transplanted each year. Additionally, left ventricular assist devices (LVADs) are now implanted as frequently as hearts are transplanted. LVADs are being used as a bridge to transplantation or as an alternative to transplantation in individuals not selected for transplant listing (destination therapy) [2]. Fortunately, for the growing heart failure population optimal therapy has improved in recent years, substantially changing the trajectory and in some cases the direction of severe myocardial dysfunction.

The general indications for heart transplantation (Table 30.1) have been stable over the past decades. However, heart failure therapy has evolved to include additional treatments prior to defining a patient as refractory [3]. Improved heart failure outcomes are the result of neurohomonal modulation with medications, reduction in sudden cardiac death with implantable defibrillators, and improved myocardial contraction with resynchronization pacing devices in patients with wide QRS on electrocardiogram [4]. Thus, the risk assessment for when a transplant is needed has changed, in an era where availability of organs has decreased. This chapter will focus on the selection of patients for heart transplantation with a discussion of allocation policy changes that have had a major impact on the characteristics of patients undergoing transplant in recent years. It serves as a companion to Chapter 39, which covers the management of patients on the waitlist for heart transplantation, and also complements Chapters 44, 48, and 49, which detail intensive care unit management of patients with heart failure, ventricular assist devices, and the emergence of the artificial heart, respectively.

Heart failure: A symptomatic and progressive syndrome

Heart failure is a common chronic problem in the US experienced by over 6 million people. The New Heart Association (NYHA) symptomatic classification has long been used to classify patients, ranging from those with asymptomatic or mild symptoms (class I–II) to those with marked or severe limitations (class III–IV). Symptoms usually respond to treatment of fluid congestion, but over time may become refractory. Therefore, it is helpful to think of a continuum of disease states that has been staged with important prognostic implications. Refractory end-stage heart failure is characterized as stage D [5]. Estimates vary, but as many as 150 000 people with heart failure in the US may have entered stage D. Of these, 75% are aged over 65 years and have associated co-morbidities, including diabetes mellitus, chronic kidney disease, and peripheral vascular disease. However, tens of thousands of stage D patients would live longer lives with heart transplantation if there suitable donors were available. Due to the mismatch of need and availability of donor hearts, heart transplant programs are forced to make decisions based not only on the individual's outcome, but also on ethical concerns for allocation of a scarce resource.

Heart transplant listing outcomes

Results of heart transplantation have improved in recent years with 1-year survival approaching 88–90%, compared to 80% in the 1990s (Figure 30.1). Five-year survival is approximately 75%. Of adult patients who survive 1 year, half can expect to live for 14 years and close to a third will live for 20 years [1]. According to the United Network of Organ Sharing (UNOS), of adults listed for heart transplantation in 2008, 60% underwent transplant within 12 months, 25% were still waiting, and 10% had died, while 5% were removed from the list either because of improvement or unfavorable reasons. By 36 months, 70% were transplanted, 8% were waiting, and 12% had died on list, while 10% had been removed. In recent years, approximately 3400 candidates are added to the list each year [6].

Notable is the fact that 77% of the heart transplant programs perform fewer than 20 transplants each year. The larger volume programs, those with 20 or more transplants each year, perform 52% of the total transplants (Figure 30.2) [1].

Left ventricular assist devices: Changing the landscape of stage D heart failure therapy

As discussed in depth in Chapter 48, mechanical circulatory assistance has been available for years, including LVADs, right ventricle assist devices (RVADs) or biventricular assist devices (BiVADs) to

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Table 30.1. General indications for heart transplantation

Common:
- Severe systolic dysfunction with advanced symptoms despite optimal therapy, and objective evidence supporting poor 1-year survival

Less common:
- Complex congenital heart disease with severe symptoms not amenable to palliative or corrective surgery
- Restrictive or hypertrophic cardiomyopathy with severe heart failure refractory to therapy
- Persistent life-threatening ventricular arrhythmias refractory to treatment
- Severe, disabling ischemia not amenable to revascularization

bridge critically ill patients to heart transplantation. A major change in the advanced heart failure environment has been the expanded use of continuous flow LVADs (Figure 30.3). These pumps are smaller and more reliable than previous generation devices and have resulted in improved outcomes, not only for patients awaiting transplant but also for patients as a permanent or "destination" therapy. Following LVAD implantation, patients can be discharged within 2 weeks and have a good ambulatory status within the first 2 months. The Interagency Registry for Mechanically Assisted Circulatory Support (Intermacs) reported approximately 1000 implants in 2009 and 1800 in 2011 in the US, approaching the number of heart transplants [2]. The indications for these implants were either as bridge to transplant (BTT) for patients deteriorating on continuous inotropic support; bridge to candidacy for transplant (BTC), i.e. support until a potentially modifiable contraindication is resolved; or as long-term, destination therapy (DT). In 2011 23% of implants were BTT, 37% were BTC, and 38% were DT [7]. There has been a marked increase in the use of LVADs as a BTT, with approximately one-third of patients transplanted in 2010 supported by these devices (Figure 30.4)

Improvement in LVAD technology has increased survival for patients with severe heart failure. Currently, 1-year survival for patients supported by continuous flow LVADs approaches 75% and 2-year survival 62%. The clinical results with LVADs are strongly linked to the severity of illness at the time of the implant. Patients in carcinogenic shock have substantially inferior results. If these

patients, as well as those with serious co-morbidities, are excluded from analysis, 2-year survival approaches 80%, which is similar to that for heart transplantation [7]. Longer-term data are limited.

Despite improvements with LVAD technology, infection, thrombosis, and bleeding remain problematic. Over 25% of patients who currently have LVADS are on antibiotics for bacterial infections, most commonly involving the skin where the driveline exits to the controller and battery source [8]. Patients require chronic anticoagulation with warfarin. Device thrombosis may result in stroke or device malfunction, which may require pump exchange. The need for chronic anticoagulation and the occurrence of acquired von Willebrand factor deficiency in these patients may result in gastrointestinal bleeding from arteriovenous malformations, with clinical bleeding occurring in up to 20% of patients [9]. Based on these complications, which impact long-term results, heart transplantation remains the favored therapy over destination LVAD therapy.

LVADs are being used increasingly to bridge unstable patients to transplantation. Overall results are comparable to non-device patients even though surgical complexity is increased. There is a downside to LVAD bridging in addition to the potential complications mentioned. Patients with LVADs are at risk of developing alloantibodies, manifest by an elevated panel reactive antibody (PRA) percentage (discussed in depth in Chapter 89). This has implications for the likelihood of finding a suitable donor. Elevated PRA may be due to transfusions needed for surgical or gastrointestinal bleeding; however, patients without transfusions have developed elevated PRA post implant. It appears that up-regulation of the immune system from the interaction of the body with biomaterials from the LVAD may be responsible, although not all antibodies measured in LVAD recipients are anti-HLA antibodies [10]. Some candidates for heart transplantation are at higher risk for complications with LVAD support. These candidates include patients with severe right ventricular failure, non-dilated cardiomyopathies, multiple prior sternotomies, or prior mechanical valve replacement, particularly aortic. Thus, patients should initially be evaluated for transplant and if a candidate, should be assessed for potential LVAD bridging candidacy in the event of deterioration. Patients not accepted for transplant should be assessed for suitability for DT.

Heart allocation in the US

Allocation of donor organs in the US is determined by UNOS policies [10]. The Thoracic Organ Transplantation Committee, composed of transplant physicians, nurse coordinators, transplant hospital representatives, organ procurement organization (OPO) representatives, and a patient representative, develops and monitors heart and lung allocation policies. Regional review boards provide additional oversight, including reviewing requests for high priority by exception. Heart allocation consists of three priority statuses designed with the intent of hearts going to candidates who are more critically ill (Table 30.2).

As indicated, the highest priority (1A) candidates may be critically ill at the transplant center hospital or may be out of the hospital with an LVAD under the 30-day rule or one that has serious complications such as thrombosis, device infection, or mechanical failure. Patients with LVADs who do not meet these criteria are 1B, as are patients on continuous inotropic support. Outpatients not meeting these criteria are status 2 and patients who are not immediately suitable to be transplanted can be temporarily inactivated to status 7. Waiting time accrued is only meaningful when based on level. For example, a patient who is listed 1A for 1 day will take priority over one who has been status 1B for 3 months or status 2 for 3 years. Regarding ABO typing, O hearts are prioritized to O or B recipients, A to A or AB recipients, and B to B or AB recipients.

In 2006, heart allocation was altered such that if a status 1A or 1B patient in the local OPO was not a match, instead of allocation to local status 2 candidate, first priority is given to 1A and 1B patients within a 500 mile radius of the donor surgery hospital. This geographic design was intended to reduce waitlist mortality while keeping organ ischemia time to <4 h so that transplant outcomes would not decline (Table 30.3) [11]. As a result, there has been a marked decrease in status 2 recipients being transplanted, but without an adverse impact on overall transplant outcomes [12].

In 2011, only 6% of heart transplants were status 2, with 62% status 1A and 32% status 1B (Table 30.4). In our current era of implantable cardiac-defibrillator therapy (ICD) and resultant decrease in sudden death, the outcome of status 2 patients on the waitlist is similar to the 1-year survival with heart transplantation. This fact, along with the low possibility that a patient will be transplanted as status 2, has led some to question the need for listing patients in this category [12,13]. However, a significant percentage of status 2 patients will deteriorate over a short period of time and for this reason there are advocates of the current listing system [14]. There is regional variability with regard to waiting times

Table 30.2. UNOS priority status for heart transplant

Status 1A – Admitted to the transplant hospital and one of the following:
- Hemodynamic monitoring and continuous infusion of high-dose inotrope or multiple inotropes
- Mechanical circulatory support with intra-aortic balloon pump, extracorporeal membrane oxygenator (ECMO), or total artificial heart
- Mechanical ventilator

Status 1A – Without requirement for hospitalization:
- Left (LVAD) and/or right ventricular assist device (RVAD) may be 1A for 30 days at any point determined by the program
- LVAD or RVAD with objective evidence of significant device-related complication or life-threatening ventricular arrhythmias

Status 1B:
- Continuous infusion of inotrope
- LVAD or RVAD

Status 2:
- All candidates not meeting 1A or 1B criteria

for transplant and to numbers of status 2 patients transplanted. Waiting times are also impacted by body size, ABO type, and allosensitization. In some regions, a large male with O blood type might reasonably expect to receive a transplant based on 1A waiting time. Listing that patient as status 2 will not impact when he receives a heart.

It is obvious that organ availability limits the number of patients who benefit from heart transplantation. The process of surviving to a heart transplant is challenging to the patients and families. Patients with heart failure often experience prolonged time periods in the hospital, may require continuous home inotropic infusions, and more than one-third may require intra-aortic balloon pump or LVAD as a BTT. Patients undergoing LVAD placement will have a period of recovery followed by an uncertain period of waiting, often determined by highest priority listing when a serious complication occurs. Transplant centers educate patients about the hardships that they may endure on the waitlist, although the variability in waiting makes defining a path for an individual difficult.

The decision to list a patient for transplant is made by a multidisciplinary committee with the expectation that those listed will ultimately be transplanted with a good outcome. Favorable outcomes are needed to ensure proper use of a limited organ supply, to limit individual suffering, and to protect the continuation of the transplant program in a highly scrutinized regulatory environment. Thus, the selection of a patient for heart transplantation requires more than the possibility that that person's death might be delayed by the surgical implantation of a donated organ. Because of the differences in organs suitable for transplant, heart transplant programs have more stringent exclusion criteria than kidney and liver transplant programs.

Patient selection for listing for heart transplantation

The evaluation of patients for cardiac transplantation may occur urgently for the unstable patient in the hospital setting or be a stepwise process in the outpatient setting for ambulatory patients, including treatment adjustment, assessing response to therapy, and assessing adherence.

The following questions need to be considered prior to listing a patient for heart transplantation:

1. Does the patient have refractory end-stage heart disease? This includes a review of all reasonable therapeutic options, including optimization of medical therapy.
2. Does the patient have co-morbidities that will adversely impact survival and quality of life post transplantation?
3. Are there adequate support mechanisms to insure a successful outcome?
4. Does the patient have awareness of the commitment required to go through the waiting period, the transplant period, and the rest of his/her life?
5. Has the patient's autonomy to decide to undergo transplant been appropriately supported based on his/her expectations and desires?

Determination of end-stage heart disease

Over 95% of patients undergo heart transplantation for myocardial or "pump" failure, most commonly of chronic duration. Rarely, transplants are performed for intractable angina or for life-threatening arrhythmias in the absence of severe myocardial failure. According to the International Society for Heart & Lung Transplantation (ISHLT) registry, in the past 5 years non-ischemic dilated cardiomyopathy accounted for 54% of recipients and ischemic cardiomyopathy was the etiology in 37%. Congenital heart disease, valvular heart disease, and retransplantation each represented 3% of the total number of transplants [1].

The development of the cardiology subspecialty certification for Advanced Heart Failure and Cardiac Transplantation in part materialized due to the growth of surgical heart transplant programs in the 1980s. As referrals and waiting times grew, heart failure clinics were established to care for the population of patients with advanced chronic disease. The cardiologists in these centers worked in a multidisciplinary team to evaluate and chronically manage patients with severe left ventricular dysfunction. Patients who were previously thought to have intractable heart failure symptoms were noted to improve with the strategies employed by these programs.

Since that time numerous large clinical trials in chronic heart failure therapy have defined appropriate therapy for patients with systolic heart failure [4]. Optimal medical therapy now consists of titrated dosing of an angiotensin-converting enzyme (ACE) inhibitor, titration of beta-blocker, use of an aldosterone antagonist along with dose adjustment of loop diuretics to maintain appropriate volume status. African–American patients benefit from the addition of combination hydralazine/nitrate therapy. Appropriately selected patients with wide QRS duration benefit from cardiac resynchronization therapy (CRT). Beta-blockers and CRT therapy have both been shown to improve myocardial structure and function, and can reverse cardiac dilation. Patients with left ventricular ejection fractions (LVEFs) below 35% may have a survival benefit with ICD therapy. Guidelines have been developed with recommendations for these therapies as well as for referral of patients with refractory symptoms to a multidisciplinary disease management team [5]. The components of a heart failure disease management program [15] are listed in Table 30.5. These components can improve the lives of individuals with heart failure and may impact the need for transplantation.

It is important to recognize that while an individual seeks medical attention due to the symptoms of heart failure, there are a variety of disease states that may be the root cause of his/her problems. In some instances, treatment of these root causes can result in reversal of systolic dysfunction. At one end of the spectrum is the symptomatic patient with a LVEF of 15% due to tachycardia-mediated cardiomyopathy. Catheter ablation of the electrical focus in the atria or ventricles causing tachycardia may be curative [16]. Additionally, certain patients with dilated cardiomyopathy and left bundle branch block may be "super responders" to CRT with biventricular pacing systems [17]. At the irreversible end of the spectrum is the patient with a remote massive myocardial infarction who has deteriorated on medical therapy to a state of hypotension, tachycardia, and diuretic resistance. In between are patients with chronic severe left ventricular dysfunction who may be on inadequate doses of beta-blockers, and have inadequately treated hyper-

Table 30.5. Components of heart failure disease management

- Strategies to promote adherence
- Optimization of medical therapy
- Proactive interventions for symptomatic change
- Assistance with social and financial concerns
- Access to providers when needed

tension, chronic volume overload due to medication and diet adherence issues, untreated obstructive sleep apnea, or poor rate control of atrial fibrillation. These are patients who have a chronic disease state/co-morbidities that may result in NYHA class IV symptoms or if properly treated, may have mild or asymptomatic status.

Determination of need to evaluate for transplantation

The hospitalized patient

The majority of heart transplant evaluations can be performed on an outpatient basis; however, certain patients may need to be transferred to the transplant center for urgent evaluation. Patients with cardiogenic shock from suspected fulminant myocarditis may require mechanical support and transplant evaluation, particularly if their etiology is determined by biopsy to be giant cell myocarditis [18]. Included in this category are patients who are hemodynamically unstable after coronary interventions for acute myocardial infarction or those with refractory ventricular arrhythmias. In patients with chronic heart failure, the inability to wean inotropic support, the development of progressive renal or hepatic dysfunction, or the development of recurrent arrhythmias should prompt transfer to the transplant center.

The ambulatory patient with chronically treated heart failure

The majority of patients with severe left ventricular dysfunction are on complex medical regimens and generally have ICDs to prevent sudden cardiac death. Their chronic management is often through local cardiology outpatient settings. Many of these patients have favorable quality of life with occasional exacerbation of symptoms managed by dose adjustment of medications and lifestyle interventions. The challenge is to determine when prognosis has slipped to the point of necessitating advanced therapies.

Appropriate timing of transplant evaluation is done with the concept that patients may require time to meet requirements for listing, as well as to be engaged in shared decision-making about advanced therapies [19]. Although transplant testing results may be obtained rapidly, many patients require further evaluation, including routine health assessment with colonoscopy or specialty consultation for co-morbidities such as diabetes. Additionally, patients with numerous co-morbidities or psychosocial concerns may require a period of time in follow-up at the center to show that they are capable of maintaining a complex treatment program. Conversely, evaluation of patients too early may result in excessive testing and costs to the patient. Additionally, inappropriately early transplant evaluation may stress the resources of the center in attempting to manage the complexities of our current healthcare insurance and regulatory system. Once the transplant evaluation phase begins there will be many individuals involved and numerous communications with required documentation. Therefore, it is common for patients to initially be seen by a heart failure cardiologist in an advanced heart failure clinic prior to commencing the evaluation phase.

The heart failure clinical course is quite variable, making predictions for individual patients seen in clinical practice difficult. However, the clinician should heed certain warning signs that a patient's prognosis has deteriorated and that advanced therapies need consideration. The European Society of Cardiology has developed a definition of "advanced chronic heart failure" that should prompt the clinician to refer for transplant or LVAD consideration.

Table 30.6. European Society of Cardiology criteria for advanced chronic heart failure

1. Moderate-to-severe symptoms of dyspnea and/or fatigue at rest or with minimal exertion (NYHA functional class III or IV)
2. Episodes of fluid retention and/or reduced cardiac output
3. Objective evidence of severe cardiac dysfunction demonstrated by at least one of the following:
   - **(a)** Left ventricular ejection fraction <30%
   - **(b)** Pseudonormal or restrictive mitral inflow pattern by Doppler
   - **(c)** High left and/or right ventricular filling pressures, or
   - **(d)** Elevated B-type natriuretic peptide
4. Severe impairment of functional capacity as demonstrated by either inability to exercise, 6-min walk distance <300 m, or peak oxygen uptake <12–14 mL/g/min
5. History of at least one hospitalization in the past 6 months
6. Characteristics should be present despite optimal medical therapy

Reprinted from Metra et al. [20] with permission of Oxford University Press. Copyright © 2007.

All of the listed criteria should be present after optimal medical therapy has been implemented or attempted (Table 30.6) [20].

Additional factors that independently should raise a red flag are involuntary weight loss [21], the development of intolerance to ACE inhibitors or to beta-blockers due to symptomatic hypotension [22], or signs of the development of the cardiorenal syndrome [23].

Ideally, patients should be assessed objectively in the outpatient setting. In ambulatory patients, cardiopulmonary exercise testing can quantitate functional limitation, determine if the limitation is primarily heart failure related, and provide important prognostic information over the coming year. The peak oxygen consumption (peak VO_2), assuming adequate effort and achievement of anaerobic threshold, helps to stratify patients into risk categories. Peak VO_2 of <14 mL/kg/min had previously been used as an indication for heart transplantation [24]. However, studies in the era of beta-blockers, ICDs, and resynchronization devices have led to a lower cut-off point of <10–12 mL/kg/min [25,26]. Patients with clinical stability and favorable peak VO_2 results can be reassured that they have a favorable prognosis for at least 1 year.

Over 100 demographic, clinical, and laboratory variables have been associated with heart failure outcomes, including ischemic etiology, resting heart rate, prolonged QRS complex, low blood pressure, serum sodium, uric acid, hemoglobin, brain natriuretic peptide (BNP) level, ejection fraction, and left ventricular size among others. Multivariate risk scores have been developed to assess prognosis in populations of outpatients with heart failure.

The 20 variable Seattle Heart Failure model (SHFM) has been validated in a broad population of heart failure patients for providing a 1–5-year estimates of survival and average life expectancy (http://depts.wahington.edu/shfm/). It tends to underestimate risk in the very advanced stages [27]. The Heart Failure Survival Score (HFSS) was developed specifically for transplant selection, but prior to beta-blocker use and ICD therapy. It may add value in identifying the low-risk patient in whom transplantation may be safely deferred [28]. Neither of these scores should be used solely in determining transplant candidacy, but they do assist the clinician in determining which patients may require formal evaluation. Some centers include this information in the decision to list or to defer listing [25].

Heart transplant evaluation phase

After a thorough evaluation in the advanced heart failure clinic, patients assessed to be in need of and without absolute contraindications to heart transplantation are given the opportunity to

Table 30.7. Heart transplant evaluation

- Right heart catheterization with vasodilator challenge when indicated
- Cardiopulmonary exercise testing (CPX) – may be done pre-evaluation on an outpatient basis
- Electrocardiogram (ECG)
- Echocardiogram
- Pulmonary function test with bronchodilators and diffusion capacity for carbon monoxide (DLCO) (patients with history of nicotine use, asthma, or amiodarone therapy)
- Consultations with mental health social worker, social worker, financial coordinator, and nutritionist. Pharmacist is notified and performs a chart review; available for additional consultation as needed
- Hematologic profile with differential, platelet count, PT and PTT, comprehensive metabolic profile, TSH, PSA (if male patient >50 years old), lipid profile, Mg
- Serologic testing for HIV, hepatitis B and C,
- CMV, EBV, toxoplasma (post transplant implications)
- PRA antibody screen
- Comprehensive urine drug and nicotine screens
- Blood type and screen ×2
- 24-h urine collection for creatinine clearance and protein
- PPD skin test, pneumovax (if not previously received), hepatitis B vaccine
- Additional diagnostics or consults as indicated

PT, prothrombin time; PTT, partial thromboplastin time; TSH, thyroid stimulating hormone; PSA, prostate-specific antigen; HIV, human immunodeficiency virus; CMV, cytomegalovirus; EBV, Epstein–Barr virus; PPD, purified protein derivative.

Table 30.8. Contraindications to heart transplantation

Absolute:
- Severe, irreversible pulmonary hypertension
- Active malignancy
- Systemic illness with poor prognosis
- Severe obstructive pulmonary disease

Relative:
- Advanced age (>70 years)
- Uncontrolled infection
- Active peptic ulcer disease
- Diabetes mellitus that is poorly controlled or with end-organ damage (neuropathy, nephropathy, or proliferative retinopathy)
- Severe obesity
- Cachexia
- Severe peripheral vascular disease
- Severe cerebrovascular disease
- Intrinsic renal disease with decreased estimated glomerular filtration rate (eGFR) <40 mL/min/1.73 m^2
- Hepatic dysfunction with bilirubin >2.5 mg/dL or transaminases 3× normal
- Cirrhosis
- Chronic viral infection (hepatitis B, hepatitis C, HIV)
- Amyloid
- Active systemic lupus
- Active sarcoid with multisystem involvement
- Recent pulmonary infarction (due to risk of abscess on immunosuppression)
- Poor functional status from stroke or muscular dystrophy
- Swallowing or vomiting disorders
- Poorly controlled hypertension
- Active or recent substance abuse (tobacco, alcohol, illegal drugs)
- Unstable mental illness
- Recent non-adherence to therapy
- Lack of social support structure
- Psychosocial or financial barriers to strict medication adherence
- Inadequate transportation for follow-up at transplant center

undergo the transplant evaluation phase. This is performed by a multidisciplinary team and includes appointments with a transplant nurse coordinator, a social worker, a nutritionist, a mental health specialist, and a financial coordinator, and a medication review by a pharmacist. Additionally, a variety of tests are performed to further assess the need for transplantation, contraindications to transplantation and for donor organ compatibility [ABO type and panel reactive antibody (PRA)]. A list of the tests and consults performed at our center is given in Table 30.7.

In the US the listing criteria for heart transplantation are determined at the local level of the transplant program, usually through a multidisciplinary selection committee that meets on a defined basis. Each heart transplant program determines absolute and relative contraindications that have been derived based on experience and registry results, with limited data from randomized clinical trials. Clinical guidelines have been published that offer a general approach [26,29]. Contraindications are considered based on surgical risk as well as long-term impact on longevity, quality of life, and the potential degree to interfere with or be exacerbated by post-transplant immunosuppressive therapy.

Absolute and relative contraindications are listed in Table 30.8. The relative contraindications listed are those that might be modifiable, may be determined based on degree, or may be considered acceptable at some but not all programs.

It is helpful to consider the relationship between a potential contraindication and the heart failure disease state:

1 Some conditions may be due to chronic or acute low output heart failure, elevated intracardiac pressures, and volume overload with tissue congestion, activated neurohormones, or the result of complications during hospital treatment. These may potentially be reversible with heart failure treatment and time.
2 Other contraindications may have contributed to the etiology of heart failure and if not modifiable, may result in ongoing health issues post transplant.
3 Some contraindications may be worsened by immunosuppressive therapy.

Pulmonary vascular resistance

Secondary pulmonary hypertension occurs in most patients with advanced heart failure and if irreversible, can result in acute right ventricular failure at the time of transplant. Twenty percent of early deaths after heart transplant are due to right ventricular failure [30]. The donor heart is often functionally abnormal following brain death and the ischemic time necessary for procurement and implantation. In this setting, a high pulmonary vascular resistance (PVR) may result in circulatory shock due to the inability of the right ventricle to pump enough blood volume to the left side. The ISHLT registry has consistently shown a linear relationship between PVR and post-transplant mortality [1]. Commonly accepted exclusion criteria include a PVR of >6 Wood units or a transpulmonary gradient of >15. However, pulmonary artery pressures can often be improved acutely with pulmonary vasodilator therapies; failure to show an acute response should not permanently exclude a patient from consideration. Chronic infusions of milrinone, dobutamine, or prostaglandin E_1 may result in improved pulmonary hemodynamics. Chronic sildenafil or bosentan therapy appears to be safe and has resulted in successful transplantation [30,31]. The reversibility of previously fixed pulmonary artery hypertension has been demonstrated with chronic LVAD support, a therapy that reduces left atrial pressure and restores cardiac output [32]. With the use of these therapies it appears that the majority of patients initially deemed to have unacceptable pulmonary resistance will ultimately not be excluded for this reason. Once listed for transplant, serial right heart catheterizations every 6–12 months should be considered to exclude the development of fixed pulmonary hypertension.

Malignancy

Active malignancies, other than some skin cancers, are a contraindication to transplantation due to the impact of immunosuppression on tumor growth and longevity. Additionally, it is difficult to manage chemotherapy and transplant immunosuppressive medications simultaneously. For candidates who are in remission, oncological consultation is indicated to define the risk of recurrence or second malignancy to determine if a specific cancer-free waiting period is required to assess prognosis. Our center will consider listing patients with a low likelihood of recurrence, which we consider to be at <10% recurrence.

The number of patients with heart disease from chemotherapy is increasing [33]. Anthracyclines have improved cancer survival for breast cancer, lymphoma, sarcoma, and leukemia. Newer agents, including trastuzumab and the tyrosine kinase inhibitors, have been implicated in cardiac toxicity and the development of chemotherapy-induced cardiomyopathy (CCMP). Two-thirds of patients undergoing heart transplantation for CCMP have been female, which is interesting given that approximately 75% of heart transplant recipients are male. Cancer recurrence has been low. When this group is compared to patients with dilated cardiomyopathy, the incidence of infection and skin cancer has been higher, but the incidence of rejection has been lower with overall comparable survival. Patients with CCMP requiring LVAD therapy may be at higher risk for right ventricular failure and have been more likely to require right ventricular assist device support [34].

Heart transplantation in patients with prior mediastinal radiation has emerged as a significant safety and efficacy concern due to increased surgical bleeding from intense scaring of mediastinal structures, as well as the risk of postoperative pulmonary complications. Patients with prior mediastinal radiation have often had prior cardiac surgery, which adds to this risk. Additionally, malignancy recurrence appears to be higher in these patients [35,36].

Age

The median age for heart transplant recipients is 54 years; over 25% of recipients are over the age of 60 years, while only 2% are older than 70 years [1]. Older candidates are more likely to have co-morbidities and are more prone to immunosuppressive complications such as renal dysfunction, osteoporosis, steroid-induced diabetes mellitus, and malignancy. Older recipients are less likely to have rejection and may require less intensive immunosuppression [37]. The 2006 ISHLT update stated that patients should be considered if they are ≤70 years of age [26]. Centers generally base decisions on physiologic parameters, with more restrictive criteria in patients above age 65 years [38,39]. The growing scarcity of donor hearts creates an ethical dilemma: offering a finite resource to an older person might preclude a younger recipient from being transplanted. Some centers have therefore created alternative lists using marginal donor hearts, although the improved results with LVADs may be a preferred option [40].

Diabetes mellitus

Diabetes mellitus is present in almost 25% of outpatients with systolic heart failure and in ~40% of those hospitalized [41]. In recent years, 25% of patients undergoing heart transplantation had diabetes mellitus [1]. Many centers consider the presence of end-organ damage, including nephropathy, neuropathy, or proliferative retinopathy, to be exclusion criteria. Patients with autonomic dysfunction are considered to be at particularly high risk for complications [26]. The most recent registry data found that diabetes had only a modest impact on 5-year survival [1]. This likely reflects selection of patients with a lower risk profile as well as improved glucose management in the surgical period. Immunosuppression with steroids as well as with tacrolimus (especially in African–Americans) may result in new onset or worsening of diabetes following transplantation. Close to 40% of patients will have diabetes within the first 5 years after transplantation [1].

Obesity

Pretransplant obesity with a body mass index (BMI) >30 kg/m^2 or percentage ideal body weight (PIBW) >140% has been associated with poor outcomes after heart transplantation. Obese patients have increased complications after heart surgery, including infection, venous thromboembolism, and pulmonary complications. Increased rejection has also been noted in heart and other solid organ transplant recipients [42,43]. Weight gain is common in all heart transplant recipients and obesity may be worsened by steroid immunosuppression, particularly in the first year. Almost 40% of heart recipients have a BMI of >30 kg/m^2 by 5 years post transplant. Many centers require weight loss to <140% of ideal body weight prior to transplant listing. Patients with severe compromise may undergo LVAD implantation to allow survival while weight loss is attempted. This can be successful; however, for severely obese patients it has been rare to achieve or maintain weight loss post LVAD placement and these patients remain on LVAD support long term [44,45].

Renal dysfunction

Renal dysfunction post heart transplantation is multifactorial and strongly linked to long-term outcomes. Over 16% of patients have a creatinine of >2.5 mg/dL by 5 years and patients with this degree of dysfunction have a four times greater risk of death [46,47]. Predicting which patients will have severe kidney disease post transplant is problematic. Renal dysfunction is common in patients with advanced heart failure and is often reversible with normalization of hemodynamics. However, conditions that cause heart disease, including hypertension, diabetes mellitus, and atherosclerosis are also major risk factors for intrinsic renal disease. Additionally, heart failure can cause permanent fibrosis of the kidneys through chronic neurohormonal activation as well as chronic hypoperfusion.

Renal function should be assessed by estimated glomerular filtration rate (eGFR) or creatinine clearance, preferably when the patient's status is stable. Renal ultrasound should be performed in those with abnormal results. The presence of severe echogenicity or of bilaterally small kidneys is indicative of serious intrinsic disease. However, markedly hypoperfused kidneys may appear abnormal on ultrasound. In these patients, renal biopsy to establish etiology as well as to assess severity of fibrosis may be helpful in candidate selection [48]. Some centers list irreversible renal dysfunction with creatinine clearance of <40 mL/min as a contraindication, but practices vary. Our center does not have an absolute cut-off for creatinine clearance, but decisions are based on chronicity of dysfunction, biopsy results, and other co-morbidities. Combined heart and kidney transplant can be performed in selected individuals with favorable results.

Amyloid

Amyloidosis is a clinical disorder caused by deposition of misfolded, insoluble proteins in tissues. There are many different types

of amyloidosis, with two common types warranting discussion in relation to heart transplantation. In light chain (AL) amyloidosis the protein is produced by a clonal population of bone marrow plasma cells. Infiltration of numerous organs over a period of months is common and up to 50% of patients may have signs of cardiac involvement. Only 5% of patients have disease that manifests isolated to the heart [49]. Amyloid initially impacts the interstitium and with progression causes myocardial necrosis. Clinically, there is restrictive physiology with thick myocardium and with disease progression, there is decline in the ejection fraction. Usual therapies for systolic dysfunction including ACE inhibitors and beta-blockers are generally not helpful and are poorly tolerated. Digoxin should be avoided. The literature reports fewer than 100 patients who have had heart transplants with 5-year follow-up for AL amyloid. In recent years, patients have been carefully screened for clinical extracardiac involvement and have received post-transplant chemotherapy, sometimes followed by hematopoietic stem cell transplant. Despite this, the 5-year survival is significantly less than in those without AL amyloid and there is often disease progression in other organs [50,51]. Many centers will not consider transplant in patients with AL amyloid. Unfortunately, cardiac amyloidosis often occurs in patients who were previously healthy, making this an emotionally difficult disease.

Transthyretin (TTR) amyloid also commonly infiltrates the heart. Unlike AL amyloid it is slowly progressive, but may result in advanced heart failure. The familial form is due to a mutated TTR that is produced in the liver. Liver transplantation is a potential option for those without significant heart involvement and there have been approximately 26 heart–liver transplants performed for severe heart disease. New small molecule pharmaceuticals may arrest the disease and make liver transplantation unnecessary [52]. A wild-type TTR is another form and the liver is not involved. Patients with TTR amyloid appear to have better results than those with AL amyloid, which is related to the slower nature of progression. However, data are limited.

The restrictive physiology that all types of amyloid cause makes managing these patients on a waitlist difficult: there is the concern that the new heart will become involved or that extracardiac disease will limit survival.

Chronic viral infections

A study from over a decade ago reported that patients with hepatitis B surface antigenemia pretransplant had significant hepatic complications, but without clear impact on survival [53]. In the current era, with well-tolerated antiviral therapy against hepatitis B, liver complications appear to be controlled with lamivudine therapy. Some patients have developed resistance, requiring alternative antivirals [54–56]. Hepatitis C is of greater concern for several reasons. Antiviral therapy is much less well tolerated. Additionally, a large retrospective study showed decreased post-transplant survival in patients with pretransplant hepatitis C virus positivity. Of note is the fact that the 5-, 10-, and 15-year survival in those with hepatitis C was 73%, 47%, and 25% compared to 77%, 67%, and 47% in the matched non-hepatitis C patients, indicating that long-term outcomes are substantially impacted [57].

Traditionally, human immunodeficiency virus (HIV) infection has been considered a contraindication to solid organ transplantation. The use of highly active antiretroviral therapy (HAART) has markedly improved outcomes of patients with HIV and transplantation has been investigated in kidney and liver populations [58]. In kidney transplantation, a non-randomized trial of 150 carefully selected patients showed acceptable graft survival at 1 and 3 years, although inferior to overall kidney transplant results [59]. Immunosuppression management is very complex in these patients due to drug interactions between protease inhibitors and calcineurin inhibitors. An unexpectedly high rejection rate was noted in these patients. There have been isolated reports of heart transplantation in patients with HIV suggesting favorable short-term outcomes, but experience appears to be limited to a few centers with fewer than 15 reported cases in the literature [58,60]. Because HAART therapy may result in coronary atherosclerosis, heart disease is likely to increase in this population of patients.

Psychosocial factors

While medical factors have been better defined and more thoroughly assessed with regard to outcomes in transplantation, psychosocial factors are recognized to be very important in relationship to rejection, graft function, infection, and survival [61]. Success after transplant is dependent on the ability to obtain medications that easily cost over $1000 per month and may involve 20% co-pays (i.e. for Medicare recipients), and the ability to follow complex medication schedules and to take medications that are needed to treat immunosuppressive side effects [62]. Early intervention for rejection and infection is dependent on patient and caregiver recognition of change in status as well as appropriate transportation to the medical center for urgent or routine follow-up care. Depressions, social isolation, prior history of non-adherence, and substance abuse have all been associated with worse outcomes [61]. The severe physical impairment that patients experience before and after heart transplantation may contribute to temporary mental impairment; thus, an identified support person is required by many heart transplant programs. Married patients appear to have better outcomes [63].

Selection committees involve a social worker, a mental health expert, and other team members in determining if the patient has a readiness level to manage illness, an appropriate support system, psychological stability, and appropriate lifestyle to ensure success. To date, assessment has not been standardized across programs, but attempts are being made to establish tools to identify patients who may have excessive risk and thus establish standardized criteria for recipient selection [64].

Complex congenital heart disease and heart transplant outcomes

Patients with complex congenital heart disease are a unique population. The success of pediatric cardiac surgery has allowed patients with congenital heart disease to live into adulthood. Unfortunately, debilitating heart failure can develop. Patients transplanted for congenital heart disease have inferior short-term outcomes due to complications from reoperation and bleeding from collateral circulation. Patients with single ventricle physiology appear to be at higher risk compared to those transplanted with two-ventricle physiology [65]. Chronic hepatic congestion may play a role. Despite the higher 1-year mortality, 10-year survival is the same as for those without congenital disease [66].

Assessment of potential candidates

Risk stratification of a potential heart transplant recipient involves consideration of a variety of characteristics, including etiology of heart failure, prior surgeries or treatments (i.e. radiation), concomitant chronic medical conditions, as well as degree of patient acuity resulting in multiorgan compromise. Psychiatric stability,

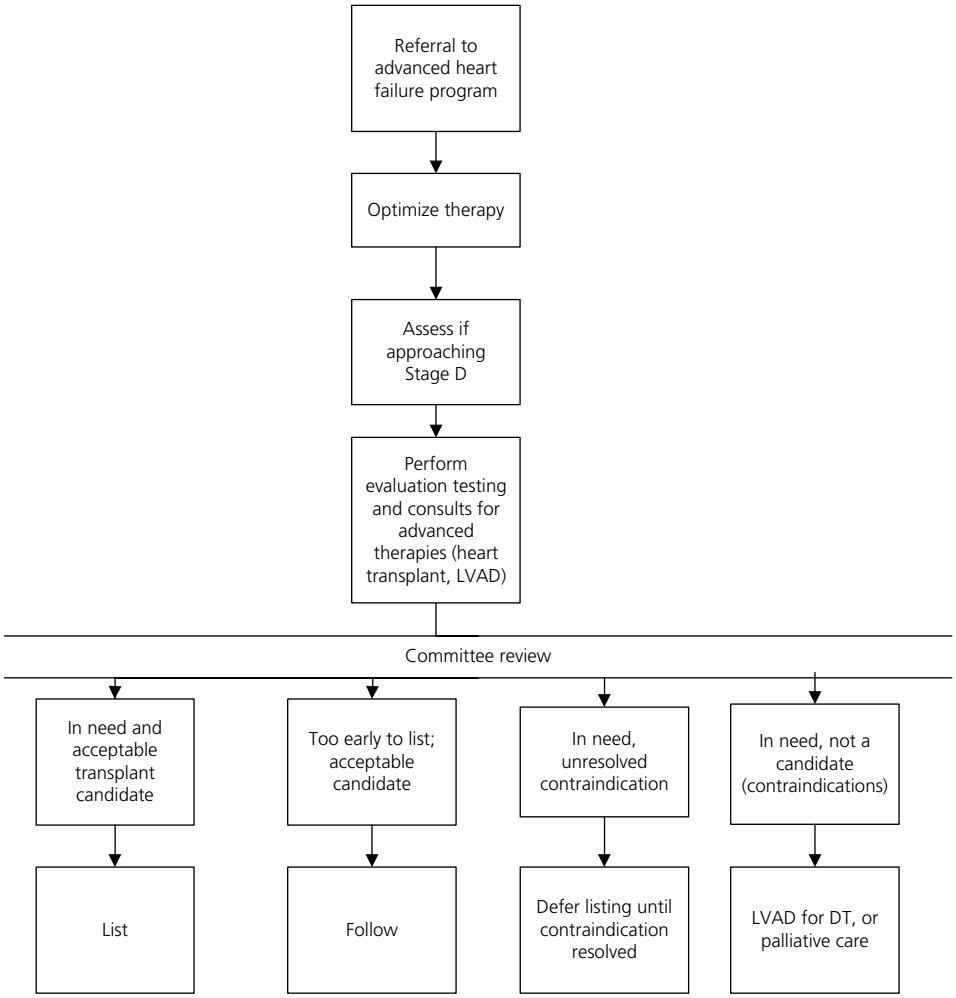

Figure 30.5. Approach to heart transplantation

rehabilitative potential, and social support are important but more difficult to quantitate. Each candidate's ability to overcome difficult pretransplant or surgical phase complications should be assessed and discussed in committee as well as with the patient and family. Patients with several characteristics that may decrease survival require careful consideration. Attempts are being made to develop risk stratification scores that identify patients who fall into unacceptably high risk for poor 1-year survival [67].

Decision regarding transplant listing

The approach to heart transplant evaluation at our program is reviewed in Figure 30.5. Following the evaluation testing and consultations the advanced heart failure therapeutics committee meets to determine candidacy for transplant and/or LVAD therapy. The committee uses exclusion criteria that are defined by our program and attempts to apply these criteria with consistency. Our criteria are reviewed on a regular basis and are changed by the committee. Much of the discussion at our meetings relates to concerns about potential problems with adherence to therapy. Patients who are excluded from transplant are informed verbally and in writing that they may seek an opinion at another center.

Centers do vary in their criteria and may need to adjust these based on the center's outcomes. In the US, detailed program-specific data are publicly reported through the U.S. Scientific Registry of Transplant Recipients (SRTR). Reports are updated every 6 months and include waitlist mortality, transplant rates, and survival, which is adjusted to give observed and expected outcomes. This information, easily accessed on the internet, is used by regulatory agencies, insurance providers, medical professionals, and patients. Centers may be at risk of losing certification if their results substantially deviate from expectations. Indeed, not only are transplant programs evaluating patients, but US programs are being highly evaluated through public reporting.

Heart transplant programs, which do low volumes compared to kidney and liver programs, are challenged by the need to be risk restrictive to assure favorable outcomes, not only to ensure the best use of an organ but from a practical standpoint to sustain the existence of the program. In has been argued that in a changing environment, it is challenging for the SRTR to adequately adjust outcomes for risk. A consensus report that related to all solid organ transplants stated that not appropriately adjusting for risk may cause programs to avoid performing transplants on suitable but surgically higher risk patients [68]. Many of the contraindications to transplant are relative and they are additionally dynamic as medical treatments for co-morbidities improve and immunosuppressive strategies change. Transplant programs are generally careful to test barriers gradually, rather than implementing sudden

changes to numerous criteria, given the relative lack of randomized clinical data.

Decision-making in advanced heart failure

The advanced heart failure therapeutics committee makes the determination of what treatment options are appropriate at its center for each individual. These options are reviewed with the patient and family, with the recognition that heart transplantation and LVAD therapy are disease-exchanging therapies that can improve longevity and quality of life, but with the need to adjust to the burden of surviving to transplant as well as the long-term maintenance of required therapies [69,70]. Ideally, all patients should be offered palliative and supportive care consultation in order to assist them and their families with disease burden. This care includes consideration of the physical, psychological, spiritual, and social needs of the patient and family. Some patients may not be candidates for or may elect not to undergo maximum therapies for heart failure progression. It is important for the advanced heart failure team to continue to offer care beyond the decision of the committee and the decision of the patient.

Summary

Heart transplantation is a highly effective treatment for end-stage heart failure, but its implementation remains severely limited by a shortage of donor hearts. This limited donor availability and the growing prevalence of heart failure has led to a widening gap between those in need of heart transplantation and those who will receive a transplant. Therefore, heart transplant candidacy is more restrictive than candidacy for other organs, and the consideration of candidacy involves not only establishing the patient's suitability for the procedure, but a pragmatic consideration of alternative therapies. Fortunately, therapies for heart failure are improving, which may prevent or delay the need for transplant. Additionally, improvements in chronic LVAD technology have resulted in better capability to bridge patients to transplants and to improved survival for patients who are not transplant candidates. Heart allocation policies based on severity of illness have made it uncommon for the patient without continuous inotropic therapy or LVAD to be called in from home for a transplant. Thus, an understanding of the priority system is important not only in managing the patient's illness, but also in managing his/her expectations. In all, candidacy selection is optimal when a patient whose condition uniquely requires a heart transplant is delivered to the waitlist in a timely manner and in a condition that is conducive to recovery from the procedure.

CHAPTER 31

Patient Selection and Indications for Lung Transplantation

Julia B. Becker and Edward R. Garrity Jr
Section of Pulmonary and Critical Care Medicine, University of Chicago Medicine, Chicago, IL, USA

Introduction

Lung transplantation is performed for end-stage lung disease of many causes, with chronic obstructive pulmonary disease (COPD), idiopathic pulmonary fibrosis (IPF), and cystic fibrosis (CF) representing the majority of causes for transplants performed. To obtain a survival benefit, referral for transplant should take into account the prognosis for any given condition. Patient selection requires a careful assessment of pretransplant medical conditions that have a large impact on post-transplant survival. In this chapter, we discuss general indications and contraindications for lung transplant. We review recommended criteria for transplant for the most common disease processes and provide review of the most recent literature that may inform patient selection. This chapter complements Chapter 40, which covers list management and the lung allocation score in depth.

Indications

The 29th official lung and heart–lung transplant report of the Registry of the International Society for Heart and Lung Transplantation was released in 2012. Lung transplant has become an increasingly common procedure, with 3519 transplants performed in 2010; an increasing share of the transplants is bilateral [1,2]. COPD and IPF were the leading indications for transplant, with IPF gaining share from 16% in 2000 to 28.3% in 2010 (Table 31.1) [1].

In 2006, the International Society for Heart and Lung Transplantation (ISHLT) released the most recent guidelines for the selection of lung transplant candidates [3].

Given the current challenge of chronic rejection and high mortality rate relative to other solid organ transplants, as well as the limited availability of donor lungs, lung transplantation should be limited to those in whom a survival benefit is expected. Overall median survival in the most recent report is 5.5 years; those who survive at least 1 year had a median survival of 7.7 years [1]. Thus, selected patients should have end-stage lung disease having failed maximum medical therapy with a 50% expected survival of <2–3 years or with significant symptoms, which the ISHLT has defined using the New York Heart Association (NYHA) classes for functional status. NYHA functional class III (symptoms with minimal activity) and class IV (symptoms at rest) are considered indications for transplant [3]. In addition, given the rigors of transplant, patients must be in relatively good health.

Contraindications

Absolute contraindications

The ISHLT's 2006 guidelines included absolute contraindications (Table 31.2). Some of these contraindications are now being overcome in transplant.

Malignancy

While malignancy in general is a contraindication, certain subtypes of lung cancer have been proposed as appropriate indications for lung transplantation. The terms "adenocarcinoma in situ" and "minimally invasive adenocarcinoma" of the lung have been adopted in a recent interdisciplinary classification scheme to replace the term "bronchoalveolar cell carcinoma" [4]. Patients with bilateral or multifocal carcinoma of this sort have been treated with lung transplantation without short-term demonstration of recurrence [5,6]. However, several series of patients transplanted for advanced minimally invasive adenocarcinoma demonstrated a high rate of recurrence [7,8].

Patients with end-stage lung disease and stage I non–small-cell lung carcinoma have also been treated with lung transplant, though often unintentionally, with good success. One survey of ISHLT lung transplant centers reported 43 cases of incidentally found primary lung carcinoma in patients transplanted for other indications; those with stage I carcinoma and minimally invasive adenocarcinoma demonstrated low rates of recurrence or disseminated disease, while those with stage II or III non–small-cell lung cancer had high rates of death from recurrence of lung cancer [9]. The Cleveland Clinic reported a 2% (four cases) incidence of undetected lung carcinoma in 214 consecutive transplant patients between 1991 and 2000, with no evidence of recurrence or decreased survival in the three patients with stage I disease; of note, this review was prior to the age of routine computed tomography, and presumably some of those patients would currently be excluded from transplant [10].

Significant chest wall/spinal deformities

Due to mechanical difficulty with surgery and with postoperative mechanical ventilation and pulmonary toilet, thoracic transplantation in patients with significant deformities is rarely performed. There have been a handful of cases reported of patients transplanted with severe scoliosis or chest wall deformities [11–13] and in at least one patient, scoliosis contributed to recurrent airway stenosis requiring frequent bronchoscopy and intervention [14].

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Table 31.1. Indications for adult lung transplants performed from January 1995 to June 2011 [1]

Diagnosis	Single lung (n = 13721) Number (%)	Bilateral lung (n = 20831) Number (%)	Total (n = 34102) Number (%)
Chronic obstructive pulmonary disease/emphysema	6048 (45.6)	5549 (26.6)	11587 (34.0)
Pulmonary fibrosis			
Idiopathic	4420 (33.4)	3495 (16.8)	7925 (23.2)
Other	498 (3.8)	659 (3.2)	1157 (3.4)
Cystic fibrosis	219 (1.7)	5469 (26.3)	5688 (16.7)
α1-Antitrypsin deficiency	741 (5.6)	1332 (6.4)	2073 (6.1)
Pulmonary arterial hypertension	82 (0.6)	982 (4.7)	1064 (3.1)
Bronchiectasis	54 (0.4)	891 (4.3)	945 (2.8)
Sarcoidosis	251 (1.9)	614 (2.9)	865 (2.5)
Obliterative bronchiolitis	91 (0.7)	260 (1.2)	351 (1.0)
Retransplant			
Obliterative bronchiolitis	259 (2.0)	254 (1.2)	513 (1.5)
Non-obliterative bronchiolitis	166 (1.3)	191 (0.9)	357 (1.0)
Connective tissue disease	140 (1.1)	281 (1.3)	421 (1.2)

Table 31.2. Absolute contraindications to lung transplantation

1. Malignancy in the last 2 years, with the exception of cutaneous squamous and basal cell tumors. In general, a 5-year disease-free interval is prudent.
2. Untreatable advanced dysfunction of another major organ system (e.g. heart, liver, or kidney). Coronary artery disease not amenable to percutaneous intervention or bypass grafting, or associated with significant impairment of left ventricular function, is an absolute contraindication to lung transplantation, but heart–lung transplantation could be considered in highly selected cases
3. Non-curable chronic extrapulmonary infection, including chronic active viral hepatitis B, hepatitis C, and human immunodeficiency virus
4. Significant chest wall/spinal deformity
5. Documented non-adherence or inability to follow through with medical therapy or office follow-up, or both
6. Untreatable psychiatric or psychological condition associated with the inability to co-operate or comply with medical therapy
7. Absence of a consistent or reliable social support system
8. Substance addiction (e.g. alcohol, tobacco, or narcotics) that is either active or within the last 6 months

If performed, surgical approach and donor selection would need to be tailored to the thoracic size [13].

Non-curable extrapulmonary infection

Three decades of progress in human immunodeficiency virus (HIV) treatment have changed the prognosis to that of a chronic disease. One case of an HIV- and hepatitis B virus (HBV)- positive patient successfully transplanted for CF has been reported with excellent lung function and no unusual complications 2 years post transplant [15]. A review of 170 hepatitis C virus (HCV) seropositive patients who received lung transplant demonstrated no difference in survival, although the majority of patients were not viremic [16]. A small group of HCV-positive lung transplant recipients at Cleveland Clinic with no evidence of cirrhosis have shown no increased mortality [17].

Untreatable advanced dysfunction of another major organ system

In general, advanced dysfunction has been a contraindication to lung transplant. However, a combined organ transplant may be considered. Based on Organ Procurement and Transplantation Network (OPTN) data as of November 25, 2011, there have been 17 kidney–lung, 44 liver–lung, two heart–lung–kidney, two pancreas–lung, and one liver–pancreas–lung transplants performed in the US since 1988.

Lung transplant in combination with dialysis has been associated with increased 1-year mortality [1,2,18], but small numbers limit the data.

The largest experience is for liver–lung transplants, typically performed for CF complicated by cirrhosis or for portopulmonary hypertension or hepatopulmonary syndrome complicating cirrhosis. Available series have reported no difference in survival compared with single organ transplant patients [19–26].

Adherence and addiction

A careful assessment of social support and adherence by experienced transplant psychologists and social workers is essential. One available tool is the Transplant Evaluation Rating Scale, which has been used to assess patients prior to organ and bone marrow transplants [27].

Non-adherent behaviors to immunosuppression, lifestyle, and general medical prescriptions are common in recipients of solid organ transplants, estimated to affect nearly half of organ transplant patients, including those who live alone [28]. Pretransplant non-adherence is associated with late acute rejection [29]. Pretransplant non-adherence with medication taking, lower social support, lower personality trait scores for "conscientiousness," and higher educational level have been shown to be predictors of non-adherence with an immunosuppressive regimen at 1 year post transplant [29]. Rates of adherence among lung transplant recipients have varied in different studies and with different definitions of adherence [30,31]. Lung transplant patients may have more non-adherent behavior than other solid organ transplant patients, in part due to the higher medication needs [30].

Prior tobacco smoking is common in patients who have end-stage lung disease, so interest in smoking behavior is critical. One survey with self-reported rates of smoking showed 100% abstinence post transplant [32]. However, self-reported rates tend to underestimate smoking compared with biologic markers such as

urine cotinine [33], and one can imagine substantial desire among a lung transplant recipient to report total abstinence. We suggest biologic testing is performed in those patients considered high risk for smoking recidivism.

Relative contraindications

The relative contraindications to transplantation are, not surprisingly, an area of more clinical debate.

Age

While 2006 ISHLT guidelines recommend against transplantation in recipients over the age of 65 years [3], the practice has been controversial. Registry data indicate that older patients have been transplanted at increasing frequency, with 28 transplants in 2000 (1.6%) documented in patients aged 66 years or older. In contrast, in the first 6 months of 2011, 13.5% of transplants were done on recipients in this age group [1] despite increased mortality with advanced age. Results to support a precise upper age limit for transplant are lacking since studies use different definitions for older patients. In a matched cohort study from the Toronto group, 42 patients over the age of 60 years were compared with matched patients younger than 60 years. Survival at 1, 2, 3, 4, and 5 years was significantly worse in the older cohort, due to increased infectious causes in the early period post transplant followed by increased malignancy [34]. A later retrospective review of over 8000 patients included in the UNOS database from 1999 to 2006 stratified patients in age quartiles. Age over 60 years, the highest age quartile, was associated with a 37% increase in risk of death at 1–2 years, while short-term 30- and 60-day mortality was no different from younger patients. Within the quartile of patients over the age of 60 years, the oldest patients (age >70 years) had a substantially increased risk of short-term mortality. Unlike in previous studies, age was thought to be protective against infection and rejection [35]. In the current ISHLT report, patients older than 65 years had decreased median survival (3.6 years vs. 6.5 years) compared with patients aged 35–49 years, and decreased long-term survival (39% vs. 51–56% at 5 years) compared with patients younger than 60 years old [1].

Other studies, many of which report results with carefully selected recipients, have demonstrated that transplants in older patients may be performed with similar mortality to that in younger patients [36–38]. Criteria used to select older patients included body mass index (BMI) in the accepted range, and absence of obstructive coronary artery disease, peripheral or cerebrovascular disease, renal insufficiency, or debilitation [38]. A larger series comparing survival rates for patients aged under 60, 60–65, and older than 65 between January 2006 and May 2008 found no survival difference, but did find that complications differed by age group, with malignancy and drug toxicity more common in patients over the age of 65 years, and rejection more common in those aged 60–65 years [39].

Several series have suggested single lung transplant (SLT) may be tolerated better in the older population, leading some centers to only consider SLT in older patients. Meyer et al. reviewed 2260 recipients of lung transplant for COPD [1835 SLT and 425 bilateral transplants (BLT)] and found that a mortality benefit existed for BLT until the age of 60 years, after which SLT had improved mortality [40]. A similar review of transplanted patients with pulmonary fibrosis demonstrated no benefit for BLT over SLT [41]. However, there are some contradictory studies. Series have shown similar 30-day [42] and 1-, 2-, and 5-year survival for patients over 60 years undergoing BLT versus SLT [43], and a large review of UNOS data demonstrated no mortality effect of SLT versus BLT in patients over 60 years [44].

Nutritional status

Nutritional status is frequently abnormal in patients with chronic lung disease; in one study, only about half of patients were deemed to have a normal nutritional status, with the remainder being underweight or overweight [45]. The ISHLT guidelines suggest against transplanting patients with BMI of $\geq 30\,kg/m^2$, though they do not comment on underweight recipients [3].

A link between increased BMI and mortality is fairly consistent, supporting a BMI threshold for transplant. The Toronto program and others have shown similar deleterious effects of excess weight on outcomes [46–48] A Spanish study of 256 transplanted patients, including 38 obese patients, was one of the few to find no statistical difference in mortality between BMI groups, although there were trends towards increased mortality and longer mechanical ventilation in the obese [49]. Overweight and obesity have also been associated with increased incidence of primary graft dysfunction [50].

Underweight had been suspected to be a risk factor for death [51]. More recently, very large reviews of the lung transplant databases have shown effects of body mass index at both extremes, stratifying patients into underweight (BMI $<18.5\,kg/m^2$), normal weight (BMI 18.5–24.9 kg/m^2), overweight (BMI 25.0–29.9 kg/m^2), and obese (BMI $>30\,kg/m^2$) by World Health Organization categories. Lederer et al. retrospectively reviewed 5978 lung recipients in the UNOS registry with CF, COPD, or diffuse parenchymal lung disease to evaluate the effect of BMI. BMI other than normal was associated with increased risk of death overall and at 1 and 5 years, with hazard ratio for overall mortality of 1.15–1.16 for being the underweight, 1.14–1.17 for the overweight, and 1.20–1.25 for the obese [52]. In the largest evaluation, Allen et al. reviewed 11 411 lung transplants performed between 1998 and 2008 from the UNOS database and for whom adequate data were available to stratify them by BMI. There was a small but statistically significant increase in mortality for every BMI strata above or below normal BMI, with odds ratio for death for overweight of 1.06, for obese of 1.16, and for underweight of 1.14 in multivariate analysis. The increased risk of death appeared to be short term mortality (only seen within the first year) for patients who were overweight and obese, but manifested later (after 1 year) in underweight patients [53].

Other medical conditions that have not resulted in end-stage organ damage

Coronary artery disease

Underlying coronary artery disease (CAD) has been associated with increased mortality in the univariate analysis of a Brazilian transplant cohort [54]. Intervention for pre-existing CAD may be implemented prior to lung transplant or at the time of transplant. The UCLA group recently reported a 10-year experience during which 27 patients with discrete coronary lesions and preserved left ventricular ejection fraction underwent coronary revascularization prior to lung transplant with no difference in survival or causes of death [55]. This echoes previous series, which showed similar success [56,57]. Of note, all patients demonstrated preserved cardiac function and had discrete (i.e. not diffuse) coronary artery lesions.

Diabetes

Diabetes is a common co-morbidity in lung transplant patients, particularly patients with CF. Although the number of patients with diabetes in their series was small, Plantier et al. found that pretransplant diabetes was independently associated with death from all causes and from cardiovascular causes [58]. Likewise, a small retrospective review of 25 patients transplanted for CF demonstrated increased morbidity and mortality for those with pretransplant CF-related diabetes [59], though interestingly, a larger study suggested no impact of diabetes on survival in CF patients and improved 1-year survival for those patients with pre-existing diabetes [60]. There has been no systematic assessment of the effect of diabetes control on success post transplant, although Bradbury et al.'s experience suggests that uncontrolled diabetes played a role in some post-transplant readmissions [59]. We suggest careful selection of diabetic patients to include those with good control, and to engage expert consultation in management of blood sugar in the perioperative setting.

Gastroesophageal reflux disease

Gastroesophageal reflux has been recognized as a cause of allograft dysfunction after lung transplant with both increased rates of bronchiolitis obliterans syndrome and acute rejection episodes [61,62], as well as worse short-term forced expiratory volume in 1 s (FEV_1) and early survival compared to patients without reflux [63]. Gastroesophageal reflux is highly prevalent among candidates for lung transplant and may be asymptomatic, requiring invasive testing [64–66]; this condition also worsens post transplant [67], perhaps in part related to medication-induced gastroparesis [68].

Treatment may require surgical intervention. Proton pump inhibitor therapy alone may affect gastric acid, but does not prevent non-acid reflux and gastric aspiration [69]. Fundoplication after transplant has been associated with improvement in bronchiolitis obliterans [70]. Laparoscopic fundoplication has also been performed successfully in patients pre transplant [71] and may preserve lung function in patients pre and post transplant [72,73].

Thus, we suggest that invasive testing for esophageal reflux should be performed on patients prior to transplant and surgical management should be considered. In those patients with severe, symptomatic disease that is refractory to treatment, reflux may be a relative contraindication to transplant.

Critical or unstable condition

Use of mechanical ventilation, artificial lung surrogates, and hospitalization at the time of transplant are associated with increased 1-year risk for mortality. According to ISHLT data, being hospitalized in any setting at the time of transplant confers increased risk of death [1,2], and in European experience, urgent transplantation is associated with lower survival than traditional transplantation [74]. Transplantation in critically ill patients, including those supported with mechanical ventilation and artificial lung surrogates, is a burgeoning area.

The use of mechanical ventilation at the time of transplant is associated with increased early mortality. In the 2011 ISHLT report, the 390 patients transplanted on mechanical ventilation from January 1996 to June 2009 had a relative risk of death at 1 year of 1.57 in comparison to a COPD SLT. In US and European experience, patients on mechanical ventilation and extracorporeal membrane oxygenation support (ECMO) had significantly lower 1-year survival than non-urgent transplants [75–77], but with a substantial survival benefit compared with not transplanting [75,76]. In the UNOS data, with a cohort consisting mainly of younger patients with CF, those on mechanical ventilation had unadjusted survival at 1, 6, 12, and 24 months of 83%, 67%, 62%, and 57%; those on ECMO, 72%, 53%, 50%, and 45%; and those unsupported 93%, 85%, 79%, and 70%, respectively [75]. Smaller series have had mixed results [78–81], but current experience suggests that transplant for mechanically ventilated patients should be carefully restricted to those with single organ failure, no resistant airway colonization, and the ability to participate in physical therapy and rehabilitation [82,83].

Single center series have reported numbers of patients who have been transplanted while on ECMO, with patients demonstrating higher perioperative and short-term mortality, but acceptable mid-term survival, even equaling traditional transplant when contingent on 3-month survival [84]. Other smaller series have demonstrated some success with a Novalung venovenous device [85,86] or with devices for extracorporeal carbon dioxide removal in the absence of hypoxemia as bridges to transplant [87]. Devices placed to allow ambulation and physical therapy while on support have shown promise in early use as bridges to transplant [88–92]. Intriguingly, patients bridged with ECMO therapy who avoid mechanical ventilation appear to have improved survival compared with those bridged with mechanical ventilation [93–95]. There are no existing guidelines about when and how to utilize ECMO technology when bridging to transplant. The topic of artificial lungs and mechanical lung surrogates is covered in depth in Chapter 50.

Colonization with highly resistant or highly virulent bacteria, fungi, or mycobacteria

Active infection is a contraindication to transplant with the concern for causing sepsis-related deaths with intense immunosuppression. The suppurative lung diseases (CF and non-CF bronchiectasis) are characterized by colonization with microbes that may become resistant. The specific risk factors for transplant mortality in a non-CF population have not been well described. Airway colonization in CF is described separately in the disease-specific section of this chapter.

Severe or symptomatic osteoporosis

Osteoporosis and osteopenia are highly prevalent in lung transplant recipients [96–98]. Therapy with bisphosphonates and resistance training have been shown to be effective prophylaxis in lung transplant recipients [99,100], but those who have advanced disease prior to transplant are at risk for severe complications as osteoporosis routinely worsens after transplant [98,101,102]. Given the steroid therapy that accompanies lung transplant, those patients with very severe or symptomatic osteoporosis would be at risk for excessive complications post transplant.

Other considerations

Previous thoracic surgery

Previous thoracic surgery, particularly previous pleural procedures, is associated with increased bleeding in the perioperative period, but has not been associated with increased mortality [103–105] and should not in general be considered a contraindication to transplant. However, pleural adhesions are associated with increased technical challenge during transplant [106].

Clinical circumstances require adjustment of surgical technique based on surgeon preference as specific scenarios, e.g. with previous pneumonectomy, heart transplant, or unilateral pleural adhesions, may impart increased risk [107–109].

Obstructive lung disease

Chronic obstructive pulmonary disease

COPD remains the most common indication for lung transplantation to date [1,18]. Its heterogeneous course makes prognostication difficult and thus, raises challenges for selection of patients for transplantation.

Survival benefit

Hand in hand with the challenge in prognostication, survival benefit for transplant in COPD is less clear. In early experience, prior to the current lung allocation method, emphysema had an improved waitlist survival than other diseases [110]. Thabut et al. have created a statistical model that estimates that, of 8182 people on the lung transplant waitlist, 50.1% of those undergoing SLT and 63.7% of those undergoing BLT would have a survival benefit. This model has not yet been validated [111]. The analysis by Charman et al. also supports a survival benefit for transplantation in COPD [112].

Prognostication

Recent large population studies have demonstrated that progression of COPD is heterogeneous. An observational study of 2163 patients with COPD showed a highly variable decline in FEV_1 over 3 years, with 38% having a decline in FEV_1 of >40 mL/year; 31% a decline of 21–40 mL/year, 23% a range from −20 to +20 mL/year, and in 8% an increase of >20 mL/year. Patients with very severe COPD declined less than those with less severe disease [113]. Many characteristics have been found to be markers for mortality in COPD, including FEV_1, lung hyperinflation, weight loss with low BMI, anemia, exercise capacity, dyspnea, health-related quality of life and activity level, use of oxygen supplementation, distribution of emphysema, and exacerbations [114–117].

FEV_1

Dating back to earliest attempts to prognosticate, survival in COPD has been tracked by FEV_1, with Burrows et al. noting an overall 58% mortality for a group of 200 patients followed over 7 years. Patients with a FEV_1 of <0.75 L had substantially worse survival than those with a FEV_1 of 0.75–1.24 L, with the best survival for those with a FEV_1 of >1.24 L. It was also noted that FEV_1 dropped by a mean of 56 mL/year, but was highly variable [118].

A post-bronchodilator FEV_1 association with mortality was confirmed in observational studies of non-hypoxic patients with COPD followed for 3 years [119].

Exacerbations

Mortality following hospitalization for acute exacerbations of COPD has long been noted to be high, with 1-year mortality reported in various studies of 22–59%, and highest among those with a $PaCO_2$ of ≥50 mmHg (49%) [120] or admitted to an intensive care unit (59%) [120–123]. The link between repeated exacerbations requiring hospitalization and mortality was established by a prospective analysis of 304 patients with COPD followed over 5 years. Patients with three or more exacerbations per year had a hazard ratio for death of 4.13, and for one to two exacerbations a hazard ratio of 2.0 compared with patients with no exacerbations, a risk that was independent of lung function or age [115]. More recently, large population-based studies have confirmed that each exacerbation confers an increased risk of death regardless of other exacerbations and of baseline lung function [124].

Table 31.3. Variables and point values used for the computation of the Body Mass Index, Degree of Airflow Obstruction and Dyspnea, and Exercise Capacity (BODE) index

Variable	Points on BODE index			
	0	1	2	3
FEV_1 (% predicted)	≥65	50–64	36–49	≤35
Distance walked in 6 min (m)	≥350	250–349	150–249	≤149
Modified Medical Research Council dyspnea scale	0–1	2	3	4
Body mass index	>21	≤21

Pulmonary hypertension

Elevated pulmonary artery diastolic pressure has been associated with death on the lung transplant waitlist for patients with emphysema [125]

BODE index

Celli et al. in 2004 released a landmark prognostication score for COPD known as the BODE index, referring to BMI (B), degree of airflow obstruction (O), dyspnea (D), and exercise capacity (E) measured by the 6-min walk test (6MWT). Patients with higher BODE scores (Table 31.3) were at higher risk of death, with improved concordance compared with FEV_1 [126].

Extrapolation to a transplant population is limited as the score was validated in predominantly elderly patients as well as an almost entirely male cohort [126]. However, Lahzami et al. found that a BODE score of ≥7 may predict those patients expected to have a mortality benefit from transplant [127]. Further studies have supported the usefulness of the BODE index for prognosis, both as a single measurement and when tracking longitudinal change. Martinez et al., in a review of 609 patients with severe emphysema (FEV_1 ≤45%, residual volume ≥150%) enrolled in the National Emphysema Treatment Trial, found that increased mortality was independently associated with a higher modified BODE score [117]. An analysis of the same patient population found that changes in the modified BODE score at 6, 12, and 24 months were predictive of future mortality [128]. A recent large study prospectively followed both BODE score and FEV_1 over at least three measurements for 751 patients in the US and Spain from 1997 to 2008. The group with an increasing BODE score but stable FEV_1 (n = 69) demonstrated higher mortality [129].

A modification of the BODE score using cardiopulmonary exercise testing (CPET) with VO_{2max} [130] did not improve prognostication, and one replacing 6MWT with severe exacerbations performed equally well and may simplify scoring [131]. Of particular note is that the use of BODE, or any index, is not now part of the lung allocation score (LAS) used for priority rating, although it is recommended as a transplant referral criterion.

Other composite indices have been developed, including the HADO score (Health status, Physical Activity, Dyspnea scale, and Obstruction) [132] and a classification and regression tree (CART) analysis utilizing age, FEV_1, dyspnea, physical activity, general health, and number of hospital admissions in the previous 2 years [133]. These have not supplanted the BODE index to date and have not been routinely adopted in the transplant evaluation.

Lung volume reduction surgery

Lung volume reduction surgery (LVRS) should be considered as an alternative or a bridge to lung transplantation in eligible patients.

LVRS has been used to improve hyperinflation in patients with heterogeneous emphysema and has been demonstrated to improve physiologic parameters of obstruction, air trapping, oxygenation, and exercise tolerance [134]. In a randomized controlled trial, LVRS improved mortality in patients with upper lobe predominant disease and low exercise ability [135]. Surgically treated patients showed improvements in a modified BODE score associated with improved mortality [128]. Successful LVRS has been shown to extend time before lung transplant is needed without significantly impacting post-transplant morbidity and mortality [136–140], although patients with unsuccessful LVRS represented a group at increased risk for transplant [139,140]. In one series, 24 of 31 patients could be deactivated from the transplant list after LVRS [136]. Patients with a FEV_1 of <20% as well as a diffusion capacity for carbon monoxide (DLCO) of <20% or homogenous emphysema are at high risk of death from LVRS [141] and are not eligible for this procedure.

Procedure choice

While both SLT and BLT are performed for COPD, BLTs are gaining favor. A review of the ISHLT/UNOS registry from 1991 to 1997 looked at 2260 lung transplant recipients (1835 SLT, 425 BLT) with COPD and concluded that there was a survival benefit below the age of 60 years for BLT; above the age of 60 years, mortality favored SLT [40]. The Washington University group in 2002 published its experience with 306 patients from 1998 to 2000 transplanted for emphysema and found a significant 5-year survival benefit for BLT in both COPD and α-1 antitrypsin deficiency (AATD) patients. Five-year survival overall was unchanged between COPD and AATD, and was no different from other diagnoses, and even early hospital survival was unchanged between COPD and AATD [142].

Guidelines for transplant

Based on the above information, the ISHLT recommends referral for patients with a BODE index of >5, and transplantation for those with a BODE index of 7–10, or at least one of the following: history of hospitalization for acute exacerbation associated with acute hypercapnia, pulmonary hypertension and/or cor pulmonale, FEV_1 of <20% or a DLCO of <20% or homogenous emphysema [3].

Alpha-1 antitrypsin deficiency

Emphysema related to AATD, a genetic disorder with an autosomal co-dominant inheritance, is the fourth most common indication for lung transplants and accounted for 7% of the transplants in the most recent ISHLT registry [18]. It is an under-recognized contributor to obstructive lung disease [143] that causes accelerated lung disease in young persons [144], particularly those exposed to smoking [145]. The most common severe deficiency, with clinical manifestations that include emphysema and/or end-stage liver disease, is in patients homozygous for the ZZ allele [143]. US [146] and Danish registries [147] have confirmed that mortality in patients with AATD is frequently related to emphysema, in both smokers [148] and never smokers [149]. Transplant criteria used to select patients are the same as those for non-AATD emphysema, with prognostic data supporting the use of FEV_1 as part of the selection criteria. Mortality rates in AATD are significantly related to FEV_1, with highest mortality in those with a FEV_1 in the lowest tercile (<35–37.5% predicted) [145,150,151]. Additionally, DLCO and CT scan score have been shown to be associated with respiratory death [150,151]. Augmentation therapy with enzyme replacement should be considered in all patients as it may slow progression of FEV_1 decline and improves overall mortality [145].

Diffuse parenchymal lung disease

Diffuse parenchymal lung disease is a frequent indication for transplantation. Idiopathic pulmonary fibrosis (IPF) is now the second most common indication for transplant, representing an increasing proportion of lung transplants performed. Among the other diffuse parenchymal lung diseases, transplants are also performed for lymphangioleiomyomatosis, sarcoidosis, and at times for collagen vascular disease associated interstitial lung diseases (ILDs) [2,18].

Idiopathic pulmonary fibrosis and fibrotic non-specific interstitial pneumonia

Prognosis

The American Thoracic Society released an updated classification of the idiopathic interstitial pneumonias based primarily on histopathology [152]. IPF, with its pathological pattern of usual interstitial pneumonia (UIP), has a uniquely poor prognosis when compared to other histopathologic patterns, and thus it is crucial to diagnose it appropriately when considering a patient for transplant. In comparison with patients with desquamative interstitial pneumonia (DIP) and respiratory bronchiolitis interstitial lung disease (RBILD) with an 80% 5-year survival, and fibrotic nonspecific interstitial pneumonia (NSIP) with a 70% survival, patients with UIP in one series were found to have a 20% 5-year survival [153]. Similarly, a prospective analysis of 315 patients with diffuse parenchymal lung disease demonstrated substantially worse survival for IPF (2 year of 48.4%, 5 year of 35.4%) compared with the other diseases (2 year 74.9–100%, 5 year 69.5–91.6%) [154]. Survival benefit for patients with IPF who are transplanted has been established in several evaluations [112,155,156].

The timing of listing and transplant must be informed by the patient's prognosis, with the goal to identify those patients with high short-term mortality for immediate listing and to hold off on transplantation for those who may be predicted to have a more indolent course. This assessment has been made more challenging by the at times rapid and unpredictable decline of patients with IPF [157]. Among patients with mild to moderate disease followed in an observational study, death was often described as acute or abrupt or subacute with a sharp increase in dyspnea or A–a gradient shortly before death [158]. Median survival was previously thought to be 2–3 year;, however, there is increasing recognition that the clinical course is variable and may include some patients with much longer survival [157]. Recent registry data indicate a survival median of 55.6 months for those with mild disease, with a median of 27.4 months for those with severe disease by forced vital capacity (*FVC*) [156]. The 2006 ISHLT guidelines for the referral of patients with ILD include histologic or radiographic evidence of UIP irrespective of vital capacity, or histologic evidence of fibrotic NSIP [3]. Patients with a histologic diagnosis of both UIP and NSIP (discordant biopsies) have been shown to have similarly poor prognosis to those with UIP alone and may be considered for transplant with the same category [159].

Prognosis

Pulmonary function

Different parameters of pulmonary function have been associated with survival. Assessment of vital capacity at baseline has been associated with mortality, although the value at which increased

risk is conferred has varied between studies: ≤60% predicted [160], and with cut-offs ranging from *FVC* of 60% to 83% [161]. More recently, Nathan et al. noted that patients divided by *FVC* (mild ≥70%, moderate 55–69%, severe <55%) had correspondingly worse median survival of 55.6, 38.7, and 27.4 months, respectively [156]. Latsi et al. found that patients with high short-term (2 year) mortality had lower baseline *FVC* (62.0% vs. 78.7%) [162].

Longitudinal change in *FVC* has been noted to be associated with increased mortality in multiple studies [163–167], and even marginal changes in *FVC* (5–10%) over 6 months conferred higher mortality than in those with stable disease [164].

DLCO

DLCO has been correlated with survival, though like *FVC*, the value of importance differs in different studies, with ranges from 30% to 45%, and with other studies noting a continuous increase in mortality with decreasing DLCO below 50% predicted, and the worst outcome in those with a DLCO of <20% predicted [156,161,162,168,169]. In a group of 487 patients with IPF seen at the Mayo Clinic, decreased DLCO was associated with a relative risk of 1.4 for every 10 percentage point decrease [166]; Mogulkoc et al. also found that DLCO was significantly associated with survival on multivariate analysis with a hazard of death increasing by 4% for every 1% decrease in DLCO [169]. In longitudinal analysis, a decline in DLCO of >20% at 1 year was found to be significantly associated with mortality [167], though lower levels of change in DLCO were not significant in some analysis [164,170].

Alveolar–arterial oxygen gradient (A–a gradient)

Decline in A–a gradient has had mixed results, with some suggesting mortality association [165] and others finding none [170].

Pulmonary hypertension

Pulmonary hypertension has been associated with worsening outcomes in IPF [160,168,171] and combined pulmonary fibrosis and emphysema [172], with 5-year survival declining as mean pulmonary artery pressure (PAP) rose above 17 mmHg.

Exercise tolerance

Performance and longitudinal change on 6MWT provides useful prognostic information. In a population of 822 patients followed longitudinally, the risk of death was over four times greater for patients whose 6MWT distance decreased by more than 50 m, and was three times greater for patients whose walk distance declined by 26–50 m [173]. A similar value of 29–34 m was found in a previous analysis [174]. In an Israeli population awaiting lung transplant, distance on 6MWT has been inversely associated with risk of death while listed for transplant [175].

Likewise, abnormal heart rate recovery 1 and 2 min after 6MWT, desaturation, and lowest saturation on climbing or on 6MWT have also been associated with poorer prognosis and may be associated with pulmonary hypertension [176–178].

Radiology

High-resolution computed tomography (HRCT) characteristics have been reproducibly found to be predictive of mortality [169,179,180]. The extent of fibrosis was associated with increased risk of death, and patients with more fibrosis were also more likely to have a low DLCO and *FVC*, and an increased A–a gradient [180]. The risk of death increased by 106% for every unit increase in HRCT fibrosis score [169].

Mechanical ventilation

The mortality for patients with IPF who require mechanical ventilation for acute respiratory failure is exceedingly high. Traditionally, patients requiring mechanical ventilation have been excluded from consideration for transplant [161]. In one retrospective review of 34 patients with IPF presenting with respiratory failure, 15 were placed on invasive mechanical ventilation with 100% inhouse mortality; there was a 74% mortality for the 19 patients placed on non-invasive ventilation. Of the five surviving patients, four died within 6 months of discharge [181].

Guidelines for transplantation

Based on much of the above information, the 2006 ISHLT guidelines suggest referral for any patients with UIP or fibrotic NSIP, and transplantation for histologic or radiographic UIP with a DLCO of <39% predicted, ≥10% decrease in *FVC* over 6 months, desaturation <88% during 6MWT, or honeycombing on HRCT scan. Patients with NSIP are recommended for transplant if they have a DLCO of <35%, or a ≥10% decrease in *FVC* or a >15% decrease in DLCO over 6 months [3].

Given the variation in cut-offs for prognosis, an exact physiologic parameter may be controversial; for example, Flaherty et al. suggested listing patients with a *FVC* or a total lung capacity (*TLC*) of ≤65% predicted and a DLCO of ≤45% predicted [161]. Subjective variables such as progression in dyspnea scores and cough have been associated with mortality, but have not been incorporated into transplant guidelines [165,177,182]. Thus, a full assessment of a patient's clinical course and co-morbidities must be taken into account when making the decision to list.

Single versus bilateral lung transplant

Several analyses have found a survival benefit favoring BLT over SLT despite the initial challenge of a longer and more difficult surgery. A review of the UNOS database from 1987 to 2008 found a 1-year conditional survival benefit for BLT over SLT in younger patients [183]. UNOS data from 2005 to 2007 also demonstrated better 1-year survival for BLT in patients with the highest risk as measured by the highest lung allocation score (see Chapter 40) [184]. In another evaluation of IPF patients, post-transplant 6MWT and best FEV_1 were better for BLT recipients, as well as their having better 1-year, overall, and bronchiolitis obliterans syndrome-free survival compared to SLT; this benefit held despite significantly higher preoperative mean PAP for BLT recipients [185]. Other evaluations have shown an overall worse 30-day and 1-year survival for IPF patients compared to patients with other diagnoses, and no difference between SLT and BLT [41,186].

Other diffuse parenchymal diseases

Connective tissue disease with associated lung disease

Transplantation for pulmonary fibrosis associated with connective tissue disease represents only 0.8% of transplants [18], at least in part due to concerns over systemic disease complicating transplant as well as a better prognosis in comparison to IPF [187]. Diffuse lung disease has been associated with multiple connective tissue diseases, including systemic sclerosis, polymyositis/dermatomyositis, rheumatoid arthritis, mixed connective tissue disease, systemic lupus erythematosus, and Sjögren's syndrome [161]. Given limited experience, there are no specific recommendations for timing of referral or transplant.

Systemic sclerosis

Pulmonary disease is ubiquitous in patients with systemic sclerosis, but is progressive in a minority of patients [188]. Patients have been transplanted with success [189–192], with one center reporting 14 patients transplanted successfully with 1-year survival no different from that for IPF patients, albeit with more acute rejection seen [189]. The systemic disease associated with scleroderma can contraindicate transplant, including skin ulceration, chronic kidney disease, and esophageal dysmotility with aspiration [193]. Patients to be considered for transplant for scleroderma should have minimal systemic disease and progressive lung disease.

Idiopathic inflammatory myopathies

Polymyositis, dermatomyositis, clinically amyopathic dermatomyositis, and antisynthetase syndrome are associated with ILD in 35–40% of patients, with some experiencing progressive respiratory decline [194]. The associated muscle weakness may be a contraindication to transplant [161] as it would preclude rehabilitation and pulmonary clearance. Transplant may be considered in a patient with progressive lung disease as measured by serial pulmonary function tests (PFTs) and quiescent systemic disease.

Rheumatoid arthritis, mixed connective tissue disease, systemic lupus erythematosus, and Sjögren's disease

ILD is seen with varying frequency in rheumatoid arthritis, with debilitating pulmonary disease demonstrated in 1–4% of patients; severe inflammatory arthritis remains the most important contraindication to transplant in this group [161]. A UIP pattern on HRCT and on biopsy is seen more frequently in rheumatoid arthritis compared with other connective tissue disease-associated ILD, and correspondingly appears to be associated with a worse prognosis [195]. Pleural disease is common in systemic lupus erythematosus, but progression of overt fibrotic lung disease appears rare and the disease most likely progresses slowly; in a small series of 14 patients with interstitial disease and lupus only two died of progressive lung disease [196,197]. In one sequential series of 144 patients with mixed connective tissue disease (MTCD), 96 (66.6%) had evidence of active ILD, the majority of which resolved after therapy, although 13 patients remained with some fibrosis on HRCT and one with honeycombing [198]. In patients with MCTD, there is an association between esophageal dilatation and ILD [199], raising concern that this could be an additional contraindication to transplant. Finally, ILD complicates the course of Sjögren's disease for many patients, in one series affecting nine of 20 patients followed [200].

The approach to transplantation is similar to that of the other connective tissue diseases, in that patients with progressive pulmonary disease and minimal systemic disease should be referred to a transplant center.

Sarcoidosis

A multisystem disease, sarcoidosis may lead to significant other organ dysfunction (e.g. heart, liver) that can preclude transplantation. Sarcoidosis currently accounts for 2.6% of lung transplants performed [18]. Those patients with advanced pulmonary sarcoidosis have been shown to have a high mortality on a lung transplant list; of 43 patients with sarcoidosis listed for lung transplant at the University of Pennsylvania Medical Center, 23 (53%) died while listed. Listed patients had a 31% survival at 3 years, while the 12 transplanted patients had a 50% survival at 3 years [201]. The waitlist survival has been shown to be similar to that for IPF, although the patients with sarcoidosis had a higher burden of pulmonary hypertension [202].

Prognosis

Pulmonary hypertension has emerged as the most important risk factor for mortality in sarcoidosis [203]. In multivariate analysis, a right atrial pressure (RAP) of $\geq$15 mmHg was independently associated with increased risk of death [201]. In a review of 405 patients listed for transplant for sarcoidosis in the US between 1995 and 2000, risk of death was associated with increased pulmonary artery pressure, increased need for supplemental oxygen, and African–American race [204].

Guidelines for transplantation

Given these findings, the 2006 ISHLT guidelines have recommended referral for patients with NYHA functional class III or IV, and transplant for patients with NYHA functional class III or IV along with hypoxemia at rest, pulmonary hypertension, or RAP $>$15 mmHg [3].

Lymphangioleiomyomatosis

Lymphangioleiomyomatosis (LAM), which is the indication for 1.1% of the transplants in the most current ISHLT report [18], is a rare disease that had been considered to occur only in women of child-bearing age and to be nearly uniformly fatal within 10 years when it was first described [205,206]. With increased awareness, detection, and the creation of rare disease registries [207], the full spectrum of the disease is now understood to include older women and some who have a slow and indolent course with 10-year survival reported as high as 91% [208–211]. In a LAM registry that enrolled patients from 1998 until 2001, one-third of patients either received or were listed for lung transplant for LAM [212].

Transplant concerns

Although survival post transplant has been comparable to other conditions, disease-specific complications after transplant have included recurrent pneumothorax and chylothorax requiring intervention, and surgery may be complicated by previous pleural procedures leading to increased bleeding [104,213–215]. Transplantation for LAM has also rarely been complicated by recurrence of disease [214–216]. These risks must be adequately conveyed to a patient during the process of transplant evaluation.

Prognosis

Decreased maximum oxygen consumption corresponded to disease severity by FEV_1 and DLCO, and the patients undergoing transplant in one study had an average VO_{2max} of 41.7% predicted [217]. Disease progression has typically been defined by a decrease in FEV_1 and/or DLCO, both of which have been correlated with CT scan extent of disease and histology score [218,219].

Guidelines for transplantation

Decline of FEV_1 and DLCO are highly variable, with yearly decline in FEV_1 anywhere from none to 285 mL/year in rapidly progressive disease [218], with one study showing an average loss of 110 mL/year of FEV_1 [208]. Only one treatment, sirolimus, has proven to have some efficacy in slowing decline of lung function [220]; its effect on progression to lung transplant for LAM remains to be seen.

Serial assessment of lung function and functional capacity remains the best way to determine those patients heading for

decline who may require transplant. The 2006 ISHLT guidelines recommended referral for NYHA functional class III or IV, and transplantation for severe impairment in lung function and exercise capacity or hypoxemia at rest [3]. If serial lung function measurements demonstrate rapid decline despite therapy, earlier referral should be considered.

Pulmonary Langerhans cell histiocytosis (eosinophilic granuloma)

Transplantation

Pulmonary Langerhans cell histiocytosis (PLCH) is a rare diagnosis for lung transplant, reflecting that the disease for many patients may stabilize or regress [221].

A retrospective review of 39 patients transplanted throughout France for PLCH demonstrated survival of 76.9% at 1 year, 63.6% at 2 years, 57.2% at 5 years, and 53.7% at 10 years [222]. Median survival in two retrospective studies has been similar at 12.5 and 13 years [223,224]. Advanced disease is very commonly associated with severe pulmonary hypertension unrelated to the degree of pulmonary function impairment, with the disease directly causing a pulmonary vasculopathy [221,222,225–227]. Pulmonary hypertension is nearly ubiquitous among those transplanted [222].

Timing for transplantation

As in LAM, serial assessment of lung function and functional capacity is required as there are no precise prognostic tools for this rare disease. Attention to the severity and progression of pulmonary hypertension should be considered when listing. The 2006 ISHLT guidelines recommended referral for NYHA functional class III or IV, and transplantation for severe impairment in lung function and exercise capacity or hypoxemia at rest [3].

Cystic fibrosis and other causes of bronchiectasis

Cystic fibrosis (CF) is a major indication for lung transplant, accounting for 16% of transplants between 1995 and 2010 [2]. CF is a multisystem disease affecting younger patients than the typical transplant diagnoses. Survival benefit for patients undergoing transplant for CF has been consistently demonstrated [110,112,228,229], and in some analyses has been the best among transplant diagnoses [228,229].

Bronchiectasis not associated with CF may have a variety of causes, among them congenital, related to autoimmune disease or malignancy, related to previous infection, and related to immune deficiency [230]. These disorders have been treated similarly to CF with regard to lung transplant [3].

Guidelines for transplantation

The 2006 ISHLT guidelines suggested that patients be referred if they demonstrate a FEV_1 of <30% or a rapid decline in FEV_1, particularly in young female patients; exacerbation requiring ICU stay, increasing frequency of exacerbations requiring antibiotics, refractory or recurrent pneumothorax, or recurrent hemoptysis not controlled by embolization [3]. Transplantation was recommended for oxygen-dependent respiratory failure, hypercapnia, or pulmonary hypertension [3].

Prognosis

Prognosis in CF has improved steadily over the years; according to the Cystic Fibrosis Foundation Registry annual data report for 2010, median survival has improved from age 27 years in 1986 to age 38.3 years in 2010. Respiratory failure remains the most common cause of death for patients with CF [231]. Among the factors associated with survival, FEV_1, gender, age, pulmonary hemodynamics, supplemental oxygen requirement, hypercapnia, and frequency of exacerbations were incorporated into the ISHLT guidelines in 2006 [3]; other factors that may impart increased mortality include diabetes, 6MWT, and nutritional status [232–235].

FEV_1

The traditional transplant referral basis of a FEV_1 of 30% predicted came from an early study by Kerem et al. in 1992. In a retrospective study of 673 patients between 1977 and 1989, patients having an FEV_1 of <30% predicted, $Pao2$ of <55 mmHg, and Pco of >50 mmHg had a 2-year mortality rate of over 50% [236]. This mortality rate implied an appropriate time for transplant to confer survival benefit. Worsening FEV_1 has also been associated with death while listed for transplant; in one series, patients who died awaiting transplant had a significantly lower FEV_1 (15% predicted) compared to those who were successfully transplanted (21% predicted), as well as a lower 6MWT distance [237]. FEV_1% predicted has been included in several predictive models for survival for CF [233,238,239].

As CF survival has improved, more recent studies have suggested that FEV_1 cut-off of 30% is insufficient as an absolute cut-off for transplant. Augarten et al. evaluated 40 patients with a FEV_1 of <30% predicted, and found that there was a trend for patients who were not transplanted to have improved survival [240].

The mortality rate of 50% at 2 years described by Kerem et al. has not been reproduced in follow-up evaluation of patients with severely decreased lung function, suggesting that evolution in CF treatment has impacted survival. One retrospective review was performed of 61 patients with a consistent FEV_1 of <30% at the University of Minnesota. Of 49 deceased patients with a FEV_1 of <30% predicted, only one-third had reached that level within 2 years of death. The remainder lived with this severe reduction in FEV_1 from a range of 2 to 14 years. Survival analysis indicated that the median life span for patients with a FEV_1 of <30% predicted was 3.9 years [241]. Another series found that 178 patients with a FEV_1 of <30% predicted had a median survival of 4.6 years, with 25% living >9 years in the pretransplant era (1986–1990) [242]. George et al. followed 276 patients with a FEV_1 of <30% predicted identified between 1990 and 2003 and followed until 2007 at one center in the UK, finding that median survival improved from 1.2 years in 1990 to 5.3 years in 2003. The largest gain happened between 1994 and 1997, co-incident with the availability of DNAse in the UK as well as improved nutritional status for the cohort [243].

Rate of decline of FEV_1 also has been indicated to be a useful parameter to predict mortality and timing for transplant [244]. For patients who survived for less than the median, the rate of FEV_1 decline was higher (1.8% predicted per year) compared to patients who survived for longer than the median (0.73% predicted per year), with the rate of decline in FEV_1 was a significant predictor of death. There was an increase in the relative risk of death of 1.3 for every 1% predicted per year increase in the rate of decline[241]. Augarten et al. also found that rate of decline of FEV_1 contributed independently to mortality [240].

Gender

Female gender has been associated with increased risk of death in many studies [231,233,236,245–248], though a handful have also

evaluated for gender and not found an effect [240,241,249]. The mechanism of a gender disparity is unclear.

Age

Younger age has been implicated in increased mortality. Age younger than 18 years has been associated with shorter survival [235,236,241]; in the review by Kerem et al., younger patients (<18 years) had a relative risk of death of 2.0 [236].

Exacerbation frequency

Acute exacerbations are associated with worse outcome. Number of admissions has been correlated with mortality [248,250] and more severe admissions requiring intensive care are associated with worse outcomes [235,251].

Pulmonary hemodynamics

Pulmonary hypertension is associated with death and thus has been incorporated into transplant referral criteria. Patients dying while awaiting transplant were more likely to have severe pulmonary hypertension, with patients dying on the list having worse mean pulmonary artery pressure, P_{aCO_2}, and systemic vascular resistance compared with patients either receiving transplant or alive and waiting [252]. The severity of pulmonary hypertension was also associated with death in a small series of 27 patients [248], and another review of 146 patients listed for lung transplant for CF at Barnes Jewish Hospital showed that higher pulmonary artery pressure was an independent risk factor for death while awaiting transplant [232].

Predictive model

One predictive model for 5-year survivorship was proposed in 2001 and was created and validated using data for patients in the Cystic Fibrosis Foundation Patient Registry. The model included age, FEV_1, gender, weight-for-age z score, pancreatic sufficiency, diabetes, *Staphylococcus aureus* infection, *Burkholderia* cepacia infection, and annual number of acute pulmonary exacerbations [233]. The same researchers found that using their model to identify patients with a <30% 5-year survival resulted in transplant survival benefit for that group, while using only the criterion of FEV_1 <30% predicted resulted in equivocal survival benefit. Groups with higher expected survival by predictive model had either equivocal or negative survival effect from transplant [253]. Despite these findings, the predictive model has not been formally incorporated into transplant referral.

Infection risk

Airway microbial colonization and infection are a chronic problem for patients with CF. For this reason, virtually all lung transplants performed for cystic fibrosis are bilateral.

The microbial milieu for an individual patient has been evaluated for both mortality and risk for transplant. The presence of *B. cepacia* infection has been associated with an odds ratio for death of 4.12 in the predictive model of Liou et al. [233]. Likewise, *Burkholdaria cepacia* infection has been associated with an increased risk of infectious death after transplantation [254,255] and at many centers is considered a contraindication to transplant. Recent analysis has agreed that the increased risk seems to be particular to *B. cenocepacia* [255–257], which in one series of 75 transplant patients at Duke was associated with substantially reduced survival compared with both those infected with other *B. cepacia* and those not so infected [256].

Other microbial colonization aside from *Burkholderia* has not demonstrated a significant impact. Liou et al. reported a survival benefit to *S. aureus* colonization in their predictive model [233]. Patients with pan-resistant bacterial infection aside from *B. cepacia* were found to have decreased survival at one center compared with patients not so infected, though their survival compared favorably to UNOS data. Microbial colonization in that cohort was mostly with resistant *Pseudomonas aeruginosa*, *Stenotrophomonas*, and *Achromobacter* [258].

Liver disease

Significant liver disease, in many patients evolving to cirrhosis, is common in CF; cumulative incidence of hepatic involvement is thought to be 27–35%, most frequently focal biliary cirrhosis which in a subset of patients progresses to multilobular cirrhosis and complications of end-stage liver disease [259]. Liver disease has been seen to be an independent risk factor for death or lung transplantation [260]. Successful lung transplant has been performed in patients with well-compensated cystic fibrosis liver disease who had preserved hepatic synthetic function with no adverse effect on outcomes [261,262]. Those with advanced liver and lung disease may be considered for a combined lung–liver transplant.

Critical illness and mechanical ventilation

Some small series have reported success in transplant of patients with CF who require mechanical ventilation [78–80]. Transplant should be limited to those patients who remain with single organ failure, no systemic infection, and able to participate in physical therapy [263].

Pulmonary arterial hypertension

Pulmonary hypertension, a disorder of many different etiologies [264], has long been an indication for lung transplantation. Idiopathic pulmonary arterial hypertension has represented a decreasing share of the total number of transplants performed, now representing 3.1% of the total transplants since 1995 [1]. Patients with idiopathic pulmonary arterial hypertension (IPAH) demonstrate high short-term mortality, but good long-term survival compared with other transplant patients, second only to those with CF [1,2]. The decreasing percentage of transplants for IPAH has been influenced by modern therapy leading to improved prognosis.

Prognosis

Prior to the current age of therapy, prognosis was grim for patients with pulmonary arterial hypertension; the survival for a group of 57 patients with pulmonary hypertension who did not receive transplants was reported at 35% at 3 years [265]. Median survival was estimated at 2.8 years from the NIH registry, and was negatively impacted by mean PAP ($\geq$85 mmHg vs. $\leq$55 mmHg), mean RAP (<10 mmHg vs. $\geq$20 mmHg), and mean cardiac index (<2 L/min/m^2 vs. $\geq$4 L/min/m^2) [266]. Subsequent evaluations have confirmed that right heart failure and RAP of $\geq$12 mmHg were associated with poor survival at baseline [267].

The substantial mortality benefit obtained from long-term prostacyclin infusion [266,268,269] has resulted in decreased referrals for transplant. A lack of response to therapy is predictive of mortality and influences transplant referral. Patients presenting with NYHA functional class IV have been shown to have worse survival compared with patients in NYHA class III, and patients who did

not have improvement in functional class or a 30% fall in pulmonary resistance had significantly increased mortality [267].

6MWT has been independently related to mortality, with survival decreased in patients able to walk less than 332 m in 6 min [270]. Patients enrolled in the randomized controlled trial of epoprostonol who died had significantly lower 6-min walk distances as well [268].

Referral

Based on the above prognostic data, the ISHLT recommended referral for NYHA functional class III or IV or rapidly progressive disease, and transplantation for persistent NYHA class III or IV despite therapy, <350 m or declining 6MWT, failing therapy with prostacyclin, cardiac index of <2 L/min/m^2, or RAP >15 mmHg [3].

Despite the effectiveness of medical therapy, survival for progressive disease remains better with lung transplantation for patients with severe disease [271], although waitlist mortality has not been improved by the recently implemented lung allocation score (discussed in Chapter 40) [272]. Serial assessment remains important to identify those patients with a declining course who will require surgical therapy [273].

Summary

Lung transplantation remains a complex procedure that is reserved for individuals likely to derive sustained benefit from its successful conduct. Although many causes of end-stage lung disease are appropriate for referral—most commonly, COPD, IPF, and cystic fibrosis—a thorough assessment of the patient's co-morbidities, anatomical considerations, and social situations is required to make an appropriate referral. A partnership between the referring physician and the transplant service, aiming to optimize the patient's condition and suitability for transplant, is required to achieve the best outcomes.

CHAPTER 32

Patient Selection and Indications for Pancreas and Islet Transplantation

Alexandra Turner[1] and Nicole A. Turgeon[2]

[1] Emory Transplant Center, Department of Surgery, Emory University School of Medicine, Atlanta, GA
[2] Emory University Hospital, Atlanta, GA, USA

Introduction

Type 1 diabetes mellitus (T1DM) is a disease characterized by the inability to regulate blood glucose as a result of autoimmune destruction of the β cells of the pancreas. The β cells comprise approximately 1–2% of the pancreas. T1DM affects over 1 million people in the US and is a multisystem disease that may result in nephropathy, neuropathy, gastropathy, cardiovascular disease, peripheral vascular disease, and retinopathy [1,2]. In the past, one in five people with TIDM died and one in four developed end-stage renal disease (ESRD) within 20 years of diagnosis. Prognosis improved with the era of intensive insulin therapy, originally described in the landmark publication of The Diabetes Control and Complications Trial in 1993 [3]. Today the long-term survival with T1DM has improved dramatically, and the rate of development of ESRD has leveled off. Intensive glucose management delays the onset and progression of diabetic nephropathy, retinopathy, and neuropathy compared to conventional therapy [3]. Longitudinal studies have shown a marked improvement in serious diabetic complications among patients receiving intensive insulin therapy compared to conventional therapy: the incidence of nephropathy is reported as 9% compared to 25% for conventionally treated cohorts, retinopathy incidence has improved to 21% from 47% in the conventional group, and the incidence of ESRD has improved to 1% from 2% [4,5]. However, intensive insulin therapy also results in more frequent hypoglycemic events, up to three times that experienced on conventional therapy [3]. Although intensive insulin therapy has its merits, it has not completely eliminated the secondary complications of diabetes. In addition, patients are required to perform frequent daily blood glucose measurements and insulin injections, and follow a meticulous diet, all of which may contribute to a negative impact on quality of life and significant healthcare costs.

Solid organ pancreas transplantation is a surgical option for the treatment of T1DM. The most immediate benefit to patients undergoing pancreas transplantation is improved quality of life as a result of less intensive blood glucose management [6,7]. Simultaneous pancreas–kidney transplantation (SPK) is currently the "gold standard" for patients with T1DM and ESRD, resulting in normalization of hemoglobin A1c (HbA1c) and elimination of hypoglycemic unawareness. SPK is the most commonly performed solid organ pancreas transplant, accounting for 65% of pancreas transplants performed in the US in 2007, and is the most durable with current median graft survival of 12–16 years.

Pancreas after kidney (PAK) transplant is another option for patients with T1DM who have already received either a deceased or living donor kidney transplant. Pancreas transplant alone (PTA) and islet cell transplantation are options for patients who have failed medical management with symptoms of hypoglycemic unawareness and labile blood glucose management with preserved renal function. Transplantation of the islets of Langerhans is a minimally invasive technique that eliminates transplantation of the exocrine portion of the gland. Islet transplantation is also associated with fewer periprocedural complications than whole organ pancreas transplant [8]. This chapter will cover the general factors involved in selecting patients who are likely to benefit from pancreas or pancreatic islet transplantation and distinguishing them from those most likely to benefit from medical management of their disease. It also will cover factors influencing the timing of a pancreas transplant relative to a kidney transplant for patients with diabetic nephropathy. It complements Chapter 41, which covers waitlist management of patients awaiting pancreas transplantation.

History

The first pancreas transplant was performed in 1966 at the University of Minnesota as a simultaneous duct-ligated segmental pancreas with a kidney from a deceased donor (Table 32.1). The patient remained insulin-independent for 6 days but experienced multiple complications due to duct ligation [9]. The rationale for pancreas transplantation at the time was to prevent recurrence of diabetic nephropathy in the transplanted kidney. The success of pancreas transplantation has since been associated with advances in surgical technique and management of immunosuppression. Management of the pancreatic duct was the principal surgical challenge in the evolution of pancreas transplantation. The second SPK transplant in 1967 involved drainage of exocrine secretions via a duodenal–cutaneous fistula. This graft functioned for 2 months before failing due to rejection [9]. Subsequent variations included duct obstruction with acrylate glue and neoprene, which led to pancreatitis and exocrine fibrosis [10,11], and duct drainage to the peritoneum, which led to chemical peritonitis [12]. Ductal drainage to

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Table 32.1. Evolution of pancreas transplantation. The principal challenge was management of the pancreatic duct. With improved technique and immunosuppression, enteric duct drainage is the most common technique in use today.

Year	Development	Outcome	Institution
1966	First pancreas transplant Segmental gland duct ligated	Insulin – independent 6 days, failure due to pancreatitis	University of Minnesota
1967	Duct drainage by duodenal-cutaneous fistula	Rejection at 2 months	University of Minnesota
1973	Duct drainage to ureter	Urinary stones, acidosis, dysuria	Albert Einstein/ Montefiore
1977	Duct obstruction by acrylate glue	Pancreatitis, exocrine fibrosis	University of Sydney
1979	Duct drainage to peritoneum	Chemical peritonitis	University of Miami/University of Wisconsin
1983	Duct drainage to bladder	Urinary stones, acidosis, dysuria; easier management of leak and detection of rejection	University of Wisconsin
1996	Duct – enteric drainage (side–side proximal jejunum)	Physiologic, difficult to manage leak	Karolinska Institute, Stockholm

the recipient ureter was described in 1973 [13], which was modified as drainage to the urinary bladder via pancreaticocystostomy [14]. This was later modified to duodenocystostomy [15]. Enteric drainage using a Roux-en-Y limb was described concurrently [16].

Early attempts at whole pancreas transplantation yielded high mortality and complication rates, with rare insulin independence. In 1980 the International Pancreas Transplant Registry (IPTR) reported a 1-year graft survival of 21% with a 1-year mortality of 39% [17]. The 1970s–1990s brought significant advances in surgical technique, organ preservation, and immunosuppression, resulting in dramatic improvement in outcomes. With the advent of cyclosporine and refinement of the duodenocystostomy technique, Sollinger reported an 80% 1-year graft survival in 1983 [18]. The majority of pancreas transplants were performed using this technique for the next decade, as bladder drainage had the advantages of easier management of anastomotic leaks (via a Foley catheter) and easier detection of rejection (via a decline in urinary amylase). However, postoperative urologic complications occurred with an incidence of 15–30%, necessitating the conversion to enteric drainage. Bladder drainage was also associated with dehydration and metabolic acidosis due to the loss of pancreatic exocrine secretions [19]. With improvement in operative technique and the development of more potent immunosuppressive agents such as tacrolimus in the early 1990s, enteric drainage became the most common technique. More than 80% of pancreas transplants reported to the IPTR since 2003 have been performed using enteric drainage [18]. Several studies have shown that graft survival and incidence of technical complications are equivalent between the two techniques [20–24]. Additional discussion of the history of the pancreas transplant procedure can be found in Chapter 60.

Patient selection

The criteria for candidacy and placement on the waitlist vary for each transplant center. For SPK, absence of endogenous insulin production and a documented glomerular filtration rate (GFR) of <40 mL/min/1.73 m^2 are absolute requirements for listing eligibility. Age, insulin requirements, body mass index (BMI), cardiovascular status, peripheral vascular disease, and smoking status are also important considerations. Pancreas transplantation is associated with a 2% higher absolute mortality than kidney transplant alone within the first 90 days postoperatively [25]. This increase in absolute mortality between pancreas transplant and kidney transplant alone is equilibrated after 12–24 months post transplant. Compared to remaining on the waitlist, the relative risk of death is similarly increased within the first 90 days post transplant, and thereafter the risk of death is higher for those remaining on the waitlist. Gruessner et al. compared patient mortality of waitlisted versus transplanted patients as reported to the United Network for Organ Sharing (UNOS)/IPTR database from 1995 to 2003 [26]. Within the first 90 days post transplant, the mortality hazard ratio was 1.95 for SPK and 4.64 for PAK ($P < 0.0001$). After 90 days the mortality hazard ratio was <1. Patients were most likely to die from cardiovascular or cerebrovascular causes with a functioning transplant in the early postoperative period. Mortality was independently associated with a recipient age older than 45 years and pretransplant dialysis.

In summary, in order to derive a benefit from pancreas transplantation, patients must survive the operation, as early postoperative mortality is significantly higher than with kidney transplantation alone. Pancreas recipients are therefore selected on their relative fitness in an attempt to optimize survival benefit.

Simultaneous kidney and pancreas transplantation

SPK is currently the "gold standard" for patients with T1DM and ESRD. The most immediate benefit to patients undergoing pancreas transplantation is improved quality of life: freedom from insulin injections, frequent glucose monitoring, and dialysis [6,7]. Although pancreas transplantation has been shown to attenuate the development of diabetic nephropathy, retinopathy, and cardiovascular disease, it has been unclear whether this translates into a survival benefit for patients compared to kidney transplantation alone [27]. Recent studies have been divided on a survival benefit in SPK recipients, with some showing benefit after 10 years with a functioning kidney transplant compared with a living donor renal transplant alone [28–30] and others showing no survival benefit associated with SPK when compared to recipients of living donor kidney transplants at 10 years [31–34]. Recipients of SPK transplants have significantly improved graft and patient survival compared to recipients of deceased donor kidney transplants. However, Rayhill et al. examined patient survival after SPK, living related and unrelated renal transplant (LRT), and deceased donor renal transplant (DDK) in 600 patients from a single center from 1986 to 1996. The 10-year patient survival was similar for SPK and LRT transplanted patients: 75% and 80% respectively. Recipients of deceased donor transplants had a significantly worse 10-year patient survival of 62% ($P < 0.01$). Additionally, renal allograft survival was similar between SPK and living related donor (LRD) groups at 10 years and significantly higher in these groups compared to recipients of DDK [34]. A registry analysis of 13 000 patients with T1DM enrolled on the pancreas transplant waitlist from 1988 to 1997 confirmed these findings. The adjusted 10-year survival was 67% for SPK recipients, 65% for LRT recipients, and 46% for DDK recipients (P 0.05) [33].

Equivalent survival at 10 years after SPK and living donor renal transplant likely reflects the high quality of organs selected for pancreas transplantation; donors are typically young with a low

BMI (<35 kg/m^2), without cardiovascular disease or hemodynamic instability prior to donation. Minimized organ preservation times for donor pancreata and the simultaneously transplanted kidney may also contribute to the improved long-term survival rates in this population [35–37]. These factors have been shown to correlate with a lower incidence of pancreas graft thrombosis and improved graft survival [36]. SPK recipients are also generally younger and in better health than kidney-only recipients, further confounding comparisons between recipients of SPK, DDK, and LRT. A recent study examined recipient outcomes after SPK and DDK with organs from the same donor to eliminate donor-specific variables between the two groups. There was no difference in adjusted renal allograft and patient survival up to 9 years post transplant [38]. This premise notwithstanding, SPK organ quality may more closely approximate kidney transplantation from a living donor rather than a deceased donor [37,39].

However, there is a survival benefit associated with SPK versus LRT beyond 10 years post transplant. This is attributed to fewer cardiovascular deaths, reflecting the long-term systemic effects of normoglycemia. Morath et al. examined 11 000 patients after SPK, LRT, and DDK reported to the Collaborative Transplant Study (CTS) from 1984 to 2000. All were patients with T1DM under the age of 45 years with ESRD. In those transplanted between 1984 and 1990, 18-year patient survival was significantly improved in recipients of SPK versus LRD with a functioning renal allograft at 10 years post transplant. Patient survival was 74% at 18 years for recipients of SPK, 60% after LRT, and 40% after DDK ($P \leq 0.001$). SPK patients with a functioning pancreas at 10 years post transplant had significantly improved long-term survival when compared to patients without a functioning pancreas (80% vs. 50%; $P < 0.0001$). Superior SPK survival versus LRT was corroborated by Cox regression analysis, which considered pretransplant cardiac risk (hazard ratio 0.55; $P = 0.0005$). Multivariate analysis confirmed that the risk of cardiovascular death was significantly lower in recipients of SPK versus LRT (relative risk 0.56; $P = 0.007$) and DDK (relative risk 0.77; $P = 0.049$). The long-term patient survival after SPK is superior compared to LRT or DDK in patients with a functioning kidney transplant at 10 years post transplant; and in this group, patients with a functioning pancreas had superior survival compared to those without a functioning pancreas. Death was more commonly cardiovascular in patients without pancreas transplant, which may reflect the significant positive cardiovascular impact of long-term normoglycemia [28].

In summary, SPK is the gold standard for the treatment of patients with T1DM and ESRD. The most immediate benefit to patients after SPK compared to those receiving kidney transplant alone is improved quality of life. There is evidence that SPK diminishes the development of diabetic nephropathy, retinopathy, and cardiovascular disease. A survival benefit for recipients of SPK is evident after 10 years with a functioning pancreas and renal allografts when compared to T1DM after living related renal transplants alone. SPK recipients had fewer cardiovascular events than recipients of LRT, reflecting the long-term systemic effects of normoglycemia [28].

Pancreas after kidney transplantation

PAK is considered for patients with T1DM who have already received a living donor or deceased donor kidney transplant for ESRD. Given the high mortality of waitlisted patients for SPK (46% at 4 years) and the proven benefit of kidney transplant for patients with T1DM [40], pursuing kidney transplant prior to pancreas transplant is a viable option for patients in regions with long wait times for SPK or those who have a matched living donor for kidney transplantation.

The role of PAK has historically been controversial. Renal transplantation confers a survival advantage compared to dialysis, and jeopardizing a functioning kidney allograft for a pancreas transplant with an unclear survival benefit may not be advantageous [40,41]. Earlier studies have demonstrated conflicting results; one study showed a long-term survival disadvantage with PAK [compared to kidney transplant alone (KTA)] and another demonstrated a survival advantage evident after 4 years with a functioning pancreas allograft [26,42]. With improved surgical technique and immunosuppression, the recent literature has supported increased or equivalent survival in patients who receive a pancreas after living donor kidney (PALK) versus living donor KTA, and an improved GFR in patients after PALK versus living donor KTA up to 10 years post transplant [43,44].

PAK has been shown to worsen GFR post transplant compared to SPK [45]. As a result, identifying the patient population that will benefit most has been the subject of recent investigation. In particular, the decline in GFR is thought to be a result of the combination of increased immunosuppression and higher doses of nephrotoxic calcineurin inhibitors (CNIs), the impact of surgery on the renal transplant itself, and immunologic factors, such as a new set of alloantigens, which may lead to an increase in rejection episodes [44]. In an analysis of 126 patients 3 years post PAK, risk factors for kidney graft loss included a pre-PAK GFR of <45 mL/min/1.73 m^2, pre-PAK acute rejection episode, pre-PAK proteinuria, and pancreas transplant interval of >1 year after kidney transplant [46]. A larger registry analysis of 2776 patients demonstrated improved overall kidney graft survival in PAK patients when compared to young T1DM kidney transplant patients, after controlling for selection bias. Stratifying PAK kidney allograft survival by GFR, improved 10-year allograft survival was noted with pretransplant GFR of 40–49, 50–59, and 60–69 mL/min/1.73 m^2. Pretransplant GFR of 30–39 mL/min was not associated with a survival advantage over KTA, although the 10-year graft survival for these patients was still 69%. Pancreas allograft failure was a significant risk factor for kidney allograft failure. This study found no relationship between timing of PAK and kidney graft failure [47].

In summary, PAK is associated with improved long-term patient survival and improved kidney allograft survival for recipients with a pretransplant GFR of >40 mL/min/1.73 m^2. Patients with preoperative episodes of kidney rejection, and patients at high immunologic risk or marginal kidney allograft function may not benefit from PAK [44]. Like all forms of pancreas transplantation, patients must be fit enough to benefit from the surgical procedure [48].

SPK versus PAK

Although PAK outcomes have improved, median pancreas graft survival for SPK remains superior. Median graft survival is 12–16 years for SPK and 7 years for PAK [49]. Diminished graft survival in PAK is related to increased rates of immunologic graft loss, presumably due to a separate antigenic stimulus or difficulty in monitoring the pancreas allograft for acute rejection [25]. From 2004 to 2008 the rate of immunologic pancreas graft loss was 14% for PAK and 5% for SPK at 3 years in a registry analysis of all US and international pancreas transplants [25]. A comparison of SPK versus PALK in T1DM recipients from 2000 to 2007 in the Organ

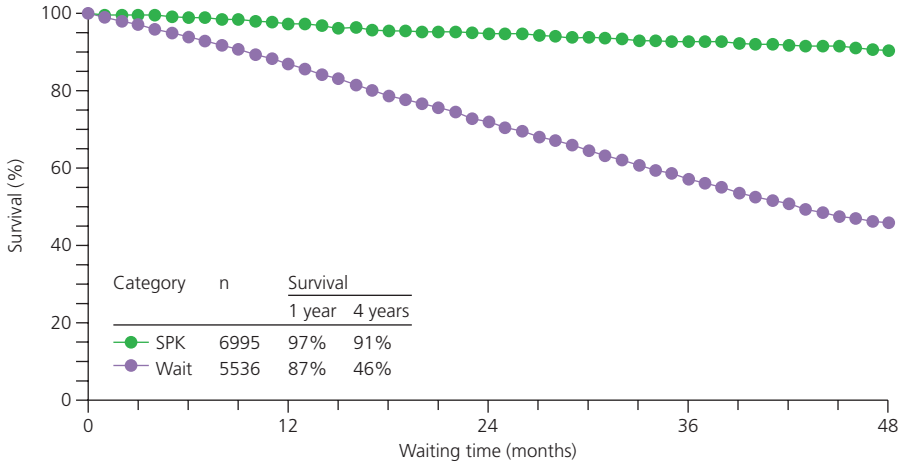

Figure 32.1. Patient survival at 4 years after simultaneous pancreas–kidney transplantation (SPK) compared to those remaining on the waitlist. Longer wait times are associated with increased mortality in patients listed for SPK, with reported 46% mortality after 4 years on the waitlist in a registry analysis of 12 478 patients listed for SPK from 1995 to 2003.

Procurement and Transplantation Network (OPTN)/UNOS database confirmed these findings. Death-censored pancreas allograft survival was significantly and independently associated with SPK versus PALK; 5-year survival was 80% for SPK and 64% for PALK ($P < 0.01$). Overall patient survival between the two groups 5 years after pancreas transplantation was similar. Notably, the rates of rejection 1 year post transplant were significantly higher in PALK as compared to SPK (16.88 vs. 10.97%; $P < 0.01$) [50].

Advising patients to pursue SPK versus PALK ultimately depends on the waitlist time for SPK. All things considered equal, SPK is the gold standard for patients with T1DM requiring renal transplant. Length of time on the waitlist must be balanced against time spent on dialysis and availability of living donors. SPK waitlist time varies by blood type and region. In 2007 the US national median time to SPK transplant was 498, 341, 337, and 165 days for O, A, B, and AB blood types, respectively, according to the Scientific Registry of Transplant Recipients (SRTR) database [48]. Longer wait times are associated with increased mortality in patients listed for SPK, with reported 46% mortality after 4 years on the waitlist in a registry analysis of 12 478 patients listed for SPK from 1995 to 2003 (Figure 32.1). Patients listed for PAK had 18% mortality over the same amount of time, highlighting the potential impact of ESRD on patient mortality [26]. The decision to proceed with SPK versus PALK should therefore be made on an individual/center basis. Patients on dialysis facing a long wait time for SPK should proceed with living donor kidney transplantation (if available), whereas patients who are predialysis should be listed for SPK (Figure 32.2) [48].

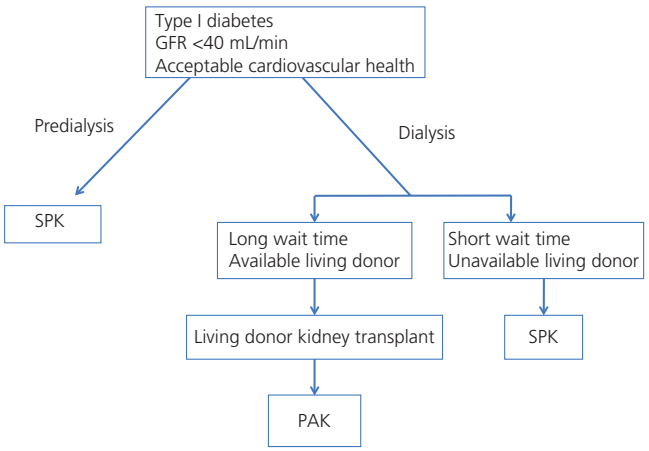

Figure 32.2. Algorithm for simultaneous pancreas–kidney transplantation (SPK) versus pancreas after kidney transplant (PAK). SPK is the gold standard of treatment for type 1 diabetic patients requiring renal transplant who are fit enough to survive the operation. Given the high mortality of patients on the waitlist for SPK (Figure 32.1), time on the waitlist must be balanced against availability of living donors for renal transplant. Patients on dialysis facing a long wait time for SPK should proceed with living donor renal transplant (if available) and then pursue PAK transplantation. Patients on dialysis in regions with short SPK wait times should be listed for SPK. Patients who are predialysis should be listed for SPK.
Data from [26,48].

Indications for pancreas transplantation alone and islet cell transplantation

Pancreas transplantation alone (PTA) accounts for 10% of all pancreas transplants performed in the US. Islet transplantation (IT) is currently experimental and is only available under research protocols. Indications for PTA and islet cell transplant are similar and include frequent acute and debilitating metabolic complications such as hypoglycemia, hyperglycemia, and ketoacidosis; incapacitating aversion to and/or clinical challenges with exogenous insulin therapy; and consistent failure of exogenous insulin therapy to mitigate these complications [8]. The benefits of addressing these complications with PTA or IT should outweigh the risks associated with lifelong immunosuppression, such as serious infection and cancers. Candidates include patients with preserved renal function able to withstand the nephrotoxic effects of CNIs: GFR >80 mL/min/1.73 m^2 and/or serum creatinine <1.5 mg/dL pretransplant (Figure 32.3). If these criteria are met, recipients are less likely to develop renal failure requiring dialysis or future kidney transplantation [51]. The overall incidence of kidney failure reported in two

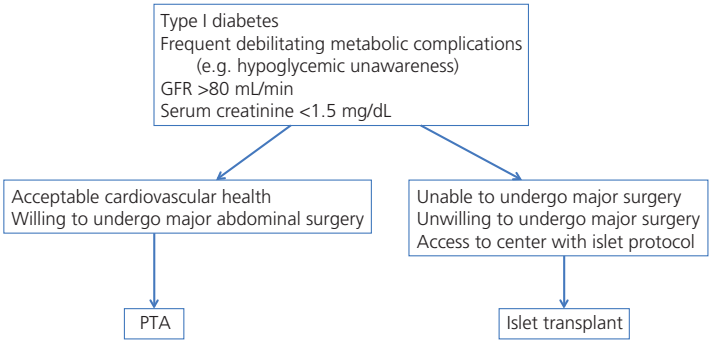

Figure 32.3. Algorithm for pancreas transplant along (PTA) versus islet transplant. PTA and islet transplantation are considered for type 1 diabetic patients experiencing potentially fatal metabolic complications such as hypoglycemic unawareness. Patients must have sufficiently preserved renal function able to withstand the nephrotoxic effects of calcineurin inhibitors, the mainstay of post-transplant immunosuppression. Patients willing and able to undergo major abdominal surgery should proceed with PTA as this is the most durable way to achieve insulin independence. Islet transplantation is currently experimental and offered at only a few transplant centers. It is an option for patients who would not otherwise qualify for or desire major abdominal surgery.

large single-center series after PTA was 10–15% at 5 years [51,52]. Patients selected for PTA must be fit enough to benefit from the operation, considering its associated morbidities and mortality. IT is associated with significantly less procedural morbidity and mortality and will be discussed in detail below. The procedural aspects of IT are covered in depth in Chapter 61.

Pancreas transplant alone

Patients with T1DM experiencing metabolic complications such as blood glucose lability and frequent episodes of hypoglycemia and hypoglycemic unawareness have a severely compromised quality of life. Additionally, hypoglycemic unawareness has the potential to be fatal [2,53], and frequent episodes of hypoglycemia have been shown to adversely affect cognition in children and adults [2]. For this subset of patients with T1DM, PTA may be indicated. PTA is less durable than SPK or PAK with a graft half-life of 5 years [49].

The rationale for PTA has been debated in the literature, as a direct result of the lack of data regarding mortality associated with episodes of hypoglycemic unawareness. Patients selected for PTA do not have renal failure and are thus not necessarily considered to have an immediately life-threatening condition, making it difficult to utilize waitlist mortality as an outcome measure. Venstrom et al. analyzed 672 patients waitlisted for PTA between 1995 and 2000 and found that the relative risk of death was higher for patients after PTA versus those waitlisted (RR 1.57; $P = 0.06$) [42]. Gruessner et al. analyzed the same population but eliminated patients with multiple transplant center listings, such that each patient was counted only once. Additionally, they accounted for patients who had been removed from the waitlist to undergo KTA. After these modifications, the overall hazard ratio for mortality after PTA was 0.66 ($P = 0.12$), a trend toward favoring transplantation. Importantly, the hazard ratio after day 366 was 0.15 ($P < 0.0001$) [26]. Thus, for this selected group of patients, survival is at least equivalent to patients remaining on the waitlist and at best improved for recipients with >1 year of survival with a functioning pancreas allograft. The mortality advantages of PTA are not as striking as for recipients of SPK and PAK, however, and this procedure should be reserved for a subset of patients experiencing debilitating metabolic complications [26].

Patients selected for PTA must have sufficiently preserved renal function to withstand the nephrotoxic effects of CNIs, the mainstay of immunosuppression after pancreas transplantation. PTA is an independent risk factor for post-transplant renal failure reported in a single center review of 131 patients. Mean GFR decreased by 33 mL/min/1.73 m^2 at 4 years post transplant ($P < 0.0001$) [52]. A total of 10% of patients developed renal dysfunction requiring dialysis. Of patients who suffered a >40 mL/min/1.73 m^2 drop in GFR, the only significant risk factor by multivariate analysis was BMI; 70% of patients with a BMI >30 kg/m^2 suffered a decline in GFR of >40 mL/min/1.73 m^2 post transplant [52].

The largest published series of patients undergoing PTA is from the University of Minnesota (n = 513) and demonstrated that 12% of those treated with tacrolimus (n = 239) developed renal failure. The authors identified creatinine >1.5 mg/dL and age younger than 30 years as significant risk factors for post-transplant renal failure by multivariate analysis ($P < 0.0001$ and <0.07, respectively). They noted a trend toward renal failure in patients treated for two or more rejection episodes and concluded that, as younger patients had more episodes of treated rejection, their risk of renal failure was higher [51].

Although renal failure is a risk of PTA, there is evidence that the long-term metabolic control provided by pancreas transplantation has a beneficial effect on diabetic nephropathy. Solitary pancreas transplantation has been shown to improve the diabetic lesions associated with nephropathy after 10 years of normoglycemia [54]. Fioretto et al. examined the biopsies from eight patients pretransplant at 5- and 10-year intervals after transplant and found a statistically significant decrease in glomerular and tubular basement membrane thickness at 10 years post transplant ($P < 0.0001$). There was no improvement in GFR pre and post transplant, although there was a trend toward decrease in urinary albumin excretion [54]. Similarly, Coppelli et al. documented the disappearance of nephrotic syndrome in six patients after PTA with a 36-month follow-up, albeit without a significant change in creatinine clearance [55].

In summary, PTA is recommended for a subset of T1DM patients with poor metabolic control causing debilitating quality of life or potentially fatal complications. Patients selected for PTA should have excellent renal function, with a creatinine of <1.5 mg/dL and a GFR of >80 mL/min/1.73 m^2 predictive of patients who will not go on to develop renal failure after CNI exposure [51]. Other risk factors for renal failure include a BMI of >30 kg/m^2 and age younger

than 30 years, which should be taken into consideration when selecting patients for the operation [51,52]. Patients should also be in excellent cardiovascular health to optimize their perioperative outcome.

Islet cell transplantation

Intensive insulin therapy has markedly improved the incidence and progression of secondary diabetic complications at the cost of increasingly frequent episodes of severe hypoglycemia. IT is a more physiologic means of obtaining glucose control than injected exogenous insulin and has been shown to achieve insulin independence in selected patients with T1DM over the past decade.

IT represents a minimally invasive alternative to PTA. The indications for the two procedures are the same, namely persons with T1DM experiencing hypoglycemic unawareness and/or extreme metabolic lability, negatively impacting quality of life [8]. IT is currently experimental and is performed at fewer than a dozen centers worldwide [56].

The first successful alloislet transplantation was performed in 1990 at Washington University in St. Louis, Missouri; the patient achieved insulin independence lasting up to 25 days post transplant [57]. Long-term insulin independence after IT proved elusive, however, until the landmark publication describing the Edmonton Protocol in 2000 [58]. The Edmonton Protocol consists of refined techniques for islet processing, number of islets infused, and a steroid-free immunosuppressive regimen including tacrolimus, sirolimus, and dacluzimab. All seven patients who received IT on this protocol were insulin-free at 1 year post transplant [58]. The Edmonton Protocol was reproducible at other centers. At three such centers, the insulin independence rate was 90% at 1 year [59]. The first multicenter trial using the Edmonton Protocol was reported in 2006 [60]. Of 36 patients enrolled in the trial, 44% were insulin independent at 1 year, and 13% were insulin independent at 2 years. Results varied by site, as centers with the most familiarity with IT were able to achieve the best results: 67% insulin independence at 1 year. Complete graft loss was experienced by 28% of patients by 1 year post transplant, defined as a decrease in C-peptide to <0.3 ng/mL (C-peptide is produced by islets in amounts equal to insulin and is a more reliable indicator of endogenous insulin production than insulin levels). The remaining 28% of patients had partial graft function (C-peptide >0.3 ng/mL and an exogenous insulin requirement for adequate glycemic control). Patients with partial graft function experienced improved glycemic control and protection from severe episodes of hypoglycemia, however, with reductions in pretransplant HbA1c, insulin requirement, and fasting blood glucose. The authors concluded that, though long-term insulin independence was difficult to achieve, IT provided considerable metabolic benefits in the majority of patients who experienced partial graft function [60].

Although the IT procedure is associated with substantially less morbidity and mortality than PTA, the results are significantly less durable than whole organ transplantation. At 5 years post transplant, 10% of the original Edmonton islet recipients remained insulin independent, compared to 50% of PTA recipients [49,51,61]. Although few patients remained insulin independent, 80% demonstrated C-peptide positivity and improved glycemic control without hypoglycemic unawareness [61]. Of all alloislet transplants reported to the Collaborative Islet Transplant Registry (CITR) from 1999 to 2007, 23% of IT recipients remained insulin independent at 3 years post transplant, and 29% were insulin dependent with positive C-peptide levels and marked improvements in glycemic control and hypoglycemic unawareness. Most of these patients reported to the CITR received islets from multiple donors [62].

Like PTA, IT involves a risk-to-benefit ratio that must be determined on an individual patient basis. IT has been shown to improve episodes of severe hypoglycemia and hypoglycemic unawareness as long as some residual graft function is present [63,64]. Patients with functioning islet grafts report improved quality of life as it relates to fear of hypoglycemia [65–67]. These benefits must be balanced against the risks of lifelong immunosuppression. The original immunosuppressive drugs used in the Edmonton protocol, tacrolimus and sirolimus, may have deleterious effects. Tacrolimus is known to adversely affect renal function [68], and both drugs have been shown to impair insulin sensitivity and islet vascularization [69,70]. A progressive decline in GFR after islet transplantation was demonstrated in patients participating in the original Edmonton trial: GFR declined by 0.39 mL/min/1.73 m^2 per month [71]. GFR deterioration was also noted in the subsequent multicenter trial of the Edmonton Protocol: average GFR declined by 0.45 mL/min/1.73 m^2 per month [60].

Compared to persons with T1DM receiving intensive medical therapy, however, Warnock et al. noted no significant difference in decline in GFR. This study compared IT recipients maintained on tacrolimus or sirolimus to patients with T1DM managed with best medical therapy for a mean 3-year follow-up [72]. Additionally they noted improvements in HbA1c and in retinopathy progression in IT recipients compared to the control population [72]. Still, some argue that the benefits of IT are not outweighed by the risks of immunosuppression [73]. Single-center studies have subsequently successfully employed CNI-free protocols or CNI-minimizing protocols in ITs from a single donor in an attempt to minimize these risks [74,75].

Several recent studies have demonstrated beneficial effects of IT on diabetic micro/macroangiopathy, cardiovascular function, and renal allograft survival in the context of kidney transplantation, a population that is already immunosuppressed [76–78]. Fiorina et al. found an improvement in renal allograft survival 6 years after IT compared to those receiving KTA [78]. Gerber et al. reported comparable glucose control in patients 5 years after SPK and those who received a kidney allograft with simultaneous IT [79].

The majority of ITs to date have required more than one donor to gain sufficient islet mass to achieve insulin independence, potentially putting patients at risk for HLA sensitization [62]. Campbell et al. reported 34% of patients had developed de-novo anti-HLA antibodies after failed IT, the majority of whom had received islets from two donors. Of recipients who had discontinued immunosuppression, 70% had a panel-reactive antibody (PRA) of $>50\%$. This degree of sensitization would make subsequent kidney or pancreas transplantation more difficult. The authors acknowledged HLA matching for islet recipients was not feasible, as the pool of donors was extremely limited. Transplanting islets from a single donor would decrease the number of HLA mismatches, but broad sensitization could still occur if there were many mismatched epitopes from the single donor [80]. Recent trials using alternative immunosuppression based on the biologic agents efaluzimab (anti-LFA-1) and abatacept (CTLA4-Ig) have shown no allosensitization compared to Edmonton protocol-treated controls [75]. New immunosuppressive regimens along with the ability to list unacceptable HLA antigens at the time of transplant may favorably impact the development of anti-HLA antibodies in this population.

In summary, IT is experimental and is best performed at experienced clinical research centers. Although long-term insulin

independence is difficult to achieve, the majority of patients at 5 years post transplant have at least partial graft function that protects them from extreme hypoglycemia or hypoglycemic awareness, the main indications for transplantation [61].

For persons with T1DM experiencing hypoglycemic unawareness and debilitating metabolic complications, PTA remains the "gold standard" of treatment. Patients selected for PTA must have excellent renal function and should be healthy enough to survive the operation. Like PTA candidates, IT candidates should have excellent renal function able to withstand the nephrotoxic effects of CNIs. While still an experimental therapy, IT is an alternative to PTA in patients who would not otherwise qualify for or choose to undergo major abdominal surgery. The risks and benefits of both procedures should be weighed on an individual patient basis.

Summary

Pancreas transplantation in all its forms remains a reasonable alternative for patients with T1DM who have progressive secondary complications and are physiologically capable of enduring the substantial surgical procedure that it entails. Its success has improved over time, but remains associated with not insignificant morbidity and as such, should not be considered solely as a means of eliminating the need for exogenous insulin. IT remains less successful than whole organ pancreas transplantation, but is a less morbid procedure. Thus, IT remains an investigational alternative primarily for patients with severe hypoglycemic unawareness. Both are conscribed by a relative shortage of suitable donor organs and thus, the allocation of this resource should be carefully considered and reserved for those patients most likely to benefit.

CHAPTER 33

Patient Selection and Indications for Intestinal and Multivisceral Organ Transplantation

Douglas G. Farmer and Robert S. Venick
David Geffen School of Medicine at UCLA, Los Angeles, CA, USA

Introduction

Intestinal transplantation (ITx) and multivisceral transplantation (MTx) have continued to evolve over the past two decades from an experimental procedure to one that is routinely performed at several specialized medical centers throughout the world. Indeed, one of the major steps forward for this area was the first description of indications [1]. Since that time, there have been several other reports specific to this topic [2–6]. Yet, until recently, these indications have changed very little. Regardless, it is arguable that patient selection is one of the most important issues impelling a successful transplant and post-transplant course. In this chapter we will describe the indications for ITx including those for the isolated intestine and multivisceral types of transplants. This information is useful in understanding the content in Chapters 42, 62, and 63, which cover waitlist management for patients who have been listed for and are awaiting ITx/MTx, and the procedures themselves, respectively.

Intestinal failure

Irreversible intestinal failure is the basis for most but not all indications for ITx and prompts the inclusion of the intestine in grafts performed in the face of other complicated problems that require the consideration of a MTx. It is defined as the inability to sustain one's fluid, electrolyte, caloric, micro- and macro-nutrient requirements through the gastrointestinal tract [7]. Clinically it is synonymous with the need for parenteral nutrition (PN) for >60–90 days, and in children it can contribute to the inability to grow and develop appropriately. Like other solid organ failures, there are both reversible and irreversible conditions leading to intestinal failure. Etiologies are commonly classified broadly into mucosal disorders, motility disorders, and surgical/anatomical disorders. The latter are commonly referred to as short bowel syndromes.

Patients with reversible intestinal failure should *not* be considered as candidates for ITx or intestine-containing MTx. Conversely, those with irreversible intestinal failure should. Several prognostic factors that are considered when deciding on the rehabilitative potential of intestinal failure are shown in Table 33.1 [8–10]. Note, these factors apply mainly to the subset of intestinal failure etiologies that are surgical/anatomical.

Intestinal adaptation is the process whereby the failed intestine recovers full function and enteral autonomy. It is characterized by elongation of the villi, deepening of crypts, decreased gastrointestinal motility, as well as dilation and elongation of the intestine. This process is energy dependent, requiring sufficient calories and micronutrients and can take months to years. For this reason, PN has been instrumental in optimizing the adaptive potential in patients with intestinal failure.

Not surprisingly, younger patients have a better adaptive potential. Further, most studies support that the adaptive process is maximized at approximately 24–36 months after the onset of intestinal failure, although there are case reports of late adaptation. The length and location of remnant small intestine is crucial for adaptation. The longer the remaining intestine, the better the adaptive potential. The ileum is more adaptive than the jejunum. The role of the ileocecal valve is controversial. Some consider its positive prognostic value lies in the fact that the presence of an ileocecal valve is almost always accompanied by ileum. Likewise, it may be a surrogate marker for the presence of colon. Others feel that it is important in itself to prevent colonic backwash and bacterial overgrowth. Regardless, patients with an ileocecal valve do better than those without. The presence of colon is also important for adaptation. In these cases, not only does the colon absorb excess fluid from the succus entericus but it also, through commensural bacteria, can digest and absorb some calories. Therefore, restoration of enteric continuity through the surgical takedown of enterostoma and fistulas is extremely important for adaptation. Lastly, the health and function of the remnant intestine is crucial. Remnant bowel that has suffered ischemic insults or has active disease processes such as inflammatory bowel diseases tends not to adapt well, regardless of the above factors.

Parenteral nutrition-related complications

In general, irreversible intestinal failure alone is not a sufficient indication for ITx and similarly, does not impel one to consider an intestinal component to a MTx. ITx is intended to target those patients with permanent intestinal failure who are at risk for death with prolonged TPN administration. This is because the survival of patients with permanent intestinal failure on uncomplicated home TPN is quite good and in many cases equals or exceeds that seen after ITx [11]. Exceptions do exist, as discussed below.

In contrast, patients with irreversible intestinal failure who develop one or more major parenteral nutrition-associated

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

complications should be considered for ITx. In these instances, outcomes after transplantation exceed those seen with complicated long-term TPN administration.

The most concerning TPN-associated complication is liver disease. Variously named TPN cholestasis, parenteral nutrition associated liver disease (PNALD), or intestinal failure-associated liver disease (IFALD), it remains a leading cause of morbidity and mortality in this patient population. The exact etiology of liver disease in this setting is unclear. Several theories exist, including a lack of enterally stimulated bile flow, and components or deficiencies of parenteral nutrition; discussion of these is beyond the scope of this chapter [12]. Risk factors for IFALD include: prematurity, low birth weight, lack of enteral nutrition, central venous catheter infections, small bowel bacterial overgrowth, excessive parenteral carbohydrate, protein or lipid administration. In children, IFALD usually presents as a cholestatic liver injury that can progress to biliary cirrhosis. In adults, the disease is usually more of a steatotic liver injury with or without inflammatory hepatitis. It falls into the non-alcoholic steatohepatitis (NASH) category. Once liver disease becomes evident, it is difficult to reverse, with progression to end-stage liver disease.

Typically, irreversible intestinal failure with liver disease is a major indication for ITx. There are groups that advocate proceeding with isolated ITx at the early onset of liver disease to prevent the progression to end-stage liver disease. This is a rational approach as it prevents the candidate from prolonged waiting time on the liver transplant list—a proposition plagued with a high mortality rate. However, with newer preventive strategies for early IFLAD, discussed below, this practice is being reconsidered. Once advanced liver disease with cirrhosis is present, combined liver–intestinal or multivisceral transplantation is required. When decompensation occurs in the cirrhotic IFALD patient, death typically follows rapidly.

A second common indication for ITx relates to central venous access. Patients who develop thrombosis or occlusion of the major central veins need to be considered for transplantation, especially if two or more central veins or the vena cava is involved. There are interventional radiology techniques wherein chronically thrombosed or stenotic central veins can be dilated, stented, or thrombolysed [13]. However, these techniques should not be considered a good long-term solution, but rather a means to improve access to allow for safe perioperative management with transplantation.

The other major central venous catheter-related complication that is a driving force for referral to an intestinal transplant center is bloodstream infection (BSI). BSIs can be common in this patient population, with the best series reporting instances of 0.5 BSI per year on TPN [14]. There are subsets of patients who have a much higher incidence of BSI and commonly lose catheters to infection. High rates of BSI are an indication for ITx. Other related indications besides incidence are organism types with resistant bacterial or fungal BSI (very concerning); metastatic foci of BSI such as endocarditis or abscesses; and systemic inflammatory response conditions requiring critical care admission, pressors and/or mechanical ventilator support. Table 33.2 summarizes the common indications, and their relationship to the above-mentioned co-morbidities that have been reported in the recent literature.

Table 33.1. Prognostic factors influencing the outcome of intestinal failure/adaptation

- Patient age
- Time since onset of intestinal failure
- Length of remnant small bowel
- Anatomical portion of remnant small bowel
- Presence of ileocecal valve
- Length of remnant colon
- Presence of enterostoma
- Presence of underlying intestinal disease/disorder

Other indications not meeting the standard criteria

Unresectable desmoids or gastrointestinal stromal tumors

Low-grade malignancy or the potential for the development of low-grade malignancies can be an indication for ITx and, based on the degree of tumor extension, can require resections that necessitate a MTx [15]. It is important to state that these are lesions that are unresectable by conventional surgical means. They typically are either desmoid-type tumors or gastrointestinal stromal tumors that involve the root of the mesentery. The spectrum of familial adenomatous polyposis syndromes (Gardner's syndrome) [16] can also be an indication for ITx. With each indication, complete tumor

Table 33.2. Indications and their associated conditions leading to intestinal transplantation

Author	Irreversible IF	Liver disease	BSI	Vascular access	Other	OTHER
Kaufman et al. [1]	Yes	Yes	Yes (metastatic foci; SIRS; Tx resistance)	Yes (2/4 infant; 3/6 child)	Ultra-SGS, gastrocolonc discontinuity; congenital mucosal disorders; untreatable fluid/electrolyte disorders; chronic pain	NONE

Avitzur & Grant [5]	Yes	Yes	Yes (2-year SIRS 2/2 bacteria; 1-year SIRS 2/2 fungus; 1-year shock; 1-year ARDS)	Yes (2/6 all)	Ultra-SGS, gastrocolonc discontinuity; frequent severe dehydration; congenital mucosal disorders; tumor requiring massive resection	POOR QOL

IF, intestinal failure; BSI, bloodstream infection; Tx, treatment; ARDS, acute respiratory distress syndrome; SGS, short gut syndrome; SIRS, systemic inflammatory response syndrome.

resection with negative margins is imperative. Replacement of removed organs using modified multivisceral or multivisceral grafts is most common. However, newer techniques involving ex-vivo tumor resection with autotransplantation have recently been successfully applied to this patient population, potentially altering the transplant indications [17].

Porto-spleno-mesenteric vein thrombosis

The standard approach to patients with thromboses involving the portal, mesenteric, and/or splenic vein involves endoscopic and medical therapies followed by surgical shunt therapies. However, there is a group of patient that requires transplantation, usually due to underlying liver disease. In the vast majority of cases, isolated liver transplantation with portal venous revascularization using thrombectomy techniques, venous conduits, or portocaval transposition is standard [18]. However, there is a small subset of these patient in whom there is no suitable venous inflow option for isolated liver transplantation. These patients should be considered for MTx. The experience in general is limited to a few cases each year at specialized transplant centers [19].

Non-reconstructible gastrointestinal tract/ultrashort gut syndrome

A non-reconstructible gastrointestinal tract is one in which the entire midgut is surgically absent, rendering restoration of fore- and hind-gut continuity surgically impossible or impractical. These patients frequently have a blind end duodenum with tube gastrostomies draining foregut secretions. Ultrashort gut syndrome patients have less than 10 cm of remnant jejunoileum ending in an ostomy or surgically anastomosed to the colon. In either case, the prognosis for adaption is poor and parenteral nutrition complications are frequent. In addition, these patients represent challenges for medical management with frequent episodes of dehydration and electrolyte disorders. These issues have resulted in an aggressive approach to transplantation with successful outcome [20].

Potential evolution in indications

The traditionally accepted indications for ITx have been obscured by new preventive medical therapies. Specifically, the minimization of intravenous lipids, and the introduction of intravenous omega-3–based lipid solutions have reduced the prevalence of IFALD, thus altering the landscape of intestinal failure management. Lipid sparing techniques ($\leq$1 g/kg/day) have become a relatively common preventive and therapeutic approach for patients with IFALD. In small single-center experiences, this approach has successfully normalized cholestasis [21], providing clinicians with the opportunity to continue to work towards intestinal adaptation. More recently, omega-3 fatty acid (O3FA) emulsions (Omegaven; Fresenius Kabi, Bad Homburg, Germany), which are readily available throughout Europe and Asia, and in the US through research-based and compassionate use protocols, have shown the ability to prevent and reverse cholestasis in the majority of children with IFALD [22,23,24]. O3FA solutions lack phytosterols, contain higher amounts of vitamin E, and tend to be dosed at 1 g/kg/day. Newer emulsions containing soybean oil, medium chain triglycerides, olive oil, and fish oil have been touted as potentially more physiologically balanced and effective in preventing IFALD [25]. While the novel lipid therapies have demonstrated an excellent safety profile and are clearly effective at reversing cholestasis, the long-term efficacy in high-risk intestinal failure patients unable to come off parenteral nutrition is unknown.

Summary

ITx and MTx have evolved dramatically over the past two and a half decades and are now established modalities used in the treatment of patients with intestinal failure, or selected locally aggressive tumors requiring intestinal resection for cure. As experience has been gained, specific indications for transplantation have been clearly delineated. Further expansion beyond these criteria awaits further improvement in outcomes. Newer developments in the management of patients with intestinal failure will potentially impact the traditional indications for ITx and MTx. The full extent of this is yet to be seen.

CHAPTER 34

Role of Primary Care Provider in the Referral and Care of Abdominal Organ Transplant Patients

Peggy B. Hasley,[1] Kristine S. Schonder,[2,3] and Ron Shapiro[3]

[1] Department of Internal Medicine, University of Pittsburgh, Pittsburgh, PA
[2] University of Pittsburgh School of Pharmacy, Pittsburgh, PA, USA
[3] Thomas E. Starzl Transplantation Institute, University of Pittsburgh, Pittsburgh, PA

Introduction

By the end of 2007, 183 222 persons were recorded in the Organ Procurement and Transplantation Network (OPTN) as living with a functioning solid organ transplant [1], and 27 000 patients undergo organ transplantation annually in the US. Patient survival rates have improved for all solid organ transplant types, with the exception of pancreas transplant alone, pancreas after kidney, and intestine. Five-year survival rates are >70% for most organ transplant recipients [1]. As a result of the current success of transplantation, a growing number of patients are expected to survive to leave the hospital and ultimately return to their primary care physicians (PCPs) for continued care.

As more transplant recipients survive beyond the initial months after surgery, they can be expected to develop more chronic medical conditions that are associated with their immunosuppressive therapy. These conditions include hypertension, diabetes, hyperlipidemia, obesity, cardiovascular and cerebrovascular disease, chronic kidney disease, and osteoporosis. The PCP specializes in the primary and secondary prevention of chronic medical conditions and thus is well suited to provide care for patients after transplantation. In a survey of liver transplant centers in the US, 40% expressed the expectation that the PCP should be the principal medical provider 1 year after transplantation. An additional 40% employed a combination of subspecialists and PCPs to manage their transplant recipients [2]. PCPs should be prepared to manage the primary care of transplant patients.

The purpose of this chapter is to assist PCPs in the management of chronic medical conditions occurring after abdominal transplantation, as well as to provide advice regarding specific disease prevention through screening, immunization, and contraception. A companion chapter covering similar topics for thoracic transplantation follows in Chapter 35.

Coordination of care

Coordination of care between PCPs and subspecialty and surgical practitioners is critical to optimize health outcomes of transplant patients, as well as to minimize duplication of tests and avoid errors. A meta-analysis reporting on the coordination of care between PCPs and subspecialty physicians showed that interactive communication between practitioners can improve patient outcomes in the areas of mental health and diabetes care [3]. Though coordination of care has proven benefits, optimal strategies of collaboration have yet to be developed. While systems to employ health information technology and reports on performance are well established components of current primary care practices, methods to improve communication between practitioners are underdeveloped [4]. In a survey of transplant hepatologists [5], over 60% indicated that chronic medical conditions after transplant should be managed by PCPs. However, less than 40% of hepatologists were satisfied with the level of involvement of the PCPs in the care of their patients. While 70% of respondents indicated that they had appropriate levels of communications with PCPs, the majority of respondents were dissatisfied with the amount of communication that they received from PCPs. Ultimately, transplant hepatologists felt that their patients were receiving inadequate control of their chronic medical conditions after transplantation.

One collaborative care model for transplant recipients could involve inclusion of PCPs within the transplant team to assist with optimization of post-transplant care. Other models could include shared electronic medical records, email-based messaging regarding complex medical decision-making, or communications among physicians through shared interdisciplinary team members.

Before the development of the electronic medical record, PCPs communicated with subspecialty colleagues by telephone. During this call, relevant background information and questions for the consultant could be communicated. With the onset of shared electronic medical record systems, an initial phone call is often not made. The Associates of Specialty Professors Workforce Committee developed guidelines for communication between generalists and specialists in the co-management of patients with chronic medical conditions [6]. Included in these guidelines are the following recommendations:

1. The generalist should send an initial note to the specialist that includes the reason for consultation, the question to be answered, and the background data that have been collected by the generalist.
2. The generalist should send copies of clinic notes after the referral has been made.
3. The specialist should consider using "disease-specific templates" to communicate guidelines and recommendations to the generalist.

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Other models of pretransplant care include the establishment of multidisciplinary teams that include advanced practice nurses [7] and the use of telemedicine to provide pretransplant care to patients located in a rural setting [8].

Prior to transplantation PCPs, play a critical role that can affect the long-term prognosis of their patients after transplantation. The establishment of open lines of communication with subspecialists, appropriate timing of referrals, identification and treatment of modifiable risk factors, and working with patients to improve adherence to treatment plans are important goals for pretransplant care.

Timing of referral to subspecialists

PCPs can optimize post-transplantation prognosis, reducing mortality and morbidity, by achieving guideline-directed targets of other chronic medical conditions. In a cohort of 5978 adults with severe lung disease, Cox models were employed to determine an association between body mass index (BMI) prior to transplant and the risk of death after transplant. This study revealed that after a mean follow-up period of 4.2 years, death rates for underweight and overweight patients were 15% higher compared with normal weight transplant recipients [9]. Other chronic medical conditions, including pretransplantation chronic kidney disease (CKD), have been shown to increase post-transplant morbidity [10,11].

Research on the appropriate timing of referral to subspecialists has not been developed for most chronic medical conditions, with the exception of CKD. The Generalist Subspecialist Collaborative has developed initial guidelines for the co-management of cardiovascular diseases, diabetes, CKD, asthma and chronic obstructive pulmonary disease, osteoarthritis and polymyalgia rheumatica, irritable bowel syndrome, and inflammatory bowel disease [6]. The authors acknowledge that this is an area that is in need of more research to guide generalists and specialists in the identification of their individual and shared roles.

Late referral to specialists of patients with CKD has been shown to result in an increase in the morbidity, mortality, and cost of medical care [12–16]. Cass et al. have shown that CKD patients who are referred to subspecialists within 3 months of the initiation of renal replacement therapy [reliant renal care (RRC)] were less likely to be put on the transplant waitlist, and less likely to receive a transplant up to 2 years after the initiation of RRC. The authors postulate that the reasons for this lack of access to transplantation are that patients are sicker at the start of RRC and that there is not enough time to go through the pretransplant evaluation to allow patients to bypass dialysis and undergo pre-emptive transplantation [13]. PCPs can improve their patients' access to appropriate care by referring to a nephrologist well before RRC is needed.

Optimizing adherence

Medication adherence and proactive patient self-care are key components to a successful outcome after transplantation. Several studies have shown that even minor deviations in the extent of adherence with immunosuppression are correlated with graft rejection. In addition, clinical event-free survival has been shown to be shorter for patients who deviate from adherence to medicines [17–19]. In a study of immunosuppressant adherence after transplantation, Dew et al. showed that patients identified the quality of care given as an important determinant of adherence [20]. PCPs usually have a long-standing relationship with their patients prior to transplantation. As a result, PCPs are well suited to the task of identifying patient risk factors for non-adherence and assisting their patients with strategies to improve adherence to complex medical regimens. Patient factors that have been shown to be associated with a reduced adherence are male gender, a sense of lower self-efficacy, anxiety and depression, personality disorders, neurocognitive disorders, and a lack of social support. Patient pretransplant behaviors that predict post-transplant non-adherence include pretransplant non-compliance with medicines, alcohol abuse, and non-compliance with monitoring vital signs [21,22]. PCPs can assist in the pretransplantation assessment of adherence and can counsel their patients on the importance of medications and lifestyle adherence as a means to improve both pre- and post-transplant quality of life as well as the likelihood of obtaining a transplant. PCPs can improve post-transplant outcomes by diagnosing and treating anxiety and depression, by providing pill boxes and through guideline-supported interventions on tobacco use, alcohol abuse, and dependence, and arranging for improved social support systems for their patients. Many of the milestones developed by Bell et al. for adolescents to achieve prior to transition to adult care can be adapted to the pretransplant patient to improve post-transplant adherence [23] (Table 34.1).

Table 34.1. Recommended milestones for patients to achieve before transplantation

- Understanding of and ability to describe the original cause of their organ failure and need for transplantation
- Ownership of their medical information in a concise portable accessible summary
- Awareness of the long- and short-term implications of the transplant condition on their overall health and other aspects of their life (e.g. infection prevention, cancer surveillance)
- Comprehension of the effect of their illness on their sexuality and reproductive health, including:
  - Effect of pregnancy on their own well-being
  - Effect of their medications on fertility
  - Any potential teratogenicity of their medications
  - Role of genetic counseling and genetic risk of their disease recurrence in future offspring, if pertinent to their condition
  - Their own increased susceptibility for sexually transmitted disease
- Demonstration of a sense of responsibility for their own healthcare:
  - Knowledge of the names (and shapes/colors), indications, and dosages of their transplant and ancillary medications (or carry that information in wallet/purse)
  - Call for their own prescription refills and renewals
  - Prepare their own medication dose boxes, if not done by their pharmacist
  - Independently communicate their healthcare needs to their providers
  - Know when and how to seek urgent medical attention, including health emergency telephone number(s)
  - Ability to make, keep a calendar of, and follow through with their own healthcare appointments
  - Understanding of their medical insurance coverage and eligibility requirements
- Capacity to provide most self-care independently

Chronic medical conditions post transplantation

Hypertension

Cardiovascular diseases are the most common cause of death in transplant recipients [24,25]. Hypertension, as defined by the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure VIII, is a systolic blood pressure of >140 mmHg and a diastolic blood pressure of >90 mmHg, or the need for hypertensive therapy [26]. In transplant recipients, donor characteristics, host characteristics, and immunosuppressive

agents contribute to the development of hypertension [27,28]. Host characteristics that increase the risk of hypertension include pre-transplant high blood pressure, high BMI, CKD, and post-transplant hyperthyroidism. Donor characteristics that can lead to hypertension in the recipient include older age, male gender, and hypertension [29–31]. No large prospective studies exist as to the appropriate targets for blood pressure control in transplant recipients, but current guidelines state that the target blood pressure for liver and kidney transplant recipients is <130/80 mmHg [32,33].

The diagnosis of hypertension in transplant recipients can be challenging. Blood pressure readings in the office compared with those done before and after office visits show the presence of a significant white coat hypertensive effect [34,35]. Self-measurements of blood pressure have been shown to be significantly higher in transplant recipients [36]. One study of 200 renal transplant recipients [37] showed that continuous 24 h ambulatory recordings have the greatest sensitivity in diagnosing hypertension. Nocturnal hypertension with an absence of nocturnal dipping was found in this population [37].

Treatment of hypertension in the general population traditionally includes weight loss, sodium avoidance, and regular exercise. Little data suggesting the efficacy of these interventions exist for transplant recipients. When urine sodium excretion was used as a measure of dietary salt intake in a population of renal transplant recipients, no association between sodium excretion and blood pressure could be found [38]. Nevertheless, guidelines for the management of hypertension in renal transplant recipients still include sodium restriction to <2.4 g/day, achievement of normal weight, and regular exercise [39].

Several classes of antihypertensive agents, including calcium channel blockers, angiotensin-converting enzyme (ACE) inhibitors, angiotensin-receptor blockers, beta-blockers, and diuretics have been shown to be effective in transplant recipients [40–51]. One large prospective trial comparing the efficacy of nifedipine versus lisinopril revealed that renal transplant function was superior with nifedipine [52]. In a retrospective study of liver transplant recipients [53], hypertension did not occur more often in patients treated with cyclosporine compared to tacrolimus. However, careful reductions in doses of calcineurin inhibitors (CNIs) after transplantation have been associated with improved blood pressure control [54].

In general, transplantation patients have hypertension that is difficult to control [55,56], and two or three agents are often required concurrently. Better control has been shown to reduce morbidity and cardiovascular mortality in the renal transplant population [57]. CNI levels are increased by the addition of dihydropyridine calcium channel blockers; thus, these agents are often used so that lower doses of expensive CNIs can be used. Additional special considerations in the transplant population are that CNIs (particularly tacrolimus) may contribute to hyperkalemia, and thus, the use of ACE inhibitors, angiotensin-receptor blockers, and potassium-sparing diuretics should be used with careful follow-up of potassium levels after initiation of these agents. Diuretics would be expected to counteract the sodium- and fluid-retaining effect of CNIs and prednisone. For patients with concurrent myocardial infarctions, proteinuria, and gout, beta-blockers, ACE inhibitors, and valsartan should be considered for the co-management of these conditions, respectively.

Hyperlipidemia

Hyperlipidemia is common after solid organ transplantation. One year after transplant up to 66% of liver and 60% of renal transplant recipients have developed an abnormal lipid profile [58–66]. The causes of hyperlipidemia in the transplant population are multifactorial and include post-transplantation obesity, diabetes, and hypothyroidism. In addition, the choices of antihypertensive agents and of immunosuppressive agents have also been shown to affect lipid levels [62,64–66].

Guidelines for lipid targets in renal and liver transplant recipients have been published [67,68]. The National Kidney Foundation Kidney Diseases Outcomes Quality Initiative recommends that renal transplantation patients be placed in a cardiac risk equivalent group of the National Cholesterol Education Panel (NCEP) Adult Treatment Panel (ATP) III [67]. Thus, the low density lipoprotein (LDL) cholesterol goal is set at <100 mg/dL, and the level at which drug therapy should be initiated is >130 mg/dL (and should be considered at levels >100 mg/dL). Two large randomized controlled trials (RCTs) have shown successful reductions in cardiovascular or overall mortality for transplant recipients who were treated for hyperlipidemia [69,70].

Initial treatment of hyperlipidemia should focus on weight reduction, dietary adjustment, and encouragement of exercise. A diet consisting of 25% energy from lipids, <10% from saturated fats, and <500 mg of cholesterol per day [71] was shown to produce significant reductions in LDL cholesterol for renal transplant recipients, but not low enough to achieve LDL targets of <100 mg/dL. The American Phase 3 diet has also been shown to reduce lipid levels in the renal transplant population [72]. Though no studies have shown that physical exercise has effectively improved lipid panels and reduced mortality in the transplant population, levels of physical activity have been shown to be low after transplantation [73] and studies have shown that transplant recipients do tolerate exercise programs and can reach levels of exercise that are similar to the non-transplant population [74]. If diet and exercise are insufficient to achieve LDL targets, PCPs should consider, in conjunction with transplant physicians, whether or not an adjustment in immunosuppressive therapy is feasible. Immunosuppressive regimens that reduce exposure to cyclosporine and to corticosteroids have been shown to improve lipid abnormalities [75–78].

For patients who do not achieve targets for LDL cholesterol with changes in diet and exercise, drug therapy is recommended. All classes of lipid lowering agents, including statins, bile acid resins, cholesterol absorption inhibitors, fibrates, nicotinic acid, and omega-3 fatty acids have been studied in the transplant population [69,70,72–107].

Statins are considered first-line therapy for transplant recipients [67]. Fluvastatin and pravastatin are not metabolized by the CYP450 3A4 system and thus have a lower likelihood of affecting levels of CNIs. PCPs should be aware of an increased risk of statin related myopathy, and levels of creatinine phosphokinase (CPK) should be checked along with transaminases 4–6 weeks after initiation of therapy or adjustment of the doses. Statins that are metabolized through the 3A4 pathway, such as simvastatin and atorvastatin, should be started at lower doses and should be associated with frequent checks of CNI levels.

In general, bile acid-binding resins are less well tolerated than statins [84], but may be considered for patients who have experienced severe side-effects from statin therapy. Their usefulness is debated in transplant recipients because of the controversy surrounding their impact on the absorption of immunosuppressive agents [108,109].

Only one cholesterol absorption inhibitor, ezetimibe, has been studied in transplant recipients. Combinations of statins with

ezetimibe have been shown to lead to further safe reductions in lipids [99–103]. However, no long-term study has demonstrated significant benefits in terms of reduction in cardiovascular morbidity and mortality.

The role of fibrates in the treatment of hyperlipidemia should be limited in transplant recipients. Only a few small studies of the impact of fibrate therapy have shown an effect [110], while the risk for myopathy in the transplant population is of concern. Fibrate use should be reserved for patients with severe elevations in triglycerides who are intolerant of statin therapy.

Nicotinic acid has not been studied significantly in the transplant population, possibly because of its known gastrointestinal, renal, hepatic, and flushing side-effects. One study to date [91] has reported niacin to be safe and effective at improving lipid panels.

Omega-3 fatty acids have been shown to represent an alternative to fibrates in the treatment of severe hypertriglyceridemia. A meta-analysis of omega-3 fatty acids in renal transplant patients showed significant reductions in triglycerides, without any change in glomerular filtration rate (GFR), graft survival, or incidence of rejection [107].

Diabetes

In 2005, new-onset diabetes after transplant (NODAT) was defined as a fasting plasma glucose of 126 mg/dL (7.0 mmol/L) or above. Patients with a fasting plasma glucose (FPG) of 110–125 mg/dL (6.1–6.9 mmol/L) were defined as being glucose intolerant and those with a FPG of <110 mg/dL (6.1 mmol/L) were defined as having a normal glucose. These definitions were based on the definition for diabetes of the World Health Organization [111]. Since these definitions were published, the American Diabetes Association has altered the cut-off points for the definitions of glucose intolerance to a FPG of 100–125 mg/dL (5.6–6.9 mg/dL) [112]. In a systematic review of the literature, Montori et al. showed that the incidence of new-onset diabetes mellitus after solid organ transplantation ranged from 2% to 50% [113]. A more recent study from a single center in the US showed that 74% of renal transplant recipients developed NODAT [114]. These studies were done prior to the most recent American Diabetes Association approved criteria for the diagnosis of diabetes, which would be expected to increase the percentage of transplant recipients diagnosed with diabetes.

Risk factors for the development of diabetes are similar to those for renal and liver recipients. Non-modifiable risks for diabetes include age, non-white ethnicity, male gender, family history of diabetes, hepatitis C, and polycystic kidney disease. Modifiable risk factors include pretransplant weight, steroid use, CNIs (particularly tacrolimus), and pretransplant degree of glucose intolerance [115–122].

To diagnose NODAT recent published guidelines suggest that post-transplant testing of FPG should begin weekly for the first 4 weeks, then at 3, 6, and 12 months, then annually after transplantation [123]. Hemoglobin A1cs (HbA1cs)should not be performed in the immediate post-transplant period, since many transplant recipients receive transfusions of packed red blood cells, which can alter the results. However, once patients are diagnosed with NODAT, HbA1cs should be checked on a routine basis [123].

Very little research exists on the efficacy and safety of diabetes treatments in the transplant population. Consensus conference guidelines have been published for renal transplant recipients [123,124]. Reynolds et al. have presented a simplified algorithm for the management of NODAT. For patients with a FPG of >250 mg/dL, initial therapy should include diet, exercise, and insulin therapy. To improve control and decrease tissue resistance, the addition of metformin, thiazolidinediones, or pramlintide is recommended. For patients with a FPG of <250 mg/dL at diagnosis, the first-line therapy should be diet, exercise, and metformin. If the HbA1c is >7% after 3 months, then the addition of a sulfonylurea or glinide, thiazolidinedione, exenatide, or sitagliptin should be initiated. If after 3 months of therapy the HbA1c remains >8%, then insulin is recommended. If the HbA1c ranges from 7% to 8%, then a thiazolidine, exenatide, or sitagliptin could be considered as an alternative to insulin [125]. New data on the association of thiazolidenediones and heart failure make these agents a less desirable choice for transplant recipients [126].

Osteoporosis

The prevalence of osteoporosis in a population of patients with end-stage solid organ disease is 31% among patients with liver failure and 24% among patients with kidney failure [127]. After transplantation, exposure to immunosuppressive agents including steroids, sirolimus, cyclosporine, and mycophenolate increases the likelihood of reduced bone mineral density (BMD) [128–130]. Within the first years after transplantation, further losses in BMD have been shown to occur in the renal transplant population [131]. In addition to immunosuppression, the presence of diabetes [132], decreased weight, and increased post-transplantation creatinine [130] has been shown to increase the risk of osteoporosis in this population. Correlation between low T scores on the dual X-ray absorptiometry test and vertebral fractures was shown in one study of renal transplant recipients [133]. In this study, a Cox proportional hazard analysis showed that the risk of fractures was increased in patients with osteoporosis by 3.5 times (95% CI 1.8–6.4) and in patients with osteopenia by 2.7 times (95% CI 1.6–4.6) [133]. A retrospective registry of 33 479 renal transplant recipients revealed an adjusted incidence ratio for fractures of 4.59 (95% CI 3.29–6.31). When hospitalized for hip fracture, this population had a hazard ratio for mortality of 1.60 (95% CI 1.13–2.26) [134]. Since bone loss progresses rapidly within the first year post transplantation, bone density testing should be performed soon after transplant and prophylaxis considered for patients who meet the criteria for osteopenia.

While no study of osteoporosis treatment has demonstrated reduced fracture rates for transplant patients, several treatments have been shown to slow the reduction in post-transplant BMD. One study of 57 simultaneous kidney–pancreas transplant recipients was able to demonstrate increased T scores at the lumbar spine and femoral neck during a follow-up period of 4 years [129]. The success of this study was attributed to the steroid-sparing immunosuppressive regimen employed in this population, coupled with an aggressive treatment protocol [129]. Other treatments with proven benefits on BMD have included vitamin D [135], and calcitonin [136]. A meta-analysis of five RCTs of bisphosphonate therapy in a population of 180 renal transplant recipients showed that this treatment resulted in a reduced decline in the BMD of the lumbar spine within 6–12 months after transplant. No major side-effects of bisphosphonate therapy were detected in this population [137].

Palmer et al. performed a meta-analysis of 24 RCTs (1299 patients) in renal transplant recipients and showed that bisphosphonates, vitamin D, and calcitonin were effective in improving BMD of the hip. None of these interventions showed a reduction in fractures [138].

A protocol for detection, treatment, and monitoring osteoporosis based upon published guidelines for the transplant population

improved screening and prevention practices for patients with kidney and pancreas transplants [139].

In addition to minimization of steroid dosing, transplant recipients should be encouraged to prevent osteoporosis through regular weight-bearing exercise and alcohol and smoking cessation. Adequate calcium intake (1000 mg/day for men, 1200 mg/day for premenopausal women, 1500 mg/day for postmenopausal women) and vitamin D intake (400–1000 IU/day) are also currently recommended; however, recent studies of a possible association between calcium and vitamin D supplements and cardiovascular mortality in the non-transplant population may result in a modification of these recommendations [140]. Bisphosponate therapy should be considered for patients with T scores of <-2.5. Prevention of osteoporosis with bisphosponates should be considered on an individual patient basis, recognizing that there has not been any proof that this treatment prevents fractures. No studies have been published to date that address the safety or efficacy of strontium, selective estrogen receptor modulators, cyclical parathyroid hormone, or the RANKL inhibitors (denosumab) in the transplant population.

Fertility and contraception

Impairment in normal menstrual function that is present before transplantation has been shown to resolve after transplantation in women who receive kidney and liver transplants [141,142]. Similarly, normal fertility has been reported after renal transplantation in men [143–145]. In contrast, male renal transplant recipients who received immunosuppression with sirolimus were shown to have a significant reduction in total sperm count, decreased proportion of motile spermatozoa, and a decreased fathered pregnancy rate compared with transplant recipients who did not receive sirolimus [146].

The National Transplantation Registry Database now reports that 919 transplant recipients have had 1418 pregnancies and 1451 live births, including twins and triplets [147]. Because of the return to fertility, PCPs should counsel their patients before and after transplantation regarding the use of contraception.

Studies of contraceptive efficacy have been reported in the transplant population for hormonal combination contraception [148–150]. One study of renal transplant recipients demonstrated that the intrauterine device had reduced efficacy in the renal transplant population [151]. No studies to date have reported on the efficacy of progestin-only oral contraception, depomedroxyprogesterone acetate (DMPA), barrier contraception, or emergency contraception in this population. Most experts consider barrier contraception to be the safest form of contraception in the transplant population.

The following issues are of particular concern to the transplant population. Combination oral contraceptive agents have been shown to inhibit the cytochrome P450 3A4 pathway [152] and thus may cause increased levels of CNIs. They also can cause decreased clearance of steroids such as prednisolone [153] and thus increase the risk of steroid-related side-effects. Patients on chronic CNIs are at an increased risk for atherosclerosis. Thus, any transplant patient with known coronary or cerebrovascular disease has an absolute contraindication to combination oral contraception. Patients who have hypertension, diabetes, or hyperlipidemia have a relative contraindication. The primary concern about DMPA in transplant recipients is the increased risk of osteoporosis associated with the use of this agent [154]. In addition to efficacy concerns, the intrauterine device also poses additional problems for the transplant recipient because of the increased risk of infection associated with immunosuppression.

Table 34.2. Contraindicated and safe vaccines in transplant recipients

Contraindicated live virus vaccines	Safe killed virus vaccines
• Varicella	• Human papilloma virus
• Herpes zoster	• Hepatitis A
• Intranasal live attenuated influenza virus	• Hepatitis B
• Measles, mumps, rubella	• Influenza (injectable form)
• Oral polio	• Diphtheria toxoid
• Oral live attenuated typhoid	• Tetanus toxoid
• Calmett–Guerin bacillus (BCG)	• Pertussis
• Yellow fever	• Hemophilus influenza type B (HIb)
	• Inactivated polio
	• Pneumococcal
	• Meningococcal
	• Rabies
	• Typhoid
	• Japanese encephalitis virus

Immunization

The potent immunosuppressive regimens for transplant recipients make them candidates for appropriate immunization protocols. Though killed virus- and toxin-derived vaccines are safe in the transplant recipients, many transplant recipients (up to 89%) are not adequately informed about immunizations [155]. Antibody responses to inactivated virus immunizations have been shown to be protective for influenza [156–159], pneumococcus [160,161], and hepatitis B virus [162,163]. A rapid decline in titers has been demonstrated for hepatitis A virus [164] when patients are immunized after transplantation.

Because of the rapid decline of antibody response to immunizations in the transplant population, studies are underway on the effects of booster immunizations. A booster influenza immunization strategy has been shown to increase therapeutic titers in the liver transplant population [165].

PCPs should advise patients to update all immunizations before transplantation and should counsel their patients to avoid family members who have received live virus vaccines for 2 weeks. Though preliminary studies have shown that live virus vaccines with measles, mumps, rubella and varicella are safe in selected pediatric liver transplant recipients [166], PCPs should continue to council adult transplant recipients to avoid live virus immunizations. Table 34.2 shows vaccines that are considered to be safe and those that are contraindicated in transplant recipients.

Smoking in transplant recipients

The Center for Disease Control (CDC) reports that smokers comprise 25.5% of the population in the US. It would thus not be surprising that tobacco use is common among transplant recipients. Studies of liver, kidney, and simultaneous kidney–pancreas transplant recipients have shown independent risks of increased morbidity and mortality associated with smoking. Among liver transplant recipients, smoking has been demonstrated to increase mortality [167], malignancy rates [168,169], biliary complications [170], and post-transplant length of stay and resource utilization [171]. Kidney transplant recipients with a history of smoking also have reduced survival [172–174] and an increased risk of graft failure [173,175], major cardiovascular disease, and malignancy [173].

In a retrospective study of 997 live donor kidney recipients, Nogueira et al. showed that a history of ever smoking conferred a greater risk of death when compared with never smokers (adjusted HR 1.47; 95% CI 1.08–1.99; $P = 0.01$) [172], and even among those who were not actively smoking at the time of their transplant. Kasiske et al. demonstrated in a retrospective chart review of 1228 renal transplant recipients that there was a dose effect of tobacco on mortality rates, and that if recipients had quit smoking over 5 years prior to transplant, the mortality rates were reduced [173]. Smoking has also been shown to cause progression of macroangiopathy and mortality in type 1 diabetic patients who have undergone simultaneous kidney–pancreas transplantation [176].

Banas et al. reported that a significant proportion (27.6%) of renal transplant patients were able to quit smoking [177]. In a cohort of patients undergoing liver transplantation for alcohol-related liver disease, DiMartini et al. showed that 3 months after transplantation 50% had returned to smoking [178].

Despite the negative impact of tobacco on transplant recipients, there are no data on the efficacy of tobacco cessation assessment and counseling or pharmacologic interventions in this group. Tobacco cessation techniques that have been shown to be successful in the general population, such as motivational interviewing techniques, nicotine replacement therapy, and bupropion could be considered in the transplant population. While varenicline is successful in the general population, it should be used with caution in transplant recipients because of the increased risk for anxiety and depression associated with the use of the drug [179,180]. At present the guidelines for the care of the renal transplant recipient state: "Active measures against tobacco smoking are recommended" [181].

Cancer screening

Immunosuppressive therapy is associated with an increased risk of malignancy through the reduction of cancer immunosurveillance, the increased risk of cancer promoting viral infections, and the possible direct carcinogenic effects of immunosuppressants. As a result, transplant recipients have been shown to be at three- to four-fold increased risk of developing cancer compared to the general population [182]. Increased standardized incidence ratios, defined as the ratio of the observed number of cancers over the expected number of cancers, have been shown to occur for non-Hodgkin's lymphoma, cancers of the cervix, vulva, kidney and thyroid, Kaposi's sarcoma, and non-melanoma skin cancer [183]. Independent risk factors for the development of cancer in the transplant population have been shown to include the duration and intensity of immunosuppression [184], hepatitis C virus infection, smoking, alcoholism, sun exposure [185], male gender, and age older than 45 years [184].

Despite the fact that malignancy is one of the most common causes of post-transplant mortality [186,187], transplant recipients are often unaware of this increased risk [188]. In a self-administered survey of 338 transplant recipients, Kauffman et al. demonstrated that 35.5% report knowing "nothing" or "not much" about the warning signs of cancer. Less than half reported knowing "a lot" or "all" about important cancer risk factors. Only 30.3% reported that they had learned "enough" about cancer prevention. It is therefore not surprising to learn that a telephone survey of 60 liver transplant recipients in one academic transplant program revealed that yearly screening for skin or oral cancer occurred in only 40% of patients. Breast cancer screening took place in 38% of the women, and 11% of women had received cervical cancer screening in the past 2 years [189].

PCPs should be aware of this increased risk among their transplant recipients and follow current guidelines for screening and cancer surveillance published by the United States Preventive Services Task Force, the Canadian Medical Association, and the American Cancer Society [190–192]. While these publications do not include guidelines for screening in transplant populations, recent guidelines for cancer screening have been published for liver [68] and renal [39] transplant recipients. In addition, it is important for PCPs to counsel their patients regarding the increased risk for malignancy before undergoing transplantation, as well as the importance of taking steps to prevent cancer, such as smoking and alcohol cessation, prevention of obesity, eating a healthy diet daily, the use of sun block with an SPF of at least 30, and human papillomavirus (HPV) immunization prior to transplantation.

Drug interactions

Drug interactions are commonly reported with immunosuppressive agents and can manifest as pharmacokinetic or pharmacodynamic interactions. Pharmacokinetic interactions arise from alterations in absorption, metabolism, distribution, and elimination, and can lead to increases or decreases in drug concentrations. Pharmacodynamic interactions arise from additive toxicities of two drugs. Table 34.3 summarizes drug interactions for patients taking immunosuppressive agents.

Table 34.3 Common drug interactions with immunosuppressive agents

Drug	Interaction	Comments
Calcineurin inhibitors (CNIs): cyclosporine (CSA); tacrolimus (TAC)		
Azole antifungals:	Increase CNI concentrations	Decrease CNI dose and monitor levels twice weekly
Fluconazole	Increase by 30–40%	
Itraconazole	Increase by 50%	
Ketoconazole	Increase by up to 80%	
Posaconazole	Increase CSA by 25%; increase TAC by 66%	
Voriconazole	Increase by 40–50%	
Dihidropyridine CCBs:	Increase CNI concentrations:	Monitor CNI levels weekly or twice weekly
Diltiazem	Increase by 25–50%	
Verapamil	Increase by ≤25%	
Macrolide antibiotics:	Increase CNI concentrations:	Azithromycin is best alternative with less potential for interaction
Clarithromycin	Increase by 25–50%	
Erythromycin	Increase by 50%	

(*Continued*)

Table 34.3. (*Continued*)

Drug	Interaction	Comments
Other antimicrobials:		
Amphotericin B	Additive nephrotoxicity	Use lipid products or alternative antifungal, if possible
Aminoglycosides	Additive nephrotoxicity	Use alternative antimicrobial, if possible
Anidulafungin	Increased anidulafungin concentrations (CSA only)	No dose adjustment needed
Caspofungin	Increased caspofungin concentrations	Avoid with CSA; monitor liver function tests with TAC
Rifabutin	Decreased CNI concentrations	Monitor CNI levels weekly or twice weekly
Rifampin	Decreased CNI concentrations	Monitor CNI levels weekly or twice weekly
HMG Co-A reductase inhibitors (statins):	Increased statin concentrations (CSA > TAC)	Start statin at lower dose and titrate upward slowly; monitor closely for rhabdomyolysis
Atorvastatin		Avoid lovastatin with CSA and TAC
Fluvastatin		Fluvastatin and pravastatin may have less potential for interaction
Lovastatin		Avoid simvastatin with CSA
Pravastatin		
Rosuvastatin		
Simvastatin		
Bile acid resins:	Decreased CNI absorption	Separate dose of CNI from bile acid resin by 4 h
Cholestyramine		
Colsevelam		
Colestipol		
SSRIs:	Increased CNI concentration	Use alternative SSRI or antidepressant if possible
Fluvoxamine	Increased concentrations at high doses only	
Fluoxetine		
Paroxetine		
Other antidepressants:		
Nefazodone	Increased CNI concentrations	Avoid combination; use alterative antidepressant agent
St. John's wort	Increased CNI concentrations	Avoid combination; rejection reported with CSA
Anticonvulsants:	Decreased CNI concentrations	Monitor CNI levels weekly or twice weekly
Carbamazepine		Use alternative agent when possible (i.e. for neuropathy)
Phenobarbital		
Phenytoin		
Protease inhibitors:	Increase CNI concentrations (>100% for ritonavir-based regimens)	For ritonavir-based regimens: use single low-dose CNI (CSA 25 mg or TAC 0.5 mg) and monitor CNI level daily before redosing; CNI often dosed as single dose weekly
Amprenavir		
Atazanavir		
Fosamprenavir		Less effect from fosamprenavir; unknown magnitude for atazanavir and tipranavir (may use lower CNI dose twice daily and monitor CNI level)
Indinavir		
Lopinavir		
Nelfinavir		
Ritonavir		
Saquinavir		
Tipranavir		
NNRTIs:	Altered CNI concentrations:	Monitor CNI levels and adjust dose accordingly
Delavirdine	Increased CNI concentrations	
Efavirenz	Decreased CNI concentrations	
Etravirine	Increased CNI concentrations	
Nevirapine	Decreased CNI concentrations	
Antacids	Decrease TAC absorption (only)	Separate doses from TAC by at least 2 h
Miscellaneous agents:		
Cimetidine	Increase CNI concentrations	Use alternative H_2 blocker
Mycophenolate mofetil (MMF); mycophenolic acid (MPA)		
Antacids	Decreased MMF/MPA absorption	Separate doses from MMF/MAP by at least 2 hours
Antivirals:	Additive bone marrow suppression:	Monitor CBC for evidence of bone marrow suppression
Acyclovir	*Renal failure*:	Decrease MMF/MPA dose accordingly
Ganciclovir	Increase MPA concentrations	Decrease antiviral dose accordingly
Valacyclovir	Increase antiviral concentrations	
Valganciclovir		
Bile acid resins:	Decreased MMF/MPA absorption	Separate dose of MMF/MPA from bile acid resin by 4 h
Cholestyramine		
Colsevelam		
Colestipol		
Proton pump inhibitors:	Decreased MMF/MPA absorption	Use H_2 blocker or increase MMF/MPA dose
Lansoprazole		
Omeprazole		
Pantoprazole		
Rabeprazole		
Azathioprine		
Bile acid resins:	Decreased azathioprine absorption	Separate dose of azathioprine from bile acid resin by 4 h
Cholestyramine		
Colsevelam		
Colestipol		
Xanthine oxidase inhibitors:	Increased azathioprine concentrations	Reduce dose of azathioprine by 50–75%
Allopurinol		
Febuxostat		
Proliferation stimulation inhibitors: sirolimus; everolimus		
Same interactions as with calcineurin inhibitors		

CCB, calcium channel blocker; SSRI, serotonin reuptake inhibitor; H_2 blocker, histamine-2 blocker; NNRTI, non-nucleotide reverse transcriptase inhibitor.

Table 34.4. Summary of recommendations for the primary care of transplant patients

Coordination of care	Primary cphysicians (PCPs) and specialists should assure that they collaborate closely on transplant patients; establishing the division of labor between specialists and generalists would optimize care and reduce redundancies
Timing of referral	Early referral of patients with chronic kidney disease (CKD) increases the likelihood of pre-emptive transplantation and can reduce morbidity, mortality, and the cost of care
Optimizing adherence	PCPs should work to improve adherence by diagnosing and treating depression, anxiety, and substance abuse
Hypertension	• Blood pressure target is <130/<80 mmHg for liver and renal transplant recipients and for all transplant recipients with CKD or other cardiac risk equivalents • All classes of blood pressure agents have been shown to be effective in the transplant population
Hyperlipidemia	• The target LDL is <100 mg/dL for renal transplant recipients • HMG-CoA reductase inhibitors that are not metabolized by the CYP450 3A4 system should be considered as first-line therapy for hyperlipidemia (fluvastatin, pravastatin) • Transplant recipients on calcineurin inhibitors (CNIs) are at increased risk of statin myopathy, and thus CPK levels should be checked along with transaminases during follow-up
Diabetes	• Transplant recipients should be carefully screened for new-onset diabetes after transplant • Recommendations of the American Diabetes Association should be applied to the transplant population
Osteoporosis	• Transplant recipients are at increased risk of developing osteoporosis • Vitamin D supplements, calcitonin, and bisphosphonates have been shown to reduce the decline in bone mineral density over time
Fertility and contraception	• Women of child-bearing age should be counseled about the need for contraception after transplant • Barrier contraception is considered the safest form of contraception in the transplant population • Combination hormonal contraception has been shown to be effective in this population, but may cause an increase in CNI levels
Immunization (see Table 34.2)	• Killed virus and toxin-derived vaccines are safe in the transplant recipient • Transplant recipients should avoid live virus vaccines and family members who have received live virus vaccines for 2 weeks
Smoking	• Active measures including motivational interviewing and nicotine replacement therapy are recommended
Cancer screening	• Transplant recipients are at 3–4 fold increased risk for developing cancer compared with the general population • PCPs should follow guidelines on cancer screening that are published for liver and renal transplant recipients

The CNIs, cyclosporine and tacrolimus, are substrates for cytochrome P450 3A4 (CYP 3A4) enzymes, a common pathway for the metabolism of many drugs. As a result, many pharmacokinetic drug interactions are reported with the CNIs. The proliferation signal inhibitors (PSIs), sirolimus and everolimus, are also substrates for CYP 3A4 enzymes. There are fewer reported drug interactions with the PSIs, but this is mainly related to the fact that these agents are not used as extensively as the CNIs. It is expected that drugs that interact with the CNIs will also alter PSI levels in the same way. Drugs that inhibit CYP 3A4 activity will decrease the metabolism of CNIs and PSIs, thereby increasing serum concentrations of the immunosuppressive agents. These interactions are generally mediated by competitive inhibition of the CYP enzymes; therefore, serum concentrations of the immunosuppressive agents will be expected to increase almost immediately, within 24 h, of starting the interacting agent. If the magnitude of the interaction is known, it is wise to empirically decrease the dose of the immunosuppressive agent correspondingly at the time the interacting drug is started. Alternatively, drugs that induce the activity CYP 3A4 enzymes will be expected to increase metabolism of CNIs and PSIs, thereby reducing serum concentrations of the immunosuppressive agents. Unlike inhibition, induction of CYP activity requires an up-regulation of enzyme production, which generally occurs over the course of several days. Therefore, serum concentrations of the immunosuppressive agents will not be expected to fall for several days and will not reach the steady-state nadir for nearly a week after starting the interacting drug. When starting a drug that is known to induce CYP enzyme activity, the interaction is best managed by monitoring serum concentrations of the immunosuppressive agents more frequently and adjusting the dose once serum concentrations begin to fall.

Drugs and herbal products known to stimulate the immune system should be avoided when possible to prevent potential rejection. Herbal products known to stimulate the immune system that should be avoided include, but are not limited to: echinacea, alfalfa, and black cohosh.

Summary

PCPs have the opportunity to affect dramatically the burden of chronic medical conditions that occur as a result of immunosuppressive therapy after solid organ transplantation. Table 34.4 provides summary recommendations on the primary care of the transplant recipient.

CHAPTER 35

Role of Primary Care Provider in the Referral and Care of Thoracic Organ Transplant Patients

Remzi Bag,[1] Arvind Bhimaraj,[2] and Sireesha Garikipati[3]

[3] University of Texas Medical Branch, Galveston, TX, USA

Introduction

Since the initial successful heart transplantation in 1967 by Christiaan Barnard and combined heart and lung transplantation by Bruce Reitz and Norman Shumway in 1981, the field of thoracic transplantation has evolved with major advances in the selection of candidates, operative techniques, critical care management, immunosuppression, long-term screening, and follow-up. Although there are no data on the prevalence of lung failure requiring lung transplantation, 10% of heart failure patients are estimated to be in an advanced stage (ACC/AHA stage D) [1]. Transplantation has become an increasingly viable option for such patients who remain symptomatic despite optimal medical treatment and other surgical interventions. By the end of 2011, approximately 100 000 heart, 38 000 lung, and 4200 combined heart–lung transplants were reported to the International Society of Heart and Lung Transplantation (ISHLT) [2]. While the number of lung transplants performed annually in the US has gradually increased, that of heart transplants has fluctuated over the past decade [3], with 1670 adults undergoing lung and 1853 undergoing heart transplantation in 2009 [4]. With improving survival rates over the years, the number of patients living with heart or lung transplants has increased gradually to 20 369 and 7425, respectively, in 2009 [4]. Accordingly, more patients now are referred for transplant evaluation and co-managed by the transplant center and non-transplant physicians while listed and waiting for organ availability than in any previous year on record. As post-transplant patients live longer, they are expected to develop new chronic medical conditions, some related to their original illness, and some as sequela of immunosuppressive therapy. Moreover, as years pass from transplantation, surveillance for rejection and follow-up become less vigilant and patients, particularly stable ones, may return back to their primary care physicians (PCPs) for all general medical care unrelated to the transplant. Partnership between transplant and non-transplant physicians is required to provide comprehensive care in the transplant candidates for timely referral, evaluation, timing of transplantation, optimization of comorbidities, and preparation for transplantation; and in the recipients for long-term care and management of pretransplant and new comorbid conditions. PCPs can manage most common comorbidities arising in the thoracic transplant patient, including hypertension, diabetes, dyslipidemia, osteoporosis, and infections; help patients maintain a healthy lifestyle, diet, and exercise; and are on the front line to screen for malignancy (Table 35.1).

The purpose of this chapter is to assist PCPs in the management of chronic medical conditions occurring after thoracic transplantation, as well as to provide advice regarding specific disease prevention through screening, immunization, sexual and reproductive health, and health maintenance. Chapter 34 is a companion chapter covering similar topics for abdominal transplantation.

Coordination of care

Although it is recognized that collaboration between specialists and community physicians leads to improved outcomes [5] and elimination of errors by shared information, standards of coordination of care are not established for lung or heart transplantation. Communication between the transplant team and generalist is the primary feature improving care for transplant recipients. Poor communication between the providers can impair patient safety, decrease patient satisfaction, and increase economic burden of care. Direct voice or written communication has been the mainstay of information exchange, and has well-recognized limitations. In the future, broader utilization of health information systems is expected to improve coordination of care with better communication and collaboration between specialties. Initial consultation requests should include the background data collected and the question to be answered. Copies of clinic notes should be shared between the providers in a timely manner even when there is no or little change in status [6]. In general, given their proximity and relationship to the patient, non-transplant physicians can best achieve continuous management of health maintenance, preventive care, and common chronic comorbidities [6]. The generalist's office is tailored to provide these services with appropriate facilities, electronic reminders, support staff, and proper patient education materials.

The medical care of heart and/or lung transplant patients is unique because of the possibility of acute or chronic rejection; immunosuppression with its associated risk for toxicity, infection,

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Table 35.1. Major domains for contribution of care by non-transplant healthcare providers

Pretransplant phase
- Identification of candidates for transplantation
- Timely referral
- Optimization of treatment of chronic respiratory or heart failure:
  - Medical treatment
  - Pulmonary or cardiac rehabilitation
  - Adherence
- Treatment of pre-existing comorbidities
  - Hypertension
  - Diabetes mellitus
  - Dyslipidemia
  - Osteoporosis/osteopenia
  - Mood disorders (anxiety, depression)
- Avoid sensitization by limiting transfusion of blood products
- Health maintenance
  - Preventive care and age-appropriate cancer screening
  - Counseling against substance use
  - Exercise, cardiac or pulmonary rehabilitation
  - Weight optimization
  - Immunization

Post-transplant phase
- High index of suspicion for rejection and infection
- Avoid drug interactions
- Contact transplant center as indicated (Table 35.2)
- Treatment of pre-existing and de-novo comorbidities (as above)
- Health maintenance (as above)
- Adherence

Table 35.2. Indications for non-transplant physician to contact the transplant center

General
- Hospitalization
- Change in medication (addition or deletion)
- Hypotension or unexplained drop in systolic pressure of 20 mmHg from baseline
- Increase in resting heart rate of >10 bpm over baseline
- Fever ≥101 °F or any unexplained fever ≥100.5 °F for ≥48 h
- 2 lb or more weight gain in 1 week
- Unexplained weight loss of >5 lb
- Elective surgery

Cardiopulmonary
- Increased shortness of breath
- Pneumonia
- Any respiratory infection in a lung transplant patient
- Decline of >10% in FEV_1 in lung transplant patients
- Syncope
- Chest pain other than musculoskeletal
- Myocardial infarction, arrhythmia, change in ejection fraction

Gastrointestinal
- Abdominal pain other than constipation or gas
- Nausea, vomiting, or diarrhea
- Major abdominal disease

Neurologic
- Cerebral vascular event
- Seizure
- Mental status changes

Other
- New-onset renal failure
- Malignancy
- Intolerance to oral medications
- Non-compliance

Modified from the American Society of Transplantation guidelines [7].

and malignancy; the modification of presenting signs and symptoms by antirejection medications; and the toxicities and drug interactions of antirejection medications. Moreover, there are allograft-specific issues such as painless ischemia in heart recipients and airway strictures and hyperexpansion of the native lung in lung transplant recipients. Because of the unique management issues, the American Society of Transplantation recommends that major changes in the clinical condition of a transplant recipient are communicated to the transplant center in a timely manner (Table 35.2) [7]. Such communication is also important for listed patients who are usually provided with instructions to directly report and access the transplant team for any clinical changes. Based on Organ Procurement and Transplantation Network (OPTN) data, approximately 700–800 patients on a waitlist for a heart or lung transplant die annually [8]. Worsening heart failure, as indicated by need for inotropic support, could potentially need escalation of interventions that finally can lead to an upgrade in the listing status. Changes in functional capacity, worsening oxygenation with increased supplemental oxygen requirements, need for continuous mechanical ventilation, pulmonary hypertension, changes in spirometry, creatinine or arterial blood gases in lung transplant candidates should be communicated to the transplant center as they affect the listing status for organ allocation. Hospitalizations and illnesses like infections, pulmonary emboli, and strokes, should also be communicated to the listing center to be translated into changes in transplant candidacy.

Pretransplant phase

Early identification and referral of patients with end-stage heart or lung disease for advanced therapies is an important step in the care of chronic heart or respiratory failure; and is discussed in detail in Chapters 30 and 31. Transplantation should be discussed with the candidate early in the course of a progressive decline in health, long before the patient needs to confront it as an immediate personal option. Timely referral allows thorough evaluation, discovery, and mitigation of previously unknown comorbidities, improved nutritional and functional status, and preparation of the patient and his/her family for the life-changing events of transplantation. Although the average wait from listing to transplantation has substantially improved in the US after the introduction of lung allocation scoring system in 2005, wait times for some subgroups, such as patients with antibodies against human leukocyte antigens (HLAs), may be as long as 2 years. Disease-specific candidate selection for transplantation usually follows the published international guidelines and is discussed in detail in Chapters 30 and 31 [9–13]

Optimization of medical treatment

With advances in critical care and immunosuppression, and as detailed in Chapters 79 and 106, there has been improvement in short and long-term survival after thoracic transplantation in the past decade. However, thoracic transplant outcomes trail those of liver or kidney transplantation. Efforts to physically, medically, emotionally, and psychosocially optimize the patient and prepare him/her for surgery may reduce the risk of complications and improve outcomes.

Pulmonary and cardiac rehabilitation

Exercise performance is reduced in chronic respiratory or heart failure. The functional impairment results from reduced aerobic capacity and decreased maximal oxygen consumption, and correlates with dyspnea, muscle strength, pulmonary function, or central and peripheral circulatory abnormalities. Skeletal muscle

dysfunction is well documented in both chronic obstructive pulmonary disease (COPD) and congestive heart failure (CHF), but is also present in other forms of chronic respiratory failure [14–17].

Measures of functional capacity (maximum oxygen consumption during cardiopulmonary exercise testing, 6-min walk test, clinical staging of functional class, etc.) are important prognostic factors in patients with chronic cardiac and respiratory failure. Lower exercise capacity is associated with lower survival in patients with these conditions; therefore, it may have an impact on survival to transplantation and beyond [18–23].

Both lung and heart transplantation are major surgical procedures that carry substantial risk of perioperative complications and mortality. Although randomized controlled trials of the benefits of pulmonary rehabilitation prior to lung transplantation are lacking, patients with maximum preservation of exercise tolerance and undergoing postoperative rehabilitation have faster recovery and better outcomes in thoracic surgical procedures. Physical training is safe and effective with improvements in functional capacity, dyspnea, and health-related quality of life in COPD, interstitial lung disease, cystic fibrosis, pulmonary hypertension, and heart failure [24–29]. Exercise training was associated with modest significant reductions for hospitalizations, all-cause mortality, and cardiovascular mortality in a large cohort of patients with chronic heart failure [30].

Preoperative pulmonary or cardiac rehabilitation may identify persons who are non-adherent, too debilitated, or lack adequate social support, and therefore who may be poor or suboptimal candidates for transplantation [31].

Despite increasing validation of the role exercise training plays in the modification of exercise intolerance, challenges remain in its routine therapeutic application including acceptance, limited insurance coverage, tailoring of exercise programs to best address the needs of subgroups of patients, and improved short and long-term adherence to exercise training and a physically active lifestyle [32]. Referring physicians are encouraged to prescribe exercise training in the form of cardiac or pulmonary rehabilitation and daily exercise programs as an adjunct intervention in the management of the patient with chronic heart or respiratory failure, starting with the diagnosis and continuing after the transplantation.

Optimizing weight and nutritional status

Pretransplant nutritional status varies according to the underlying lung disease and may lead to underweight, overweight, or obesity. The cause of malnutrition in individuals with end-stage lung or heart disease is multifactorial, including decreased dietary intake, increased energy expenditure, release of inflammatory cytokines, malabsorption, and frequent hospitalizations. Body mass index (BMI) is commonly used to classify underweight (BMI $<18.5\,kg/m^2$), overweight (BMI 25–29.9 kg/m^2), obesity (BMI $\geq 30\,kg/m^2$), and extreme obesity (BMI $\geq 40\,kg/m^2$). Obesity is a worldwide epidemic with increasing prevalence in the recent decades. Results from the 2007–2008 National Health and Nutrition Examination Survey (NHANES) indicate that an estimated 73.9% of US adults have a BMI of $\geq 25\,kg/m^2$, with 34.2% overweight, 33.8% obese, and 5.7% extremely obese [33].

Obesity is listed as a relative contraindication in the international guidelines for selection of lung transplant candidates [13]. The United Network for Organ Sharing (UNOS) data show that >15% of lung transplantations in the US were performed on obese patients. Given that 73.9% of US adults are overweight or obese, this percentage is likely to rise. Overweight and obese patients are considered at risk for developing associated morbidities such as hypertension, dyslipidemia, type 2 diabetes, coronary heart disease, stroke, malignancy, and other diseases, and therefore are at increased risk for both perioperative and long-term mortality and morbidity. Moreover, obesity is an independent risk factor with obese patients showing a two-fold increased risk of primary graft dysfunction after adjusting for center, diagnosis, cardiopulmonary bypass, and transplant procedure [34]. Single-center retrospective studies suggest obese individuals have a mortality risk more than three times greater than that for non-obese individuals [35,36]. In a large retrospective multi-institutional data analysis, the increase in mortality risk was 15% for obese patients and 14% for underweight (BMI $<18.5\,kg/m^2$) patients after lung transplantation [37]. In another retrospective analysis of a US cohort of recipients with COPD, cystic fibrosis, and diffuse parenchymal lung disease, the three most common diagnostic groups for lung transplantation, the adjusted odds of death were greater for any patient outside of normal BMI for either 1 year or 5 years, with 1-year mortality of 27%, 40%, and 34% greater among overweight, obese, and underweight patients, respectively, compared with normal weight recipients [38]. The increased risk of death is mediated by primary graft dysfunction, respiratory failure, infection, cardiac disease, and cancer in overweight and obese patients. Deaths in underweight patients can be attributable to infection, diaphragmatic weakness, respiratory failure related to poor nutritional status, and chronic allograft dysfunction [34,37,38]. Nutritional depletion and underweight are also risk factors for death while on the waitlist [39,40].

There is strong evidence that weight loss decreases the associated morbidity and mortality of transplantation [41]. Because the majority of lung transplant recipients fall outside the normal BMI range, there is a significant opportunity to improve survival outcomes. Primary providers are encouraged to follow available guidelines to optimize nutritional status of transplant candidates with appropriate corticosteroid withdrawal and avoidance, nutritional counseling and dietary modification (including enteral nutritional support in the underweight), exercise and lifestyle changes for all patients, and surgical and other treatments in select patients [42,43]. Bupropion and the selective serotonin reuptake inhibitor (SSRI) fluoxetine at high doses (60 mg/day) have both appetite suppressant and mood altering properties. Early mortality rates following bariatric surgery are 1% or less in large published controlled trials. In case reports for lung transplant candidates, bariatric surgery was helpful not only to achieve sustained weight loss, but also lead to a reduction of comorbid conditions [44,45].

Overweight and obese lung transplant recipients have lower fat-free mass, and lower levels of physical activity and resting energy expenditure compared to normal weight recipients. Moreover, substantial weight gain occurs in the first year after lung transplantation with increased risk of late mortality attributable to abnormal BMI [38,46,47]. Therefore, lung transplant recipients should continue to be mindful about their dietary intake and participate in pulmonary rehabilitation and exercise programs after lung transplantation in order to prevent the development of overweight or obesity.

For the cardiac transplant candidate, BMI is an important predictor of survival on the waitlist and post-transplant outcomes, including perioperative morbidity, post-transplant cardiovascular comorbidities, long-term complications, and mortality [48]. ISHLT

guidelines recommend that candidates should achieve a BMI of $<30\,kg/m^2$ (or percentage ideal body weight of <140%) before being listed for cardiac transplantation [12]. Obese individuals are underrepresented in the demographics of orthotopic heart transplantation (OHT), wait substantially longer for organs, and are less likely to receive OHT once on the waiting list. Moreover, metabolic syndrome pre heart transplant and/or its development in the early post heart transplant period negatively impacts long-term prognosis [49]. Analysis of 19593 OHT recipients in the UNOS database found that a BMI of $18.5–34.9\,kg/m^2$ does not have a significant impact on mortality, perioperative morbidity, post-transplantation cardiovascular comorbidities, and the long-term complications of transplantation [50]. Therefore, the presence of metabolic syndrome or obesity with a BMI of $>30–34.9\,kg/m^2$ pre transplant is not necessarily a contraindication for heart transplantation; instead, the patient requires close monitoring and alternative treatment regimens. However, the relationship between BMI and post-transplant outcomes is U-shaped with the extremes [i.e. the underweight (BMI $<18.5\,kg/m^2$) and obese (BMI $>35\,kg/m^2$)] experiencing worse outcomes. The diminished survival in the underweight patients results from excess morbidity in the first year post transplantation, whereas the diminished survival in those with a BMI of $>35\,kg/m^2$ appears to be due to increasing mortality beyond the first postoperative year [50]. Hence, many centers consider a BMI of $>35\,kg/m^2$ as a contraindication for OHT due to concerns of postsurgical and long-term decreased survival [50]. Because nutritional status is a potentially modifiable risk factor, the development of strategies designed to optimize nutritional status in end-stage heart failure patients may prolong survival in the absence of transplantation and lessen the short-term risks in the post-transplant period, thus expanding the benefit of transplantation [51–54].

Optimizing adherence

The treatment regimen of a transplant patient consists of lifelong medications, including immunosuppressants; monitoring for signs and symptoms of rejection, infection or other complications; avoidance of risk factors for cardiovascular disease and cancer (i.e. diet and exercise prescriptions, non-smoking); avoidance of abuse/dependence on alcohol or illegal drugs; as well as attending regular clinical check-ups and therapeutic drug monitoring [55]. Non-adherence to treatment regimens is widespread and varies from 7.5% to 37% in heart or lung transplantation [55–61].

Although psychological factors and medical adherence are recognized as being important in the transplant outcomes (and are covered specifically in Chapter 120), no standard approach to psychological assessment currently exists for heart or lung transplant candidates [62–64]. Non-adherence is more common in adolescents and patients with anxiety and depression, personality disorders, and neurocognitive disorders. It is worse in patients who live alone, are unemployed or lack social support [65]. Thoracic transplant candidates experience high levels of psychological distress while awaiting transplant and both pretransplant and post-transplant psychological functioning have been found to predict post-transplant quality of life, adherence to treatment, and medical outcomes [66]. Because of their desire to win acceptance from the transplant team, some patients may be guarded and refrain from sharing their concerns with transplant center professionals [66]. Referring physicians who have a long-term relationship with the patients, are uniquely qualified to identify patients who are non-adherent or who may benefit from adherence-enhancing interventions. No single intervention proved to be superior in increasing medication adherence in organ transplantation, but a combination of interventions including patient-focused cognitive, educational, behavioral counseling and psychologic interventions in a team approach may be effective in the long term [67,68]. PCPs can also help improve adherence by lifestyle interventions (exercise, tobacco, alcohol, and substance use), diagnosing and treating anxiety and depression, and addressing social support systems for their patients.

Avoid transfusion of blood products

The presence of anti-HLA antibodies in the sera of transplant recipients, or "humoral sensitization," has been associated with an increased frequency of acute rejection and decreased survival. Patients who are not sensitized and listed for transplant can become sensitized due to various causes, of which exposure to foreign antigens via transfusion of blood products is an important potentially avoidable etiology. The benefit of transfusion of any blood products needs to outweigh the risk of sensitization in transplant candidates.

Post-transplant phase

The important principles to consider while caring for a thoracic transplant recipient are the altered immune system, denervated graft (heart or lung), and a high potential for drug–drug interactions.

Allograft rejection

Rejection after the first weeks of transplantation can be classified into acute cellular rejection (T-cell mediated), acute humoral rejection (antibody and hence B-cell mediated), and chronic rejection. Acute rejection in the lungs manifests as acute vascular rejection or airway inflammation. Chronic rejection is mostly in the form of coronary allograft vasculopathy for the heart and chronic airway rejection (obliterative bronchiolitis) for the lung graft. Chronic vascular rejection is seldom recognized in the lung as it requires open lung biopsy. The complexities and controversies of rejection are beyond the scope of this chapter but are discussed in Chapters 71 and 72. There is a significant variation between centers in techniques used to detect, define, and treat the different kinds of rejection.

While acute cellular rejection is most common in the first 6 months to a year after heart transplantation, with a significant decline in its contribution to mortality beyond 3 years, primary graft failure (loss of cardiac function with no detectable rejection) causes 15–20% of deaths beyond 1 year post transplantation [3]. Irrespective of cause, any compromise in cardiac graft function changes the clinical outcome; hence, high index of suspicion and early recognition of rejection or graft failure is important to intervene with higher level of immunosuppression. Most centers perform surveillance endomyocardial biopsies frequently in the first post-transplant year. Gene expression profiling of the peripheral blood mononuclear cells (Allomap®) may also be used as a non-invasive surveillance tool. In either strategy, surveillance represents only a cross-sectional sampling and cannot reliably predict future episodes with significant residual risk for rejection. Healthcare providers need to be wary of atypical and subtle signs of heart failure as a manifestation of graft dysfunction. Due to denervation of the heart, patients might not have chest discomfort due to

ischemia or a high left ventricular filling pressure. General malaise, early satiety, nausea, and vomiting due to gut congestion are a few atypical presentations.

Rejection is more frequently seen in lung transplant recipients than other commonly performed solid organ transplants. About 35% of lung recipients are treated for allograft rejection in the first year of transplant [2]. After the first year, risk of acute rejection substantially decreases, but is never eliminated. The overall median survival for adult lung recipients is 5.5 years, with mortality mostly due to chronic rejection, the incidence of which increases after the first several months and reaches 50% at 5 years [2]. Rejection episodes can be asymptomatic or manifest with dyspnea, cough, sputum production, fever, hypoxia, rales, wheezing, or rhonchi. Radiographic abnormalities if present are non-specific. Spirometry may show a decrease in forced expiratory volume in 1 s (FEV_1) and forced vital capacity (*FVC*) in up to 60% of rejection episodes [69], but is unable to differentiate between rejection and other causes of allograft dysfunction such as infection, airway complications (stenosis in particular), or pleural effusion. Centers using home spirometric monitoring confirm any decline of >10% with formal spirometry. As clinical presentation, laboratory, and radiographic findings are non-specific and unable to differentiate between the various etiologies of graft dysfunction, including infection, rejection, malignancy, and airway stenosis, etc., non-transplant physicians are encouraged to discuss the findings with the transplant center and arrange for definitive diagnostic studies.

Cardiac allograft vasculopathy (CAV) involves the entire extent of the coronary vasculature and is characterized by intimal thickening due to smooth muscle cell proliferation and extracellular matrix deposition with varying degrees of inflammatory cells; calcification and atheroma formation are uncommon [70]. CAV causes long-term morbidity and mortality with >50% of recipients affected by 10 years post transplant and 10% of patients dying within 1 year of diagnosis. Coronary angiogram is commonly used to screen for CAV. Intravascular coronary ultrasound (IVUS) is more sensitive, but is not universally available. Computed tomogram (CT) angiography is also emerging as a new technology to identify vasculopathy and graft dysfunction [71,72]. Dobutamine stress echocardiogram not only detects significant CAV, but also is a good prognostic marker for mortality [73].

Though immune mechanisms play a predominant role in the pathogenesis of CAV, many metabolic risk factors, including insulin resistance and hypercholesterolemia, contribute to the onset and progression [74–76]. In a recent study using an IVUS definition of CAV, metabolic syndrome was associated with an eight-fold increased incidence of CAV [77]. Classic risk factors of coronary atherosclerosis, such as age and hypertension, were not consistently associated with CAV [78–80]. Currently there is no consensus on the goals of therapy for any of the metabolic risk factors. However, control of blood pressure, lipids, weight optimization, and smoking cessation should be targeted for the heart transplant recipient just as it is for a non-transplant individual. The role of the non-transplant physician is paramount in controlling such risk factors and possibly reducing the burden of CAV.

There is no effective therapy to significantly impact the outcomes once CAV sets in. Small studies have suggested calcium channel blockers and angiotensin-converting enzyme (ACE) inhibitors to have a protective effect on the development of CAV [81,82]. The proliferation inhibitors sirolimus and everolimus reduce the rate of progression and probably decrease mortality, as shown in small studies, but the side-effect profile of these drugs has precluded their widespread use. All heart transplant recipients should be prescribed a statin irrespective of their cholesterol profile as these delay the onset and progression of CAV [83,84]. Beyond lipid lowering, this class of medications inhibits antigen induction on endothelial cells, monocytes, and macrophages [85]. Early postoperative initiation has been shown to be beneficial, impacting both mortality and rejection [86]. Interactions with calcineurin inhibitors (CNIs) and mTOR inhibitors can lead to higher risk of myopathy and rhabdomyolysis. Hence, pravastatin and fluvastatin are the preferred agents due to their minimal drug interactions. The maximum allowable dosage in patients receiving these immunosuppressants is 80 mg/day. With close clinical and muscle enzyme monitoring, atorvastatin may be considered for moderate-to-severe hypercholesterolemia, despite some metabolism by the P450 system.

Infection

Thoracic transplant recipients are at high risk for various infections due to intense immunosuppression, particularly in the first 12 months and at times of augmentation for treatment of episodes of rejection. Other predisposing factors in lung recipients include loss of cough reflex due to denervation, ineffective mucociliary clearance, and loss of mucosal barrier postoperatively due to cell death resulting from lack of bronchial artery vascularization and ineffective lymphatic drainage. Moreover, the transplanted lower respiratory system remains open to the environment with continued exposure to irritants and micro-organisms. Specific coverage of the infectious issues in long-term transplant recipients is discussed in Chapter 94.

Transplant patients receive extensive education on lifestyle changes to avoid infections, as discussed in Chapter 94 [87]. Prophylactic antimicrobial regimens vary by the thoracic transplant center and commonly include medications for *Pneumocystis jiroveci*, *Toxoplasma gondi*, Candida infections, and cytomegalovirus (CMV). Some lung transplant programs use prophylaxis against aspergillus species. Infective endocarditis is uncommon in OHT but has a high mortality risk of 80%; therefore, prophylaxis is a reasonable option during dental procedures [88,89].

Due to immunosuppressant-induced changes in innate and adaptive immunity, transplant recipients may not always manifest typical signs and symptoms of infection. Vague and generalized symptoms of malaise and fatigue could suggest significant bacteremia and septicemia even in the absence of systemic inflammatory response syndrome. In addition, non-infectious causes of fever such as rejection occur commonly in thoracic transplant recipients. Otherwise uncommon atypical and rare bacterial, mycobacterial, fungal, and viral organisms can cause significant infections in the immunosuppressed thoracic organ recipient. Epidemiologic exposure (nosocomial, community, donor- or recipient-derived infections), travel, and pet history can provide clues to the most likely etiology.

The infection timeline of a transplant patient (not specific to thoracic transplant) can be divided into the first month; the first 1–6 months; and beyond 6 months after transplant [90]. Between 1 and 6 months is the period for the immunomodulating viruses (cytomegalovirus, Epstein–Barr virus, human herpesvirus-6, and the hepatitis viruses B and C) to cause clinical disease; and in combination with a higher immunosuppressant level can lead to opportunistic infections such as *Listeria monocytogenes, Aspergillus fumigatus*, and *Pneumocystis jiroveci*, even without an intense exposure. Beyond 6 months, most patients have a preserved graft

function are at risk mostly for community acquired respiratory infections including viruses (influenza, parainfluenza, and respiratory syncytial virus), while those with any graft dysfunction and or rejection are chronically maintained on higher doses of immunosuppressants and hence at higher risk for opportunistic infections with such organisms as *Pneumocystis jiroveci, Listeria monocytogenes, Cryptococcus neoformans*, and *Nocardia asteroides*.

Early postoperative screening, prophylaxis, and pre-emptive treatment regimens have decreased the incidence of infections. These strategies, while changing the timeline, also lead to the emergence of infections due to organisms with antimicrobial resistance. Early and specific microbiologic diagnosis is essential for guiding treatment and minimizing non-essential drug therapy [91]. Invasive diagnostic procedures are often required for accurate and timely diagnosis. Diagnosis of both infection and rejection require a high index of clinical suspicion as the signs and symptoms are non-specific. Non-transplant physicians are encouraged to contact the transplant center when suspicion of infection or rejection arises, to coordinate the diagnostic studies and appropriate and timely treatment, particularly when the immunosuppression is most intense to circumvent the high risk of rejection in the first post-transplant year.

Hypertension

Hypertension is highly prevalent after heart or lung transplantation, occurring in 50–90% of the recipients [2,92]. Patients often have an abnormal circadian blood pressure profile with nocturnal and diastolic hypertension, making self-monitoring crucial in the identification and treatment of hypertension to goal blood pressure [93,94]. Classic pretransplant risk factors such as high BMI, chronic kidney disease, and hyperthyroidism contribute to hypertension post transplant. In addition, arterial rigidity [95], CNIs (systemic vasoconstriction, renal vasoconstriction and hypersympathetic state, imbalance between prostaglandins and thromboxane and endothelin) [96,97], abnormal baroreceptors [98], and salt sensitivity [99] are mechanisms that have been implicated in development of hypertension post-transplant. The incidence of hypertension and renal dysfunction are comparable in both tacrolimus- and cyclosporine-treated patients [100]. High blood pressure along with other risk factors is suspected to contribute to the occurrence and worsening of CAV in heart transplant recipients [80].

Assessment of hypertension, treatment goals, and lifestyle changes, including weight loss, sodium avoidance, and regular exercise are similar to the general population [101]. When choosing an antihypertensive, comorbid conditions and drug interactions should be considered. Calcium channel blockers might have a physiological advantage to counteract CNI-mediated hypertension. Diltiazem has a significant interaction with CNIs (increases serum levels), while amlodipine does not and hence could be a safe first choice, followed by ACE inhibitors or angiotensin receptor blockers (ARBs). In the presence of proteinuria or diabetes, ACE inhibitors or ARBs are preferred, with close monitoring of serum potassium and renal function [102]. In the presence of azathioprine, ACE inhibitors may cause myelosuppression and should be avoided. Diuretics help reduce concomitant volume overload. Diltiazem has also been shown to reduce the progression of CAV in heart recipients. Beta-blockers are safe for lung transplant recipients, but should be avoided in OHT, especially early after the surgery as the denervated heart is more prone to bradycardia.

Diabetes mellitus

In the ISHLT registry, the prevalence of diabetes at 1 and 5 years is 26.2% and 39.6% for lung transplant recipients; and 28% and 40% for heart transplant recipients, respectively [2,103]. A higher prevalence up to 65% was reported in patients with cystic fibrosis [104]. New-onset diabetes mellitus after lung transplant (NODAT) occurred in 33.4% of the 2991 lung recipients in the UNOS database during the median follow-up of 2 years [105]. Pre-existing diabetes in about one-fifth of recipients can worsen due to steroids and CNIs. Glucocorticoids induce insulin resistance, stimulate lipolysis, and increase hepatic glucose production, while CNIs inhibit insulin secretion through interaction with transcription factors and alteration of mitochondrial function [106,107].

Although post-transplant diabetes mellitus (DM) is recognized as an independent risk factor for cardiovascular events, infections, and graft failure, the effect of DM after lung transplantation has not been studied adequately, with conflicting results on its impact on outcomes [104,108,109]. The use of steroids, CNIs (particularly tacrolimus), weight gain with ensuing insulin resistance, postoperative stress, and infections increase the risk of diabetes or pose challenges for diabetic control [100,110,111]. Other risk factors for NODAT include male gender, recipient age >50 years, African–American ethnicity, and cystic fibrosis [105].

Diagnostic criteria are similar to those for non-transplant patients, except that the hemoglobin A1c (HbA1c) should not be used in the immediate post-transplant period as transfusion of packed red blood cells can alter the results. The international consensus guidelines on NODAT recommend fasting plasma glucose monitoring weekly during the first month, then every 3 months for 1 year, and annually thereafter. A glucose tolerance test is also recommended in patients with impaired fasting glucose concentration in order to increase diagnostic yield [112].

The management of DM after transplantation is similar to that for non-transplant patients, with consideration given to drug toxicities or interactions. In patients with normal or adequate renal, hepatic, and cardiac function, most of the available classes of medications (including insulin sensitizers, insulin secretagogues, and incretins) can be tried before proceeding to insulin. Choice of agent should be tailored to the individual patient. Use of a combination of two or three glucose-lowering agents could be considered. Metformin has been used; however, patients with an unstable glomerular filtration rate may be at increased risk of developing lactic acidosis. High-dose corticosteroids used for induction of immunosuppression or treatment of acute rejection may require temporary insulin therapy for glycemic control. Insulin can be in the form of a single injection of intermediate- or long-acting insulin at bedtime. Better glucose control may be achieved with lower insulin dose plus an oral agent. If the desired level of control is not achieved with initial therapy, then a more aggressive approach will be needed, such as an insulin pump [112]. After hospital discharge, close monitoring of blood glucose during the first year is recommended.

Longstanding poor glycemic control may require conversion of tacrolimus to cyclosporine. Some transplant centers attempt to minimize corticosteroid exposure. Corticosteroid dose reduction needs to weigh the risk of rejection and hence only be done in select patients by the transplant center. Lifestyle modifications such as exercise and weight optimization, and a heart healthy diet with reduced saturated fat and cholesterol, increased complex carbohydrates, and fiber are recommended. In addition to hyperglycemia, appropriate surveillance for complications and the control of comorbidities such as dyslipidemia and hypertension need to be

optimized [113]. Annual screening is performed for diabetic complications as in the general population.

Dyslipidemia

One and 5-year prevalence of hyperlipidemia in lung transplant recipients is 24.7% and 57.5%, respectively [2]. Approximately 66% of the OHT recipients have at least one dyslipidemia despite universal statin usage [114]. Risk factors include personal or family history, inactivity, diet, obesity, hypothyroidism, diabetes, and immunosuppressive medications, including corticosteroids, sirolimus, and CNIs. In one study of 212 heart transplant patients, older age, everolimus use, and lack of statin and/or tacrolimus use were associated with increased low density lipoprotein (LDL) levels, while male gender, pretransplant CAD diagnosis, and lower ejection fraction were associated with low high density lipoprotein (HDL) levels in multivariate analysis [114]. Only higher BMI correlated with a high triglyceride levels. The association of dyslipidemia and specific lipid parameters with CAV or mortality has not been proven, but association of hyperlipidemia with the development of atherosclerotic CAD was shown in larger studies [115,116]. Optimal lipid level goals are not known. In the absence of specific guidelines for lung or heart transplant recipients, guidelines for kidney transplant recipients and the National Cholesterol Education Program's (NCEP) most recently updated recommendations (LDL cholesterol goal of <100 mg/dL) can be used [117,118]. Drug therapy is initiated for a LDL of >130 mg/dL (and should be considered at levels of >100 mg/dL) after 3 months of lifestyle interventions consisting of diet and exercise. Initial drug therapy of hypercholesterolemia should be a statin ([119,120]). Statin use was associated with improved function and survival of lung allografts by prevention of acute and chronic rejection [121]; and delayed onset and slow progression of CAV in heart transplant recipients [83,84]. Ezetimibe may be added to the statin if the response is suboptimal [122,123]. Although side-effects of statins are uncommon, careful monitoring for these, including diabetes, memory loss, confusion, muscle weakness and pain for myopathy and rhabdomyolysis, is warranted. Of the statins, fluvastatin and pravastatin have lower risk of rhabdomyolysis when used in combination with CNIs. Non-transplant physicians should be aware of the increased risk of rhabdomyolysis with a statin and CNI combination; muscle enzymes such as creatinine phosphokinase and aldolase should be followed after initiation of therapy or dose changes. Other potential therapeutic drugs include gemfibrozil, nicotinic acid, and fish oil supplements at high doses [124,125]. Combination of fibrates along with statins requires caution and close follow-up and should be limited to patients with severe elevation of triglycerides. Small studies have shown beneficial reduction of triglycerides with omega-3 fatty acids in patients using m-TOR inhibitors [125]. Bile acid-binding resins may decrease the absorption of immunosuppressive medications, particularly immunosuppressive agents that bind to lipids [118]. Therefore, it is prudent to avoid administering a bile acid sequestrant from 1 h before to 4 h after the dose of CNI and to monitor therapeutic drug levels.

Bone health

With risk factors such as tobacco, inactivity, vitamin D deficiency, low BMI, and prior corticosteroid use, the prevalence of osteoporosis is reported to be up to 61% in lung transplant candidates [126,127]. Other risk factors such as malabsorption and hypercatabolic state may be contributory in patients with cystic fibrosis who have lower bone mineral density (BMD) than those with other causes of end-stage chronic respiratory failure [128–130]. Osteopenia or osteoporosis was observed in more than half of the pretransplant patients with severe CHF [131]. Due to the high prevalence of osteopenia and osteoporosis, vitamin D levels and BMD should routinely be included in the evaluation of lung or heart transplant candidates. Referring physicians and transplant centers should proactively start treatment for abnormal BMD and hypovitaminosis D before the transplant. BMD at the lumbar spine and femoral neck has a significant decrease in the first year after heart or lung transplantation due to high doses of corticosteroids and immunosuppressive therapy [132–136]. Atraumatic fracture rates of 18–38% and a loss of BMD of 4–12% were reported in the first year following lung transplant [130,135–137]. Biochemical markers of bone resorption were significantly higher in patients who sustained bone loss and/or fractures [135].

For prevention and treatment of osteopenia and osteoporosis, physical activity including regular weight-bearing exercises, and avoidance of tobacco and alcohol should be encouraged [138–141]. All patients should receive the recommended daily allowance for calcium (1000–1500 mg/day) and vitamin D (400–800 IU/day). Any vitamin D deficiency should be treated to keep serum 25-hydroxyvitamin D level above 30 ng/mL. Replacement doses of vitamin D and calcium do not reliably prevent clinically significant bone loss after transplantation [134–136]. Calcitriol was shown to decrease the rate of bone loss in the first year after lung or heart transplant, but close monitoring of serum and urinary calcium is required [142,143]. Calcitonin has shown no benefit in preventing early bone loss after transplantation and hence should not be used [144,145].

Controlled randomized and non-randomized studies of heart and lung recipients and ISHLT guidelines suggest that the most effective choice to prevent the increased bone resorption and rapid bone loss early after transplantation is a bisphosphonate [146–150]. Both intravenous (pamidronate, zoledronic acid, ibandronate) and oral (alendronate, risedronate) formulations are available. Bisphosphonates slightly increase the risk of atypical femur fractures. It is not clear if oral bisphosphonate therapy is associated with an increased risk of esophageal cancer. Oral bisphosphonates should be taken first thing in the morning after awakening, with a full glass of plain water. Patients should remain in an upright position for at least 30–60 min after the dose. Recombinant human parathyroid hormone (teriparatide) is effective for treatment of glucocorticoid-induced osteoporosis, but was not shown to improve BMD early after kidney transplantation [151,152]. Due to cost, it should be reserved for those with severe osteoporosis or esophageal dysfunction (stricture, achalasia, scleroderma esophagus, etc.) or intolerance to bisphosphonates.

For follow-up, proximal femur and lumbar spine BMD should be assessed by DEXA or equivalent scan in all adult transplant patients at 1 year and annually thereafter if they remain on corticosteroids [149]. Follow-up testing can range from 2 to 3 years based on the presence of osteopenia or normal range of BMD.

Psychological issues

The psychological stress of receiving a thoracic organ transplant is quite often under-recognized by transplant professionals [153]. In a study from Italy, 41% of heart transplant patients were found to have major depression, while 12% had transplant-related post-traumatic stress disorder [154]. Personality disorders, dysfunctional coping strategies, complications, and side-effects of

immunosuppressant medications, stressful events, limitations in job performance, sexual dysfunction, and lack of psychosocial support contribute to depression [155]. Onset of complications including chronic rejection can cause a decline of functional status associated with a dramatic increase in depressive symptoms. Psychological illness negatively influences the recipient's ability to cope with the new organ and could lead to decreased quality of life, unmet expectations, and non-adherence to rehabilitation and pharmacologic therapy. Effective and reliable psychotherapeutic or psychopharmacologic interventions for depression and anxiety may improve adherence and health-related quality of life. SSRIs are well-tolerated and efficacious for depression, panic disorder, and post-traumatic stress disorder, and replace tricyclic antidepressants as the first-line intervention. Among them, citalopram and escitalopram appear to have the least risk of drug–drug interactions [156]. Adjustments in dosage are required when renal or hepatic impairment is present. Although benzodiazepines are often the drugs of choice for the management of anxiety and insomnia associated with depressive symptoms, caution is suggested with the use of these agents in lung transplant candidates and recipients because of the risk of dependence, the reduction in upper airway muscle tone, and blunting of the arousal response to hypercapnia [157]. Mirtazapine can be effective in anxiety disorders and for depression accompanied by anorexia and insomnia. Complementary therapies and interpersonal, group, family, supportive, or cognitive psychotherapy may help the recipient cope with the psychological adaptation to transplantation [62,155]. A high-intensity exercise program was found to improve exercise capacity, self-perceived health, anxiety, and depression in heart transplant recipients [158].

Self-medication for depression with St. John's wort should be discouraged as there are serious problems including toxicity; contamination with heavy metals, micro-organisms, and pesticides; adulteration and drug–drug interaction leading to lowering of cyclosporine levels [155].

Depression in thoracic transplant candidates or recipients is often regarded as a normal, understandable, and predictable reaction to the physical illness, and remains underdiagnosed and undertreated [159]. Moreover, depressive symptoms in this population may be harder to detect and as there may be atypical features such as irritability, cognitive disturbance, frustration, headache, gastrointestinal complaints, fatigue, sleep problems, decreased appetite, or vague somatic aches [160]. Non-transplant primary providers could make a significant contribution to the health and survival of transplant patients by being vigilant about the psychological stressors, recognizing the associated illnesses by utilizing standard instruments to screen for and treat the common mood disorders, with the caveats discussed above. Referral to psychiatrists with special interest in transplantation may be required for treatment and monitoring in difficult cases.

Return to work, recreation, and life

Transplant patients look and feel their usual self soon after transplant and many wish to resume their pretransplant healthy lifestyle. In the US and other countries, post-transplant employment rates vary greatly from 22% to 86% with follow-up from 1 to 12 years; higher rates are found when the definition of employment is broad, including any paid work or return to school [161–165]. Many patients face issues of coping with maintaining normalcy with a transplanted organ compounded by employer fears of higher health insurance burden and more sick days off work. In spite of the complexities of the task of reintegration of these patients into society, they should be encouraged to be active and productive in order to achieve better physical and mental outcomes. The only restrictions to be enforced are those to avoid activities that could potentially expose them to infections. Recreational activities with increased risk of infection should be avoided. Public pools are a source of infections and hence should be avoided particularly when crowded. Consumption of raw animal protein and handling of raw meat during activities (cooking or hunting) should be avoided.

There are no specific studies addressing limitations in return to driving and operating a vehicle in heart or lung transplant patients. With a 3–10% incidence of syncope in heart transplant recipients, restrictions related to such an occurrence are applicable. State laws differ, but most require a 6-month syncope-free period prior to returning to operating a vehicle. Every effort should be made to identify and correct the cause of syncope. Symptomatic bradycardia should warrant a permanent pacemaker placement. Sinus node dysfunction is declining with many centers adopting a bicaval surgical technique instead of the older biatrial method in heart transplantation [166]. Although one small study showed an incidence of 18%, the true incidence of sudden cardiac death is unknown due to lack of autopsy studies [167].

Sexual and reproductive health

Normal fertility, which most patients have after heart or lung transplantation, poses complex medical, psychosocial, and ethical problems. This complex issue is discussed in depth in Chapter 97. Uncertainties exist, including the risks that pregnancy presents to the graft, the patient herself, and the long-term risks to the fetus [168]. The National Transplantation Pregnancy Registry (NTPR) has acquired experience with 2000 pregnancy outcomes in female transplant recipients: 71–76% of the pregnancies of female kidney recipients produced a livebirth and for the other organs, the live-birth likelihood ranged from 50% to 86% [169]. The incidence of birth defects in the liveborn appears similar to the general population, except for pregnancies with mycophenolic acid exposure that have a 23% incidence of birth defects [169,170]. Long-term follow-up of the offspring of transplant recipients has provided reassurance [169]. The American Society of Transplantation Consensus Conference on Reproductive Issues recommended that individual factors should be considered when offering advice for timing of pregnancy, including risk of acute rejection and infection, concomitant therapy with potentially toxic and teratogenic medications, and adequacy of graft function [168]. Although the patients are at risk of certain maternal, fetal, and neonatal complications, including hypertension, pre-eclampsia, infection, preterm birth, and low birth weight, successful pregnancy outcomes have been reported following heart or lung transplantation [171]. Heart transplant recipients planning to conceive need a baseline graft evaluation with an angiogram if not performed in the last 6 months to document absence of CAV and intact graft function. In the lung recipient, the baseline pulmonary function test should show stable findings. With intact graft function, the physiological changes of pregnancy are usually well-tolerated by heart transplant patients.

Although there is very limited information on pregnancy after lung transplantation, the risk of allograft rejection during and after pregnancy appears significant. Pregnancy in cystic fibrosis lung transplant recipients is feasible, but should still be regarded as a risky undertaking as there is an increased risk of acute rejection in half and progressive allograft dysfunction in all patients after delivery [172].

With the availability of newer agents for which pregnancy safety has not been established, it is unclear how to best modify immunosuppressive agents or treat rejection during pregnancy. To minimize the risk of graft rejection, it is important to maintain an adequate level of immunosuppression with close monitoring throughout pregnancy and in the postpartum period, keeping in mind the risk of fluctuations related to changing body volume and glomerular function. With recent developments in assisted reproductive technologies, controlled ovarian hyperstimulation and gestational surrogacy may be a safer option for patients with a thoracic transplant who wish to have a genetic child [173,174].

Genetic counseling is crucial for patients with hereditary diseases, including congenital heart disease, familial cardiomyopathy, heritable pulmonary hypertension, cystic fibrosis, familial pulmonary fibrosis, and alpha-1 antitrypsin deficiency as their primary transplant etiology. Women who underwent cardiac transplantation for peripartum cardiomyopathy should be advised to avoid pregnancy due to the high risk of recurrence.

The timing of conception after a heart transplant is an area of debate. Most recommend waiting for 2 years before becoming pregnant. Patients need to be counseled regarding the relatively limited long-term survival of thoracic transplant recipients and the impact of pregnancy on long-term outcomes that further confound the ability to participate in raising the child.

Available contraception options are similar to the non-transplanted patient. Intrauterine devices are mostly avoided for fear of infections. Barrier precautions, personal or partner sterilization in adults, and hormonal contraception in adolescents are effective options. Depo-medroxyprogesterone acetate intramuscular injection every 3 months is effective, but is associated with decreased bone density. Combination oral contraceptives can cause decreased clearance of steroids and inhibit the cytochrome P450 3A4 pathway, leading to increased levels of CNIs. If combination hormonal contraception is considered, a thorough screening for hypercoagulable state and monitoring of immunosuppressant drug levels is therefore necessary. Hormonal contraception should not be used in patients with significant hypertension, vasculopathy, liver disease, and estrogen-sensitive cancers.

Risk of infection is significant and extreme aseptic precautions need to be practiced during routine vaginal examination. Suspected infections need to be treated while awaiting cultures. Routine antibiotic prophylaxis is also recommended during delivery. Individuals with multiple sexual partners should be counseled on safe sex practices and screened for sexually transmitted infections.

Although the numbers are small, available data suggest that paternity by cardiac transplant recipients may be safe [175]. Erectile and sexual dysfunction is common after heart transplantation with an impact on perceived quality of life [176,177]. Specific psychological causes need to be addressed prior to embarking on therapy. Phosphodiesterase inhibitors are safe as first-line treatment modalities [178]. Treatment with the m-TOR inhibitors sirolimus and everolimus may cause a decrease in testosterone level, and disruption of spermatogenesis with decreased counts and motility [179].

Immunization

The incidence of vaccine-preventable diseases is high, with approximately 45 000 adult deaths annually in the US from such causes, the majority from influenza. PCPs and patients are advised to complete all routine vaccination per national guidelines before transplantation. A survey of the pediatric lung transplant programs showed that the vaccines were more commonly provided by the PCP pre-transplant (69%) rather than post-transplant (38%) [180]. Immunization schedules are periodically updated [181,182]. The US Centers for Disease Control and Prevention (CDC) National Center for Immunization and Respiratory Diseases website provides direct access to vaccination recommendations and links to other vaccination-related websites (http://www.cdc.gov/vaccines).

Solid organ transplant recipients are assumed to have altered immunocompetence and live, attenuated vaccines should not be administered. Pretransplant patients on high-dose steroids (equivalent to either $\geq$2 mg/kg of body weight or $\geq$20 mg/day of prednisone administered for $\geq$14 days) or immunosuppressive medications should also avoid live attenuated vaccines, including intranasal live attenuated influenza virus, varicella, herpes zoster, measles, mumps, and rubella [183]. As there are no alternatives to the last five of the aforementioned, it is of particular importance that vaccine series for these are completed pretransplant as indicated. Patients are advised to avoid family members who receive live attenuated vaccines for at least 2 weeks.

The CDC considers heart or lung transplant candidates or recipients to have high-risk medical conditions and recommends they receive influenza and pneumococcal vaccinations regularly.

Cancer screening

Malignancy is a major cause of late deaths in both heart and lung transplant survivors [184]. The general topic is discussed in Chapter 95. In addition to the usual risk factors in the general population (such as exposure to tobacco and alcohol, age, genetics), immunosuppression-induced reduction of cancer immunosurveillance and higher risk of oncogenic viral infections contribute to the increased incidence [185]. Immunosuppressed organ allograft recipients have a three- to four-fold increased risk of developing tumors, but the risk of developing certain cancers is increased several 100-fold [186]. With the exception of breast and prostate cancer, the incidence of most of the common malignancies seen in the general population is increased [187]. Moreover, there is a higher frequency of some relatively rare tumors, including post-transplant lymphomas and lymphoproliferative disorders (PTLDs), Kaposi's sarcoma (KS), renal carcinomas, in-situ carcinomas of the uterine cervix, hepatobiliary carcinomas, anogenital carcinomas, and various sarcomas.

Incidence of lung cancer is increased after heart or lung transplantation [188–191]. In single lung recipients, it occurs in the native lung, particularly in patients with primary COPD or idiopathic pulmonary fibrosis, and a history of smoking. The cancer is usually diagnosed at an advanced stage with poor outcome [192]. Efforts to improve screening are recommended, as aggressive management and treatment may be beneficial for earlier stage disease [188]. Patients with cystic fibrosis had a significant incidence of colon cancer (5.7%) with onset ranging from 246 days to 9.3 years post transplant [193]. Colonoscopic screening may identify patients with premalignant colonic lesions and prevent progression to colonic malignancy.

Skin cancer, especially squamous cell and basal cell carcinoma, is the most frequent malignancy in organ transplant recipients. Other skin cancers, including melanoma, Merkel cell carcinoma, and KS, are also more common than in the non-transplant population. Voriconazole, an azole antifungal commonly used in lung transplantation, induces photosensitivity and increases the risk of skin cancer post transplantation [194].

The majority of malignant lymphoproliferative disorders occurring following solid organ transplantation are B-cell origin PTLDs [195]. Preventative measures include reducing immunosuppression to the lowest level compatible with good allograft function and prophylactic measures against certain virus infections.

Maintenance immunosuppression with the m-TOR inhibitors sirolimus and everolimus, is associated with a significantly reduced risk of developing any post-transplant de-novo malignancy and non-skin solid malignancy [196].

Cancer screening and prevention in thoracic transplant recipients is not thoroughly studied. Computed tomography of the chest, abdomen, and pelvis was not useful in a single-center observational study of cardiac transplant patients [197]. For screening and cancer surveillance of thoracic transplant recipients, PCPs may follow current published guidelines from the American Society of Transplantation, the United States Preventive Services Task Force, and the American Cancer Society for cancer screening in renal transplant patients [198,199]. Other preventive measures include appropriate antiviral prophylaxis and vaccination, and patient behavioral education and modification (avoidance of tobacco and alcohol, healthy diet, etc.), regular use of sun block; monthly self-examinations, and annual dermatologic examinations [200–202].

Preparing for surgical procedures

Thoracic transplant recipients can safely undergo surgical procedures with caution to certain aspects of care. Individuals on sirolimus and everolimus may have impairment in wound healing; the risks and benefits of stopping these agents for major surgeries should be discussed. Significant corticosteroid exposure necessitates stress-dose steroids for risk of adrenal insufficiency during major surgery. Conversion of CNIs and cell cycle inhibitors to intravenous or sublingual formulations while the patient is nil per mouth should be done in consultation with a transplant physician, and therapeutic drug levels must be monitored. Although leukoreduction may decrease sensitization, unnecessary transfusion of blood products is best avoided. Cytomegalovirus (CMV)-negative blood products are needed for CMV-naïve recipients.

Drug interactions

The immunosuppressants commonly used in transplant medicine include corticosteroids, CNIs (cyclosporine, tacrolimus), mTOR inhibitors (sirolimus, everolimus), and antimetabolite cell cycle blockers [azathioprine and mycophenolate mofetil (MMF) or derivatives]. These medications, covered in depth in Chapter 98, have a narrow therapeutic index and relatively small changes in dose or concentration lead to serious therapeutic failures or serious adverse drug reactions. Such consequences may be persistent, irreversible, slowly reversible or life threatening, and may result in hospitalization, persistent or significant disability, graft loss, or incapacity and death [203]. Therapeutic drug monitoring is routinely done for m-TOR inhibitors and CNIs. Target serum level varies based on time from transplant and individual patient rejection burden. CNI and mTOR inhibitors are metabolized through the cytochrome P450 system and have significant interactions with many other commonly used medications leading to subtherapeutic or toxic levels (Table 35.3). Initiation or cessation of therapy with these medications warrants consultation of the literature and coordination with the transplant center and frequent (at times daily) therapeutic drug monitoring. Co-administration of sirolimus and azole antifungals is contraindicated by the manufacturer. However, two case series found no clinically significant toxicity and stable trough concentrations when the doses of voriconazole and posaconazole were in advance decreased by 90% and 33–50%,, respectively [204,205].

Table 35.3. Significant drug interactions for the cytochrome P450 system

Inducers (risk of rejection)	Inhibitors (risk of toxicity)
Carbamazepine	Amiodarone
Nafcillin	Azole antifungals:
Phenytoin	Fluconazole
Phenobarbital	Itraconazole
Pioglitazone	Ketoconazole
Rifabutin	Posaconazole
Rifampin	Voriconazole
Troglitazone	Calcium channel blockers:
St. John's wort	Diltiazem
	Nicardipine
	Verapamil
	Cimetidine
	Ciprofloxacin
	Macrolides:
	Clarithromycin
	Erythromycin
	Glucocorticoids
	Indinavir
	Grapefruit juice

Concomitant use of the following medications with azathioprine may lead to severe bone marrow suppression and cytopenias: allopurinol, captopril, and other ACE inhibitors [206,207]. Concurrent use of MMF and proton pump inhibitors may result in reduced exposure to the active metabolite of MMF, leading to increased risk of rejection.

All changes in immunosuppressant medications should only be made by the transplant center [7]. If any other medications are to be added or eliminated, the literature and drug interaction tables should be consulted. If any change in medications, including generic drug substitution, occurs, the transplant center should be informed so that heightened close therapeutic drug monitoring can be implemented until a steady-state level is achieved.

Summary

Thoracic transplantation has become an increasingly commonplace component of medical care and its improving survival rates have introduced thousands of patients back into the community who are able to conduct productive lives, but who also require heightened scrutiny by medical professionals. In general, the issues facing long-surviving transplant recipients are similar to those facing the general community, although their presentation is altered by immunosuppressive drugs. Partnership between transplant and non-transplant physicians is required to provide comprehensive care for transplant candidates for timely referral, evaluation, optimization of comorbidities, and preparation for transplantation; and for the recipients for management of common medical comorbidities, immunization, screening for malignancy, and counseling for healthy lifestyle. The single most important factor in this process is ongoing communication between the primary care and transplant teams.

CHAPTER 36

Alloantibodies, Sensitization and Virtual Crossmatching

Howard M. Gebel and Robert A. Bray
Histocompatibility and Molecular Immunogenetics Laboratory, Emory University Hospital, Atlanta, GA, USA

Introduction

In 1969, Patel and Terasaki reported that a positive pretransplant cross-match between recipient serum and donor lymphocytes was associated with a high risk of hyperacute renal allograft rejection (see Chapter 3) [1]. Subsequently, the risk of rejection was shown to be strongest when positive cross-matches were due to pre-existing antibodies directed to donor HLA antigens, particularly when those antibodies fixed complement. The association between pretransplant donor-directed HLA antibodies and allograft rejection was so compelling that Patel and Terasaki insinuated that it was malpractice to transplant patients without performing a pre-transplant cross-match. Such sentiments meant that the histocompatibility laboratories that supported transplant programs needed to be operational 24/7/365 in order to perform prospective lymphocyte cross-matches. The paradigm was uncomplicated: simply avoid transplanting patients possessing HLA antibodies (i.e. sensitized recipients) with donor organs expressing one or more of the corresponding HLA antigens. Early studies [2,3] suggested that with detailed prescreening of patient sera to identify HLA antibodies, it was possible to predict which HLA antigens to avoid before a physical cross-match was even performed. This first iteration of what today is called the virtual cross-match (vXM) was completely rational, but its utility was severely hampered by the limitations of the technology at that time. Furthermore, the underlying assumptions, that all positive reactions were the result of clinically relevant HLA antibodies and that all negative reactions assured long-term graft survival, were incorrect. In part, this was because the early assays used to identify HLA antibodies and perform cross-matches were neither sufficiently specific nor sensitive enough to identify all relevant HLA antibodies [4]. Thus, although avoiding donor-directed HLA antibodies was conceptually appealing, the methods to do so were not up to the task. Adding to these serious issues was that the serologic HLA typing assays used to assign HLA antigens were frequently subjective and incomplete, which meant that HLA antigens were not always correctly or completely identified.

In recent years, the development of solid phase testing platforms using purified HLA antigens (class I or class II) permitted the identification of HLA antibodies with a specificity and sensitivity not previously attainable [5,6]. Similarly, implementation of molecular typing methods led to the fine resolution of HLA antigens and characterization/definition of individual alleles [7,8]. Collectively, these developments led to objective identification of HLA antigens expressed by potential organ donors and an exact assessment of the HLA antibodies present in the sera of sensitized recipients. The concept of virtual cross-matching was ready to move from theory to practice. This chapter will summarize the development of the fundamental assays used in modern transplant histocompatibility testing and principles governing their proper deployment in the clinic. The chapter is complemented by Chapter 6 outlining the fundamental mechanisms of antibody-mediated rejection, Chapter 4 outlining the structure and function of histocompatibility molecules, and Chapter 89, detailing the use of antibody testing as a postoperative biomarker.

Assays

Serologic antibody testing

Initially, complement-dependent cytotoxicity (CDC) assays were used prospectively to determine whether patients awaiting transplantation were sensitized to HLA antigens [9–12]. Briefly, HLA-typed cells from at least 30 donors were incubated with patient serum and complement. Target cell death was interpreted to mean that the panel member expressed at least one HLA antigen to which the patient serum had a corresponding antibody. The logic behind performing this test was twofold. First, it provided valuable information to the patient, namely his/her likelihood of being cross-match compatible (and therefore transplantable) with a random donor. Second, it was possible to define HLA specificities, which could then be used to predict compatibility with specific donors. In its simplest form, the percentage of panel cells reacting with a patient's serum was considered to correspond to the breadth of his/her sensitization. For example, if 10 of 30 panel cells reacted with serum from a patient, that patient was considered to have panel reactive antibody (PRA) activity of 33%. This patient would then

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Table 36.1. The two tables represent an HLA typed (class I only) cell panel. In this example, there are 24 typed panel members being tested with a patient serum. Twelve of 24 cells (darkly shaded) reacted with the patient serum, corresponding to a panel reactive antibody activity (PRA) of 50%. All 12 cells express HLA-A2, meaning the antibody specificity is to that antigen. Note, however, that four of the HLA-A2-positive cells also expressed HLA-B44. Since HLA-B44 was not present except in the context of HLA-A2, a second antibody to HLA-B44 may be present

be informed that he/she would be cross-match compatible with two of every three random donors. However, the validity of this interpretation was predicated on whether the frequency of HLA antigens in the cell panel reflected the frequency of those antigens in the donor population. Initially, cell panels were assembled at the transplant center using randomly selected healthy volunteer donors or based on their HLA phenotypes. Subsequently, frozen cell panels became commercially available from several vendors. Unfortunately, there was no standard approach to select donors to be panel members. Thus, the HLA phenotype composition of panel members did not necessarily reflect the frequency of those HLA antigens among the deceased donor population. Accordingly, if the serum sample referred to above contained an antibody to HLA-A01 and was tested on three different cell panels, where none, half, or all of the target cells expressed HLA-A*01, the PRA would be correctly interpreted as 0%, 50%, and 100%, respectively. Which of those results most accurately reflects the distribution of HLA-A*01 in the population of individuals who become organ donors? In reality, the frequency of HLA-A01* in the US donor population is 23% [13], meaning none of the PRA values from the above example is correct.

Another far-reaching complication of using PRA values derived from cell panels composed of random HLA phenotypes is the impact on deceased donor renal allocation when all antibodies are not identified. It is well-recognized that highly sensitized patients (currently defined as patients with a PRA of $\geq$80%) are significantly disadvantaged compared to non-sensitized patients with regard to finding compatible donors [14]. In the US, renal transplant recipients are prioritized for transplantation based on a point system. The more points a patient accumulates, the higher up they move on the waitlist managed by the United Network for Organ Sharing (UNOS) [15]. When a patient's point value puts him/her at the top of the waitlist, he/she is afforded the opportunity to be cross-matched with blood-type compatible donors. Points are awarded to recipients for the degree of HLA-DR matching with the prospective donor (two points for a two HLA-DRB1* match, one point for a one HLA-DRB1* match) and wait time (one point per year of waiting). In an attempt to reduce the disparity of transplantation between highly sensitized and non-sensitized patients, UNOS awards four additional points to highly sensitized (PRA >80%) patients. With nearly 100 000 patients currently awaiting a deceased donor kidney [16], the point system has been considered an equitable approach to deceased donor renal allocation. It is not unusual for highly sensitized patients to have also accrued several points for waiting time (they are, after all, difficult to match) and have four additional points for PRA; such patients routinely are at the top of the list. However, being at the top of the list does not guarantee that a patient will be transplanted. The patient must still be cross-match compatible with his/her donor. Historically, preliminary cross-matches were performed as a triage maneuver, filtering out patients with a positive cross-match and permitting those whose cross-matches were negative to move on to the next (or "final") phase where a current sample from the patient was cross-matched with cells from the intended donor. This, so-called "final cross-match" would have to be compatible (i.e. negative) in order for the patient to proceed to transplant.

Until recently, cross-matches with sera from highly sensitized patients were frequently positive [17]. At least part of the reason for this was due to incomplete assignment of unacceptable antigens using HLA-typed cell panels [18]. For example, in Table 36.1 all of the cells reacting with the patient serum express the HLA-A*02 antigen, while none of the non-reactive cells expressed HLA-A*02. This reaction pattern suggests the patient has a single HLA antibody directed to the HLA-A*02 antigen. Therefore, only HLA-A*02 would be considered to be an unacceptable antigen for the patient. Donors possessing all other HLA antigens would be considered provisionally compatible with the patient (i.e. vXM negative). However, closer examination of Table 36.1 reveals that all cells expressing HLA-B*44 also express HLA-A*02. If the patient also had antibodies to HLA-B*44, their detection would be masked by the HLA-A*02 antibodies. In this example, if HLA-A*02 were considered the only unacceptable HLA antigen, a donor expressing HLA-B*44 (but not HLA-A*02) would be considered acceptable; the final cross-match, though, would be unexpectedly positive. In addition to incomplete identification due to masked antibodies, cell panels were not the ideal targets to identify the entire repertoire of antibodies among broadly sensitized (i.e. $\geq$80% PRA) patients. As such, their sera were routinely cross-matched with any blood group-compatible donor. If the cross-match was positive, the donor was considered incompatible with that patient. Complicating matters further was the sensitivity of the cross-match that was performed (reviewed in [19]). When first implemented, cross-matches were performed using a complement dependent cytotoxicity (CDC) assay to identify clinically relevant antibodies. However, it soon became apparent that patients without CDC-detectable

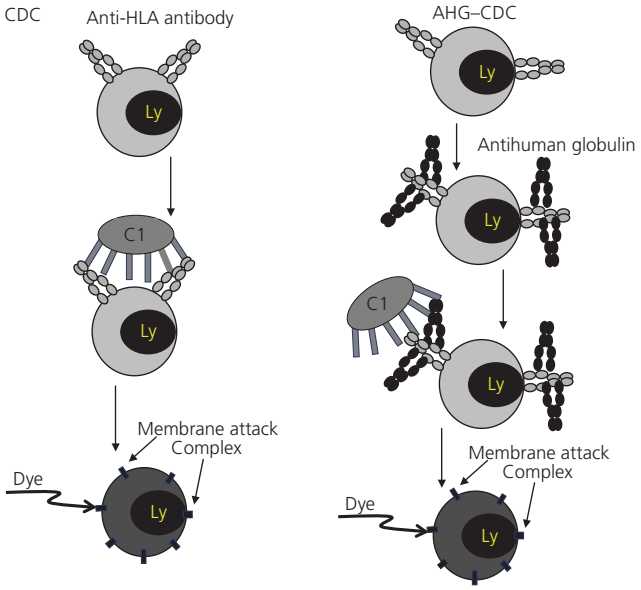

Figure 36.1. Complement-dependent and antihuman globulin augmented complement-dependent cytotoxicity assays to detect HLA antibodies. Donor lymphocytes are incubated with patient serum and complement (CDC assay) or patient serum, antihuman globulin, and complement (AHG-CDC). Antibody by itself or augmented with AHG activates complement and the damage to lymphocyte membranes is detectable by the uptake of a vital dye.

antibodies still experienced early antibody-mediated graft rejection/graft loss. This led to modifications of the assay, including extended incubations, extra washes, and enhancement with an antihuman globulin (AHG) reagent [10], the latter eventually becoming the laboratory gold standard for many years (Table 36.1). However, even with this augmented technique to identify antibodies, there was still a group of patients who experienced early episodes of rejection or graft loss attributable to donor-directed antibodies. Furthermore, cytotoxicity testing usually identified only class I HLA antibodies. As the field of organ transplantation matured, it became evident that it would be prudent to also identify whether patients had antibodies against class II specificities (e.g., HLA-DR, HLA-DQ) prior to transplant [20].

The development and implementation of the flow cytometric cross-match (FCXM) provided the transplant community with an extremely sensitive new assay, one that allowed simultaneous evaluation of T and B lymphocytes, meaning an assay was now available to look at targets (B cells) that expressed class II histocompatibility antigens. At the time, published data suggested there was little, if any, clinical relevance of class II HLA antibodies and most transplant centers proceeded to transplant as long as the T-cell cross-match was negative. However, those early studies were of questionable reliability because they were typically based on low numbers of B cells that had to be physically separated from T cells. Additionally, there was a failure to recognize that B cells, like T cells, express class I antigens. Multiple studies demonstrated that T-cell–negative, B-cell–positive cross-matches resulting from low titer antibodies to donor class I antigens were associated with early graft loss (1-year graft survival of 50–67%; reviewed in [19]).

Another feature of the FCXM was that it identified donor-directed antibodies that did not fix complement and whose clinical impact, though questionable, was nonetheless worrisome. Indeed, antibodies detected only by flow cytometry were associated with increased episodes of rejection and graft loss [21–23]. However, other studies reported that the FCXM offered no additional benefit over cytotoxic cross-matches [24]. Although apparently contradictory, one explanation for these differences was that some positive FCXMs were not due to HLA antibodies. Apparent false-positive cross-matches could occur as a consequence of autoantibodies, non-specific binding of immune complexes (frequent in patients with autoimmune diseases such as systemic lupus erythematosus) and/or Fc binding of IgG molecules to Fc receptors expressed on lymphocytes [25,26]. B cells were particularly susceptible to these non-specific binding issues. One study reported that up to 75% of positive B-cell cross-matches were due to non-HLA antibodies and, hence, clinically irrelevant [27]. However, this same study also showed that when the positive B-cell cross-matches were due to HLA antibodies (specifically, class II antibodies), graft survival was significantly lowered. This study underscored the challenge of using B cells as targets and the need to consider additional explanations when a B-cell cross-match was unexpectedly positive.

Tipping point

In the early 1990s, advances in molecular biology (specifically the development of the polymerase chain reaction) enabled DNA-based HLA antigen testing to be performed. By the mid-1990s, the introduction of multiplexing microparticle technology and cytometry-based instrumentation permitted the detailed assessment of HLA antibodies and the accurate determination of an individual's HLA type. Currently, multiplexing fluorescence-based solid phase assay technology is the most commonly used platform in the clinical HLA laboratory. This technology has the ability to simultaneously distinguish and analyze up to 100 uniquely coated microparticles [4,28]; see following section. By documenting whether patient sera possess donor-reactive HLA antibodies, a lymphocyte cross-match (positive or negative) can now be more reliably interpreted. Indeed, with solid phase data, a positive lymphocyte cross-match can be categorized as clinically irrelevant versus relevant, and, if relevant, the positive cross-match could be interpreted as a risk factor for rejection or a definitive contraindication to renal transplantation (reviewed in [19]). Thus, in a manner similar to how the introduction of calcineurin inhibitors as immunosuppressants revolutionized transplant medicine in the early 1980s, multiplexing technology revolutionized clinical histocompatibility testing.

Solid phase revolution

Since T and B lymphocytes express a multitude of membrane proteins in addition to HLA, the assignment of HLA antibody specificity using membrane-dependent assays was daunting. The development of solid-phase assays utilizing purified HLA proteins devoid of all other cell membrane components helped make antibody identification more manageable. The first iteration of solid phase testing was an enzyme-linked immunosorbant assay (ELISA) using affinity purified HLA class I isolated from platelets as target antigens to detect HLA class I antibodies in patient sera [29]. Although this approach discriminated HLA from non-HLA antibodies, the specificity of positive sera was not readily identifiable. Although ELISAs were an improvement over membrane-dependent assays, they were cumbersome and not as sensitive as flow cytometric-based methods. Furthermore, even after the implementation of ELISAs to identify antibodies to class II HLA antigens,

separate tests were needed to distinguish class I from class II antibodies.

The next breakthrough in HLA antibody testing came when Pei et al. described a methodology wherein purified HLA class I and class II proteins isolated from Epstein–Barr virus (EBV)-transformed cells lines were attached to microparticles and analyzed by flow cytometry [5]. In contrast to ELISA, the FlowPRA® (One Lambda, Inc, Canoga Park, CA, USA) permitted simultaneous identification of antibodies to both HLA class I and class II antigens on a standard flow cytometer. Additional advantages of solid phase analysis of antibodies included objective and semi-quantifiable analysis of data, no requirement for viable target cells, and a consistent and renewable source of HLA antigens for coating microparticles. Microparticle-based assays have gone through several configurations since their inception. The FlowPRA® was a simple and straightforward assay to determine whether HLA antibodies were present. Briefly, it combined 60 separate microparticles, 30 coated with class I antigens and 30 coated with class II antigens (Figure 36.2a). Each individual microparticle in the mix was coated with a different class I (A, B, C) or class II (DR, DQ,DP) phenotype derived from a single EBV-transformed cell line. Class I-coated particles were discernable from class II-coated microparticles based on two parameters, size and fluorescence. Class I-coated microparticles are larger and non-fluorescent compared to class II-coated microparticles, which are smaller and internally stained with a red fluorescent dye. Beads exhibiting increased fluorescence when stained with fluoresceinated antihuman IgG compared to background controls are considered positive. Positive reactions are determined by the number and fluorescence intensity of the microparticles. Since an individual class I or class II microparticle represents 1 in 30 (~3%) of the total number of events, each positive reaction must demonstrate a distinct peak of fluorescence above that of the negative control and contain at least 3% of the total gated events to be considered.

Although the FlowPRA® assay identified HLA antibodies and was significantly more sensitive and specific than cell-based assays or the ELISA, the assay could not determine the HLA specificities to which the antibodies were directed and another test was developed, namely a flow-based specificity assay. In this assay, the cluster of HLA phenotypes (class I or class II) isolated from the EBV cell lines were attached to individual bead populations just as described for the FlowPRA® screening test; however, each individual microparticle was internally stained with a specific amount of red fluorescent dye. Up to 11 different beads could be uniquely identified on a single fluorescence axis and using such a panel of targets, individual antibody specificities could be assessed (Figure 36.2b) [6].

While FlowPRA® paved the way to identify the HLA antibody specificities, there were still two stumbling blocks:

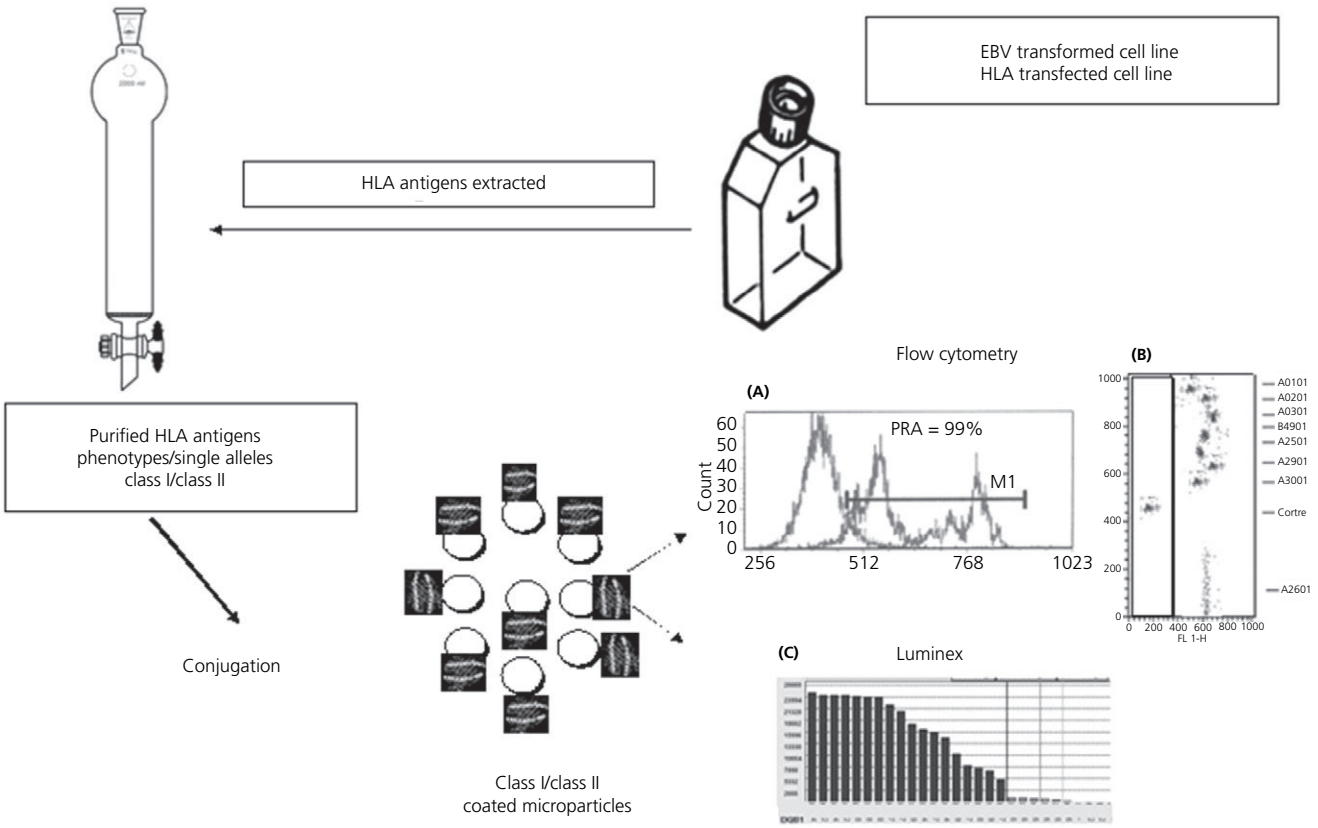

Figure 36.2. HLA class I and class II antigens (entire clusters of phenotypes or single alleles) are extracted and purified from cell lines and coated onto microparticles. Individual microparticles (n = 30) are combined to create a screening pool of HLA antigens (A) that are analyzed on a flow cytometer. The percentage bead reactivity allows for the calculation of a percentage of panel reactive antibody (PRA). EBV, Epstein–Barr virus. Alternatively, individual microparticles are assayed by flow cytometry (B) or Luminex (C) to evaluate antibody specificity The percentage bead reactivity allows for the calculation of a percentage of PRA.

1 the extensive polymorphism of the HLA complex which hampered design of the target array;
2 only 11 beads could be tested at one time (which reduced technical efficiency).

The development of another flow cytometric-based instrument (Luminex) was a major improvement in the identification of HLA antibodies because this platform permitted up to 100 individual microparticles to be evaluated simultaneously (a so-called multiplex assay) [28]. Each microparticle had a unique fluorescence signature that was derived by incorporating the microparticle with varying amounts of two fluorescent tags. For each fluorescent tag there were ten different shades, meaning one could establish a 10 × 10 matrix yielding a set of 100 uniquely identifiable microparticles. The fluorescence read-out or "reporter" molecule was of a third and distinct color that could be measured on each bead in the matrix. Then, each microparticle was conjugated with a different HLA antigen or nucleotide sequence, allowing positive immunoassay results to be automatically correlated to a unique HLA specificity (Figure 36.2c). In theory, a third and fourth set of dyes could be included, leading to the ability to detect 1000 and 10 000 analytes at the same time, respectively. Another approach to increasing the number of analytes tested would be to use a set of microparticles of a different size from the original set. The more analytes that can be simultaneously analyzed, the greater the efficiency of the test.

A significant proportion of patients awaiting transplantation possess such broadly reactive HLA antibodies that 100% of the HLA antigen-coated microparticles will be positive [30]. However, patients never actually have 100% PRA, but instead possess multiple antibodies that each react with several common HLA specificities [31,32]. With the implementation of recombinant technology, single HLA proteins could be purified and attached to microparticles. These so-called single antigen bead panels were then used to clearly delineate antibody reactivity.

At the same time that antibody detection and identification improved with new technology, so too did the ability to type HLA antigens. During the past 20 years, typing for HLA antigens shifted from serologic to molecular-based methodologies, allowing a simple test to discern between two different antigens differing by as little as a single amino acid (e.g. HLA-B*44:02 vs. HLA-B*44:03) [33]. While serologic typing distinguished a limited number of HLA specificities, molecular-based methods can identify all HLA alleles. From knowing the unique allele that is coated on to the microparticle, it was soon discovered that patients had the ability to produce allele-specific antibodies, i.e. an antibody that reacted with one allele of an antigen family. Allelic antibodies, in fact, were not uncommon and this recognition began to underscore the possibility of typing donors at the allele rather than antigen level, at least for those antigens where the frequency of alternative alleles was sufficiently high and alleic antibodies had been identified. Clearly, the vXM would not be possible without comprehensive molecular typing of donors. The era of serologic HLA typing has passed. The technologies for performing molecular-based HLA typing are reviewed in Chapter 3 [34].

Clinical application of the virtual cross-match

Although the concept of virtual cross-matching is nearly 30 years old [2], reliable implementation of this process did not become a clinical reality until 2006. Then, using solid phase antibody assays to identify HLA class I and class II antibodies with accuracy and sensitivity, Emory University and Duke University published their successful experiences using the virtual cross-match to predict compatibility among highly sensitized patients receiving deceased donor kidney and lung transplants, respectively [35,36]. Subsequently, a national study tested the ability of the virtual cross-match to predict positive cross-matches among highly sensitized patients on the UNOS waitlist and reported a predictive value exceeding 90% [37]. However, in that study, the ability to predict a negative cross-match was poor (~50%). Subsequent studies suggested that at least part of the inability to predict negative cross-matches was because of incomplete information about all the antibodies these highly sensitized patients possessed, specifically antibodies to HLA-C, HLA-DQ, and HLA-DP antigens [38]. Even though these antibodies may have been identified, they were not routinely listed as unacceptable, in part because UNOS only mandated that antigens of the HLA-A, HLA-B, and HLA-DRB1 loci be tested and reported for deceased donor organs, the implication being that antibodies to other HLA loci were not clinically relevant. This is no longer the working model at UNOS. Several studies have now been published that document that antibodies to HLA-C, DQB1, and DPB1 are associated with episodes of rejection and graft loss when patients with those antibodies are transplanted with organs possessing the corresponding antigens [39–42]. In June 2011, UNOS mandated that HLA molecular typing data be reported for the HLA-A, B, C, DRB1, and DQB1 loci. Currently, there is no requirement to mandatorily type for HLA-DPB1 or HLA-DQ alpha antigens, even though the frequency of those antibodies among potential recipient populations is on the rise. It would not be surprising if typing for these loci eventually becomes mandatory.

Since those early reports, the vXM has become widely accepted not only for deceased donors [43,44] but also for living donors, particularly those involved in paired donor exchanges [45]. For thoracic transplantation, the vXM has decreased deaths on the waitlist and permitted organs to be imported from centers up to 500 miles away, which, previously, would have been impossible because there would not be enough time to perform a prospective physical cross-match [46]. The vXM has effectively eliminated the need for costly and time-consuming preliminary cross-match trays in essentially all laboratories in the US. In Europe, Claas et al. adopted an international program of acceptable mismatching that significantly increased the number of deceased donor kidneys transplanted into highly sensitized recipients [47]. The UK also prioritizes broadly sensitized patients nationally for transplantation based on a vXM [48]. Late in 2014, UNOS will implement an allocation scheme designed to broaden access to extremely sensitized patients. Specifically, mandatory sharing of organs at the local, regional and national levels will be implemented for patients with cPRA of 98%, 99% and 100% cPRA, respectively.

The use of solid phase HLA antibody detection assays has the ability to place patients into at least three categories:
1 no HLA antibodies;
2 HLA antibodies without donor specificity;
3 donor-specific HLA antibodies (DSA).

Patients in the first category are predicted to have a negative cross-match. In fact, if the physical cross-match for a patient in this category is positive, it is generally not considered a contraindication to transplant. Patients in the second category are also vXM negative. When transplanted, these patients have a low risk of antibody-mediated rejection/graft loss and experience excellent long-term graft survival [35,49–51]. For patients in the third

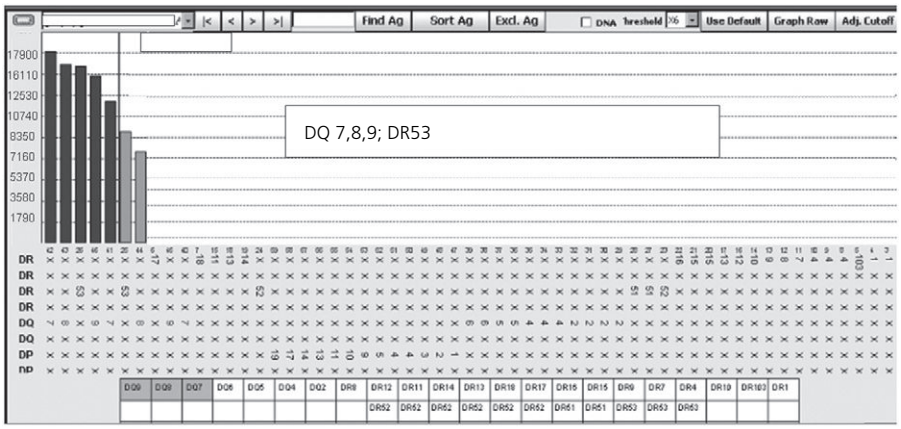

Figure 36.3. The serum in the histogram has antibodies to HLA-DQB1*03:01, 03:02, 03:03 (DQ7, DQ8 and DQ 9) and to DRB4* (DR53). The antigens corresponding to these antibodies would be listed as "unacceptable." The donor on the left would be considered unacceptable because the antibodies would be considered donor-specific antibodies (DSA) and the virtual cross-match is positive. In contrast, for the donor on the right, the same antibodies are present but they are not DSA. The virtual cross-match with this donor is negative.

category, the vXM will be positive. It is important to recognize that, for patients who have antibodies, the same antibodies may have no DSA for some donors and the vXM will be negative, but for other donors, one or more of the antibodies will be donor directed and the vXM will be positive (Figure 36.3). Recent data indicate that the physical cross-match in patients with DSA is not always positive [52–54], leading to the question of what should be the determining factor in proceeding to transplant: a DSA or a positive cross-match?

Paradigm shift

As mentioned above, the make-up of an HLA-typed panel (cells or microparticles) could easily impact whether a sensitized patient reaches the 80% threshold where four points are awarded. Until recently, four points were awarded to any patient whose reported PRA was ≥80%, even if only one unacceptable antigen was identified [55]. This approach was not particularly effective because these broadly sensitized patients who already had long waiting times received four additional points and routinely appeared at the top of each match run for each blood group-compatible donor. Positive final cross-matches were common among these broadly sensitized patients [17] and they were being transplanted at a rate far below their representation on the list of candidates awaiting transplantation. The recognition of this issue led to some sweeping changes in national organ allocation. In October 2009, UNOS implemented a new policy mandating that a patient would be awarded four sensitization points if and only if his/her percentage of unacceptable HLA antigens was ≥80%. Assessment of HLA antigen frequencies were determined from a UNOS database of >12 000 HLA-typed deceased donors. Under these new rules, PRA values are calculated (cPRA), not assigned. Patients who are awarded the four sensitization points will not be considered as recipients for donors who express one or more of the HLA antigens listed as unacceptable. The new cPRA policy was designed to establish both accountability and uniformity in reporting sensitization and to increase the efficiency of kidney allocation by eliminating offers that would be incompatible, thereby reducing the number of positive cross-matches among patients who had reached the top of the waiting list. In effect, the highly sensitized patients at the top of the list, as determined by cPRA, would be much more likely to be compatible with their donors [17]. Put simply, the numbers of positive cross-matches among the top-ranked patients were predicted to substantially diminish. This change in policy fundamentally changed how sensitized renal candidates were ranked for kidney offers. A subsequent review of national data demonstrated that within 2 years following the implementation of the new cPRA policy, the number of offers refused because patients had positive cross-matches with their prospective donors was reduced by >90% compared to the pre-cPRA era [56]. Additionally, highly sensitized patients appear to have particularly benefited from the cPRA policy based on the observed increase in the percentage of patients with >80% cPRA who were transplanted during the pre and post cPRA era (7.2% and 15.8%, respectively). These data are consistent with the tenet that, even at the national level, careful identification of unacceptable HLA antigens among highly sensitized candidates at the time of listing (and keeping the information up to date on the UNOS database) increases the probability that these patients will have negative cross-matches with donors who filter beyond the triage process.

When should an HLA antigen be considered unacceptable?

As a group, patients transplanted with DSA directed against donor HLA antigens are at higher risk for antibody-mediated damage to the graft than patients without DSA [57]. Is there a threshold level below which DSA is clinically irrelevant? The most common solid phase antibody detection systems today utilize Luminex technology, which is based on immunofluorescence reactivity that is reported as an arbitrary unit of mean fluorescence intensity (MFI). The higher the MFI value, the stronger the florescence signal

indicating the greater the quantity of antibody binding. Values range from 0 to 20 000 MFI, and as a general (but by no means universal) rule, MFI values from 300 to 2000 are considered weak, >2000 and <5000 moderate, >5000–10 000 intermediate, and >10 000 strong. The actual threshold at which to consider an antigen as unacceptable is a center-to-center decision and is based on each center's philosophy and risk aversion. Intermediate to strong antibodies generally result in a positive flow (and often cytotoxic) cross-match, while flow cytometric cross-matches with weak to moderate antibodies may be positive or negative. It is the latter type of antibodies that are the current challenge to the transplant community. If the cross-match is negative, is the DSA clinically irrelevant? It should be obvious that if thresholds to assign an antibody unacceptable are set too low, there will be patients who are denied the opportunity to be transplanted with what would be a cross-match compatible organ [58]. In contrast, by setting the threshold too high, patients could experience antibody-mediated rejection that can reduce the functional life of the allograft [59]. The literature is divided, with some groups reporting that antibodies detected solely by solid phase have no impact on graft outcome, while others report that such antibodies (even "weak" ones) are associated with increased risk for antibody-mediated rejection and graft loss.

It is likely that the discrepancies between a DSA detectable on microparticles but not cells are a combination of technical and biological variables. For example, the HLA antibody detected on the microparticle is against an allele of a given antigen, e.g. HLA-B*44:02, and the target expresses HLA-B*44:03. Even though there is only a single amino acid difference between 44:02 and 44:03, this is sufficient for a B*44:02 antibody to give a positive cross-match with a B*44:02 cell but not a B*44:03 cell. Another explanation is that the donor cell has reduced HLA expression that can occur after viral infection or in the context of certain drugs [60,61]. Other possibilities include differential avidity for antibodies binding to microparticles versus cells and expression of degraded or cryptic HLA antigens/epitopes on microparticles compared to native antigen expression on cells. Sera from some patients (even those with no known sensitizing events) bind to denatured but not native HLA antigens (and thus bind to microparticles and not lymphocytes). What those antibodies are directed to and what stimulated their production is unknown. In recent studies, one heart–lung and two renal patients displaying antibodies to denatured antigens were transplanted with donor organs expressing the relevant native antigens [52,62]. One patient (a renal recipient) has progressed to 5 years post transplant without experiencing an episode of rejection. While the other two patients are only 4 months and 1-year post transplant, neither has shown any signs of rejection to this point. There are also examples wherein patients appear to have no HLA antibodies yet present with a positive cross-match. The most logical interpretation is that those cross-matches are due to non-HLA antibodies. However, this is not always true. A simple example would be that the repertoire of HLA class I/II antigens present on the donor is incompletely represented on the microparticles used to screen for/identify HLA antibodies. Another explanation would be higher HLA antigen density on the target cell compared to the microparticles. If the donor expresses two or more antigens to which the recipient has low-level antibodies (below the threshold level considered to be positive), the cross-match could be unexpectedly positive. With increased antigen expression, more antibodies can be deposited on the cell surface, thereby yielding a higher fluorescent signal. Additionally, an antibody directed against a single epitope may be spread out over multiple microparticles that all express that epitope (e.g., an antibody to Bw4 would be present on ~60% of a target panel) and the antibody may be diluted over multiple beads, with no bead displaying MFI values above the threshold. Collectively, these data indicate that cut-off values alone may not be an appropriate approach to assigning an antibody as positive. Several other factors must be taken into account, including the sensitization history of the patient and/or whether beads below a cut-off threshold (but not negative) exhibit any pattern of antibody specificity. Otherwise, false-positive and false-negative results will not be uncommon and lead to discordant results between a vXM and a physical cross-match. Studies by Tambur et al. indicate discordant results occur in approximately 10% of patients [38]

Summary

The field of histocompatibility continues to evolve. Over the past 20 years, HLA typing has moved from serologic to molecular technology, and HLA antibody detection/analysis has transitioned from a cell-based approach to assays that rely on solid phase matrices. These advances led to a major change in the organ allocation system in the US by making the virtual cross-match a reality. The identification of unacceptable antigens with sensitive solid phase assays can effectively be used to triage sensitized recipients, such that time or resources are not needlessly expended on individuals incompatible with their prospective donors. Ischemia time is reduced and highly sensitized patients are much more likely to be transplanted then at any time in the past. Screening for HLA antibodies will determine whether a patient can go directly to transplant (e.g. no HLA antibodies) or needs further studies to identify class I and class II antibodies. If the latter, unacceptable antigens can then be identified and entered into a national computer system such that donors who possess one or more of the unacceptable antigens are not considered for allocation to the corresponding recipients (Figure 36.4). Clearly, the application of the vXM has played a substantial role in the identification of compatible donor–recipient pairs.

Unfortunately, the vXM is not perfect. One of the more controversial topics at this time is how unacceptable antigens are defined. Are thresholds being set too high or too low for any given patient? The challenge is to discriminate acceptable DSA from unacceptable DSA. Even if pretransplant antibodies were the sole risk factor for allograft outcome, more than simple quantifications of antibody levels are necessary to determine their long-term consequences. Factors such as the number and specificities of memory B cells and plasma cells, antibody affinity, complement fixing attributes, antibody titers, and antibody isotypes may all need to be evaluated. Currently, there are no routine tests that reliably distinguish patients who will do well from those who will do poorly when they have identical specificities and apparent strength of DSA pre transplant. Whether to proceed towards transplant is a philosophical decision that remains center dependent [63]. What is acceptable at one transplant center may be unacceptable at another center. On the horizon is the recognition that non-HLA alloantibodies (e.g. antiendothelial cell antibodies) are risk factors to graft survival and monitoring for such antibodies is increasing. Eventually, such antibodies and their corresponding antigens will be incorporated into the vXM of the future. The tools now available used to detect and identify HLA antibodies, while not perfect, represent the bleeding

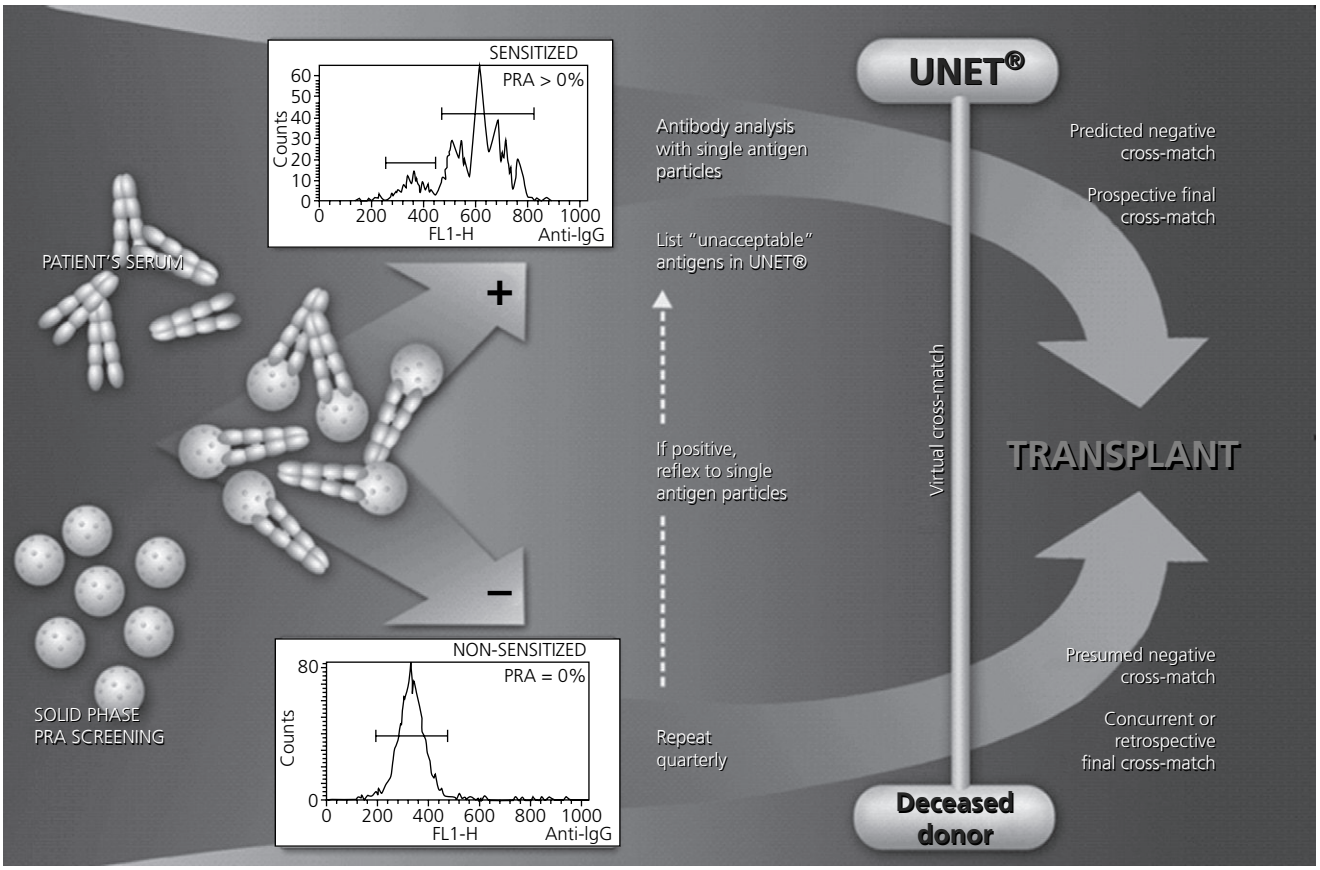

Figure 36.4. Virtual crossmatch (vXM) algorithm. Sera from potential transplant recipients are screened for the presence/absence of HLA class I and class II antibodies. Patients whose serum is class I and class II antibody negative can proceed directly to transplant and a physical cross-match can be performed retrospectively. Sera "positive" for class I and/or class II antibodies undergo detailed antibody specificity analysis with HLA antigen-coated microparticles. The HLA antigen specificities corresponding to the antibodies identified are listed as "unacceptable" antigens in the UNOS database. When a donor organ becomes available for these patients, their unacceptable antigens are used to triage incompatible combinations. Only combinations that are vXM negative will proceed to a final cross-match and (if negative) to transplant.

edge of technology. As this technology evolves, so too will our ability to apply it to the benefit of our patients.

[2] Olive View-UCLA Medical Center, Sylmar, CA, USA

Introduction

The number of deceased donor kidneys has remained far below the growing need, leading to a steady increase in patients on the transplant waiting lists, longer waiting times, and increased waitlist deaths. The Organ Procurement Transplantation Network/United Network for Organ Sharing (OPTN/UNOS) database revealed that over the past decade, approximately 22 000–34 000 kidney transplant candidates of all ages were added to the list annually. During the same time period, approximately 4300–6700 patients were removed from the list annually due to death or medical conditions that preclude transplantation. Currently, it is estimated that approximately half of the deaths on the waiting list occur among patients who are placed on the "inactive status" list. Hence, managing the waiting list patients has been one of the greatest problems facing transplant centers. This chapter discusses the categorization of waiting list status set forth by the OPTN/UNOS, factors that may have an impact on kidney waiting times, suggested guidelines for the management of adult kidney transplant candidates on the active waiting list as well as those on hold for various medical and psychosocial reasons. It complements Chapter 28, which details the indications for kidney transplantation.

United Network of Organ Sharing (UNOS) waiting list status

Kidney transplant candidates on the deceased donor waiting list can be listed in one of two status categories, status 1 or status 7. Patients are listed status 1 when they are deemed medically and psychosocially ready for transplantation at all times. In contrast, status 7 listing represents an "on hold" status; this is an inactive status and a patient with this status cannot be offered an organ due to the development of complications that temporarily precludes him/her from kidney allocation. The UNOS/OPTN policy required that such a change in medical status be reported to the OPTN. Previously, accrual of waiting time stopped 1 month after the registrant was placed on hold and the waiting time point could only be restarted when resolution of the medical complication was reported to the OPTN. However, such a policy was thought to serve as a disincentive for transplant programs to accurately report the status of their registrants to the OPTN and could result in delays in organ placement. In November 2003, an important change was implemented whereby candidates placed on status 7 for any acute issue continue waiting time accrual, thereby reducing the disincentive for accurate reporting.

Patients can be made status 7 for various medical or psychosocial reasons or both. The former may include intercurrent illnesses or hospitalizations, cancer-free waiting times, weight loss to achieve an acceptable body mass index, or cardiac or neurological rehabilitation among others. The latter may include medical non-adherence, active substance abuse or psychiatric illnesses, or lack of psychosocial support. While on the waiting list, patients can be moved from status 1 to status 7 or vice versa according to interim events. However, those who develop irreversible complications that contraindicate transplantation, such as metastatic cancer, severe coronary artery disease, or massive stroke, are removed from the waiting list. The algorithm for the UNOS listing and delisting process is shown in Figure 37.1.

Waiting times for listed transplant candidates

The waiting time for a deceased donor kidney may vary greatly based on factors such as ABO blood type, ethnic background, sensitization (peak panel reactive antibodies), and different Organ Procurement Organization (OPO) regions within the US. Other factors may include willingness to accept expanded criteria donor (ECD) kidneys (or dual ECD kidney transplants when ECD kidneys are deemed unsuitable for single use), donor after circulatory death (DCD) kidneys, Public Health Service (PHS) high-risk donor kidneys (formerly CDC high-risk donor kidney), or hepatitis C virus (HCV) donor kidneys in candidates with documented chronic hepatitis C infection.

Knowledge of the primary factors that may affect waiting times allows clinicians and transplant coordinators to formulate practical plans to ensure that candidates at the top of the waiting list are indeed suitable and ready for transplantation to minimize last minute cancellation, and candidates with suboptimal risk management are not be inappropriately transplanted.

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

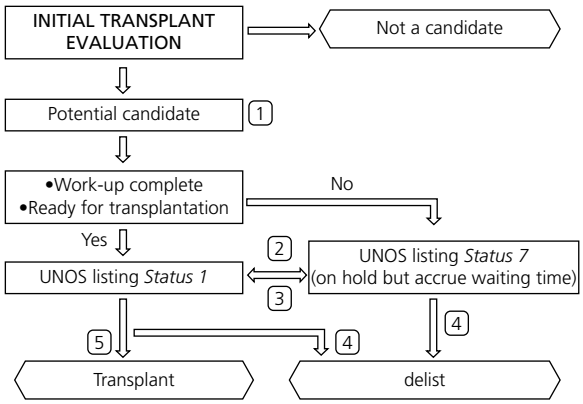

Figure 37.1. Algorithm for United Network for Organ Sharing (UNOS) listing and delisting process.

1 Discuss options (see text): Living kidney donation, ECD, dual transplant of ECD kidneys, DCD, PHS high risk, kidneys from donors with hepatitis C.
2 New medical and/or psychological issues (Status 1 → Status 7).
3 Work-up complete. All issues have been resolved (Status 7 → Status 1).
4 Development of irreversible complications that contraindicate transplantation.
5 Ongoing health maintenance and screening (see text).

UNOS, United Network for Organ Sharing; ECD, expanded criteria donor; DCD, donor after circulatory death; PHS, Public Health Service.

Effect of patient's intrinsic factors on waiting time

ABO blood types

The OPTN/UNOS database revealed that the Kaplan–Meier median waiting time for registrants listed between 1999 and 2004 ranged between 1763 and 1852 days for O blood type, 1085 and 1208 days for A blood type, 1967 and 2033 days for B blood types, and 597 to 855 days for AB blood type [1]. Hence, waiting time is longest for blood groups O and B.

Ethnic background

In the US, the ratio of Caucasian to African–American listed registrants has remained unchanged over the last decade. African–Americans account for approximately 35% of listed registrants, similar to their representation in the chronic dialysis population and approximately threefold higher than their frequency in the general population [2]. The percentage of newly listed African–American registrants is lower than their existing waiting list counterparts (30% vs. 35%), suggesting their slower rate of transplantation. In contrast, the percentage of newly-listed Caucasian registrants is higher than their existing waiting list counterparts (64% vs. 53%), reflecting their higher rate of transplantation [2]. Hispanics and Latinos account for approximately 17–18% of both listed registrants and new registrants [2]. A national registry study of non-elderly patients (18–64 years of age) initiating maintenance dialysis between 1995 and 2006 similarly demonstrated lower relative rates of deceased donor kidney transplantation among non-white compared with white patients [3]. The reduced rates of deceased donor transplantation among American Indians, Alaska Natives, and blacks reflected both lower rates of waitlisting and lower rates of transplantation among those waitlisted. However, among Asians, Pacific Islanders, and Hispanics, access to the waiting list was similar or better than for whites, but time to transplantation among those waitlisted was longer.

The OPTN/UNOS database revealed that the Kaplan–Meier median waiting times for white registrants listed between 1999 and 2004 were approximately 30–35% less than for blacks, Hispanics, Asians, and non-Hispanics, and approximately 15% less than for American Indians. Pacific Islanders had the longest waiting time among all ethnicities [1].

The discrepancies in the rates of transplantation and waiting times among different ethnicities are thought to be due to multiple factors, including personal and cultural beliefs in organ transplantation as well as organ donation, various frequencies of HLA mismatching, socioeconomic status and education levels, and variability in access to transplantation by ABO blood group and geographic location among others.

Highly sensitized transplant candidates

Approximately 40% of waitlisted transplant candidates in the US have high levels of preformed anti-HLA antibodies, also known as high panel reactive antibodies (PRAs). High PRA levels are generally thought to result from previous exposure to non-self HLA antigens, such as from pregnancies, blood transfusions, and/or prior failed transplants. The waiting times for a compatible cross-match among candidates with a high PRA may be considerably prolonged. The OPTN/UNOS database revealed that between 2001 and 2002, the Kaplan–Meier median waiting times for registered transplant candidates with PRA levels of 0–9%, 10–79%, and $\geq$80% were 1329 days ($\sim$3.6 years), 1920 days ($\sim$5.3 years), and 3649 days ($\sim$9.9 years), respectively [1]. Over the last half decade, various desensitization protocols (covered in depth in Chapter 68) have been developed to allow successful transplantation of highly sensitized patients, including intravenous immunoglobulins, plasma exchange or immunoadsorption, and rituximab (an anti CD-20 monoclonal antibody). More recently, bortezomib (a proteasome inhibitor) and eculizumab (an anticomplement C5 monoclonal antibody) have been introduced to various desensitization protocols. Currently, some centers offer desensitization programs to broadly sensitized candidates who are at the top of the deceased donor waiting list. Presently, at the University of California, Los Angeles, the top 30 candidates in each blood group are identified based on dialysis start date. Highly sensitized candidates whose identities appear on the match runs are seen in clinic and given the opportunity to participate in desensitization protocols. Generally, one patient in each blood group (except for the AB blood group) is being desensitized at the same time.

Effect of patient's location of residence on waiting time

The US is divided into 11 OPOs regions. Waiting times vary greatly by OPO region [4]. This has led some prospective transplant candidates to pursue listing at multiple centers (multilisting) served by different OPO agencies in an attempt to increase their likelihood of undergoing transplantation.

The UNOS registry data revealed that multiple listing provided an 88% greater rate of access to kidney transplantation, while reducing waiting times by nearly 50% (median waiting time: single- vs. multi-listed: 156 vs. 83 weeks, respectively, for candidates registered between January 7 1995 to 30 June 2000) [5]. Notably, multilisting resulted in a higher transplant rate in nearly all demographic, biological, and socioeconomic subgroups, including those known to have significantly less access to transplantation, such as

those of African–American ethnicity, female gender, and patients in the O and B blood groups. Multilisting did not appear to benefit patients who had health maintenance organization (HMO) coverage for their transplant. It is suggested that multilisting tends to reduce waiting time disparities among OPOs because secondary listing OPOs generally have shorter waiting times than primary listing OPOs. Nonetheless, it should be noted that while patients awaiting transplantation at centers with long waiting times might benefit from multilisting at centers with shorter average waiting times, secondary listing at transplant centers with large waiting lists was shown to be an expensive and futile process [6].

Specific options to reduce waiting time

Candidates with chronic hepatitis C

The number of listed hepatitis C antibody-positive transplant candidates who have consented to receive a hepatitis C donor kidney is generally small (<20 at the authors' institution at the time of this writing). The waiting time for a hepatitis C deceased donor kidney is relatively short (currently 2–3 years at our institution). Hence, HCV-consented patients should be followed closely to ensure that upon listing they are medically and psychosocially ready for transplantation at all times.

Public Health Service high-risk donor kidneys

The PHS has implemented specific criteria that determine a donor as high risk for transmission of viral disease, including human immunodeficiency virus (HIV) and hepatitis C. These risk factors, within 1 year of donation, include:

1. male homosexual contact;
2. non-medical intravenous, intramuscular, or subcutaneous use of drugs;
3. promiscuous sexual relations in exchange for money or drugs;
4. individuals who have had sexual contact in the preceding 12 months with any person described in 1 through 3 above *or* with known or suspected to have HIV infection through percutaneous inoculation or through contact with an open wound, non-intact skin or mucous membrane;
5. persons with known or suspected sexually transmitted disease;
6. inmates of correctional systems
7. persons who cannot be tested for HIV infection because of refusal, inadequate blood samples (e.g. hemodilution that could result in false-negative tests), or any other reasons;
8. persons with a repeatedly reactive screening assay for HIV 1 or HIV 2 antibody regardless of the results of supplemental assays;
9. persons whose history, physical examination, medical records, or autopsy reports reveal other evidence of HIV infection or high-risk behavior (e.g. diagnosis of AIDS, unexplained weight loss, night sweats, skin or mucous membrane lesions typical of Kaposi's sarcoma, unexplained lymphadenopathy lasting >1 month, unexplained fever >38.6 °C) for >10 days, unexplained persistent cough and shortness of breath, opportunistic infections, unexplained persistent diarrhea, or needle tracks or other signs of parenteral abuse).

The risk of transmission of viral disease from a PHS high-risk donor kidney is not known but has been estimated to range from 1 in 300 to 1 in 10 000. Nonetheless, in selected cases where there is anticipated prolonged waiting time or exhaustion of dialysis access sites, transplantation with a donor kidney of this category may confer a survival advantage over remaining on dialysis. Of note, a high-risk donor kidney as defined by the PHS does not include the risk of transmission of undetected malignancy from donor organ to recipient. The complete PHS guidelines can be found on http://www.publichealthreports.org/issuecontents.cfm?Volume=128&Issue=4.

Table 37.1. Factors that determine expanded criteria donors (as defined by UNOS)

Donor condition	Donor age categories (years)	
	50–59	≥60
CVA + HTN + creatinine >1.5 mg/dL	X	X
CVA + HTN	X	X
CVA + creatinine >1.5 mg/dL	X	X
HTN + creatinine >1.5 mg/dL	X	X
CVA		X
HTN		X
Creatinine >1.5 mg/dL		X
None of the above		X

X, expanded criteria donor; CVA, cerebrovascular accident was cause of death; HTN, history of hypertension at any time.
Adapted from UNOS.

Expanded criteria donor kidney

Currently, the waiting time for a deceased donor transplant is such that many waitlisted older transplant candidates die while awaiting transplantation from a standard deceased donor kidney. Furthermore, the duration of pretransplant dialysis has been shown to be associated with a significant and progressive increased risk of death-censored graft loss and risk for patient death after transplantation [7]. It is the practice at our center to offer the ECD program to all candidates aged 50 years or older. ECD kidneys are defined by donor characteristics that are associated with a 70% greater risk of kidney graft failure when compared to a reference group of non-hypertensive donors aged 10 through 39 years whose cause of death was not cerebrovascular accident (CVA) and whose terminal creatinine was ≤1.5 mg/dL. The donor factors associated with this increased relative rate of graft failure include age 60 years or older, or ages 50–59 years, with at least two co-morbid factors. The latter may include CVA as a cause of death, hypertension, and/or terminal creatinine >1.5 mg/dL (Table 37.1). Patients should be informed that candidates for ECD kidneys are simultaneously listed for a standard and ECD kidney. In selected cases, dual transplant of ECD kidneys has been offered to older recipients with excellent short- and intermediate-term allograft outcomes. Analysis of the OPTN/UNOS database consisting of 625 dual kidney transplants (DKT) and 7686 single ECD transplants demonstrated comparable 3-year overall graft survival between the two groups of transplant recipients (79.8% vs. 78.3%, respectively) [8]. It has been suggested that the salutary effect of DKT is due to greater viable nephron mass.

Donor after circulatory death kidney

One approach to expanding the pool of deceased donor organ supply has been to use organs from donors after circulatory death. A DCD kidney is by definition susceptible to variable degrees of warm ischemic damage and its use inevitably increases the incidence of post-transplantation delayed graft function (DGF) or primary non-function. The U.S. Renal Data System database demonstrated that recipients of DCD donor organs experienced nearly twice the incidence of DGF compared with heart-beating donors (42.3% vs. 23.3%, respectively). Nonetheless, DCD donor transplants experienced comparable allograft survival when compared with heart-beating deceased donor transplants at 6-year

follow-up (73.2% vs. 72.5%, respectively, P = NS) [9]. Interestingly, there was a trend for better patient survival at 6 years for DCD compared with heart-beating donor renal transplant recipients (80.9% vs. 77.8%, respectively, P = NS). Significant risk factors for allograft loss for DCD donor organ recipients include repeat transplant, DGF, donor age older than 35 years, and head trauma as a cause of initial injury. To optimize the utilization of DCD kidneys, machine perfusion parameters and viability testing have been used by a number of centers to assess the extent of kidney damage and to predict graft function. At the authors' institution, DCD kidneys are offered to preidentified and consented waitlisted candidates.

There should be a detailed discussion about the options of HCV, ECD, dual transplant of ECD kidneys, DCD, and PHS high-risk deceased donor kidneys with the potential transplant candidate at the time of initial evaluation and the options raised again during follow-up visits. The selection of these options is considered specifically in Chapter 21, 22, and 53 Living kidney donation should also be addressed (discussed in depth with regard to its conduct and ethics in Chapters 23 and 138, respectively).

Development of a new kidney allocation system: time on dialysis

At the National Conference on the Wait List for Kidney Transplantation held in Philadelphia in March 2002, a panel of experts consisting of representatives from nine US organizations proposed that time waiting for a transplant should be calculated from the point at which a patient begins maintenance dialysis rather than from completion of transplant evaluation [10]. The proposal was designed to eliminate the advantage of patients with early access to the list and provide equitable access to all suitable renal transplant candidates, particularly among ethnic minorities and economically disadvantaged patients. A pilot study to assess the impact of beginning the waiting time for a kidney transplant at the time a candidate first begins dialysis or meets a standard medical definition of kidney failure was first approved by the OPTN/UNOS Board of Directors in November 2003.

Early reports from two OPOs [One Legacy (CAOP) and Gift of Life (MIOP)] that adopted the dialysis waiting time allocation system demonstrated a trend towards an increase in the average number of years on dialysis and a decrease in the average number of years on the waiting list for patients receiving deceased donor transplants in the 18-month period after policy implementation. The apparent paradoxical increase in average number of years on dialysis prior to transplantation and a concomitant reduction in waiting time presumably reflects a higher number of transplantations among the high number of late referrals of long-time dialysis-dependent patients to transplant centers. This trend was not observed in the OPOs where this allocation policy was not implemented [11]. In the 18-month period prior to (on or before April 28 2004) or after the policy change (on or after April 29 2004), the average number of years on dialysis for deceased donor transplant recipients in the CAOP was 3.9 versus 4.8 years, respectively. In contrast, a decrease in the average number of years on the waiting list was observed after the policy change (2.3 years after vs. 2.7 years before, respectively). This increase in the average number of years on dialysis and decrease in the years on the waiting list was consistent across all ethnicities in the CAOP and MIOP (except for Hispanics and Asians in the MIOP). A slight increase in transplant rates for African–Americans was observed in some states but not in others. It is speculated that the effects may not yet be apparent in regions where waiting times may be substantial and longer follow-up is needed. Overall, there appeared to be a decrease in the average number of years on the waiting list across all ethnicities.

Based on preliminary reports, the OPTN Kidney Transplantation Committee has recently recommended that time on dialysis should be incorporated into the national allocation policy. Dialysis waiting time and an estimated glomerular filtration rate (eGFR) of $<$20 cc/min will be implemented in the national allocation algorithm in 2014.

Maintaining and monitoring waitlisted patients

The allocation policies require that all status 1-listed patients should be ready for transplantation at all times. However, guidelines for maintaining and monitoring the health of active waitlisted patients are lacking. The health status of patients, particularly cardiovascular status, may deteriorate with time spent on dialysis. The following section discusses suggested guidelines for managing waitlisted patients, including frequency of follow-up visits, storage sera for pretransplant cross-match, and general health maintenance. The latter includes cardiovascular and valvular heart disease, malignancy, and infectious disease screening. It should be noted that practices vary widely among transplant centers.

Follow-up frequency

With the ever growing number of patients placed on the waiting list and the disparity between donor organ supply and demand, regular or annual follow-up of all waitlisted transplant candidates has become impractical, particularly for large volume transplant centers where the number of waitlisted patients generally exceeds 1500/year. Hence, formulating an algorithm to update patient data remains a challenge for transplant physicians, coordinators, and social workers, particularly in regions where waiting times regularly exceed 6–7 years.

At the University Of California, Los Angeles, over the last half decade, $>$1500–2000 patients were on the waiting list each year. It is our current practice to see the top 30 patients in each ABO blood group and those whose identities appear on the "match run" annually to reassess their overall health and any demographic issues. In the US the match run is done via a UNetSM centralized computer network whereby medical information about the deceased donor is matched against transplant candidates. This match run automatically creates a ranked list of suitable candidates for each organ based on predefined factors, including tissue match between donor and transplant candidates, ABO blood type, PRA levels, time spent on the waiting list, pediatric candidates, and geographic distance between the potential recipient and the donor.

Sera storage for pretransplant cross-match

When sera from waitlisted patients are collected at a predetermined interval and are available in the HLA laboratory, a final cross-match can usually be performed without obtaining a fresh sample from the patient. At the authors' institution, sera from non-sensitized transplant candidates who are in the top 25% of the list are obtained quarterly, whereas for the remaining non-sensitized patients sera can be obtained semi-annually. For highly sensitized patients, screening tray sets should be prepared monthly. A preliminary cross-match is performed by testing donor cells on the appropriate tray set at the time of donor HLA typing.

1 Refer to Table 37.2 footnote.

2 ECG findings suggestive of a previous myocardial infarction, ST–T wave changes.

3 Center specific.

4 If necessary, PCI or CABG and cardiac rehabilitation should be performed prior to listing or transplantation.

DM, diabetes mellitus; SPK, simultaneous pancreas–kidney; Tx, transplant; ECG, electrocardiogram; CAD, coronary artery disease; ACC/AHA, American College of Cardiology/American Heart Association; PCI, percutaneous coronary intervention; CABG, coronary artery bypass graft.

Health maintenance

Cardiovascular and valvular heart disease

Cardiovascular screening

Cardiovascular screening is considered by most transplant centers as an essential component of the transplant evaluation process because of the high prevalence of clinically silent coronary heart disease among end-stage kidney disease (ESKD) patients. Furthermore, cardiovascular disease (CVD) is the leading cause of death after renal transplantation. Deaths with a functioning graft occurring within 30 days after transplantation are due to ischemic heart disease in nearly half of the cases. A detailed cardiovascular history not only predicts the operative risk but also helps in postoperative cardiac management to improve short- and long-term cardiac outcomes. However, controversies exist regarding the best strategy for pretransplant assessment and management of coronary artery disease (CAD) to prevent adverse perioperative cardiac events. Furthermore, there has been no consensus on the selection of candidates who should undergo repeated testing or the determination of the type or frequency of testing during the prolonged waiting period. The American Society of Transplantation recommends a cardiac stress test in high-risk renal transplant candidates, defined as patients with diabetes, prior history of ischemic heart disease, abnormal electrocardiogram (ECG), or age of 50 years or older. Coronary angiography should be considered only in patients with a positive stress test [12]. However, over the years this strategy has been challenged due to the now recognized reduced sensitivity and specificity of non-invasive testing in renal transplant patients compared with those of the general population. Abnormalities on myocardial perfusion study have been suggested to correlate well with the presence of CAD in the general population with mean weighted sensitivity of 88% and specificity of 74% [13], whereas in ESKD patients, sensitivities and specificities ranging from 37% to 90% and 40% to 90%, respectively, have been reported [14]. A number of transplant centers recommend direct coronary angiography in high-risk patients.

The authors' proposed algorithm for initial pretransplant cardiac evaluation and continued cardiac surveillance for waitlisted patients are shown in Figure 37.2 and Table 37.2, respectively. The authors' suggested guidelines were based in part on Lee' s cardiac risk assessment model in the general population [15], the 2007 American College of Cardiology and American Heart Association (ACC/AHA) surgical risk stratification [16], the National Cholesterol Education Program Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (ATPIII) guidelines [17], and the K/DOQI Clinical Practice Guidelines for Cardiovascular Disease in Dialysis Patients [18]. A detailed discussion of cardiac risk assessment in renal transplant candidates is beyond the scope of this chapter. Interested readers are referred to Pham et al. [19].

Valvular heart disease

Patients with ESKD on maintenance dialysis commonly develop valvular heart disease (VHD) as a result of secondary hyperparathyroidism, elevated calcium–phosphorus product, hypercalcemia, and hyperphosphatemia. Other suggested risk factors include hypertension, diabetes mellitus, hyperlipidemia, left ventricular

Table 37.2. Suggested cardiac surveillance for waitlisted transplant candidates

No known CAD or initial evaluation negative	
(a) Diabetic ESRD	Annually
(b) Non-diabetic + any of the following: ≥2 traditional[1] or unconventional[2] risk factors or ≥1 CAD risk equivalents[3]	Biannually
(c) "Lower risk"[4]	Every 3 years
Established CAD	
Medical management per ACC/AHA guidelines	Annually
Successful prior PCI	Annually
History of successful CABG	3 years post CABG then annually
Asymptomatic aortic stenosis[5]	
Mild	Echocardiogram every 3–5 years
Moderate[6]	Echocardiogram annually

[1] *Traditional risk factors:* age >45 years in men and >55 years in women, diabetes mellitus, hypertension, dyslipidemia, obesity, history of angina pectoris, congestive heart failure, previous cardiac events, smoking, family history.
[2] *Unconventional risk factors:* left ventricular hypertrophy (LVH), coronary artery vascular calcification, dialysis duration ≥2 years.
[3] *CAD risk equivalent:* type 1 diabetes mellitus (DM) > type 2 DM, atherosclerosis in other vascular beds, history of stroke.
[4] *Lower risk:* defined as not meeting criteria (a) or (b) above.
[5] Clinical evaluation annually.
[6] Cardiology consultation advisable.
ESRD, end-stage renal disease; CAD, coronary artery disease; PCI, percutaneous coronary intervention; CABG, coronary artery bypass graft; ACC, American College of Cardiology; AHA, American Heart Association.

Table 37.3. Categorization of cancers in the end-stage kidney disease (ESKD) population

ESKD related

  - Mouth, tongue, tonsil, oropharynx
  - Esophagus
  - Stomach
  - Anus
  - Liver
  - Larynx
  - Lung
  - Cervix, uteri, vagina, vulva
  - Penis
  - Eye, squamous cell carcinoma only

Not related to immune deficiency
- Rectum
- Breast
- Ovary
- Prostate

Of uncertain status
- All other cancers

Data from Steward et al. [22].

hypertrophy, uremic milieu, and anemia among others [20]. The most common abnormalities include valvular and annular thickening, and calcification of any heart valves resulting in regurgitation and stenosis. Aortic and mitral valve thickening or sclerosis occur in 55–69% and 40–60% of patients, respectively [20]. Valvular sclerosis was previously thought to have no clinical significance, but has now been recognized as a potential cause for progressive stenosis and cardiovascular mortality. Mitral annular calcification occurs in 10–50% of patients, and aortic valve calcification in 25–55% of hemodialysis patients. Calcifications of the tricuspid and pulmonic valves are rare [20]. Currently, the K/DOQI Clinical Practice Guidelines for Cardiovascular Disease in Dialysis Patients [18] recommend following the ACC/AHA guidelines to evaluate dialysis patients for the presence of VHD. Similarly, follow-up of VHD in dialysis patients should follow the guidelines for the general population, except for the frequency of follow-up for aortic stenosis (discussed further below) [18].

The optimal frequency of visits by patients with VHD has not been clearly defined, but most clinicians advocate annual history and physical examination in asymptomatic patients. Additionally, the ACC/AHA guidelines recommend an annual echocardiogram in patients with asymptomatic severe aortic stenosis (AS), every 1–2 years in those with moderate AS, and every 3–5 years in those with mild AS (class I). However, an echocardiogram should be performed annually in asymptomatic waitlisted transplant candidates with moderate or more severe AS (or in any other dialysis patients who are suitable candidates for aortic valve replacement). It has been suggested that AS progresses faster in dialysis patients than in the general population. An echocardiogram should also be performed in any patients with changing symptoms (class I). Asymptomatic patients may be considered for exercise testing to elicit symptoms and to evaluate hemodynamic responses if their clinical status is equivocal due to sedentary lifestyles (class IIb) [21]. Similar guidelines are generally recommended for waitlisted dialysis patients. Of note, the K/DOQI Clinical Practice Guidelines recommend optimization of dry weight prior to testing [18]. No specific recommendations were made for other VHDs.

Malignancy screening

Studies in ESKD patients treated by dialysis or transplantation, and in patients with HIV/AIDS, suggest that cancers can be categorized into ESKD-related, immune deficiency-related, not related to immune deficiency, or of uncertain status (Table 37.3) [22]. ESKD-related cancers include kidney, urinary tract, thyroid, and multiple myeloma. Although there has been no consensus on the type and frequency of malignancy screening in waitlisted renal transplant candidates, all patients should adhere to standard age-appropriate cancer surveillance. Suggested guidelines for cancer screening are shown in Table 37.4. In addition, screening for malignancy in adult kidney transplant candidates should focus on the kidney and urinary tract, particularly in dialysis-dependent ESKD patients (discussed further below). Serum immunofixation electrophoresis (IFE) should be performed in all transplant candidates older than 60 years of age. Chronic hepatitis B virus- and C virus-infected individuals should be screened for liver cancer. Although thyroid carcinoma has been observed at increased frequency in dialysis patients compared with the general population, thyroid ultrasound is not part of routine pretransplant screening. It has been suggested that regular thyroid ultrasound is justified in dialysis patients, although there have been no studies to confirm or refute this recommendation [23]. Hence, screening prospective renal transplant candidates for thyroid cancer should be done at the discretion of the clinicians.

Table 37.4. Preventive care recommendations for cancer surveillance in waitlisted transplant candidates

Screening for	Starting at age (years)	Early detection and preventive care	Screening frequency
Colorectal cancer	Average risk: 50	Early detection and prevention (preferred)	Colonoscopy: every 10 years, or Flex sig every 5 years, or CT colonography every 5 years
		Early detection only	FOBT annually, or Fecal immunochemical test annually
	Increased risk: 40	Colonoscopy	Every 5 years if a first-degree relative had colorectal cancer at <60 years of age @ 10 years younger than the youngest family member with diagnosis of colorectal cancer Every 10 years if the relative was 60 years of age with diagnosis of colorectal cancer Consider referral to medical genetics if two or more first-degree relatives had colorectal cancer
Females			
Breast cancer	50–75	Breast exam and screening mammography	Every 1 or 2 years
	40–49	Breast exam and screening mammography	Every 1 or 2 years (no evidence for or against for this age group)
	Before age 30 (if mother or sister had breast cancer)		
Cervical cancer[1]	3 years after onset of sexual intercourse or by age 21 whichever comes first	Pap smear and pelvic exam	Annual for conventional cytology Every 2 years for liquid-based cytology
Males			
Prostate cancer[2]	50	PSA testing (with or without digital rectal exam)	Annual if @ screening PSA is >2.5 ng/mL Every 2 years if @ screening PSA is <2.5 ng/mL
	40–45[3]	PSA testing (with or without digital rectal exam)	

[1] For age >30 years, every 2 years after three normal consecutive smears and no increased risk.
[2] Recommended by the American Cancer Society.
[3] African–Americans, relative with prostate cancer <65 years of age, or men with *BRCA1* and/or *BRCA2* mutation.
Flex sig, flexible sigmoidoscopy; FOBT, fecal occult blood testing; PSA, prostate-specific antigen.

Acquired cystic kidney disease and renal cell carcinoma screening

Acquired cystic kidney disease (ACKD) is defined as having more than three to five macroscopic cysts in each kidney in a patient who does not have a hereditary cause of cystic disease. The potential for malignant transformation of ACKD has a reported incidence of <1–7% among ACKD patients or up to a 40-fold increased risk of renal cell carcinoma (RCC) in ACKD patients compared with the general population. RCC accounts for approximately 80% of renal cell neoplasms observed in uremic patients, of which nearly 85% are asymptomatic [23]. Suggested risk factors include male gender (male-to-female ratio, 7:1), African–American ethnicity, dialysis duration, and severe ACKD with marked organ enlargement [23].

There has been no consensus on the frequency of screening for renal neoplasms in waitlisted patients. However, all suitable renal transplant candidates should have a baseline renal ultrasound. The frequency of screening should follow the guidelines set forth for dialysis patients. If there is no evidence of ACKD at initial screening, repeat ultrasound can be done annually or biannually [23]. Annual screening in patients who have been on dialysis for 3–5 years has been advocated [24]. The presence of benign cysts (Bosniak I and II) requires follow-up ultrasound every 6 or 12 months and additional contrast-enhanced computed tomography (CT) or magnetic resonance imaging (MRI) for progressive lesions. In those with moderately complex cysts (Bosniak IIF), follow-up ultrasound every 3 months and contrast-enhanced CT or MRI every 12 months is advisable. The presence of an indeterminate cystic mass (Bosniak III) or clearly malignant cystic mass (Bosniak IV) mandates further evaluation with contrast-enhanced CT or MRI and urology referral [23]. RCC may require tumor-free waiting periods prior to transplantation depending on the stage or extent of the disease (see Chapter 28). A suggested screening algorithm for ACKD and renal neoplasms is shown in Figure 37.3.

It is noteworthy that native renal cysts (NRCs) and dialysis duration have also been suggested to be risk factors for RCC post transplant [25]. In a single-center study consisting of 1036 renal transplant recipients who underwent routine ultrasound screening of their native and transplant kidneys (within 1 month post transplant, then every 5 years for those without cysts, and every 2 years for those with cysts), RCCs were diagnosed in ten asymptomatic transplant recipients at a median of 5.8 years post transplant. Based on the presence and timing of NRCs, transplant recipients were grouped into those with no NRCs (No-NRC, n = 392), new NRCs (New-NRC, n = 166), pre-existing NRCs (Pre-NRC, n = 274), and time-indeterminate NRCs (TI-NRC, n = 204). During the study period, RCC developed in ten Pre- and TI-NRC patients who had significantly longer dialysis duration than the No-NRC or New-NRC groups (6.7 ± 3.9 and 3.3 ± 3.2 years vs. 2.7 ± 3.1 and 2.6 ± 2.4 years, respectively). None of the patients from the No-NRC or New-NRC groups developed RCC. The results of the study suggest that NRC and increased dialysis duration are risk factors for RCC post transplant [25].

Screening for infectious diseases

Although practice differs among transplant centers, generally accepted standard screening includes hepatitis serologies (hepatitis B surface antigen, hepatitis B core antibody IgM and IgG, hepatitis B surface antibody, and hepatitis C antibody), HIV 1 and 2 antibody, cytomegalovirus IgG antibody, rapid plasma reagin (RPR) or *Treponema pallidum* particle agglutination (TP-PA) test for syphilis, Epstein–Barr virus (EBV) antibody panel, herpes simplex virus (HSV) and varicella-zoster virus (VZV) IgG antibodies, and PPD

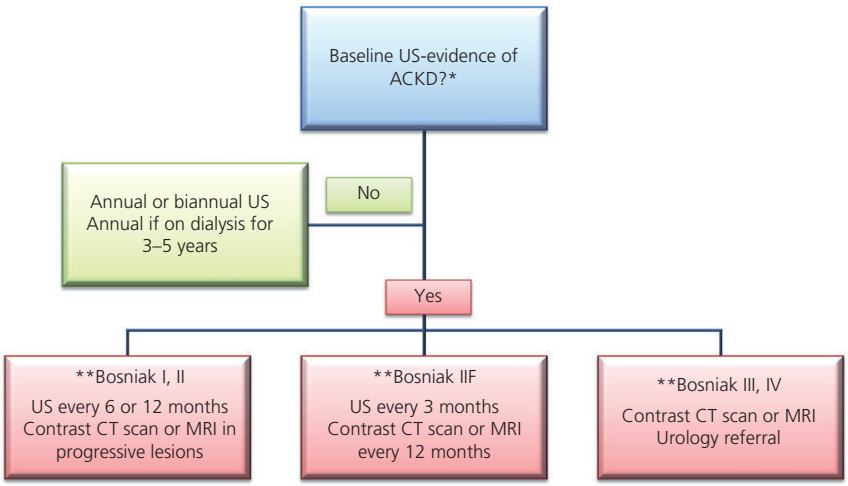

Figure 37.3. Suggested screening algorithm for acquired cystic kidney disease (ACKD) and renal neoplasms.
*ACKD: >3–5 cysts in each kidney.
**Bosniak I, II, benign cysts; Bosniak IIF, moderately complex cysts; Bosniak III, indeterminate cystic mass; Bosniak IV, clearly malignant cystic mass.
US, ultrasound.

Table 37.5. Infectious disease surveillance for waitlisted transplant candidates

Human immunodeficiency virus (HIV)	Annual screening for high-risk individuals
Hepatitis C virus (HCV)	Annual screening for ELISA-negative patients Consider PCR testing for ELISA-negative patients with abnormal transaminase levels HCV-positive patients require ongoing care, histologically advanced disease may preclude transplantation
Hepatitis B virus (HBV)	Previously unexposed patients should undergo immunization, with annual testing of antibody levels and appropriate booster doses if indicated
Tuberculosis*	PPD-positive patients should receive standard chemoprophylaxis and annual chest X-ray
Strongyloides	Annual screening in endemic areas
Epstein–Barr virus, toxoplasmosis, cytomegalovirus, herpes simplex	Annual screening not indicated

*In recent years, the PPD skin test has gradually been replaced by the QuantiFeron TB Gold test. The latter is useful in BCG-vaccinated patients to distinguish between BCG versus TB reaction on PPD test.

skin test or quantiFeron TB Gold test. In recent years, the traditional PPD skin test has gradually been replaced by the QuantiFeron TB Gold test. The latter is useful in BCG-vaccinated patients to distinguish between BCG reaction versus TB reaction on PPD test. All prospective transplant candidates are required to undergo testing at the time of initial transplant evaluation. Special serologic testing based on epidemiologic risks or exposure history include coccidioides IgM and IgG antibody, histoplasma immunodiffusion antibody or urine antigen, human T-cell lymphotrophic virus (HTLV-I/II) antibody, *Strongyloides* antibody, and *Trypanosoma cruzi* antibody [26].

Repeated serologic testing for hepatitis and HIV while awaiting a transplant are generally performed at the discretion of the referring nephrologists. At a National Consensus Conference on the management of waitlisted patients held in Philadelphia in 2002, a panel of experts set forth guidelines for periodic surveillance of certain infectious diseases among waitlisted patients (Table 37.5) [27].

Listing status awareness

A single-center survey study using the Dialysis Patient Transplantation Questionnaire (DPTQ) revealed that >50% of patients (18 of 34) who were undergoing pretransplantation work-up were unaware of their true listing status [28]. Of these patients, 88.9% (16 of 18) mistakenly thought they were listed and 11% were unsure of their listing status. Among 32 waitlisted patients, 81.3% correctly identified themselves as listed, 6.2% mistakenly thought they were not listed, and 12.5% were unsure. Notably, all of the waitlisted patients who were not aware of their listing status were status 7, indicating that they required additional testing or developed intercurrent illnesses. Nearly two-thirds of the surveyed patients had completed high school and 11% had some level of college education. Although the study population consisted predominantly of black/African–Americans (82.8%) and the results have yet to be validated in patients of other ethnic backgrounds, the finding of a substantial lack of listing status awareness among mostly high-school graduates merits attention because it suggests a lack of communication between the transplant program, patients, and referring nephrologists. It has been proposed that collecting self-reported data using the DPTQ and comparing self-reported listing status with the UNOS listing database is a quick and inexpensive screen for a correctable problem.

At the authors' institution, all listed transplant candidates are informed of their UNOS waiting list status via mail annually. Patients are advised to notify their assigned transplant coordinators (or other transplant team members) if there has been a change in demographic issues or health status, such as relocation, transfer to another dialysis center, change in contact numbers, intercurrent illnesses, or hospitalization. It is also our policy to send a list of all waitlisted transplant candidates and their current status to their corresponding dialysis unit social workers quarterly.

Management of the deceased donor waiting list: national survey

A national survey consisting of 192 UNOS-certified programs in the US revealed that 71% of programs advocate routine follow-up monitoring of all waitlisted transplant candidates via either scheduled appointments or program-initiated telephone contacts [27]. The frequency of follow-up and the requirement for adherence to

Table 37.6. General guidelines for the management of waitlisted transplant candidates

1 Each transplant program should uphold the following responsibilities:
- **(a)** Develop a well-structured system to maintain ongoing contact with its waitlisted patients
- **(b)** Develop clear lines of communication with the referring nephrologists and dialysis staff members [28]
- **(c)** Define clear expectations to patients, their nephrologists, and dialysis staff members (e.g. keeping transplant programs informed of any medical or psychosocial issues in a timely manner, ensuring that patients' blood samples are sent to the HLA laboratory at a predetermined time interval. This will allow the HLA laboratory to perform a final cross-match without obtaining a fresh sample from the patient when a kidney becomes available)
- **(d)** Closely monitor patients at high risk for cardiac events. A proposed algorithm for continued cardiac surveillance for waitlisted patients is shown in Table 37.2 [19]
- **(e)** If feasible, designate cardiologist(s) to assist in the care plan of waitlisted candidates
- **(f)** Develop standardized criteria for placing patients on hold or removing them from the waitlist to avoid allocation of kidneys to patients who are not medically ready for transplantation
- **(g)** Conduct regular multidisciplinary team meetings to address patients' active medical, surgical, and psychosocial issues relevant to their transplant candidacy. Based on the consensus decision-making, patients can be placed into one of the following categories: *List*; *Hold*; *Deferred*; *Delist*; or *Activate*
- **(h)** Identify the top 10–20 candidates in each ABO blood group based on "match run" and reassess their overall health and demographic issues to ensure their readiness for transplantation at all times
- **(i)** Develop a system to inform all listed transplant candidates of their UNOS waitlist status annually (or at regular intervals established by individual transplant programs)

2 Other aspects of the pretransplantation process should also be considered:
- **(a)** The cost implications, and medical, nursing, and administrative requirements for repeated patient evaluations and cardiac testing should be taken into account by government agencies, third-party insurers, and hospital administrations [28]
- **(b)** Meticulous attention should be paid to the health of waitlisted transplant candidates, particularly with respect to their cardiac risks, to optimize the eventual benefits and survival advantage of transplantation over dialysis [28]
- **(c)** The options of expanded criteria donor (ECD), dual transplant of ECD kidneys, and PHS high-risk deceased donor kidneys should be discussed with patients at the time of initial evaluation, and options should be reiterated during follow-up visits to facilitate the prompt and appropriate placement of these organs to preconsented patients
- **(d)** More frequent follow-up of high cardiac risk candidates and those awaiting pancreas transplants should be considered

standard cancer prevention screening (breast, cervical, and colon) are affected in part by transplant program size. Smaller programs are more likely to conform to the standard cancer screening recommendations compared with larger programs (72% of programs with $<$500 patients compared with 54% of programs with $>$500 patients; $P<0.05$). Periodic serologic testing for viral hepatitis is required by 80% of the programs, and screening for other infectious diseases is required by 52%. Regular prostate-specific antigen testing is required by 79% of programs. Asymptomatic high cardiac risk candidates, defined as those with established CAD, diabetes mellitus, advanced age, or obesity are required to undergo annual cardiac screening. Most programs performed non-invasive cardiac testing and $>$50% of transplant programs have a designated cardiologist or group of cardiologists.

Although regular follow-up and continuous updating of patients' medical, psychosocial, and demographic issues impose an enormous workload to transplant programs, the lack of such monitoring can increase the likelihood that a patient cannot be located because of demographic changes, frequency of cancellation of the transplant surgical procedure because of unanticipated or unrecognized new medical problems, and perioperative morbidity and mortality if such problems are overlooked. The frequency of the designated recipient being sent home because of unexpected medical problems was lower in smaller compared with larger programs. Such events affected $<$2% of the intended recipients in 61% of programs (80% of small programs; $P<0.001$ compared with larger programs). Seven programs indicated that $>$10% of patients were sent home because of unrecognized and/or unforeseen medical issues.

With the ever-growing number of patients placed on the deceased donor waitlist in general, and of older transplant candidates in particular, the management of waitlisted transplant candidates has become increasingly challenging for transplant programs. During the prolonged waiting period, patient's health and functional status may deteriorate or new medical or psychosocial issues may arise. These changes may render the patient unsuitable for transplantation or require additional diagnostic studies and/or management. While there have been no specific recommendations on how individuals programs should address these problems, general guidelines can be formulated and are outlined in Table 37.6.

Waiting list removals

Waiting list removals upon death, transplant, development of irremediable contraindications to transplantation, or removals for any other reasons should be reported to the OPTN within 24 h of removal.

Future studies

The need for the following future studies can be identified:

- The definition of "high risk" for cardiac events must be carefully studied and validated in prospective trials to avoid the increased cost and inconvenience of repeated testing [28].
- Prospective trials should be planned and implemented to assess the usefulness of non-invasive cardiac imaging for waitlisted patients and to determine the optimal and minimal requirements for imaging repetition [28].
- Randomized controlled trials to compare the effects of routine screening versus no screening on major adverse cardiac events are needed [29].

Summary

Waiting list management is an active process that entails ongoing communication between the dialysis units, patients, transplant coordinators, and transplant programs. Most transplant programs attempt to see transplant candidates on an annual basis. However, with the ever-growing number of patients placed on the waiting list, regular or annual follow-up of all waitlisted transplant candidates has become impractical. Knowledge of the factors that may affect waiting time may allow clinicians and transplant coordinators to formulate practical steps to ensure that patients who are at the top of the waiting list are suitable for transplantation at all times. At the

University of California, Los Angeles, it is our current practice to see the top 30 patients in each ABO blood group and those whose identities appear on the "match run" annually to reassess their overall health and demographic issues. During the follow-up visit, routine health maintenance status and cancer screening appropriate for age and gender, such as prostate-specific antigen, mammography, Pap smear, and colonoscopy are also reviewed. Although recommendations for cardiac surveillance of waitlisted patients vary among transplant centers, most advocate annual cardiac screening in diabetic transplant candidates.

In addition to reassessing patients' medical and psychosocial status, the availability of living donors should be readdressed. Currently, in an effort to maximize the utilization of living kidney donors, our program has implemented an algorithm to evaluate cross-match–positive and ABO-incompatible donor–recipient pairs. Patients are advised of living donor options, including paired exchange transplantation, positive cross-match and ABO incompatible transplantation through desensitization protocols, and living donor kidney exchange for both ABO-incompatible and cross-match–positive donor–recipient combinations. For older transplant candidates, the advantages and disadvantages of ECD kidney transplantation should be addressed.

Finally, effective communication between patients' primary nephrologists and transplant centers is invaluable in permitting waitlisted transplant candidates to be at their optimal medical health when a deceased donor kidney becomes available. Although practice guidelines vary among transplant centers, waiting list management will also need to be attuned to the changing kidney allocation system. Incorporation of dialysis waiting time and eGFR of $\leq$20 cc/min into the allocation system allows transplant centers to better predict which candidates are most likely to be offered an organ within a defined period of time. Hence, transplant centers should ensure that unsensitized patients in each blood group who have the longest waiting time are medically and psychosocially suitable for transplantation at all times.

CHAPTER 38

Waiting List Management for Liver Transplantation

John G. O'Grady
Institute of Liver Studies, King's College Hospital, London, UK

Introduction

Patients placed on the waiting list for liver transplantation have by implication a condition that will require active management up to the point the transplant actually occurs. The profile of patients on the waiting list can be broadly divided into four categories: chronic liver disease, hepatocellular carcinoma, acute liver failure, and a group of miscellaneous conditions. The majority of patients have chronic liver disease and some of the complications of liver failure that indicated listing for liver transplantation. Hepatocellular carcinoma (HCC) can complicate cirrhosis in the full spectrum of its manifestations, ranging from fully compensated disease to a degree of liver failure that independently warrants liver transplantation. This has implications for how the malignant component of the disease is managed whilst awaiting transplantation. Some other indications for transplantation are also independent of the severity of the cirrhosis, e.g. hepatopulmonary syndrome (HPS) which correlates more with the severity of portal hypertension than the associated cirrhosis. Acute liver failure is managed by emergency transplantation and, while the time spent on the waiting list is measured in days, this is a period of intensive clinical activity.

Occasionally patients listed for transplantation recompensate to an extent that it is possible to remove them from the waiting list (if minimal listing criteria apply) or they do not accrue sufficient model for end-stage liver disease (MELD) points to be allocated an organ. This scenario is most typically observed in patients with alcohol or chronic viral hepatitis as the underlying aetiologies and is mediated by ongoing abstention from alcohol and response to antiviral therapy, respectively. However, the more typical clinical course is of deterioration and about 20–30% of patients placed on the waiting list with chronic liver disease do not receive transplants either because they die, become too ill to transplant, or have tumour growth beyond transplant criteria. These failings to maintain the patient in a condition suitable for transplantation illustrate the scale of the challenges in managing patients on the transplant waiting list. Similarly, a proportion of patients with acute liver failure deteriorate to a degree that they do not receive transplants or will survive without undergoing transplantation.

This review of the management of liver disease is not intended to be comprehensive in terms of treatment protocols and options. Instead, the emphasis is on how standard approaches to care are modified or applied in the context of the expectation that the patient will proceed to liver transplantation. It serves as a companion to Chapter 29, which covers indications for liver transplantation, and also to Chapter 43, which details the intensive care management of individuals with hepatic failure.

Waiting list

In the US, the waiting list-to-transplant ratio is in the order of 2.5 : 1, while the figure in the UK is around 1.5 : 1. The most complete data regarding the composition of a waiting list come from the US. Scientific Registry of Transplant Recipients (SRTR) data for the period 1997–2006 show that at the end of that period there were about 12 000 registrants, with 72% aged over 50 years, 72% white, and 61% male [1]. All but 3% were awaiting their first transplant. The blood group distribution was 50% O, 38% A, 11% B, and 2% AB. At the end of 2006, 64% had been waiting >1 year and 47% >2 years, but the median time to transplantation was 306 days. Mortality rates, which were steadily declining, ranged from 9% to 14% depending on ethnicity. Mortality rates for different clinical situations are shown in Table 38.1. Almost half of patients with MELD scores of >30 were transplanted within 30 days bur one-fifth died within that period. Lower waiting list mortality rates have been achieved in some areas, notably parts of Spain and France with rates below 5% [2].

Factors influencing waiting times

The considerable variation in the length of time patients wait for transplantation depends on a number of issues (Table 38.2). MELD-based and related allocation systems promote the concept of the sickest patients taking priority irrespective of the length of time spent on the waiting list. In the US system, the only role for the time spent waiting is as a tiebreaker for patients with identical MELD scores. However, about 25% of patients listed for transplantation will have low and stable MELD scores, including patients with HCC or variant indications (e.g. HPS, familial amyloid polyneuropathy) and additional points need to be allocated if they are to receive transplants. There are numerous approaches to this, but one of the more sophisticated is the French individualized system that adds priority points related to 13 clinical situations [2]. The waiting time may also be influenced by the degree to which a favourable donor–recipient match is needed. This may be considered formally by using the donor-risk index (DRI) or less formally by aiming to avoid unfavourable pairings, e.g. the use of a steatotic liver from an elderly donor in a patient with hepatitis C virus (HCV)-related disease.

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Table 38.1. Waiting list mortality by clinical circumstance – SRTR data 2006

Circumstance	Mortality
Overall	11.7%
MELD 6–10	3.4%
MELD 21–30	6.5%
MELD >30	36.7%
Acute liver failure	18.7%
Metabolic disorders	14.3%
Malignant disease	12.3%
Cirrhosis (excluding cholestatic disorders)	10.9%
Cholestatic disorders	7.7%
Exceptions for hepatocellular carcinoma	11%
Other exceptions	15.0%

Table 38.2. Factors that influence waiting times and organ allocation

Parameter	Comment
Primary determinants	
"Raw" MELD score	Most widely used determinant of need
Adjusted MELD score	Compensates for patients whose need is not reflected by "raw" MELD
Time spent on waiting list	Significant factor in the UK and some parts of Europe
Secondary determinants	
Blood group	Blood group O patients tend to wait longer, effect on other groups vary with ethnicity
Donor-risk index (DRI)	Objective to find favourable match to optimize outcome
Degree of steatosis	Same concept as DRI
Size	Problem for small adults who compete with paediatric patients
Donor age	May influence allocation in patients with hepatitis C virus (HCV), although practice tends to reflect aspiration to reduce impact of disease recurrence
Viral history	Donors with evidence of viral exposure to HBV, HCV or HIV may be matched to patients with respective viruses
Little or no impact	
Histocompatability	Rarely used in liver allocation
Donor age	In absence of concerns about disease recurrence

Cirrhosis and related complications

Routine monitoring

The frequency of clinical and laboratory monitoring will reflect the severity of the liver disease and the relative stability or otherwise of the patient. Outpatient monitoring at intervals of 1–2 months is fairly typical for this population. Organ allocation systems that are based on MELD or related systems may mandate how often the laboratory results are updated. Monitoring is aimed at documenting change in the severity of the liver disease as well in electrolyte profiles or renal function that may be amenable to therapy.

Surveillance programmes for portal hypertension and HCC are standard practice for patients with cirrhosis. The details of the surveillance protocols may vary between institutions or countries, but these should be maintained after patients are placed on the waiting list for liver transplantation. Ultrasound of the liver at 4–6-month intervals addresses two components of the surveillance requirement as it typically is part of the screening process for HCC (frequently combined with alpha-fetoprotein estimations) and also assesses portal vein patency. A de-novo HCC may be detected on ultrasound, which will require staging using local protocol, most often with computed tomography (CT) and/or magnetic resonance imaging (MRI). A small proportion of these HCCs are found to be beyond transplant criteria and such patients should be removed from the waiting list. More typically, new diagnoses of HCC trigger consideration of bridging strategies while the patient remains active on the waiting list.

The development of portal vein thrombosis is relevant to the transplant surgeon as very extensive thrombosis may alter a patient's suitability for liver transplantation. Although anticoagulation is not standard management for portal vein thrombosis complicating cirrhosis, its role needs to be assessed on an individual basis in candidates for liver transplantation. The potential benefit of preventing extension of the thrombus and the impact this might have on the complexity of surgery are considered against the patient's risk of bleeding. New portal vein thrombosis results in a sudden increase in portal pressure, which could significantly alter the risk of variceal bleeding. Endoscopic re-evaluation of oesophageal and gastric varices is, therefore, indicated.

Table 38.3. Management of ascites

Intervention	Comment
Restrict salt intake	Do not compromise nutrition
Restrict fluid intake	Prioritize maintaining serum sodium >130 mmol/L
Diuretics	Titrate to safety rather than efficacy when these conflict
Paracentesis	Albumin replacement probably also beneficial
Transvenous intrahepatic portovenous shunt (TIPS)	Avoid if possible
Antibiotics	Consider prophylaxis against spontaneous bacterial peritonitis

Ascites

Intractable ascites can be the primary indication for liver transplantation and in this situation there are, by definition, few therapeutic options to consider. The emphasis in this scenario is limiting the side-effects of therapy that could impact on the transplant itself. Diuretic therapy can cause or aggravate hyponatraemia and impair renal function. Renal function is consistently identified as a correlate of outcome after liver transplantation and it is logical to minimize negative stresses on renal function. For these two reasons, it could be argued that diuretic regimens should be tailored on a safety rather than an efficacy basis, particularly as the patient is getting close to the time when there is a realistic chance of being allocated an organ. In MELD-based allocation systems, rising creatinine levels may require reduction or cessation of diuretic usage so as not to obtain advantage in respect to organ allocation. Regular or programmed paracentesis may be the only option for patients with intractable ascites, but each episode carries the risks of bleeding or infection.

Alternatively, ascites may develop or worsen in patients listed with an alternative lead indication for liver transplantation. The initial management is along standard lines, subject to the caveats outlined above (Table 38.3). These include salt restriction, limitation of fluid intake in the range of 800–1500 mL/day, diuretics and paracentesis. The normal paradigm of managing ascites would extend to consideration of transvenous intrahepatic portovenous shunt (TIPS) in selected patients with well-maintained synthetic function and no previous history of hepatic encephalopathy. However, patients with this profile are likely to be on the transplant waiting list and therefore would not be suitable candidates for TIPS. In the absence of HCC, concern regarding the possibility of jeopardizing liver transplantation with malposition of the TIPS limits the appeal of this therapeutic option.

Spontaneous bacterial peritonitis (SBP) is potentially a serious complication in patients awaiting liver transplantation. Antibiotic prophylaxis against SBP, typically with a quinolone (e.g. norfloxacin 400 mg/day), may be either used routinely in all patients with ascites or in patients considered to be at increased risk based on a previous episode of SBP or a very low albumen level in ascites. When the former policy is used, consideration should be given to extending prophylaxis to all patients on the transplant waiting list. Patients who develop repeated episodes of SBP can develop adhesions between the intestinal loops that in their most advanced form take on the appearance of a cocoon. Cocoons increase the complexity of surgery at the time of transplantation and may contribute to nutritional impairment post transplant.

Hyponatraemia

Hyponatraemia occurs in about 30% of patients with cirrhosis. It is often associated with diuretic therapy and may improve with adjustment in the use of these drugs. However, it also develops independently and then is more difficult to correct and is an indication of a deteriorating prognosis. Consequently, serum sodium levels are included in some scoring systems, including MELD-Na and United Kingdom End-stage Liver Disease (UKELD). Fluid restriction is the only currently available strategy to routinely manage spontaneous hyponatraemia. If serum sodium levels are below 125 mEq/L when an organ is allocated, corrective action with ultrafiltration is required before proceeding with the transplant as the rapid shifts in serum sodium levels that occur perioperatively and can lead to central pontine myeloinolysis.

Hepatorenal syndrome

Hepatorenal syndrome (HRS) is the most critical of the complications of cirrhosis with respect to liver transplant candidacy, occurring in up to 25% of hospitalized patients and in 40–60% of those admitted to intensive care units [2]. Type 1 is a rapid and progressive deterioration in renal function that is reflected in the definition and evolves over a matter of weeks (Table 38.4). Type 2 is more indolent and less severe. Type 1 is also associated with more advanced liver disease than type 2 HRS, which is more commonly observed in patients with severe portal hypertension. Both of these types of HRS are independent of intrinsic kidney disease, which is relatively common in patients with cirrhosis. MELD-based organ allocation systems inevitably increase the burden of renal dysfunction in patients receiving liver transplants.

The therapeutic options for HRS include plasma expansion, vasoconstriction and liver transplantation. Terlipressin is the preferred vasoconstrictor in Europe, whilst midodrine or epinephrine is more commonly used in the US. The combination of albumin and terlipressin is considered to be the first-line treatment for type 1 HRS, with improvement in up to 50% of cases [3,4]. The patients who are most likely to respond have earlier disease and exhibit a sustained increase in mean arterial pressure, although the latter does not necessarily result in improved renal function [5]. The value of this therapy should be assessed as a bridge to transplantation rather than the more conventional criterion of direct survival benefit. Transplanting patients with normal or near-normal renal function has significant benefits post transplant in terms of need for renal support, length of stay and survival [2]. There is less evidence to support the use of this regimen in type 2 HRS. Ultimately these patients, together with those with acute tubular necrosis as the basis for renal failure, may proceed to needing renal replacement therapy whilst awaiting liver transplantation.

Table 38.4. Definitions and characteristics of hepatorenal syndromes types 1 and 2

Type 1
Serum creatinine doubling within 2 weeks to exceed 2.5 mg/dL
or
Creatinine clearance reducing by at least half to <20 mL/min
Rapid and progressive in patients with advanced liver failure and in the absence of alternative explanations for renal failure
Type 2
Serum creatinine 1.5–2.5 mg/dL
Increase less rapid than in type 1
Typically liver function better preserved, but with significant portal hypertension

An unintended consequence of MELD-based allocation has been a dramatic increase in the number of patients who have combined liver and kidney transplants. Individual patients with renal failure at the time of liver transplantation benefit from receiving combined liver and renal grafts. However, many patients recover some renal function after a successful liver transplant, including at least 30% of patients who receive combined transplants. Guidelines for selecting patients for the combined approach are being refined but are not yet fully established. Patients with HRS are more likely to recover renal function than those with acute tubular necrosis (ATN). In one study, improvement in renal function was observed at 90 days post-transplant in 88% of HRS patients and 71% of ATN patients [6]. The duration of renal support pretransplant also influences the likelihood of recovery of function. The best outcomes were seen when the duration of dialysis did not exceed 4 weeks [7]. The translation of this criterion to one indicating a combined procedure generated thresholds of between 6 and 12 weeks. A practical implication of this debate is whether a kidney biopsy is required to make the decision in individual cases. Strong prognostic information may be derived from renal histology, but this needs to be balanced with the risk of haemorrhage post biopsy.

Variceal bleeding

Variceal bleeds represent the most acute of the potentially destabilizing events for a patient awaiting liver transplantation. Although the overall survival rate after variceal bleeding has improved dramatically, the risk of death remains significant at around 30% in the type of patient listed for liver transplantation [8]. Primary or secondary prophylaxis with propranalol targeted at maintaining a target pulse rate of around 60 beats per minute should be maintained unless the drug is poorly tolerated. In this situation, low blood pressure is the main limiting factor. There are no data suggesting that the endoscopic surveillance of varices or the use of endoscopic prophylaxis should change after placement on the waiting list for transplantation.

The management of episodes of variceal bleeding follows standard protocols [9]. Endoscopy remains the first-line therapy once the patient has been resuscitated with an appropriate balance of crystalloid, colloids, blood and blood products. Vasoactive drugs such as terlipressin, somatostatin and its analogues can cause spasm of the hepatic artery but this does not prejudice successful transplantation. TIPS is used to salvage patients who fail endoscopic and pharmacological intervention. In this setting, the risk–benefit profile for TIPS is much more favourable than in the context of intractable ascites, and it should be considered in the salvage of patients who are not responding to therapy and/or have bleeding gastric varices. Care should be taken when placing the TIPS not to

extend the shunt into the operative field. Bacterial infection complicates variceal bleeding in up to 66% of patients, which justifies the use of a short course of prophylactic antibiotics [2].

Occasionally, an organ is allocated to a patient at a time when he/she is being managed for active variceal bleeding and a decision needs to be reached on whether it is appropriate to proceed. There are no data to assist with this decision and it will be made on clinical intuition. The portal venous pressure can be reduced early in the transplant process, if necessary by creating a temporary shunt or with extracorporeal veno-venous bypass techniques, and this will help to secure control of the variceal bleeding. Therefore, the bleed itself does not contraindicate transplantation. However, if the bleed has triggered other complications of cirrhosis, as is often the case, it may be better to stabilize the patient before proceeding with surgery. Sepsis, aspiration pneumonia, hemodynamic instability and metabolic abnormalities are among the commoner complications encountered in this situation.

Encephalopathy

Status as a potential liver transplant recipient has limited impact on the approach to the prevention of encephalopathy. Therapies like lactulose and rifaxamin are used in the standard way. However, restriction of dietary protein to reduce the incidence of encephalopathy could conflict with attempts to improve nutritional state and therefore should not be excessive (<60 g/day). The management of an acute episode of encephalopathy is also standard with the three components of intravenous fluids, antibiotics and purgatives. In addition, any precipitating cause should be addressed.

Patients with severe encephalopathy usually require mechanical ventilation to protect the airways and maintain gas exchange. This has relevance to liver transplantation as survival rates are significantly lower in patients who are intubated at the time an organ is allocated. However, there are conceptual reasons to believe this might not apply to the same extent in patients who were intubated primarily to support them through an episode of encephalopathy. These include the relatively short period of intubation usually required and absence of other complications associated with increased mortality. Encephalopathy reverses very rapidly after successful liver transplantation and should not significantly extend the duration of ventilatory support after surgery. In contrast, patients whose encephalopathy is in the context of multiorgan failure at the time of transplantation require extended support with the associated risks.

Nutrition

Body mass index (BMI) has implications for outcomes after liver transplantation and therefore nutrition may be a focus of considerable attention in the pretransplant period. The clearest evidence relates to low BMI (<18 kg/m^2) and such patients need intense nutritional support, accepting that in very advanced liver disease the benefits may be less than anticipated from the number of calories delivered. The general principles of nutritional support apply in this population [11]. Nutritional supplements or nasogastric feeding are regularly used.

The evidence relating to the impact of elevated BMIs is less clear-cut, with some studies finding comparable outcomes in patients with BMIs >35–40 kg/m^2 while others show contradictory data. Irrespective of the evidence, many liver transplant programmes intuitively recommend obese patients to lose weight whilst awaiting transplantation. This patient population is limited in its options with respect to increasing exercise and therefore controlled reduction in calorie intake is the main approach available to them.

Acute decompensation episodes

The complications discussed above often co-exist during an episode of acute deterioration in the patient's clinical condition. Recently, the term acute-on-chronic liver failure has been used to describe this scenario, although acceptance of this term is not universal as some authorities prefer to reserve it for additional insults to the liver unrelated to the cause of the cirrhosis. Infection and variceal bleeding are the commonest triggers of multisystem failure and these in turn precipitate encephalopathy, hemodynamic instability, and renal dysfunction (Figure 38.1). These patients are usually

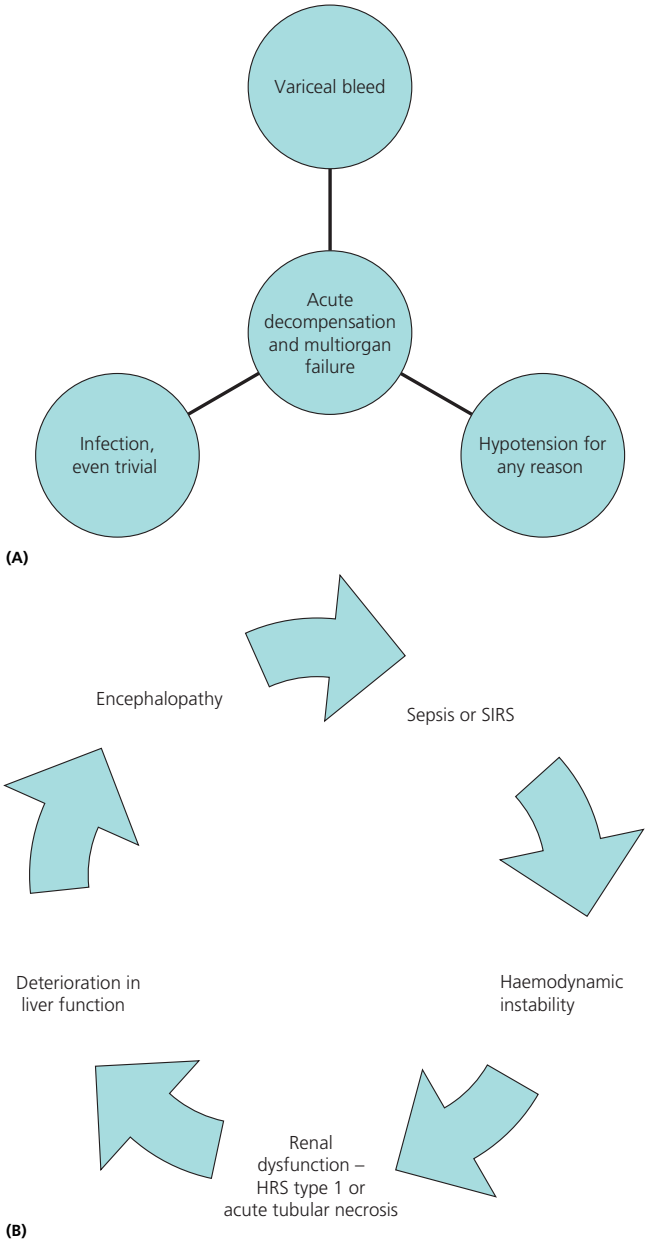

Figure 38.1. (A) Acute decompensation of chronic liver disease has three main triggers and (B) is a vicious circle of interacting complications. SIRS, systemic inflammatory response syndrome; HRS, hepatorenal syndrome.

managed in an intensive care setting and are likely to be intubated.

The decision on whether to proceed to transplantation in the context of an organ offer may be very difficult to make in this setting. The mortality rate is in the order of 40%, with most deaths occurring within a week of admission to an intensive care unit [2]. On the other hand, the 1-year survival rate for liver transplantation in this setting is around 60% or 25–30 percentage points lower than for transplantation of an ambulatory patient with chronic liver disease [1]. A judgement is required on how likely it is that the patient will improve and thereby increase his/her chances of ultimately surviving the transplant. Existing prognostic models do not perform with great precision and ultimately the decision is based on collective clinical judgement. The patients most likely to recover have MELD scores of <26, sequential organ failure assessment (SOFA) scores of <9 and variceal bleeding or encephalopathy as the indication for admission to the intensive care unit [2]. The quality of organ on offer is another dimension of the decision-making process. Patients who are progressively deteriorating may benefit more from the first available organ, while a relatively stable patient's best interests might be served by waiting for a good quality organ.

Antiviral therapy

Depending on geographical location, chronic viral hepatitis is associated with the indication for liver transplantation in between 25% and 50% of cases. Hepatitis C virus (HCV) dominates in the US and Europe, while hepatitis B (HBV) is more prevalent in Asia. HCC is associated with both viral conditions and is present in about one-third of HCV cases. The proportion of patients with HBV who have HCC is higher as antiviral therapy has significantly reduced the need for transplantation for end-stage chronic liver disease. Historically, HBV recurrence was a major problem, but strategies have now been developed to prevent or manage it in most cases. However, recurrence of HCV still is a major problem and it is only recently that the prospect of strategies to combat it have started to take shape.

Hepatitis B

The outcomes after liver transplantation in patients infected with HBV improved dramatically with the introduction of hepatitis immunoglobulin prophylaxis after transplantation. From the outset it was clear that the success of this strategy was dependent on HBV DNA levels in blood being very low at the time of transplantation. The development of a range of antiviral agents effective in controlling HBV replication enabled most patients to be rendered HBV DNA negative at the time of elective liver transplantation. The choice of agents is influenced by the speed with which control of viral replication is required and the drug resistance pattern of the virus. When there is a requirement for a rapid viral response, the use of lamivudine and tenofovir is favoured. Patients maintained on antiviral therapy whilst awaiting transplantation should be screened for emergence of drug resistance at 6-month intervals.

Hepatitis C

As with HBV, there are potential benefits to the patient if viraemia can be eradicated prior to transplantation. HCV infection may not recur in up to 70% of patients who are HCV RNA negative at the time of transplantation. However, this can only be achieved in a minority of HCV-infected liver transplant candidates. Standard therapeutic regimens using pegylated interferon and ribavirin can, realistically, only be considered in patients with well-compensated cirrhosis and thus this option is open only to some patients with HCC. In the remaining patients, an alternative approach has been described called low-dose accelerating dose regimen (LADR), which is a titrated approach with increases in dosing if therapy is well-tolerated [12]. The main concern with antiviral therapy is deterioration in liver function that may not reverse after withdrawal of therapy and can lead to an increase in the urgency with which liver transplantation is required or even death. In theory, the haematological side-effects of antiviral therapy could cause problems in the intra- and post-operative periods, but in reality most of these can be managed effectively.

There is considerable optimism that progress will be made relatively quickly in the treatment of HCV pre transplant. First, the availability of two new agents, telaprevir and boceprovir, has increased the response to interferon-based antiviral therapy and shortened treatment durations. Second, the assessment of patients suitable for antiviral therapy has become more informed on an individual basis by HCV genotype, IL28b genotype and viral kinetics after initiation of therapy. Third, there is an anticipation that drug combinations will emerge that will allow interferon-free suppression of viral replication, mirroring the progress in HBV. There is, however, no current expectation that an immunoglobulin will become available for HCV that would replicate the HBV template for prevention of viral recurrence.

HIV infection

Liver transplantation has been performed in patients infected with human immunodeficiency virus (HIV), but the procedure should still be considered experimental and applied to highly selected patients. Typical protocols will require patients to have undetectable viral loads and options for alternative antiviral drugs if resistance emerges. Consequently, close monitoring of these parameters is required throughout the waiting period. Acquired immune deficiency syndrome (AIDS)-defining illnesses after immune reconstitution generally contraindicate transplantation and should trigger a re-evaluation of transplant candidacy if they develop after placement on the waiting list. The outcomes of liver transplantation in well-selected cases are equivalent to the general population in all aetiologies except hepatitis C, where 3-year graft survival rates are only 53% [13]. Low BMI (<18 kg/m^2) and impaired renal function have been identified as pretransplant correlates of a poor outcome and patients exhibiting these characteristics should not be transplanted.

Liver support devices

Strategies to support the failing liver have a particular relevance to patients awaiting liver transplantation. It is reasonable to broadly conclude that liver support devices have so far failed to improve survival, but a number of studies have supplied evidence that a more realistic expectation from these devices is as a bridge to transplantation. The devices, which are covered in depth in Chapter 47,are categorized as non-biological and biological based on whether or not they contain a cellular component. The cellular components include normal human hepatocytes, cells derived from a human tumour cell line or porcine hepatocytes. Some approaches to liver support should be considered as hybrid as they combine both categories of device. Detoxification is an objective of all artificial devices, and a range of non-biological devices has been

developed to remove water-soluble and/or protein-bound toxins. Protein synthesis is only possible with biological devices that incorporate porcine hepatocytes, human hepatocytes derived from a tumour cell line, or human hepatocytes harvested from human organs deemed unsuitable for liver transplantation.

Albumin-based dialysis is the most widely applied device. Blood or serum coming into contact with albumin allows the transfer of protein-bound toxins. The Molecular Absorbent Recirculating System (MARS) is both the prototype and the most widely used of these devices. An early report showed an impressive improvement in deeply jaundiced patients with renal dysfunction, but in a subsequent systematic review, a 33% reduction in mortality was seen in patients with acute-on-chronic liver failure but no significant benefit in bridging patients to transplantation was identified. Two randomized controlled trials failed to show survival benefit with MARS or Prometheus over standard care [14,15]. Despite having enthusiastic protagonists, albumen-based dialysis has not gained widespread use. Experience with biological systems in patients waitlisted for transplantation is even more limited. A recent trial involving 62 patients did not show either a survival benefit or higher transplant rate with the use of an extracorporeal liver assist device (ELAD) [16].

Hepatocellular carcinoma

The majority of liver transplant programmes apply strict criteria based on tumour bulk (variably defined using number and size of nodules) when listing patients with HCC for liver transplantation, and there is a requirement to remain within these criteria up to the time of transplantation. The original and most widely used criteria are the Milan criteria, which permit a solitary lesion up to 5 cm in diameter or up to three lesions if none exceeds 3 cm in diameter. A number of other criteria are less restrictive by varying margins, including the University of California, San Francisco (UCSF) criteria and rule of 7s. The biological behaviour of HCC varies greatly and is difficult to predict at the outset, as is the response to therapeutic interventions when these are available. The management of these patients on the waiting list can be complex and work intensive with a dynamic approach combining programmed restaging with re-evaluation of therapeutic options.

Patients with advanced liver disease or any evidence of decompensation are unsuitable for locoregional therapy and depend on a favourable biological profile to remain within transplant criteria. Imaging with CT and/or MRI is used at 2–3-month intervals to reassess tumour bulk and confirm the absence of vascular invasion and extrahepatic disease. Alpha-fetoprotein levels, both absolute and relative, are also used to inform this evaluation. On the other hand, patients with well-compensated cirrhosis are likely suitable for locoregional therapy with transarterial chemoembolization (TACE), ablation techniques or a combination of both. It has been suggested that this is considered for patients with tumours of >2 cm in diameter if the anticipated waiting time exceeds 6 months [17,18]. TACE is the most commonly used primary therapy, although there is some evidence that radiofrequency ablation (RFA) may be more effective in generating tumour necrosis [19]. There are no data so far on the use of antiangeogenesis drugs (e.g. sorafenib) prior to transplantation.

The response to locoregional therapy has become an important component of the evaluation of individual patients. A good initial response followed by liver transplantation between 3 and 9 months after listing for transplantation is considered to be the best-case scenario. Up to 25% of patients progress despite locoregional therapy and "fall off" the waiting list. Whilst some consider this to be a failure of therapy, others see it as an important observation of tumour biology and patient selection. Similarly, patients who are outside the listing criteria but down-stage to within the criteria are increasingly being considered favourably for liver transplantation [20,21]. Excellent results have been achieved in patients who are successfully down-staged, with 92% survival rate 4 years after transplantation and an overall intention-to-treat survival rate of 69% at the same time point [21].

Acute liver failure

Patients listed for transplantation either have criteria suggesting a poor prognosis as determined by a range of prognostic models or have been assessed as likely to deteriorate clinically to the point of needing a transplant. The former prognostic models promote specificity over sensitivity and vice versa for assessment. Patients may deteriorate or improve and the need and suitability for liver transplantation must be constantly reviewed. In a number of series, 6–18% of the overall population were removed from the waiting list or died before an organ became available. In this dynamic process, the final decision on transplantation is made when an organ becomes available.

The majority of patients waitlisted for emergency liver transplantation will be in an intensive care environment and be mechanically ventilated for severe encephalopathy. The exception to this may be some patients with subacute liver failure and low-grade encephalopathy. The management of acute liver failure is complex as almost every physiological system is liable to fail [22]. Detailed protocols for the management of these patients are available and will not be reviewed in detail here. There are however a number of aspects of management that may be modified on the basis that the patient is awaiting transplantation. Foremost amongst these is the invasive monitoring of intracranial pressure. This is controversial because of the lack of evidence of a positive impact on survival and the associated risks, particularly intracranial haemorrhage. However, there is a higher level of support for its use when the objective is to bridge the patient safely to transplantation.

Another controversial area is the use of fresh frozen plasma to correct the coagulopathy in the absence of clinical manifestations. The argument against this practice is based on the contention that it is of no obvious clinical benefit and it undermines ongoing assessment of prognosis. In the setting of being waitlisted, the clinical benefit is in preparation for surgery and the prognosis is already considered poor in most cases. Even though the case for using recombinant Factor VII has not been made in general in acute liver failure, its use should be avoided in patients awaiting transplantation because of the possible increased risk for thrombotic events that could have serious consequences after transplantation, e.g. hepatic artery thrombosis.

Untreated sepsis is another complication that can prejudice successful transplantation and the use of prophylactic antimicrobial agents, both antibacterial and antifungal, is justified once patients have been listed for transplantation. There may also be a justification for starting renal replacement therapy sooner in patients on the waiting list to minimize the metabolic disarray at the time of commencing surgery.

The identification of those patients who are too ill to benefit from transplantation, and the deselection of waitlisted patients who deteriorate to the extent that proceeding to transplantation is futile, is

Table 38.5. Correlates of outcomes after liver transplantation for acute liver failure

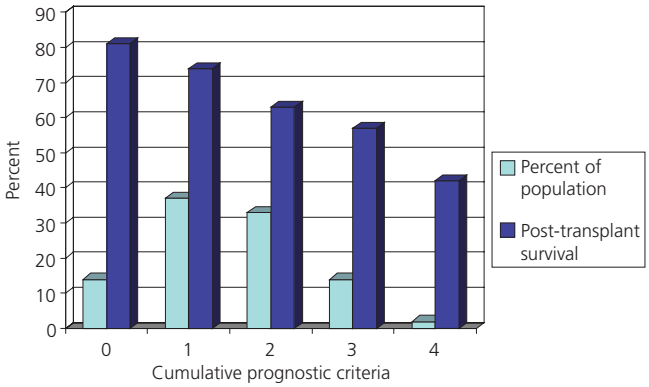

Figure 38.2. Mortality rate increases with the accumulation of poor prognostic indicators. The distribution of patients with these risk factors is shown.

a difficult but important issue to minimize wastage of a valuable resource. Two large studies have identified a number of poor prognostic indicators for liver transplantation but these have limited clinical utility in this context (Table 38.5) [23,24]. Age was identified in both studies as a poor prognostic indicator with respective thresholds of 45 and 50 years. Individually, the other clinical parameters identified are weak correlates, although the US study showed progressive decrease in survival as the prognostic criteria accumulated [23] (Figure 38.2). However, the survival rate with three of four criteria was 57%; only 2% of patients had all four criteria and their survival rate was 42%. The UK study did however highlight the importance of donor quality [24] and this is a component of the decision-making process that may be manipulated to improve outcomes.

Historically, there was a fear of irreversible brain damage after an otherwise successful transplant, but this has receded significantly in recent years. In the US, only 13% of deaths after liver transplantation were considered to be for neurological reasons [23]. However, liver transplantation is contraindicated in patients with fixed dilated pupils or other evidence of brainstem herniation. Intracranial pressure and cerebral perfusion pressure have proven to be unreliable in determining this issue. Accelerating inotrope requirements, uncontrolled sepsis and severe respiratory failure are other imprecise contraindications to transplantation. These contraindications to transplantation are to a degree age sensitive as younger patients are more resilient and more likely to reverse these complications after liver transplantation

Alcohol and smoking screening

Alcohol-related liver disease is the second largest group of patients awaiting liver transplantation. Although there are differences in alcohol policy between programmes, there is a universal expectation that transplant candidates are committed to abstinence from alcohol for life. The time spent awaiting transplantation provides an opportunity to evaluate that commitment. There is great variability in how the commitment is evaluated. A rigorous approach utilizes a written contract allied to random calls for screening of breath, blood or urine for alcohol. Regular interaction with programmes that support abstinence from alcohol may also be a requirement, e.g. Alcoholics Anonymous, although this might not be appropriate for patients with alcohol-related liver disease who are not addicted to alcohol. At the other end of the spectrum, trust-based systems screen for alcohol when a clinical event or laboratory finding arouses suspicion of active alcohol consumption.

As discussed earlier, liver function often improves after patients abstain from alcohol. At the time of listing for liver transplantation it will be assumed that most or all of the capacity for improvement has become evident. However, with lengthening waiting times a small but significant cohort of patients continues to improve for up to 18–24 months after cessation of alcohol consumption. In organ allocation systems like MELD, these patients can remain on the waiting list but with lower levels of priority. However, an active decision to remove these patients from the waiting list is required in allocation systems than couple minimum listing criteria with time spent on the waiting list.

The policy with respect to ongoing cigarette smoking is even less uniform. Patients are likely to be advised to stop smoking when they are placed on the waiting list to improve respiratory performance at the time of transplantation and reduce long-term cardiovascular and malignant risk. The extent to which this policy is monitored is poorly defined.

Summary

The waiting times for liver transplantation are generally increasing, particularly with the use of MELD-based allocation systems, and thus patients awaiting transplantation become quite unwell before an organ is allocated to them, and suffer a mortality of 5–20% between the point of listing and the allocation of an organ. Patients with cirrhosis may deteriorate at a steady rate or may acutely develop life-threatening complications. The most frequently encountered problems in patients with cirrhosis include ascites, variceal bleeding, encephalopathy and renal dysfunction, with each of these potentially triggering a cascade to multiorgan failure. Other problems relate to susceptibility to infection and poor nutrition. Patients with HCC have the additional need for treatment to suppress disease progression beyond criteria for transplantation. The management plans for these conditions may need to be adapted to the needs of patients awaiting liver transplantation. The concept of a "bridge to transplantation" has become established to evaluate some of the more complex or expensive treatments, e.g. liver support devices, as a distinct metric from the more standard survival benefit.

CHAPTER 39

Waiting List Management for Heart Transplantation

Howard J. Eisen
Division of Cardiology, Drexel University College of Medicine, Philadelphia, PA, USA

Introduction

Patients are identified as candidates for cardiac transplantation based on a number of clinical indicators of poor and declining cardiac function and poor prognosis. Failure to respond to standard medical, device-related, and/or surgical therapies may result in the determination that a patient's long-term survival would be improved with cardiac transplantation. Once placed on the transplant waiting list, the potential transplant recipient needs careful follow-up to monitor any changes in their clinical status that might necessitate changes in therapy and perhaps changes in the patient's priority status on the transplant waiting list. This chapter will cover the general management of patients awaiting heart transplantation. It serves as a companion to Chapter 30, which covers indications for heart transplantation, and also will complement the content in Chapters 44, 48, and 49, which detail intensive care unit management of patients with heart failure, ventricular assist devices, and the emergence of the artificial heart, respectively.

Management of patients with advanced heart failure on the cardiac transplant waiting list

Oral agents

Patients placed on the cardiac transplant list should already be receiving optimal or maximally tolerated oral medical therapy. This therapy is directed by guidelines defined by the American College of Cardiology (ACC)/American Heart Association (AHA) and Heart Failure Society of America (HFSA) [1–3]. These therapies include the beta-blockers shown in clinical trials to have survival benefits in heart failure patients [4–7], angiotensin-converting enzyme (ACE) inhibitors, or angiotensin receptor blockers (in patients intolerant to ACE inhibitors), aldosterone antagonists, and especially in African–Americans, the combination of the vasodilators hydralazine and nitrates [8–15]. Inhibitors of the renin–angiotensin–aldosterone system are maintained at target doses as described in the ACC/AHA and HFSA guidelines or as tolerated by the patient as reflected by systemic blood pressure, renal function, serum potassium, and symptoms. Carvedilol, long-acting metoprolol, or bisoprolol are also maintained at guideline-directed target doses or as tolerated by blood pressure. Additional oral medications that are frequently used and should be maintained in patients with advanced heart failure include loop diuretics for symptoms of congestion and in some patients, digitalis glycosides for palliation [16].

Devices

Patients listed for cardiac transplantation are at least New York Heart Association (NYHA) class III in terms of their symptoms of heart failure and will likely have had an automatic implantable-cardioverter defibrillator (ICD) implanted prior to being placed on the transplant list [17–19]. ICDs should be checked at the time of listing and at every outpatient office visit to determine if there have been any arrhythmias requiring antitachycardia pacing or defibrillation as well as the frequency of these arrhythmias. Interrogation of the ICD will also provide information regarding defibrillation thresholds, pacing thresholds, lead function, and battery life. Those patients who remain NYHA class III despite maximal medical therapy who also have QRS duration of >120 ms on their electrocardiograms (ECGs) should have undergone implantation of a biventricular pacemaker along with an ICD to improve exercise tolerance and favorably affect ventricular function and survival [20–22]. These devices should also be interrogated at the time of office visits to determine primarily if patients are being paced and thus undergoing cardiac resynchronization. If patients are spending only a relatively small part of their time with cardiac resynchronization, this could result in a deterioration in exercise tolerance and cardiac function, and could be interpreted erroneously as progression of the patient's heart failure. Efforts should be made to check patients with biventricular pacemakers are truly receiving cardiac resynchronization therapy, including suppression or cardioversion from atrial fibrillation as optimization of biventricular pacemaker function.

Intravenous therapy

Patients who have NYHA class IV symptoms of heart failure despite maximal medical therapy and, if indicated, cardiac resynchronization therapy, should undergo right heart catheterization to assess their cardiac output and index, pulmonary arterial and pulmonary capillary wedge pressure (PCWP), as well as transpulmonary gradient (TPG) and pulmonary vascular resistance (PVR) (see Table 39.1 for formulae to calculate TPG and PVR) [23]. The results of the right heart catheterization are often used to guide subsequent therapy, including further optimization of oral medications if possible, enhanced diuresis if the patients have an elevated PCWP indicative of volume overload, and initiation of inotropic therapy with the intravenous sympathomimetic dobutamine or the phophodiesterase 3 inhibitor milrinone. These may be used for a short period of several days to allow augmentation of oral heart failure medications and diuresis to improve the cardiac output and index,

or may be continued indefinitely if the patient proves to be dependent on inotropic therapy to maintain cardiac output. This is usually determined by weaning inotropic therapy and reassessing hemodynamics, including cardiac output with a repeat right heart catheterization. Patients who require indefinite inotropic therapy for maintenance of cardiac output will have an indwelling catheter such as a PICC line or Hickman, placed so that continuous administration of the inotropic therapy can be maintained. These patients can usually wait for transplant at home, but will require interrogation of their ICDs since inotropic therapy is arrhythmogenic and may result in ventricular tachycardia or fibrillation. Continuous use of inotropic therapy is associated with a poor 1-year survival rate and this needs to be addressed in cardiac transplant candidates receiving these agents [24,25]. Home nursing support is usually set up to provide patients with assistance in managing intravenous inotropic therapy at home. Oral heart failure therapy is usually maintained, although doses may be scaled back if inotropic therapy produces hypotension.

Another important issue that needs to be addressed when reviewing the results of right heart catheterization is the presence and type of pulmonary hypertension. Patients with advanced heart failure often have WHO group II pulmonary hypertension [23]. This will already have been assessed during the transplant evaluation and if the TPG or the PVR are elevated (TPG $\geq$15 mmHg; PVR $>$3.0 Wood units; pulmonary artery systolic pressure $\geq$50 mmHg), interventions with intravenous or inhaled pulmonary vasodilators [i.e. nitroprusside, nitroglycerin, nitric oxide, prostacyclin (PGI_2), nesiritide] will have been performed to demonstrate that these hemodynamic parameters can be reduced or reversed while maintaining a systemic systolic arterial blood pressure of $>$85 mmHg. This is important so that post-transplant right ventricular failure, which can be fatal, is prevented. Reversibility of TPG and PVR would have been demonstrated if there is no or minimal intrinsic pulmonary arterial hypertension, and this provides pharmacologic strategies for reducing TPG and PVR at the time of cardiac transplantation. Unfortunately, the prolonged volume overload characteristic of patients with advanced heart failure may result in intrinsic pulmonary arterial damage [23]. Therefore, repeat right heart catheterization is often necessary, especially in patients who previously had elevated TPG and PVR, to make sure that the pulmonary hypertension can still be reversed with vasodilators.

Mechanical circulatory support

Many patients with advanced heart failure who are managed with oral medical and/or inotropic therapy will nonetheless develop progressive hemodynamic deterioration. These patients often present clinically with worsening symptoms of heart failure, including fatigue and abdominal complaints, arrhythmias, hypotension, and evidence of poor perfusion with cool extremities and pulsus paradoxus. Laboratory findings of worsening heart failure, including rising creatinine, blood urea nitrogen, liver function tests, and brain natriuretic peptide, would also provide evidence of hemodynamic deterioration. For these patients, mechanical circulatory support as a bridge to transplant would be required to normalize end-organ function, and improve quality of life and survival to heart transplant, as described in depth in Chapter 48. Ideally, mechanical circulatory support should be initiated before there is significant deterioration in end-organ function. The Food and Drug Administration (FDA)-approved device most commonly used as a bridge to transplant is the HeartMate II continuous flow left ventricular assist device (LVAD), which has replaced earlier pulsatile flow devices as a result of superior 1-year survival, fewer adverse effects, and better durability in randomized clinical trials [26,27]. The HeartWare HVAD has recently also been approved as a bridge to transplant by the FDA while the Jarvik VAD is still under investigation in clinical trials [28]. In the large majority of patients with advanced heart failure requiring mechanical circulatory support, LVAD support alone will be sufficient as a bridge to transplant. However, right ventricular dysfunction after LVAD implantation is a scenario that is not uncommon. Several scoring systems have been developed to predict the likelihood of the development of right ventricular failure prior to LVAD implantation [29,30]. If right ventricular failure develops, this will usually manifest intra- or perioperatively. Strategies to manage this include continued inotropic support and in more serious circumstances, right ventricular support with temporary devices such as the CentriMag. If a patient preoperatively is considered to have a high enough risk of developing right ventricular failure severe enough to compromise the outcome of LVAD support alone, the alternatives are biventricular support with the Thoratec paracorporeal (PVAD) or implantable ventricular assist device (IVAD), both of which allow for discharge to home, or the SynCardia CardioWest artificial heart, which also has an external driver for use at home. The latter device has been shown to provide mechanical circulatory support as a bridge to transplant for critically ill patients and, as opposed to the ventricular assist devices, requires surgical removal of the ventricles [31].

Data from The International Society of Heart and Lung Transplantation (ISHLT) registry demonstrate that the percentage of patients waiting for heart transplant who are supported with mechanical circulatory support has increased between 2000 and 2010 (Figure 39.1). Patients requiring LVAD and right ventricular assist device (RVAD) support had worse outcomes post transplant compared to other groups. Those recipients not requiring mechanical circulatory support had better post-transplant survival than those requiring any form of mechanical circulatory support (Figure 39.2).

Placement of patients with advanced heart failure on the cardiac transplant waiting list

Patients will be placed on the heart transplant waiting list through the local Organ Procurement Organization (OPO) and their priority determined according to the level of medical therapy or mechanical support that they are receiving. This system of prioritization is shown in Table 39.2, and is defined by the United Network of Organ Sharing (UNOS) and the Organ Procurement and Transplant Network (OPTN) of the Health Resources and Service Administration of the U.S. Department of Health and Human Services [32]. Patients with mechanical circulatory support may be listed as status 1A for any 30-day period after implantation,

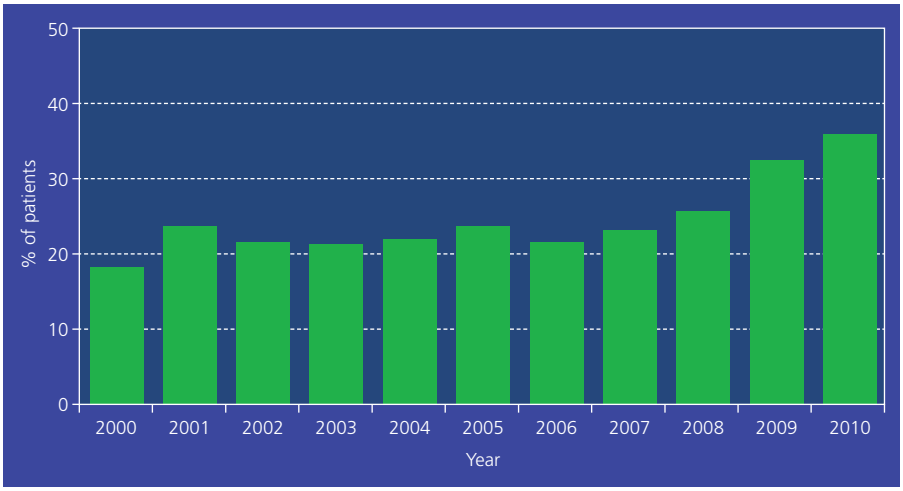

Figure 39.1. Increasing percentage of adult patients on the heart transplant waiting list requiring mechanical circulatory support. Data from the ISHLTr.

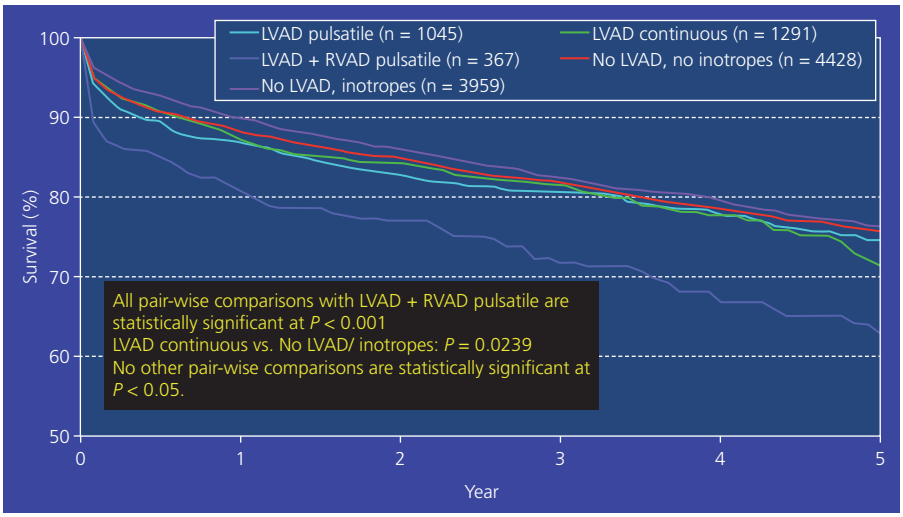

Figure 39.2. Impact of pretransplant mechanical circulatory support and the type of support on post-transplant survival. LVAD, left ventricular assist device; RVAD, right ventricular assist device. Data from the ISHLT registry.

though this is usually done at a time when the patient has recovered from surgery and is ambulatory. Patients with mechanical circulatory support may also be listed as status 1A if they have demonstrable and documented evidence of major device-related complications, such as infection, device mechanical failure, thromboembolism, or potentially lethal ventricular arrhythmias [32]. All other patients with mechanical circulatory support would be listed as status 1B. Additional patients who may qualify as status 1A include those requiring continuous mechanical ventilator support for 14 days with subsequent renewal every 14 days (these patients do have worse outcomes post transplant); and patients receiving continuous infusion of a single high dose of inotropic therapy or multiple inotropes with continuous hemodynamic monitoring of left ventricular filling pressures for 7 days, with the option for a 7-day extension if the above circumstances are unchanged. Finally, patients who do not meet the above criteria may be considered as status 1A if they have compelling urgency and clinical circumstances that can be justified and are approved by the UNOS Regional Review Board [32].

All patients receiving intravenous inotropic support or who have mechanical circulatory support who do not meet the above criterion are listed as status 1B [32]. Patients receiving only oral medications are listed as status 2 and patients on the list who for a variety of circumstances cannot at present be transplanted are listed as status 7 and are "inactivated."

Organ allocation

Donor hearts are allocated according to the policies of the OPTN and administered by UNOS. Donor hearts are preferentially allocated locally within the confines of the local OPO by recipient disease severity. If there is more than one potential recipient at a given status level, priority is given to the recipient with the longest waiting time. If no acceptable donor is identified locally, donor

Table 39.2. Adult cardiac transplant candidate priority status

Status 1A

a i. Patient with mechanical circulatory support with left and/or right ventricular assist device may receive 30 days of Status 1A after device implantation once the patient is felt to be ready clinically for cardiac transplantation (patient may be at home)

a ii. Total artificial heart

a iii. Intra-aortic balloon pump

a iv. Extracorporeal membrane oxygenator

For criteria a ii, a iii, or a iv, patients must be hospitalized at the listing transplant center; initial status 1A is valid for 14 days and must be recertified every 14 days from the initial date of listing by the attending physician caring for the patient

b. Patient with mechanical circulatory support with documented, objective evidence of significant device-related complications, most commonly device mechanical failure, device infection, thromboembolic event or thrombus of the device, or life-threatening arrhythmias. Patients may be at home. Initial status 1A is valid for 14 days and must be recertified every 14 days from the initial date of listing by the attending physician caring for the patient

c. Patient with continuous mechanical ventilation. Initial Status 1A is valid for 14 days and must be recertified every 14 days from the initial date of listing by the attending physician caring for the patient.

d. Patient receiving continuous intravenous infusion of high doses of a single inotrope (dobutamine or milrinone) or multiple intravenous inotropes, as well as continuous invasive hemodynamic monitoring of left ventricular filling pressures. Initial status 1A is valid for 7 days and must be recertified every 7 days from the initial date of listing by the attending physician caring for the patient

Exception – A patient on the transplant waiting list who does not meet the above criteria but who is felt by his/her transplant physician to be of appropriate clinical urgency and who would derive substantial benefit from transplantation. Justification for this request must be submitted by the transplant physician to the Regional Review Board for approval. Listing under this exception is for 14 days. Subsequent extensions of the status 1A-Exception listing must be prospectively approved by the Regional Review Board. Listing as status 1A without approval is referred to the Thoracic Organ Transplantation Committee and the Membership and Professional Standards Committee

The status 1A Justification Form should be submitted via UNet for initial listing or extensions. Once the status 1A time expires, the patient is automatically downgraded to status 1B

Status 1B

aa Left and/or right ventricular assist devices

bb Continuous intravenous infusion of inotropic agents

Exception – A patient on the transplant waiting list who does not meet the above criteria but who is felt by his/her transplant physician to be of appropriate clinical urgency and who would derive substantial benefit from transplantation. Justification for this request must be submitted by the transplant physician to the Regional Review Board for approval. Report of the Regional Review Board decision is referred for review to the Thoracic Organ Transplantation Committee and the Membership and Professional Standards Committee

The status 1B Justification Form should be submitted via UNet for initial listings or extensions

Status 2

Cardiac transplant candidates who do not meet criteria for status 1A or 1B (no inotropes, mechanical circulatory or ventilator support)

Status 7

Patients on the cardiac transplant list who are determined not to be suitable temporarily for transplant. These patients retain their previously accrued transplant waiting time but do not accrue new time and are not offered donor hearts. Patients who are deemed to be unsuitable for transplant indefinitely or permanently should be removed from the list

Source United Network for Organ Sharing/Organ Procurement and Transplant Network of the Health Resources and Service Administration [32]. Available at: http://optn.transplant.hrsa.gov/PoliciesandBylaws2/policies/pdfs/policy_9.pdf

hearts will be allocated preferentially according to geographic distance from the donor hospital. This algorithm follows sequential concentric circles of up to 500 miles from the donor hospital (zone A), 500–1000 miles from the donor hospital (zone B), 1000–1500 miles from the donor hospital (zone C), 1500–2500 miles from the donor hospital (zone D), or >2500 miles from the donor hospital (zone E) [32].

Management of the sensitized patient on the heart transplant waiting list

Patients with advanced heart failure who are waiting for transplants may develop allosensitization from a number of sources, including prior pregnancies, prior transfusions of blood products (including platelets), prior solid organ transplants, or the presence of ventricular assist devices for mechanical circulatory support [33]. Allosensitization presents a challenge in that it puts the recipient at risk for antibody-mediated rejection and graft failure if donor hearts are transplanted into patients with antibody specificities to antigens on the surface of endothelial cells of those hearts. From the ISHLT registry, sensitized patients [panel reactive antibody (PRA) >10%] have a higher 5-year mortality after transplant (Table 39.3). A further challenge is that allosensitization limits, sometimes drastically, the potential donor hearts available for potential recipients as transplant physicians and surgeons seek to eliminate from consideration for transplant those organs against which the recipient is sensitized. The use of the virtual cross-match (see Chapter 89) has helped to optimize donor availability. Nonetheless, it is tempting to try to modulate the alloimmune response to reduce the extent of allosensitization and thereby increase the number of potential donor hearts available for a specific potential recipient on the heart transplant waiting list. This has resulted in the development of a number of desensitization strategies to reduce allosensitization. This topic is considered in depth in Chapter 68. Desensitization protocols often are initiated when the calculated PRA exceeds 10%. These protocols use therapies that are directed against B-cell antibody production and include intravenous immunoglobulin (IVIG), plasmapheresis, mycophenolate mofetil, and rituximab [34]. While IVIG has demonstrated clinical efficacy in clinical studies, no definitive information is available and no clinical trials have been performed in patients awaiting cardiac transplantation [35]. One retrospective study showed that the combination of plasmapheresis, IVIG, and rituximab reduced PRAs from 70.5% to 30.2%, with 5-year survival post transplant and freedom from cardiac allograft vasculopathy similar to those for non-sensitized patients [34]. Often, these therapeutic approaches are ineffective and more recently, the proteasome inhibitor bortezomib has been used in conjunction with plasmapheresis and rituximab in patients who were refractory to other treatments. Two small reports of a total of ten patients suggest that bortezomib may be helpful in reducing PRAs in otherwise refractory patients [36,37]. Unfortunately, there are no prospective controlled trials of desensitization therapy in patients on the heart transplant waiting list, so therapeutic approaches are largely empiric.

Clinical assessment of patients on the heart transplant waiting list

As advanced heart failure is often a dynamic disease, patients on the heart transplant waiting list will need to undergo frequent clinical assessments to determine if their status on the waiting list needs to be changed. For example, patients who are status 2 may require implementation of inotropic therapy or implantation of an LVAD as a result of hemodynamic deterioration. They would then become status 1B. A patient with an LVAD who is status 1B may be upgraded to status 1A as a result of a life-threatening device infection or thrombus. Recommendations for follow-up after listing for cardiac transplantation were included in the ISHLT Listing Criteria Guidelines in 2006 [23]. Table 39.4 summarizes the outpatient visit and procedure schedule for patients who are on the heart transplant

Table 39.3. Elevated pretransplant panel reactive antibody (PRA) (>10%) is a risk factor for increased mortality 5 years post transplant (n = 10 507)

Variable	*n*	Relative risk	*P* value	95% confidence interval
Female recipient with prior pregnancy/male donor vs. male recipient/male donor	780	1.22	0.0286	1.02–1.45
PRA > 10%	766	1.21	0.0066	1.06–1.40
Recipient with infection requiring IV drug therapy within 2 weeks prior to transplant	1161	1.18	0.0082	1.04–1.33
Recipient history of diabetes	2177	1.14	0.0062	1.04–1.26
Diagnosis: coronary artery disease vs. cardiomyopathy	4792	1.14	0.0063	1.04–1.25
Not hospitalized just prior to transplant	5516	0.92	0.0475	0.84–1.00

PRA, panel reactive antigen.
Data from the ISHLT registry.

Table 39.4. Recommended schedule for follow-up of patients once listed for cardiac transplantation

History and physical examination – (including weight, height and calculation of body mass index)	Monthly especially for patients with inotropic or mechanical circulatory support
PRA and flow cytometry	
>10%	Every 1–2 months
VADs	Every 1–2 months
Post transfusion	2 weeks after transfusion then monthly for 6 months
Lab work (CBC, CMP, BNP)	Monthly with office visits
PT/INR	Monthly or as needed if anticoagulated for atrial fibrillation, VADs, or mechanical heart valves
GFR assessment (MDRD method)	Every 3 months
Right heart catheterization with assessment of pulmonary hemodynamics and use of vasodilators as needed	At least every 6 months (and more frequently as needed clinically
Evaluation of VAD	Monthly and more frequently if needed
Interrogation of ICDs, biventricular Pacemakers	Every 4 months and more frequently as needed clinically
Cardiopulmonary stress test	Annually (status 2 patients)
Echocardiogram	Annually; more frequently as needed in patients with VADs
ECG	Annually

PRA, panel reactive antibody; VAD, ventricular assist device; CBC, complete blood count; CMP, complete metabolic panel; BNP, beta-natriuretic peptide; PT/INR, prothrombin time/international normalized ratio; GFR, glomerular filtration rate; MDRD, Modification of Diet in Renal Disease; ICD, implantable cardioverter-defibrillator; ECG, electrocardiogram.

waiting list. Outpatients, which now includes the majority of ambulatory patients receiving inotropic or mechanical circulatory support, should be seen in the office on a monthly basis for a clinical assessment, which should include history and physical examination, and laboratory assessments of renal and hepatic function and electrolytes. Glomerular filtration rates using the Modification of Diet in Renal Disease (MDRD) formula, should be assessed every 3 months [38,39]. Right heart catheterization should be obtained in all patients on a 6-month basis to determine if there has been an increase in PVR, TPG, and/or systolic pulmonary artery pressure; if these are found to be present, therapy with pulmonary vasodilators as mentioned earlier should be initiated to determine if these markers of pulmonary hypertension are reversible. Additionally, right heart catheterization provides information regarding cardiac output and can trigger more intensive therapy with initiation or enhancement of inotropic therapy or mechanical circulatory support. For patients who have already had elevated TPG, PVR, or pulmonary arterial pressures, these assessments may need to be repeated more frequently and should be performed in patients on the transplant list who present with signs and symptoms of low cardiac output or those who have progressed to NYHA class IV symptoms despite optimal medical therapy. Patients with ICDs or on cardiac resynchronization therapy should have their devices interrogated. Patients with LVADs or other forms of mechanical circulatory support should be seen on a monthly basis and should have their support devices scrutinized. Patients with PRAs of >10% or who have LVADs should have their PRAs checked every 1–2 months [23]. Patients who require blood transfusions should have PRAs measured 2 weeks afterwards and then monthly for 6 months [23]. The transplant center should communicate with the local OPO to update it on unacceptable antigens for specific patients based on the most recent PRA results. As an increasing number of patients are waiting longer than a year for transplant, an echocardiography should be performed annually. Patients with LVADs may require echocardiography more frequently if they develop arrhythmias. Echocardiography is also useful in these patients to assess ventricular emptying from the LVADs. Patients who are status 2 should undergo cardiopulmonary exercise testing to determine if their functional class has improved to the point where they would no longer benefit from cardiac transplantation [23].

Patients who are waiting for transplant in the hospital represent a sicker population who should undergo greater scrutiny. This would potentially include more frequent invasive hemodynamic monitoring and assessment of LVAD function.

Summary

Patients with advanced heart failure who are on the waiting list for a heart transplant should have their heart failure therapies continuously monitored and optimized. Close attention should be paid to clinical deterioration, which might necessitate implementation of more aggressive supportive treatment such as inotropic or mechanical circulatory support. Changes in end-organ function should also be carefully monitored and therapy adjusted to optimize this. Changes in the intensity of therapy should be reflected in changes in the patient's listing status to one that is commensurate with his/her therapy and prognosis prior to transplant. LVAD infection or dysfunction should result in an upgrade in the patient's UNOS status to 1A. PRAs should be assessed longitudinally in those with PRAs elevated by >10% and those at risk for developing increased PRAs, including patients with LVADs or with recent blood transfusions. The role of desensitization in patients on the heart transplant waiting list has not been well established with prospective clinical trials, and may be implemented in patients with very high PRAs who have been unable to receive donor hearts as a result.

CHAPTER 40

Waiting List Management for Lung Transplantation

E. Clinton Lawrence and David C. Neujahr

Andrew J. McKelvey Lung Transplant Center, Emory Transplant Center, Emory University Hospital; Emory University School of Medicine, Department of Medicine, Division of Pulmonary, Allergy and Critical Care Medicine, Emory University, Atlanta, GA, USA

Introduction

Once lung transplant candidates are listed for transplantation, the waiting time to transplant typically varies from weeks to months, a relatively short time reflecting the severity of the conditions impelling candidacy for lung transplantation and the disease severity metrics that drive lung allocation. Thus, an understanding of list management in lung transplantation requires a working understanding of lung allocation and listing requirements as well as the common maladies facing someone with end-stage pulmonary failure. This chapter will review the current scoring system used for allocating lungs, the lung allocation score (LAS). It will address the pragmatic issues that lung transplant centers face with respect to how to educate patients, optimize them for transplant, and ensure that they have the best chance for successful transplantation. Issues including HLA sensitization, physical disability, patient compliance, and recipient size will be discussed. This chapter complements Chapter 31, which covers the specific indications bringing people to the lung transplant list.

Listing for lung transplant

United States programs

The history of the process of listing individuals for lung transplantation and organ allocation through the United Network for Organ Sharing (UNOS) in the US has been recently reviewed [1]. The period from 1984 to 2005 may be viewed as the pre-LAS era, in which organs were allocated regionally to patients accruing the longest waiting times on the transplant list, taking into account specific patient issues of donor–recipient size matching and blood group ABO compatibility. However, waitlist times increased progressively and patients with more rapidly progressive diseases such as idiopathic pulmonary fibrosis (IPF) died prior to transplant at a disproportionate rate. The unacceptably high rate of mortality persisted in lung transplantation in spite of a modification in 1995 to grant newly listed patients with IPF an additional 90 days of accrued waiting time. Concerns with the inequities in the allocation system as well as a desire to conform to the recommendations of the US Task Force on Organ Transplantation ultimately led to the adoption of the LAS in 2005 [2,3], with a goal of balancing the likelihood of surviving while on the waitlist and the probability of surviving at least 1 year following transplant.

In the current LAS era, lung transplant candidates over the age of 12 years are grouped into one of four diagnostic categories (Table 40.1). Various demographic, physiologic, and co-morbid data are entered into a formula [2], and a LAS ranging from 0 to 100 is assigned to the patient, subject to later modification as the patient's condition changes while on the waitlist. A sample LAS calculator is available (http://optn.transplant.hrsa.gov/resources) as a resource to clinicians and patients. The explicit goal of the LAS is to prioritize organ allocation to minimize waitlist mortality and maximize post-transplant survival. Importantly, with the current system, the LAS weights the probability of waitlist mortality twice as high as the odds of post-transplant survival. Organs are still allocated on the basis of recipient height range and ABO compatibility. Donor lungs are first offered locally and the patient with the highest LAS selected for the available organ within each listing region (local, zone A, zone B, etc.). Thus, lungs are first offered to the transplant centers in the local Organ Procurement Organization (OPO). If a suitable recipient does not exist locally, then the lungs are offered by regional zones, with each zone (A, B, etc.) corresponding to concentric geographic circles of 500 nautical mile radius from the donor hospital. Within each list, lungs are first offered to ABO identical patients followed by ABO compatible patients. Since implementation of the LAS system, both waitlist times and waitlist mortality have decreased [1], with a greater number of patients with IPF receiving transplants [4]. Although overall 1-year survival has not changed under the LAS system, there are data that patients with higher LASs (sicker patients) have higher morbidity [5], higher costs [6], and perhaps lower survival over time [7,8].

It has been noted that the LAS system does not adequately measure the likelihood of death on the waitlist for patients with idiopathic pulmonary arterial hypertension (IPAH) [9–11]. For this reason an appeal mechanism was implemented to increase the LAS of selected patients; e.g. an appeal for patients with IPAH increase their LAS to the 90th percentile when their right atrial pressure exceeds 15 mmHg and cardiac index is <1.8 L/min/m^2. Other modifications to the LAS have been made, such as inclusion of P_{CO_2} and bilirubin, and other refinements are likely in the future with additional data. Given that lungs are still first offered in the local OPO list prior to zonal allocation, it is still possible for a recipient to receive a lung transplant in a relatively short period of time, provided there are no other similar patients on the local list. Not

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Table 40.1. Lung allocation score (LAS) diagnosis groups and major clinical diagnoses

Group A: Obstructive lung disease Including chronic obstructive pulmonary disease (COPD); emphysema; alpha-1 antitrypsin deficiency; lymphangiomyomatosis (LAM); bronchiectasis, including primary ciliary dyskinesia; sarcoidosis with mean pulmonary artery (PA) pressure of ≤30 mmHg
Group B: Pulmonary vascular disease Including primary pulmonary hypertension (PPH); Eisenmenger's syndrome; other specific pulmonary vascular diseases, including pulmonary venous obstructive disease, chronic pulmonary thromboembolic disease
Group C: Cystic fibrosis or immunodeficiency disorders Cystic fibrosis; common variable immunodeficiency; hypogammaglobulinemia
Group D: Restrictive lung disease Idiopathic pulmonary fibrosis (IPF); pulmonary fibrosis (other causes); sarcoidosis with mean PA pressure of >30 mmHg; scleroderma/CREST; bronchoalveolar carcinoma (BAC); bronchiolitis obliterans syndrome (BOS) following lung transplant; primary graft failure following lung transplant; eosinophilic granuloma.

Reproduced from Egan et al. [2] with permission from John Wiley and Sons.

surprisingly there exists great heterogeneity within the US with respect to median waiting times for transplantation. There have been proposals within the lung transplant community to modify the allocation rules for lungs similar to those for heart, with regional recipients who are very ill taking preference over patients on the local list. At the present time, considerable controversy exists as to how to define such high urgency patients.

Other countries

Whereas the LAS system is unique to the USA, other countries have their own approaches to the issues of equitable distribution of organs. In Europe, for example, seven countries (Austria, Belgium, Croatia, Holland, Luxembourg, Germany, and Slovenia) comprise the Eurotransplant (ET) region. Lung transplant candidates in the ET region are classified as elective, urgent (U), or highly urgent (HU), with HU patients typically being in the intensive care unit and often requiring assisted ventilation [12]. Within these subgroups, time on the waitlist is taken into account. In the paper by Smits et al. [12], a pilot study was employed using LAS and LASplus grouping of patients, and found that LAS was predictive of mortality in their critically ill cohort of patients, indicating that some version of LAS may be implemented in the Eurotransplant region. In England there are six geographic zones that perform lung transplantation. Lung transplant donors are allocated first to the particular regional area in which they reside in, followed by a rotational system where the donor organs are allocated to the zone that is next on the list. There are no standards to rank recipients on the basis of medical urgency, but there are proposals to do so.

There is no comparable UNOS system for organ allocation in Canada, although Canada has a nearly identical lung transplant rate per unit population to the US. An attempt was made to centralize organ allocation including lung transplant starting in 2001, but to date, the majority of organ allocation resides at the provincial level. In 2008 the Canadian Blood Service began to address the mandate to centralize donor allocation within Canada. A national registry for living related kidney donation has been established in 2010 [13]. It is anticipated that eventually a standardized protocol for donor allocation and recipient ranking will be developed. There are five centralized lung transplant centers in Canada, and recently the directors of these centers proposed an algorithm for donor allocation that recommends favoring local allocation followed by regional, then national, similar to the algorithm in the US. With respect to ranking of organ recipients, the current Canadian system ranks patients only as being status 1 or status 2. Status 1 patients are considered stable, while status 2 patients are in need of an emergent transplant. As expected, the median waiting time for status 2 recipients is considerably shorter than for status 1.

Australia utilizes a similar decentralized system for lung transplant allocation. There are four transplant centers within the six Australian states. Donors are allocated first to the local transplant center, and if no suitable donor exists, they are offered to subsequent states on a rotational basis. This allocation system also prioritizes recipients by ABO and size match to the donor. The urgency of the recipient based on illness severity is then used for allocation.

Hence, it is important to note that in both Canada and Australia where a decentralized process of donor–recipient matching is utilized, that a high degree of discretion is required by the transplant program in terms of recipient selection. This discretion is less prominent in the US system where a highly centralized process utilizing the LAS and UNOS is employed.

Patient management while listed

Education

Both before formal listing for lung transplantation and while on the waiting list, it is important that patients and their support person(s) become fully educated about all aspects of the transplant process. Recently, the Centers for Medicare and Medicaid (CMS) in the US have formalized this process with a lengthy education document that the patient must complete at the beginning of the transplant evaluation process. There are eight core aspects to this document:

1. the evaluation process;
2. the surgical procedure;
3. alternative treatments;
4. potential medical or psychosocial risks;
5. national and transplant center-specific outcomes, as taken from the most recent Scientific Registry for Transplant Recipients (SRTR) center-specific report;
6. organ donor risk factors that could affect the success of the graft or health of the patient;
7. the patient's right to refuse transplantation;
8. if the transplant occurs in a non–Medicare-approved center, it could affect the patient's ability to have his/her immunosuppressive medications paid for under Medicare Part B.

It is obviously critical that potential transplant candidates have a realistic understanding of the potential benefits and limitations of lung transplantation and are able to make an informed decision as to whether to proceed. It is important for each patient to understand the process of organ allocation based on ABO blood type, LAS, single versus bilateral transplant, and confounding factors such as presensitization to donor HLA antigens, recipient cytomegalovirus (CMV) and hepatitis B virus (HBV) immune status, among others. Learning about the medications required post transplant, their side-effects, drug interactions, and drugs to be avoided (e.g. non-steroidal anti-inflammatory agents) by both the patient and support person(s) is critical. It is essential to have a plan in place for family or other personal support in the peritransplant period. Understanding the ongoing costs of treatment and medications following transplant and having resources for such costs and/or having a plan in place for dealing with the financial burden is emphasized in the educational process. Underscoring the fact that non-medical factors do impact patient outcome, a recent study reported that the type of insurance

coverage correlates with long-term outcomes after lung transplant [14], with patients having Medicare or Medicaid coverage having lower long-term survival than patients with private insurance. A willingness to partner with their transplant caregivers and to follow instructions for aftercare and medication adherence is also critical to a successful outcome following transplant. Finally, having adequate social support is critical in dealing with the psychological stress and medical issues in the transplant process [15].

Immunization

Prevention of certain infections through routine immunization is accomplished either prior to or while on the lung transplant waitlist. Generally accepted are immunization against *Streptococcus pneumoniae* (one center's retrospective review found only 62% percent of transplant referrals to have prior immunization [16]); HBV if immunity is lacking to allow acceptance of a donor with evidence of prior HBV infection [17]; and annual vaccination against influenza, using a killed rather than a live form of the vaccine. It is important that family members both before and after transplant have annual immunization with the killed vaccine, since immunocompromised transplant recipients may have inadequate antibody responses to the vaccinations themselves [18].

Pulmonary rehabilitation

There are numerous and compelling studies to support the importance of a structured exercise program, preferably through a pulmonary rehabilitation program for patients awaiting lung transplantation [19–26]. Indeed, the distance walked in 6 min, the 6-min walk test (6MWT), has been shown to be strongly predictive of survival while on the lung transplant waitlist [27], especially in IPF [28]. Thus, enrollment in a pulmonary rehabilitation program is prescribed by virtually all lung transplant programs, with some programs even having patients relocate close to their center to attend their own pulmonary rehabilitation program. In some cases, financial constraints and/or lack of third-party payments may require substitution with a home-based exercise program. No matter how it is achieved, patients on the lung transplant waitlist must remain as active as possible and their participation in exercise programs needs to be monitored.

Medical monitoring and treatment while listed for lung transplant

Although the time from listing to transplant under the LAS system has decreased to a median of a few months [29,30], a significant number of patients have more extended waiting times for a variety of reasons. Thus, it is important to have monitoring programs in place to update patients' LAS over time, detect new medical or psychosocial problems, and determine if patients continue to meet the criteria for lung transplantation. Patients and caregivers should understand that the LAS, similar to the Model for End-Stage Liver Disease (MELD) score used to rank liver recipients, is a dynamic score that changes in response to changes in the patient's medical status. Several factors in the LAS that strongly influence the score are the degree of oxygen use at rest and the 6MWT distance. Hence, it is essential that any change in these factors is reported to the transplant center so that the most recent values can be entered into the allocation system. Three factors in the LAS are valid for 6 months; after such time, new testing is required. These are the forced vital capacity, 6MWT distance, and serum creatinine. The infrastructure of a lung transplant program should be competent to make sure these clinical values remain current.

The clinical monitoring and testing for waitlisted patients is relatively intensive. Testing used to assure continued suitability for transplantation may include pulmonary function testing, arterial blood gases, serum creatinine, and bilirubin among other routine labs; sputum cultures in patients with cystic fibrosis (CF) or bronchiectasis; testing for panel reactive antibodies (PRA) against human leukocyte antigens (HLA); chest CT imaging at roughly 6-month intervals in patients at risk for developing malignancy [chronic obstructive pulmonary disease (COPD)/IPF] or fungal infections (CF/sarcoidosis); repeat 6MWT measurements; and repeat transthoracic echocardiogram in patients with pulmonary hypertension and possible repeat right heart catheterization if pressures are rising. Newer data are used to update the LAS as required by UNOS.

During outpatient visits at the transplant center, issues of weight gain or loss can be addressed as both severe malnutrition and obesity are risk factors for adverse outcomes following transplant [31]. Documentation of participation in a pulmonary rehabilitation program can be confirmed, along with general medical compliance and any changes in the patient's psychosocial support and insurance coverage. Random screening for drugs and/or nicotine abuse may be employed in patients considered at risk, with positive findings perhaps being cause for removing such patients from the waitlist.

It is not uncommon for patients to experience anxiety and/or depressive symptoms while waiting for transplant and such issues should be explored and dealt with, either with medication and/or referral to a psychiatrist or psychologist. Depression is associated with increased mortality while awaiting lung transplant [32]. Some transplant programs require relocation of lung transplant candidates to their local area prior to transplantation, which may engender additional hardships on the patient and family, with the disruption leading to further risk of depression. Therefore, it is essential that programs have clear center policies regarding minimal distance from the transplant center and that these policies are communicated early in the pretransplant process.

Adequate control of co-morbid medical problems such as hypertension and diabetes mellitus are assessed during the initial and follow-up visits while on the waitlist. Osteoporosis and vitamin D deficiency are quite common among patients with various lung diseases [33,34], so monitoring with serial bone density scans, along with treatment with calcium, vitamin D, biphosphonates, and/or other agents are employed [35] in waitlisted patients with decreased bone mineral density.

Lung transplant programs also need to establish mechanisms to ensure continued suitability for transplantation of potential recipients on the waitlist. In the US in 2011, roughly 500 patients were removed from the waitlist without having received a transplant. About 300 of these patients were removed for either being too healthy or too sick to undergo transplantation. These data underscore the fact that transplant suitability remains an ongoing question that needs close monitoring. There are no clear guidelines specifically directing how such monitoring should occur, but several lines of broad consensus exist. For example, most believe that sicker patients with a high LAS (>40) should be seen more frequently than more stable patients. Patients with a high LAS, particularly if the patient is deteriorating, should be seen at no longer than a monthly basis. Stable patients with COPD are seen at no longer than 3-month intervals. An additional strategy to ensure suitability for transplantation is to maintain weekly contact with waitlisted patients using methods such as a phone call or email. A second area of broad consensus is that hospitalized

waitlisted patients require a greater level of scrutiny. Most US centers have either an implicit or explicit minimal 6MWT distance that a patient must be able to cover to be considered appropriate for transplantation. A hospitalized patient experiencing an acute deterioration may fall below this threshold and in such cases, a determination may be made to accept donor lungs outside of standard inclusion criteria.

A continuing area of controversy is to what extent lung transplantation should be offered to patients who require either mechanical ventilation and/or extracorporeal membrane oxygenation (ECMO). Registry data from the International Society for Heart & Lung Transplantation (ISHLT) indicate that patients transplanted on mechanical ventilation have a significantly decreased odds of 1-year post-transplant survival [4]. Nevertheless, case series have demonstrated the feasibility of transplantation in very select individuals with results comparable to historical controls [36–38]. A common theme permeating these cases is that the majority of the patients are relatively young and without medical co-morbidities. Hence, if mechanical ventilation is to be used as a bridge to transplantation, one of the guiding principles might be to utilize it for patients in whom the odds of post-transplant survival are relatively high. While there is some uncertainty about transplantation in ventilated patients, the experience with ECMO is even less clear. This may be partly due to the fact that ECMO technology has accelerated rapidly over the past several years. This evolution encompasses both technological advances as well as new clinical decision-making approaches. Regarding the former, the use of self-contained small ECMO circuits, which require much less intensive hands-on technical support and utilize novel bi-lumen cannulas, may ultimately result in a type of ECMO delivery that can practically be tested on large groups of patients for efficacy. Regarding the latter, some clinicians have recommended the use of ECMO as upfront therapy for patients with end-stage lung failure rather than relying on ECMO as a therapy of last resort. The theoretical advantage to upfront ECMO is that it may allow for muscular conditioning and continued oral feeding with less risk of aspiration, thereby optimizing a potential recipient when donor lungs do become available. Several small case series from Europe using ECMO as a bridge to lung transplant have demonstrated the feasibility of this approach; long-term follow-up studies on large groups of patients are still lacking.

Overcoming impediments to lung transplant

There are several factors that may cause certain lung transplant candidates to wait longer than others for a donor lung. In such cases, it may be in the patient's best interest to consider listing at more than one transplant center ("dual listing"). Generally, *dual listing* involves being placed on the lung transplant list of two or more centers, where each center is "local" at a distinct OPO. Such listing effectively allows the recipient to be considered a local recipient on more than one list, thereby increasing the odds of finding a donor. Prior to dual listing, it is essential that the patient and all centers involved agree upon which center will manage the patient's care postoperatively. In most cases short- and long-term management will continue to be the responsibility of the transplanting center as the patient's survival is only counted in the statistics of the transplanting center.

Another common factor limiting individual patients' ability to receive a donor organ in a timely manner is the presence of *anti-HLA antibodies* against prospective donors. This factor limits the acceptable donor pool, thus increasing the time on the waitlist. The traditional approach to preventing acute rejection of a lung allograft by such a sensitized recipient has been to perform a prospective cross-match using recipient serum and donor cells. However, logistical issues and time constraints render such an approach impractical in many cases, thus increasing time on the waitlist. This problem has been addressed by the use of a "virtual cross-match" [39,40]. In essence, pretransplant testing will define the donor-specific class I and class II anti-HLA antibodies. During the donor evaluation process by the OPO, the donor HLA antigens will be defined, allowing the transplant team to determine if the potential recipient has antibodies specific to the donor HLA. The donor lung offer may be accepted or rejected on the basis of these data. There are many caveats to this approach, but the virtual cross-match does offer one way to address the lengthy wait for donors in sensitized patients.

A useful tool to ascertain the chances of finding a suitably matched donor is the CPRA calculator in which unacceptable antigens are entered into a computerized algorithm. A database of over 12 000 previous patient alleles is then run against these unacceptable antigens to determine the odds that the next organ will be free of any unacceptable HLA epitopes. This value can then be used to counsel patients on the chances that they will receive a transplant, as well as to decide in which patients some type of intervention must be undertaken. For example, some programs attempt to remove anti-donor HLA antibodies at the time of transplant with plasmapheresis and intravenous immunoglobulin G (IVIG) [41], or attempt to decrease antibody production in the recipient using various means prior to transplant, a process known as desensitization, which is covered in Chapter 68 [42]. However, none of the approaches to date has been sufficiently studied with long-term follow-up to be considered the accepted approach to managing the sensitized lung transplant patient. Dual listing with another transplant center(s) may also be considered in cases of very high pretransplant anti-HLA antibodies.

Another reason lung transplant candidates may not receive a donor quickly is *small recipient size*. In selected individuals, such as small CF patients, a living donor lobe for lung transplantation may be an option [43], although the clinical experience with this technique is limited to a few centers. Alternatively cadaveric donor lungs may require reduction surgery to fit the small chest of the recipient. Again, in situations where recipient size/geometry issues are predicted to increase waitlist time, dual listing may improve the patient's opportunities for receiving a donor.

Patients may experience clinical worsening while awaiting transplant. If the worsening is due to the development of a superimposed infectious process, e.g. pneumonia, the patient may be temporarily inactivated until the infection has been adequately treated. If clinical worsening results from progression of the underlying disease process, the LAS will be increased and the patient may receive a donor. However, various measures are taken to stabilize and/or improve the status of such patients, including short-term courses of corticosteroids, increased oxygen delivery, and change in oxygen delivery method to either face mask or bi-level positive airway pressure (BIPAP), delivery via a transtracheal catheter or even intubation with mechanical ventilation [44]. As noted above, select patients with profound ventilatory failure have even been supported with ECMO [45–47] until transplant could be accomplished. This and other artificial lung devises are discussed in depth in Chapter 50. Obviously, such critically ill patients have a high mortality [48] while awaiting transplant and higher morbidity and cost immediately after transplant [5,6].

Since the implementation of the LAS system, both waiting time and waitlist mortality have decreased [1], partly as a result of increased organ availability [4]. Nonetheless, there remain insufficient numbers of suitable donor lungs and individuals continue to die while awaiting lung transplant. One promising approach to increasing the number of donor lungs for transplantation is by subjecting lungs of questionable quality to normothermic *ex-vivo lung perfusion* (EVLP; covered in depth in Chapter 26) [49]. After 4 h of EVLP, a high percentage of such lungs was successfully transplanted with excellent short-term results. In the US, studies are underway to gain approval from the Food and Drug Administration (FDA) for implementation of the EVLP device and related materials in clinical lung transplantation practice.

Removal from the lung transplant waitlist

There are several ways in which patients may be removed from the lung transplant waitlist:

1. Patients may be temporarily inactivated due to intercurrent illness, travel, or change in psychosocial circumstances, and then reactivated once these issues are resolved.
2. Patients may be permanently removed from the list because of proven relapse of substance abuse.
3. Patients may be deemed to have progressed to the point of no longer being suitable candidates, e.g. overwhelming infection with septic shock and multiorgan failure syndrome.
4. Rarely, some patients may respond to simultaneous medical therapy and be deemed too well for transplant.
5. The patient may change his/her mind and decide to forego the option of lung transplantation.
6. When suitable organs become available and the patient undergoes the transplant procedure. This is the goal of the entire transplant team and we rejoice with the patient and family whenever this occurs.

Summary

Patients with end-stage pulmonary failure are critically and progressively ill, and require relatively intensive medical monitoring while on the waitlist for a lung transplant. While the recent introduction of lung allocation algorithms has helped to standardize the management of patients awaiting lung transplant, there still is regional heterogeneity in waiting times that relates to local practice patterns and organ supply. The time spent waiting for a suitable organ should be used as far as possible to optimize the cardiopulmonary reserve of the recipient, to immunologically prepare the patient through vaccination and avoidance of sensitizing events, and to educate the patient of the rehabilitation and drug therapy to come.

CHAPTER 41

Waiting List Management for Pancreas and Islet Transplantation

Jon S. Odorico
University of Wisconsin School of Medicine and Public Health, University Hospital, Madison, WI, USA

Introduction

Numerous pancreas and islet transplant options are available for patients with uremic and non-uremic diabetes. Depending on the center, one or more of these options may be available to patients and all relevant options should be discussed. For uremic patients, simultaneous pancreas–kidney (SPK) transplantation and sequential pancreas after kidney (PAK) transplantation are the principle options unless a center also offers islet transplantation, in which case options including simultaneous islet–kidney (SIK) or more commonly islet after kidney (IAK) transplantation may be offered. For non-uremic patients, the principle options are pancreas transplant alone (PTA) or islet transplant alone (ITA), the latter being restricted to approved clinical trials. For more details on pancreas and islet transplant options see Chapter 32, which covers patient selection and indications for pancreas and islet transplantation. Which one of these various options is ultimately recommended by the transplant center can impact the patient's waiting time. Conversely, the anticipated waiting times can influence which option is chosen. Important factors affecting the decision as to which option to recommend for a particular patient include: anticipated waiting time for a kidney transplant on either the SPK or kidney-alone lists, whether a patient is uremic and currently on dialysis, predialysis or has normal kidney function, allosensitization status, cardiovascular status, pancreas allograft outcomes at a particular center, anticipated pancreas waiting time for different pancreas transplant options, whether an experimental islet transplant program is available, and patient preference. As a consequence of the existence of multiple transplant options for replacing lost beta-cell function in patients with diabetes, patients can be listed on one of several different waiting lists.

The waiting list for patients with diabetes is not a single list but often encompasses multiple distinct lists. For example, at some centers uremic patients with diabetes wait on the same waiting list with other non-diabetic uremic patients, whereas at other centers they wait on a separate SPK waiting list. Patients waiting for a solitary pancreas allograft (PAK and PTA recipients) are often listed together, but on a separate waiting list from those waiting for an SPK transplant. Islet transplant recipients are also usually listed separately on a third waiting list. For uremic diabetic patients, dual listing options (i.e. kidney alone or SPK) are also available. Thus, the decision during the evaluation process to place a particular patient on specific waiting list can be a complex, multifaceted process, yet the management of these patients, *once on the waiting list*, is similar regardless of the waiting list.

This chapter will focus on key health maintenance issues and the frequently changing medical status of patients with diabetes with and without chronic kidney disease (CKD) awaiting transplantation. Among the most important health maintenance issue is cardiovascular disease evaluation and monitoring. This chapter will also outline factors affecting waiting time, and how expected waiting time can influence what type of pancreas transplant is recommended for a specific patient. Finally, the pancreas allocation system in the US will be undergoing changes in the coming years and we will discuss the limitations of the current system and how the new allocation system will hopefully improve allocation efficiency and organ utilization.

Monitoring and maintaining patient's active status on the waiting list

Multitude of medical issues and frequently changing waiting list status

Patients with type 1 diabetes mellitus (T1DM) presenting for transplantation commonly have numerous medical problems, which require close attention and work-up to manage risks appropriately. Common pretransplant medical problems include coronary artery disease, peripheral vascular disease, retinopathy, peripheral and autonomic neuropathy, gastroparesis, hypoglycemia unawareness, or other autoimmune diseases that can result in acute illnesses potentially delaying transplantation. Due to these multiple chronic medical problems and the acute illnesses they may contribute to, actively listed patients frequently need to be placed on hold/inactive status. In fact, it is not uncommon for a patient to be inactive for more than a year. A snapshot look at the United Network for Organ Sharing (UNOS) waiting list for pancreas transplantation indicates that at any one time nearly 50% of all pancreas waitlisted patients are on inactive status [1]. For example, at the end of 2009, approximately 3500 patients were on the waiting list for all types of pancreas transplants, while only 1600 of these were considered active. Within Eurotransplant, 40% of patients on the pancreas transplant waiting list at the end of 2010 were considered not transplantable (i.e. inactive status) [2]. Currently in the US, patients on inactive status (i.e. status 7) can still accrue waiting time points.

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

The frequently changing medical condition and waiting list status of diabetic patients awaiting pancreas transplantation poses a significant challenge to transplant centers. One of those challenges is communication. As patients are frequently shifted back and forth between active and inactive status as acute illnesses arise and are resolved, it is essential to maintain an open line of communication with patients and their referring physicians. This communication involves retrieving new records, undergoing repeated evaluations, holding repeated discussions at multidisciplinary candidate selection conferences, and updating the patient's UNOS registration status. As important as communication is between referring/primary care physicians and the transplant center, it is equally important for the transplant center to communicate the patient's status to the patient. A recent survey study of dialysis patients revealed that more than half of patients who were undergoing pretransplantation work-up were unaware of their true listing status [3]. Nearly 89% of these patients who completed the Dialysis Patient Transplant Questionnaire and were unaware of their true listing status mistakenly believed they were listed and 11% were unsure of their current status. Among waitlisted patients, most correctly identified themselves as listed; however, 6% mistakenly thought they were not listed and 12.5% were unsure. Importantly, all of the waitlisted patients who were unaware of their listing status were listed as inactive (i.e. status 7), indicating that they either had developed an intercurrent illness or required additional follow-up testing. Although this single-center study involving predominantly African–American dialysis patients and its findings remain to be validated for other ethnic groups or in the diabetic population, the finding of a substantial lack of listing status awareness emphasizes the need for better communication between the transplant program, patients, and their referring physicians. Thus, initial waiting list status, and all changes subsequently, should be communicated promptly in writing to patients.

The continually changing status of many patients requires a proactive approach to waiting list management, which is labor intensive, yet critical to maintaining patients ready for transplantation. Common problems affecting this diabetic population that often result in a patient being placed on inactive status include a recent cardiac event or need to complete or update cardiac testing, foot infections and/or ulcers, amputations, vascular disease interventions, eye surgeries, pneumonia, and dialysis catheter-related infections, among others. Patients are typically managed by their endocrinologists, nephrologists, or primary care physicians at distant locations and communicating changes in a patient's medical condition to the transplant center is not always seamless. Yet, it is important to avoid the presence of active medical problems at the time of an organ offer. Failing to place a patient on hold (i.e. *inactive* status), delaying treatment of his/her problems, or failing to recognize a worsening medical condition can lead to a patient not being suitable for transplant at the time of an organ offer. If a patient remains active on the waiting list despite ongoing acute medical issues and receives an organ offer, the transplant may need to be canceled, which potentially prolongs the cold ischemia time, or alternatively, a decision is made to proceed with the transplant, placing the patient at unnecessary or unrecognized risk. Thus, despite the challenges of managing a patient remotely, it is in the transplant center's best interest to proactively communicate the need to receive medical condition updates from the patient and his/her referring physicians. Consequently, many centers strive to re-evaluate patients annually and communicate with patients frequently in order to continually assess their medical status and readiness for transplantation. Whereas this re-evaluation process for very large liver or kidney transplant waiting lists may need to be prioritized to focus on only those patients with the longest waiting times, the significantly shorter SPK and solitary pancreas waiting lists at most centers allow most of the waiting list to be addressed. The facts that there are fewer patients on pancreas waiting lists and that SPK recipients are often waiting on the same list as non-diabetic uremic patients further accentuate the need for keeping the patients' medical condition optimized in order to maximize pancreas allocation efficiency and transplant rates.

Factors affecting waiting time

Transplant physicians are often asked by patients and referring physicians: what is the expected waiting time for a pancreas transplant? The answer depends on many factors including transplant center/region and degree of sensitization. Whether the waiting time is anticipated to be short (3–6 months), moderate (6 months to 2 years, or relatively long (>2 years) can influence not only how a patient is clinically managed in the pretransplant period, but may also impact what transplant option is recommended to the patient, so this is not a question to be considered lightly. Thus, knowledge of the key factors affecting waiting times allows transplant clinicians to estimate time to transplant and to formulate local health maintenance and monitoring plans to ensure that suitable candidates are ready for transplantation, thereby minimizing last minute cancellations.

Waiting time varies markedly among regions in the US, particularly for SPK transplants, and cannot always be predicted accurately. A chief determinant of waiting time for SPK recipients is whether these patients are listed with the non-diabetic uremic patients or whether they are listed separately. Those centers where SPK recipients are listed separately generally have shorter waiting times. A UNOS analysis revealed shorter waiting times for separately listed SPK candidates compared to SPK candidates listed on a combined kidney and SPK waiting list (median waiting time: 177 days vs. 645 days, respectively among all SPK candidates, and 144 days vs. 486 days, respectively among non-sensitized dialysis-dependent SPK candidates) [4]. Within a particular center or donor service area, it is easier to predict waiting times, yet these can vary as well and depend on recipient blood type, ethnicity, type of transplant, and degree of allosensitization. These patient-specific factors will be considered below in more detail.

Time on the pancreas transplant waiting list has gradually increased over the last decade in the US [1]. Compared to 1998 when nearly 60% of patients waited <1 year, now only 40% of patients are transplanted within 1 year of listing. Similarly, a decade ago only 1–2% of patients waited >5 years for a transplant, but now approximately 10% wait that long. This gradual increase in waiting time correlates with increasing numbers of inactive patients on the waiting list and an increase in retransplants and sensitized patients who tend to wait longer due to difficulty in finding a suitable match. The longer waiting times correlate with a significant decrease over the last decade in the US in the transplant rates among adult patients waitlisted for a pancreas transplant [1]. For all pancreas transplants taken together, transplant rates were approximately 60 per 100 patient-years in 1998, but have fallen to just below 40 per 100 patient-years in 2009. The fall in transplant rate over this period was greatest for PAK transplants, declining from a rate of approximately 72% in 1998 to only 20% in 2009 [1]. In contrast, the SPK transplant rate has only declined marginally over this period from approximately 60% to 48%.

What is the expected waiting time in the US for a pancreas transplant? The median waiting time for a transplant for *actively listed* candidates from 2005 to 2009 was 7.0 months for PTA, 11.5 months for SPK, and 12.8 months for PAK [1]. Naturally, waiting times for patients registered as inactive at the time of listing are significantly longer than those for active patients. For example, inactive PTA patients have a median waiting time ~40 months, SPK patients ~25 months, and PAK patients >60 months. The longer recorded waiting times for PAK patients may in part be due to the fact that some centers activate uremic T1DM patients on the PAK waiting list at the time of the living donor kidney transplant in case a deceased donor pancreas becomes available at that time, thus artifactually extending their waiting time. Regardless of the type of transplant, the median time to pancreas transplant in the US showed significant geographic variation [1]. Of the three pancreas transplant types, PAK patients have a marginally higher likelihood of still awaiting a transplant after 3 years in the US. For example, at the end of 3 years, 20.0%, 16.1%, and 24.9% of patients were still awaiting PTA, SPK, and PAK transplants, respectively. The increasing waiting times for PAK transplants correlate with the fact that in the US, fewer centers are performing PAK transplants in 2009 compared to 2004. In contrast, over this time period, a steadily increasing number of centers are performing PTA transplants, while the number of centers performing SPK transplants has remained stable.

The median time to pancreas transplant has unfortunately increased in the past decade in the US [1], in part due to the reduced probability that a donor will provide a suitable pancreas graft. The number of pancreata recovered and transplanted per donor has declined steadily since 2002 when it peaked at 0.3 and 0.24, compared to 0.21 and 0.15, respectively, in 2009. The reason for this decline is likely the increasing age, obesity, and diabetes prevalence of the US donor population. In parallel, pancreas discard rates have increased in all age groups since 1998. Despite an increasing percentage of pancreas grafts recovered from donation after circulatory death (DCD) donors across the US and an effort by Organ Procurement Organizations (OPOs) to place the most suitable pancreas grafts, pancreas recovery and transplant rates (i.e. utilization rates) across the US remain highly variable and significantly lower than for kidneys and livers.

Mortality rates and the onset of new medical problems precluding transplant in waitlisted patients affect estimates of whether a patient will receive a transplant. Regardless of the type of pancreas transplant, the overall rate of removal from the list for death or medical reasons tends to be similar [1]. Over 3 years in the US, the rate of removal tends to be up to 20% of patients, again emphasizing the need for frequent monitoring and repeat evaluation. PAK and PTA patients see the highest rates of removal from the list for medical reasons, whereas SPK waiting list patients see the lowest rate of removal for these reasons. On the other hand, SPK patients have the highest mortality on the waiting list of any type of pancreas transplant waitlisted patients, which is a consequence of the combination of uremia and diabetes-related mortality. By 3 years, 3.3% of PTA waitlisted patients had died, as had 9.4% of those listed for SPK and 2.5% of those listed for PAK. This significantly higher mortality in uremic T1DM patients awaiting an SPK transplant coupled with the long SPK waiting times in some US regions is an important consideration when deciding on SPK versus living donor kidney transplant followed by a PAK for this patient population (also see section below).

ABO blood type, sensitization, retransplantation, and ethnicity factors

Waiting time also depends on ABO blood type, degree of HLA sensitization, and retransplant status (covered in detail in Chapter 36) [1]. In the US, patients with blood types O and B wait nearly twice as long as those with blood types A and AB (i.e. median of ~20 months compared to ~10 months in 2009, respectively), a gap which has widened for unknown reasons in the last decade.

Allosensitization of the recipient is a risk factor for a longer waiting time to transplant for all types of pancreas transplants, just as it is for kidney transplants. The proportion of non-sensitized pancreas recipients on the waiting list has decreased over the past few years as the number of retransplant candidates has increased [1]. Additionally, the increasing use of sensitive methods of detecting HLA antibodies, such as Luminex® single bead assays, has probably led to increasing percentages of sensitized patients. Patients who are moderately to highly sensitized [20–79% calculated panel reactive antigen (cPRA)] witness a significantly longer waiting time than less sensitized (<20% cPRA) or non-sensitized patients. For highly sensitized uremic diabetic patients, the clinician should especially consider the several options available to these patients. The best option may be the one that corrects their CKD most expeditiously, thereby reducing excess mortality of this population while on dialysis. One option is SPK transplantation from a deceased donor without waiting list desensitization, which has an expected longer than average waiting time. Another is waiting list desensitization followed by SPK or deceased donor kidney transplantation, although there are logistical challenges with this option. A third is a living donor kidney alone via the National Kidney Registry or local donor exchange programs, if an ABO incompatible or cross-match positive living donor is available. Finally, consideration should be given to dual listing for either a deceased donor SPK *or kidney-alone* transplant, whichever becomes available first and it may also be recommended to consider multiple listing at centers in different donor service areas. An analysis of the UNOS kidney waiting list revealed that multilisted patients experienced 50% reductions in median waiting times and correspondingly higher transplant rates regardless of the demographic, biological, and socioeconomic status of the recipient [5]. Whereas multiple listing at centers with significantly shorter waiting lists has been shown to be beneficial, multiple listing at a second center with similarly long waiting times may not be fruitful [6]. Similar data related to pancreas transplantation are not presently available; however, it is likely these data can be conceptually extrapolated to pancreas transplantation.

There is currently little difference in waiting time when stratified by race in the US, although in the past black/African–American recipients experienced longer waiting times [1].

Transplant options for patients with chronic kidney disease and type 1 diabetes mellitus

For a uremic T1DM patient, there are several pancreas and kidney transplant options [7]. Chief among them is either an SPK transplant or a living donor kidney transplant followed by a deceased donor pancreas allograft. Although these are not the only options, remaining on dialysis or receiving a deceased donor kidney allograft alone are suboptimal outcomes with substantially higher associated mortality in otherwise stable patients with few co-morbidities [8–10]. A sequential PAK transplant involves two

operations and organs from two different donors, each of which requires monitoring for rejection, and generally has worse pancreas allograft survival (3-year pancreas graft survival: PAK 68% vs. SPK 78%) [1]. However, the PAK option has the potential benefit of providing rapid reversal of CKD by virtue of the patient receiving a living donor kidney transplant usually in a very short timeframe. On the other hand, the SPK transplant from the same donor affords the patient simultaneous correction of both kidney disease and diabetes with a single operation and monitoring for rejection focused on one donor, while affording the patient better pancreas graft survival and very similar kidney survival compared to living donor kidney survival [7].

Which of these options should be offered to a patient largely depends on the anticipated waiting time for an SPK transplant in a particular locale. What is the rationale? Given the very high mortality associated with the combination of CKD and diabetes, and the documented strong patient survival benefit of a kidney transplant, such patients cannot afford to wait many years for a kidney transplant due to the expected high waiting list mortality. With long waiting times at some centers in the US and around the world where SPK recipients wait on the same list with the many non-diabetic CKD patients, the primary goal of receiving a successful kidney transplant can best be accomplished with a living donor kidney. Thus, if the waiting time for an SPK transplant is anticipated to be long (perhaps >1–2 years), for either center-specific or patient-specific reasons, then a living donor kidney-alone transplant may be a very beneficial option. In other cases where the SPK waiting time is predicted to be shorter, then the SPK option has advantages over a PAK. The aforementioned recommendation of an living donor kidney followed by a PAK assumes a patient has a living donor kidney option. If not, then an SPK transplant is clearly a better long-term option associated with improved long-term patient survival and better quality of life compared with a deceased donor kidney transplant alone [9].

A few other special considerations that may modulate the relative benefits of each option are worth mentioning. If an HLA-identical living donor kidney is available, then a living donor kidney and sequential PAK option is perhaps a favored choice as HLA-identical kidneys are routinely associated with low rejection rates and significantly longer life span [11]. On the other hand, if the diabetic patient also suffers from impaired awareness of hypoglycemia and frequent hypoglycemic episodes, then there may be a more compelling reason to consider an early pancreas transplant and the simultaneous transplant option. The case of the highly sensitized uremic diabetic patient also merits consideration. Normally, this patient if lacking a living donor for a kidney transplant would be placed on the SPK waiting list because of the added benefits of the dual transplant versus a deceased donor kidney transplant alone. However, as highly sensitized patients can only receive a transplant from a subset of well-matched donors and only a subset of donors (15 of 100 donors on average in the US) provides a suitable pancreas graft, these patients can wait a long time for an SPK transplant. In this circumstance, it may make sense to consider discussing with the patient his/her placement on the kidney-alone waiting list in addition to the SPK list, and the option of accepting a well-matched kidney transplant alone if one becomes available from a donor whose pancreas is not considered transplantable. Finally, for those patients who do not have a suitable living donor matched to themselves, the National Kidney Registry provides an additional avenue to receive a living donor kidney.

Frequency of monitoring

Most centers will re-evaluate recipients on the waiting list annually or every 2 years at a minimum. A survey of transplant programs in the US indicates that 71% of centers attempt follow-up monitoring of all waitlisted kidney transplant candidates by either scheduled appointments or telephone contact [12]. Timely updating of a patient's cardiac, immunological, psychiatric, infectious disease, and malignancy status is essential to avoid non-transplantability at the time of an organ offer or increased perioperative morbidity if such problems are ignored and the transplant proceeds. At the University of Wisconsin, we aim to re-evaluate all patients on the kidney and pancreas transplant waiting lists who have had significant changes in their medical status, significant weight gain, or who have been on the waiting list for more than a year.

Centers typically collect sera monthly for cross-matching and for anti-HLA antibody testing. At the University of Wisconsin, we collect blood samples for Luminex® anti-HLA antibody testing monthly and perform quarterly testing in sensitized patients and semi-annually in non-sensitized patients or after any potentially sensitizing event such as blood product transfusion, pregnancy, or transplantation.

Cardiac screening

The combination of T1DM and CKD places this population at the highest risk for advanced ischemic cardiac disease and unrecognized cardiac events among all patients with CKD. At a minimum, frequent cardiac stress testing is necessary before and after transplantation; however, a strategy relying only on non-invasive stress tests has been challenged [13]. Indeed, diabetic uremic patients exhibit a "perfect storm" of cardiac disease risk and this impacts the need for aggressive cardiac disease screening. The rationale for aggressive cardiovascular disease screening is based on the following observations: (1) a high prevalence of cardiac disease [14,15]; (2) cardiac ischemia and infarction are commonly silent [16]; and (3) a high false-negative rate for stress tests [13,17–19]. For example, Vandenberg et al. performed non-invasive testing (either stress thallium scintigraphy or exercise radionuclide ventriculography) as well as coronary angiography in 47 asymptomatic diabetic transplant candidates. The sensitivity for detecting 75% or greater coronary artery stenosis was 62% for stress thallium scintigraphy and 50% for radionuclide ventriculography [13]. In another prospective study, dobutamine stress echocardiography had a sensitivity of 75% and a specificity of 76% [17]. Selek et al. showed that in diabetic uremic patients being evaluated for transplantation, community performed cardiac stress testing had a sensitivity of 27–47%, whether this was an exercise nuclear stress test, pharmacological stress test, or stress echocardiography [19]. Together these studies and clinical presentation dictate a frequent need for coronary angiography in patients with diabetes for cardiac screening and clearance prior to activating patients on the SPK or kidney-alone waiting list. The benefits of performing coronary angiography as the gold standard cardiac screening test in this high-risk population are further highlighted by the fact that it is not rare to witness SPK candidates dying on the waiting list due to a cardiac event despite a recent previous negative nuclear or treadmill stress test. Also, after SPK transplantation, the most common cause of death is related to a cardiovascular one [9]. Furthermore, SPK recipients exhibit a defined incidence of post-transplant cardiac ischemic events despite negative pretransplant stress tests; as high as 20% in one study [17]. Thus, at the author's

institution the majority of diabetic patients being evaluated for transplantation undergo coronary angiography.

The preference at many major pancreas transplant centers in the work-up of these uremic predialysis SPK candidates is coronary angiography regardless of the stress test result, especially if age >45 years, diabetes duration >25 years, history of tobacco use, or history of cardiac disease prior to waitlisting. It is hoped that such a policy will positively impact the frequency of perioperative cardiac events. This policy is not an issue for those patients already on dialysis at the time of referral. However, in the predialysis patient, a coronary angiogram is associated with some risk of progressive kidney dysfunction and could potentially precipitate need for dialysis initiation, thereby creating a clinical conundrum. Data clearly indicate the benefits of predialysis referral of patients for kidney transplantation and the better associated patient and kidney graft survival [20]. One would expect that this finding can be extrapolated to patients with T1DM and kidney disease as well, given the high mortality rate of patients with diabetes on dialysis. Hence, it seems important to continue to recommend referral of patients for transplantation while they still have early-stage kidney disease. Given the kidney failure risks, centers often selectively perform cardiac catheterization or avoid it altogether in predialysis patients. In this circumstance, patients can either undergo coronary angiography without ventriculogram and/or with renal protection, especially if their creatinine is still relatively low. Alternatively, patients can be added to the SPK waiting list with only a negative stress test result and coronary angiogram deferred until the patient initiates dialysis. Patients can be registered as inactive status on the UNOS waiting list, accrue waiting time, wait until beginning dialysis to undergo their screening coronary angiography, and then be activated for transplantation.

If coronary angiography demonstrates lesions >75%, patients should probably undergo revascularization with angioplasty and stent placement or coronary artery bypass. Manske et al. studied 26 asymptomatic diabetic patients who were found to have >75% coronary stenoses and randomized them to revascularization pretransplant versus medical therapy alone [18]. Patients randomized to medical therapy suffered significantly more post-transplant cardiac events than did patients who underwent interventional therapy.

In summary, the existing data on cardiovascular screening of diabetic uremic candidates for transplantation indicate it is beneficial to take an aggressive stance toward diagnosis and corrective intervention prior to transplantation.

Peripheral vascular screening

When evaluating diabetic patients for pancreas and/or kidney transplantation, it is essential to directly determine the extent and bilaterality of iliac disease as vascular inflow is a key determinant of allograft function. The presence or absence of iliac disease should be the focal point rather than the degree of distal lower extremity disease, which is nearly universally present in this population. Numerous different vascular imaging studies have been used to assess these patients over the years; however, few are better than physical exam. Doppler pulse volume recordings of the lower extremity are notoriously inaccurate due to the non-compressibility of heavily calcified blood vessels, and lower extremity angiograms do not fully assess the region of interest, namely the iliac arteries bilaterally. Plain abdominal X-ray can observe vascular calcifications in the iliac system but is not sensitive enough. The presence of lower limb amputation, particularly if for osteomyelitis, does not necessarily indicate disease involvement of iliac arteries and therefore, does not preclude transplantation. Probably the best indicator of suitable vessels for implantation of one or more allografts is a good femoral pulse exam and/or abdominal/pelvic computed tomography (CT) scan without intravenous contrast. The optimal frequency of vascular screening while on the waitlist has not been determined, yet the interim development of advanced bilateral or severe unilateral disease probably merits re-evaluation of SPK candidacy.

Miscellaneous

Some patients in unique situations may or may not be amenable to receiving organs from Centers for Disease Control and Prevention (CDC) high-risk or hepatitis C-positive donors. Local allocation and transplantation policy should dictate if and how these organs are allocated. Local listing should clearly indicate whether or not a patient is a candidate (willing) to receive a pancreas from a CDC high-risk or hepatitis C-positive donor and this patient choice may change over time while waiting. At the author's institution, the policy is to consider hepatitis C-positive donors only for those SPK candidates who are hepatitis C carriers, the rationale being the same as for allocation of a kidney transplant from a hepatitis C-positive donor to such patients. With regard to allocation of CDC high-risk donors, only those recipients who have consented are eligible and only donors whose nucleic acid testing (NAT) is negative are considered. Importantly, at the time of reassessment of the patient's waitlist status, the patient's wishes regarding CDC high-risk and hepatitis C-positive donors should be re-evaluated.

Waitlist removals

Death, transplantation, and the development of uncorrectable contraindications are reasons for removal from the OPTN waiting list within 24 h of the center being made aware of the event.

Current pancreas graft allocation system in the US

In the US, pancreas allografts are allocated to whole organ pancreas recipients first, followed by islet transplant recipients [21]. Pancreata are first allocated locally within the hospital's donor service area (DSA), then regionally within each of the 11 different regions in the OPTN, and then nationally. Highly sensitized potential recipients who have zero HLA mismatches with the donor are offered the pancreas as a priority over highly sensitized patients who are not a zero mismatch, and over other patients on the list. Within each DSA, sensitized candidates are prioritized ahead of other candidates. Patients are then stratified according to waiting time.

For pancreas and SPK offers from other DSAs, centers may opt to identify center-specific criteria that make an organ unsuitable for transplantation. Pancreata from donors aged <50 years and with a body mass index (BMI) of <30 kg/m^2 are allocated first for pancreas transplant and if rejected by all pancreas recipients, are then offered for islet transplantation or research. If the donor age is >50 years or BMI is >32 kg/m^2, then the pancreas is first offered for islet transplantation. This policy was enacted to facilitate utilization of pancreata generally deemed unsuitable for whole organ transplantation and expedite allocation for islet transplant recipients.

Considering only the allocation of pancreata for whole organ transplant, the current pancreas allocation policy has resulted in a system that is heterogeneous and varies by UNOS region across the

US. In some regions, the "pancreas follows the kidney" and SPK candidates await their turn among the many non-diabetic kidney only recipients on the waiting list, while in other regions the "kidney follows the pancreas" and separate SPK and kidney lists exist. Consequently, centers and regions have developed variances or exceptions, resulting in a patchwork, inconsistent allocation policy for pancreata for whole organ transplantation across the US. In part as a result of this, there remains a great degree of geographic inequity in pancreas utilization, access to transplantation, and transplant waiting time.

Moreover, in the current system, there are no specific diabetes-related qualifying criteria for listing patients for pancreas transplantation, other than "diagnosed with diabetes or has pancreatic exocrine insufficiency," which could adversely lead to more and more patients with type II diabetes and CKD receiving SPK transplants. Finally, many centers maintain at least two separate lists for whole organ pancreas transplant recipients: a SPK waiting list and a solitary pancreas transplant waiting list, which could be simplified into a single list for both groups.

Future US pancreas graft allocation schema

By 2011, the UNOS pancreas transplantation committee had formulated a detailed proposal to develop a more efficient, uniform national pancreas allocation system, which was recently approved by the UNOS Board of Directors and awaits implementation. The goal of the proposed new allocation system is to improve the efficiency of pancreas allocation by disentangling pancreas allocation from kidney allocation, as well as maximizing pancreas graft utilization and correcting geographic inequity in the access and waiting time to pancreas transplantation [4].

The new proposed policy seeks to:

1. Combine pancreas-alone and SPK candidates onto a single waiting list, while allowing candidates who are allocated a pancreas from the combined list but who also require a kidney transplant, to receive a kidney independently of the kidney-alone match run if they meet specific qualifying criteria.
2. Institute objective medical qualifying criteria relating to renal dysfunction and diabetes for SPK candidates to accrue waiting time.
3. Allocate deceased donor pancreata separately from the current kidney allocation system so that pancreas candidates are allocated organs that precede kidney paybacks and pediatric and adult kidney-alone recipients [4].

In an attempt to standardize the eligibility criteria and to prevent an excess number of patients with type 2 diabetes mellitus and uremia from being listed for an SPK transplant, SPK candidates who meet the following medical qualifying criteria will be able to accrue time and receive a transplant [4,22]:

- SPK candidates must qualify for a kidney transplant based on the current qualifying criteria. Thus, they must be on dialysis *or* have a glomerular filtration rate (GFR) of $\leq$20 mL/min *or* creatinine clearance of $\leq$20 mL/min.
- With regard to diabetes eligibility, the SPK candidate must meet one of the following criteria: (1) on insulin *and* with a C-peptide of $\leq$2 ng/mL *or* (2) on insulin *and* with a C-peptide of $>$2 ng/mL *and* BMI of up to the maximal allowable threshold of approximately 28–30 kg/m^2. The BMI threshold will be adjusted dynamically by the OPO contractor.
- Listing criteria for solitary pancreas transplantation will remain the same [4].

By design, the proposed changes create a single list for all pancreas candidates, thereby eliminating some complexities in pancreas allocation and establishing a uniform, national system. In addition, candidates for all types of pancreas transplants have an equal opportunity to receive offers for high quality organs. Importantly, it has been determined through modeling that this system retains high quality kidneys within the kidney allocation system in cases in which the pancreas is used for solitary transplant. Moreover, the new allocation schema where the "kidney follows the pancreas" is consistent with the allocation of kidney allografts with other extrarenal organs. It is anticipated that implementation will occur by the Fall of 2014 and that with implementation, the overall waiting times for SPK transplants will be reduced and overall pancreas graft utilization and pancreas transplant rates will improve.

Islet transplant waiting list considerations

Islet transplantation in the US is offered only within the context of Food and Drug Administration (FDA)- and Institutional Review Board (IRB)-approved clinical trials. As such, waiting list management is largely dictated by the clinical trial design or is established by local policy. One key feature of pancreas allocation for islet transplantation stems from the fact that islets from more than one pancreata are often necessary to achieve insulin independence. As it is widely believed that it is beneficial to have a short intervening period between islet infusions from the two or more islet preparations, recipients who have received at least one islet infusion are typically prioritized for a second infusion and can remain active on the waiting list.

Summary

List management for patients with T1DM is complicated by numerous factors, including significant progressive co-morbidities (particularly cardiovascular), numerous options for beta-cell replacement, and the potential need to be placed on numerous lists. Heterogeneity in allocation policy further complicates the process. Careful consideration of the factors most actively influencing the individual patient is required to navigate the challenges arising prior to a transplant. Engagement is required, particularly in the pursuit of cardiovascular disease and silent myocardial ischemia, to ensure that the patient's health is as good as it can be when a deceased donor organ becomes available.

Acknowledgments

The author would like to thank Dixon Kaufman, MD, PhD and Mike Armbrust, Senior Clinical Transplant Coordinator, for critical review of the manuscript.

CHAPTER 42

Waiting List Management for Intestinal and Multivisceral Transplantation

Kareem M. Abu-Elmagd[1] and Guilherme Costa[2]

Introduction

With increased practicality of intestinal transplantation, alone or combined with other abdominal organs, the number of candidates on the United Network of Organ Sharing (UNOS) waitlist has steadily increased over the last two decades [1,2]. Accordingly, establishment of clinical guidelines for proper management of these complex candidates is essential to reduce waitlist mortality and improve overall outcome with optimal utilization of deceased donor organs.

This chapter will focus on the clinical management of the visceral candidate waitlist with special reference to type of required allograft, current UNOS regulation, and risk factors commonly observed among this unique population.

Type of visceral allograft

The nomenclature of the various visceral allografts has recently been well defined [1,3,4]. Patients with intestinal failure or complex abdominal pathology may require the intestine alone or as part of a composite visceral graft that includes other abdominal visceral and solid organs (Figure 42.1). The three main types are isolated intestine, combined liver–intestine, and multivisceral that includes the stomach with and without the liver. When indicated, a colonic segment and/or a kidney are added to the isolated intestinal or composite visceral allograft.

The indications for visceral transplantation are fully outlined elsewhere [5] and in Chapter 30. In brief, organ failure is the primary basis for replacement. However, inclusion of the pancreas with the combined liver–intestinal graft is commonly required to maintain the allograft vascular integrity and continuity of the gastrointestinal tract. With multivisceral transplantation, both the pancreas and stomach are commonly replaced due to extensive parenchymal and splanchnic vascular disorders.

Current UNOS/OPTN regulations and allocation policy

Listing

After a thorough evaluation, the institutional selection committee determines patient candidacy. After the insurer's financial approval, patients are listed according to the UNOS guidelines. Currently, there is no waitlist designated for patients who need composite visceral allografts; as such each organ is listed separately. With logistics similar to those for other abdominal and thoracic organs, the visceral transplant candidates are listed for the same blood type with preference for small size donors due to contracture of the abdominal domain, particularly in patients with short bowel syndrome.

The UNOS categorical status that the visceral transplant candidates are listed for is based upon the type of required allograft. Patients who are in need of a liver-free allograft are listed status 1 in the presence of imminent life-threatening home parenteral nutrition (HPN)-associated complications, including disappearance of the central venous access and progression of the liver injury. Otherwise, patients are listed as status 2. For composite visceral allografts, priority on the wait list is dictated by the UNOS allocation policy for each organ, specifically the liver.

At the present time, the priority on the UNOS waiting list for liver–intestine or full multivisceral grafts is guided by the Pediatric End-Stage Liver Disease/Model for End-Stage Liver Disease (PELD/MELD) scores. Ironically, the combined liver–intestinal candidates were excluded from the PELD/MELD calculation model because of heavy disease gravity and high patient complexity [6]. The recent evolution of the liver–intestine allocation policy and its impact on current waitlist mortality is discussed below.

The current practice of individual listing of the various visceral and solid organs that constitute a composite visceral graft carries significant pitfalls, including the potential to skew many clinical, biologic, and immunologic metrics, particularly when UNOS or Scientific Registry of Transplant Recipients (SRTR) data are used for clinical research that includes outcome measures. We recently observed that some of our composite visceral allograft recipients were categorized in the SRTR report according to one of the contained organs, overlooking the intestine as the central core of the transplanted allograft. Another potential risk is inclusion of the visceral recipients who received the pancreas en bloc with other organs in any clinical outcome research related to pancreas transplantation, as there will be distinctive immunologic and non-immunologic differences [7,8].

Waiting time

Time spent on the waitlist is the product of many clinical and legislative variables. The most significant of these are type of allograft,

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

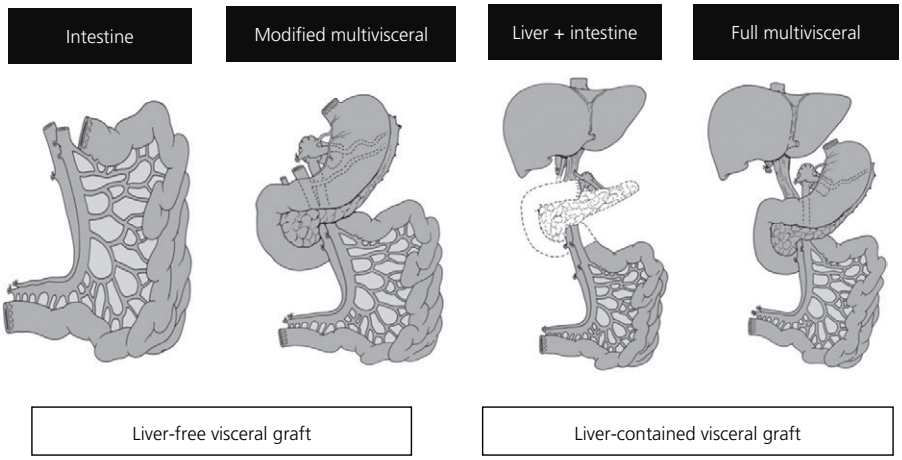

Figure 42.1. Types of visceral allografts: intestine, liver–intestine, and multivisceral. Inclusion of the pancreaticoduodenal complex (unshaded organs) is optional with the liver–intestinal allograft. A multivisceral graft must include the stomach en bloc with the other visceral organs without (modified) or with (full) the liver. The colon, pancreas, and kidney could also be added en bloc to the visceral allograft, with the exception of the liver-free visceral allograft, when the kidney can only be transplanted separately.

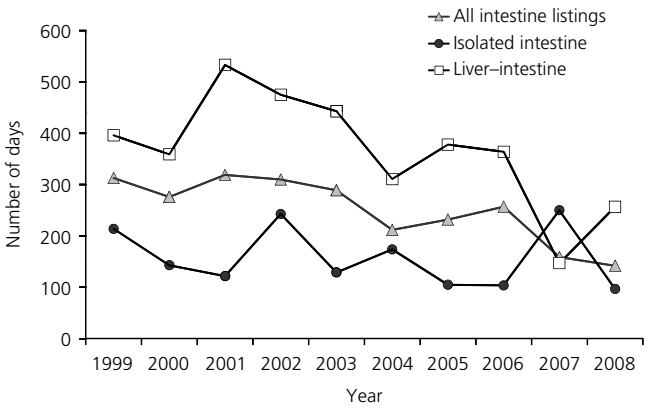

Figure 42.2. Median time to transplant for new intestine United Network of Organ Sharing (UNOS) waitlist registrations, 1999–2008. (Modified from Mazariegos et al. [1], with permission from John Wiley and Sons Ltd.)

status on the waiting list, geographic location of the Organ Procurement Organization (OPOs), and accessibility to regional and national donors. Other determining factors include recipient age, body weight, blood type, and size of abdominal cavity. For patients who are in need of liver-free allografts, the status of cytomegalovirus (CMV) seropositivity and alloantibody presence, particularly donor-specific antibodies (DSAs) when considering transplantation across a positive cross-match, are relevant indices that partly determine the time on the wait list.

In the milieu of the current Organ Procurement and Transplantation Network (OPTN) organ allocation policy, the type of visceral allograft is the major determinant of time from listing to transplantation (Figure 42.2). With the current limited demand for the intestine in isolation, the waiting time for the intestine-only allograft ranges from a few to 250 days [1]. Such a wide range reflects diverse management protocols adopted by different transplant centers, including avoidance of positive cytomegalovirus (CMV) donors for CMV-negative recipients and transplantation of liver-free visceral allografts against a positive lymphocytotoxic cross-match. Other important variables include non-optimal utilization of the intestine by many OPOs, donor geographic location with limits on cold ischemia time (CIT), and stringent donor selection criteria, including young age and hemodynamic stability with no history of significant cardiopulmonary arrest. The pediatric population seems to experience longer waiting times, probably due to body weight and size limitations [1].

The waiting time for patients who are listed for a modified multivisceral transplantation with exclusion of the liver has progressively become protracted over recent years. It has been increasingly difficult to obtain the approval of the liver transplant surgeons nationwide to retain the main celiac trunk with the visceral allograft to preserve integrity of the vascular blood supply to the transplanted stomach [9,10]. The procedure is commonly needed for patients with diffuse gastrointestinal disorders and complex abdominal pathology, particularly those with severe gastric dysmotility, Gardner's syndrome, and prior gastrectomy.

According to the most recent SRTR annual report, the median time to transplant for both the isolated intestine and liver–intestine candidates has been gradually and preferentially reduced (Figure 42.2). Such an achievement reflects the periodic multiple changes that have been made to the UNOS allocation policy combined with the continual advancement of the field. These two important evolutions have been partially beneficial to combined liver–intestine candidates, with no significant impact on the liver-free candidates. Nonetheless, the observed hectic variation in the yearly median time to transplant reflects the orphan nature of the population, with continual changes in the referral pattern, gut rehabilitation activities, and UNOS/OPTN allocation policy (Table 42.1).

Waitlist mortality

Visceral allograft candidates experience high mortality on the UNOS waiting list because of their complexity and disease gravity [11–15]. According to the UNOS database, these patients had a significantly higher unadjusted death rate compared to those listed for other thoracic and abdominal organs (Figure 42.3) [1]. Predictors for urgent referral, death on the waitlist, and early post-transplant mortality are comprehensively discussed elsewhere

Table 42.1. Changes to the Organ Procurement and Transplantation Network (OPTN) policy for liver–intestine candidates

Description	Date implemented in UNet[SM]*
I For candidates awaiting a combined liver–intestine transplant, livers may be allocated using the intestine list unless there is a status 1 liver patient in the region. Different listing status criteria were used over this period	May 1990 to February 2005
II All candidates awaiting a combined liver–intestine transplant who are registered on both waiting lists automatically receive an increase in their MELD/PELD score equivalent to a 10% risk of 3-month mortality	March 2005
III 3.9.3 modified to state that "the liver may be allocated by the local OPO to a local, regional, or national intestine recipient based upon priority for receipt of the intestine using the intestine waiting list unless there is a status 1A or 1B liver candidate locally, regionally, or nationally"	June 2007
IV Pediatric liver–intestine candidates received an additional 23 points to their calculated score. Adults still receive the additional 10%	June 2007
V Pediatric donors (0–11 years) offered preferentially to pediatric liver and liver–intestine patients	June 2007
VI Policy revised to state that livers must be offered sequentially to each potential liver recipient (including all MELD/PELD potential recipients) through national status 1A and 1B offers before being offered to combined liver–intestine potential recipients sequentially according to the intestine match run	N/A
VII Liver offers for 0–10-year-old pediatric donors are extended nationally to 0–11-year-old status 1A pediatric liver and combined liver–intestine candidates before offers are made to local adult status 1A candidates	November 2010
VIII The adult donor algorithm will be modified such that livers are offered to combined liver–intestine candidates *nationally* if there are no regional status 1A/1B candidates, or local candidates with a MELD/PELD score of 29 or higher	November 2011

* UNet[SM], a centralized computer network run by the United Network for Organ Sharing (UNOS) to match organs between deceased donors and potential recipients.
MELD/PELD, Model for End-Stage Liver Disease/Pediatric End-Stage Liver Disease; OPO, Organ Procurement Organization.

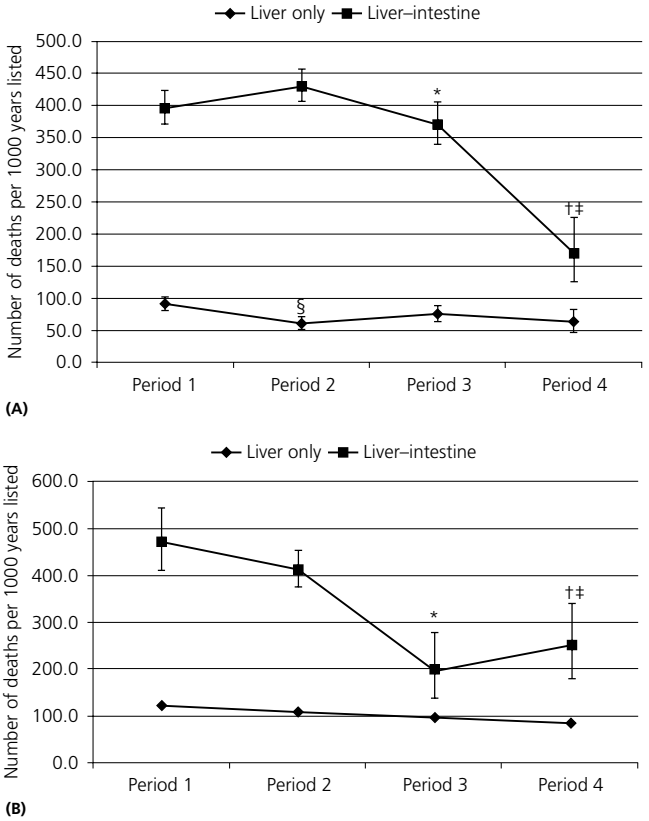

Figure 42.4. (A) The impact of MELD/PELD revisions on the mortality of liver–intestine transplant versus liver-only adult candidates. $^{*}P < 0.05$ compared with period 2; $^{\dagger}P < 0.001$ compared with periods 1 and 2; $^{\ddagger}P < 0.01$ compared with period 3; $^{\S}P < 0.05$ compared to period 1. I bars indicate 95% confidence intervals. (Reproduced from Kaplan et al. [13], with permission from John Wiley and Sons Ltd.) (B) Comparison of mortality rates in pediatric liver–intestine and liver-only candidate groups. $^{*}P < 0.001$ compared with periods 1 and 2; $^{\dagger}P < 0.05$ compared with period 2; $^{\ddagger}P < 0.01$ compared to period 1. Figure 42.3. Unadjusted death rates per 1000 patient-years at risk for patients on the United Network of Organ Sharing (UNOS) waitlist by organ, 1999–2008. (Modified from Mazariegos et al. [1], with permission from John Wiley and Sons Ltd.)

[16–22]. In brief, the degree of liver damage, hospitalization at time of transplant, cause of intestinal failure, and narcotic dependency are the most significant risk factors for poor outcome.

The series of changes that have recently been introduced to the UNOS/OPTN allocation policy (Table 42.1) have reduced the waitlist mortality of the pediatric liver–intestinal candidates, while the death rate among the adults continues to be clearly higher than that for the isolated liver candidates (Figure 42.4) [13]. Accordingly, the UNOS liver–intestine committee was approached by the primary author of this chapter in June 2009 with an evidence-based recommendation to further amend the current UNOS regulations to increase accessibility of these high-risk intestine–liver candidates to the deceased donor national pool. The aforementioned analysis of the current SRTR data showed that the liver–intestinal patients suffer a three-fold death rate compared to the liver-only waitlist candidates (Figure 42.5). Accordingly, final approval was granted by the UNOS/OPTN board to allow the liver–intestinal candidates with a MELD score of $\geq$29 to have access to the deceased donors nationwide [23].

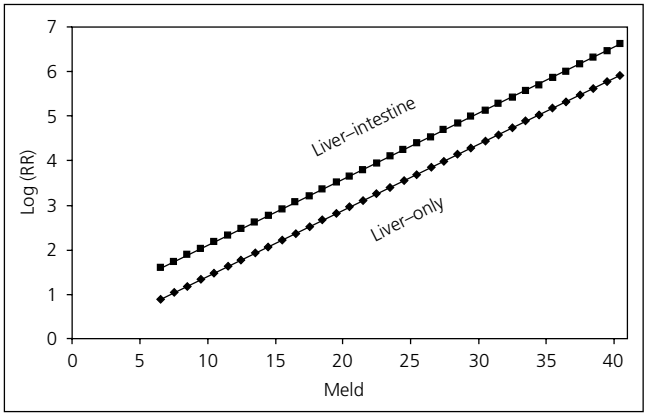

Figure 42.5. Log relative risk (RR) of mortality for liver–intestine compared to liver-only candidates on the Organ Procurement and Transplantation Network (OPTN) waiting list. Data prepared by the Scientific Registry of Transplant Recipients (SRTR) and presented to the United Network of Organ Sharing (UNOS) Liver–Intestine Committee. In November 2011, the UNOS/OPTN board approved the proposal with the modification outlined in Table 42.1.

Efforts toward improving outcomes

With the limited availability of the combined liver–intestinal donors, relentless efforts have been directed toward early referral to eliminate the need for simultaneous hepatic replacement [16–19, 24–27]. Furthermore, the concept of the comprehensive multidisciplinary team approach was introduced utilizing innovative medical and surgical modalities to restore gut functions with possible elimination of the need for transplantation [28].

It is conceivable that reduction of waiting time on the UNOS candidate list for both liver-free and liver-contained allografts could potentially reduce waitlist mortality. For liver-free allografts, technical innovation, utilization of live donors, and judicious expansion of the deceased donor pool has been utilized successfully [9,29–31]. Of great impact was the introduction of simultaneous retrieval of the intestine and pancreas from the same donor and their transplantation to two different recipients [9]. It is our recommendation to use living-related segmental intestinal transplant only for identical twins with no hereditary disorders and in countries where the law does not permit organ donation from brain dead individuals.

For candidates listed for liver-containing allografts, the continual evolution of the UNOS allocation policy has been instrumental in reducing mortality on the UNOS list, particularly among the liver–intestine pediatric candidates. Similar results are anticipated among adults upon implementation of the new algorithm of organ allocation (Table 42.1). Meanwhile, aggressive gut rehabilitation with utilization of an isolated liver allograft in children with short bowel syndrome has been successfully utilized [32]. Reduced and ABO-compatible allografts have also been used for extremely ill candidates [27,33,34]. Combined living-related segmental liver and intestinal transplantation also has been carefully introduced with a cumulative increase in the anticipated potential risks [35].

Regulatory compliance

UNOS/OPTN allocation policies, which are similar to those for other organs, must be followed. These include patient notification of listing and removal, rights for multilisting, and regular candidate status updates. With these regulations, patient care and organ utilization can be better attained.

Clinical management

Patient

Maintenance therapy

Management of intestinal failure, including HPN therapy, is the Achilles' heel of patient care. Of the major life-threatening HPN complications that should be closely monitored are line sepsis, central venous thrombosis, and liver failure. All patients should be monitored for bloodstream infection with weekly surveillance blood cultures. Clinical suspicion of central venous thrombosis should initiate diagnostic imaging with Doppler ultrasound and/or central venographic studies. Liver-free allograft candidates also should be closely monitored for development of significant liver damage that may necessitate simultaneous hepatic replacement. In contrast, candidates who are listed for a liver-contained allograft should be monitored for possible amelioration of the liver damage with elimination of the need for liver replacement. We have observed over the years a few examples of both scenarios with prompt modification of the required allograft.

Follow-up studies

Regular testing is needed weekly for most of the patients, and should include assessments of renal function and a comprehensive metabolic panel to monitor and adjust HPN therapy. Periodic assessment of hepatic enzymes, liver function tests, and measurement of micronutrient serum levels also is required. As indicated in our recent publications, yearly assessment of skeletal health is strongly recommended, including dual energy X-ray absorptiometry (DXA), and hormone and vitamin D serum levels [36,37].

Patients living a great distance from the transplant center should be closely followed by the primary care or referring physician. Weekly contact with the caring physician is mandatory, along with regularly scheduled visits to the designated transplant center.

Gut rehabilitation

Despite being on the transplant waitlist, certain candidates should continue to undergo gut rehabilitation utilizing the best available comprehensive medical and surgical therapy. Candidates on the waitlist with clinical and nutritional data suggestive of significant improvement in gut absorption should undergo gradual weaning of HPN therapy with placement on the inactive waiting list. Meanwhile, autologous surgical reconstruction for patients with preserved liver functions and isolated liver transplantation for those with end-stage liver failure should be judiciously considered [32,38].

Venous access

Management of the indwelling central venous catheter is an essential component of patient care. Sensible central line replacement, preferably by an experienced interventional radiology team, must be adopted to avoid life-threatening technical complications and to preserve a reliable central venous access for volume resuscitation during transplantation. A comprehensive discussion of proper central venous catheter placement and maintenance is beyond the scope of this chapter. However, it is our practice to prohibit the use of a previously placed central venous catheter at the time of transplantation because of the possibility of occult line infection.

Infection

Candidates with fever and/or positive blood culture should be subjected to prompt central line replacement and antimicrobial therapy. Pulmonary aspiration with recurrent pneumonia is not uncommon in patients with ultra-short gut and pseudo-obstruction syndrome, and this risk requires prophylactic measures, diagnostic imaging studies, and active treatment if indicated. Recurrent urinary tract infection is also a common source of infection among candidates with advanced hollow visceral myopathy/neuropathy that can be partly eliminated by sterile self-catheterization and intermittent antibiotic therapy.

In patients with complex abdominal pathology—particularly those with inflammatory bowel disease and irradiation enteritis—careful attention must be paid to the possible development of intra-abdominal abscesses, perforation, and enterocutaneous fistulas. Under such circumstances, patients should be placed on the inactive waiting list and considered for completion enterectomy and control of the abdominal infection, particularly in those with preserved liver functions.

Surveillance protocols

All candidates on the waitlist should undergo annual screening for malignancy, particularly high-risk patients with prior cancer or a strong family history of cancer. The surveillance should include mammogram and cervical smear in females, chest imaging in patients with smoking history, and gastrointestinal endoscopy in patients with neoplastic disorders including Gardner's syndrome. A yearly assessment of cardiopulmonary functions is also recommended for patients with hypercoagulable disorders, including Jak-2 mutations, cardiovascular diseases, or a history of recurrent pulmonary emboli. Development of de-novo malignancy such as melanoma and other skin cancers has been observed in a few of our patients while waiting for visceral transplant. Equally critical is the progression of the primary cardiovascular disease with the development of life-threatening complications that may preclude transplantation.

Allograft

The indications for visceral transplantation with and without simultaneous hepatic replacement are fully described elsewhere [5,27]. It is imperative to note that the pancreas is commonly transplanted en bloc with the liver–intestine or as part of the multivisceral graft due to technical and physiologic considerations [5,7,9]. Inclusion of the stomach as the defining organ of the multivisceral graft should only be utilized for patients with extensive gastrointestinal diseases and those with combined liver failure and portomesenteric/splenic venous thrombosis. The multivisceral graft is also commonly utilized for patients who require retransplantation after a combined liver–intestinal graft with hostile abdomen [27].

For better patient care and optimal utilization of deceased organs, it is imperative to periodically assess the medical necessity of the listed organs. It is not uncommon to add a liver or kidney after the initial listing due to development of liver or renal failure, particularly in patients with a marginal liver who are in need of retransplantation. According to the most recent SRTR/OPTN report, the most common additional organ that intestine candidates were subsequently listed for was the pancreas (20%), followed by the liver (10%) and the kidney (4%). In adults, 58% of candidates who were initially listed for both intestine and liver were subsequently listed for an additional organ, most commonly the pancreas due to the evolution of the technique with en-bloc inclusion of the pancreas [39]. In the pediatric population, 32% of candidates initially listed for intestine-only and 36% of those initially listed for intestine–pancreas were subsequently listed for liver. Furthermore, 27% of pediatric patients initially listed for both intestine and liver were subsequently listed for pancreas [1].

Elimination of one or more of the listed organs should always be considered in candidates who experience significant improvement in gut absorption or functional status of other abdominal organs. With fine adjustment of HPN formula, including the use of omega fatty acids, we have been able to eliminate the need for hepatic replacement and en-bloc pancreas transplant utilizing an isolated intestinal graft. In a few instances, the decision was made during the recipient transplant operation and the reserved organs were utilized for other candidates according to priority on the waitlist.

Donor

With the high susceptibility of the intestine to ischemia reperfusion injury compounded by the complexity of the recipient operation, only optimal donors should be considered for most candidates. The currently adopted donor criteria include young age ($\leq$55 years), low body mass index (BMI; $\leq$30 kg/m^2), hemodynamic stability, minimal pressor support, and no time or short time of cardiopulmonary arrest. Favorable biochemical markers include normal hepatic enzymes, low serum creatinine, normal range of serum lactate levels, and no evidence of disseminated intravascular coagulopathy. Despite organ shortage, particularly with inclusion of the liver, marginal donors should be considered only with great caution [31]. It is also advisable to avoid intestinal allografts with fatty mesentery.

For all visceral candidates, it is our recommendation to use ABO-identical donors. With the current availability of virtual cross-match, it is better to avoid transplanting a liver-free allograft to candidates with multiple unacceptable DSAs [8]. For patients with a contracted abdominal cavity, it is advisable to use small size donors. It is also recommended to use CMV-negative donors for CMV-negative candidates who are in need of liver-free allografts. Equally important is shortening of the cold ischemia time by synchronizing the time of both the donor and recipient operations.

Summary and future considerations

Management of the visceral allograft candidates on the UNOS waitlist is essential for continual improvement of survival outcomes before and after transplantation. Of the utmost importance are early referral, proper management of the waitlist, and further evolution of the current UNOS/OPTN allocation policy. With early referral, it is foreseeable to reduce disease gravity, extent of central venous thrombosis, and simultaneous hepatic replacement. Waitlist mortality can be further reduced by effective prophylactic, pre-emptive, and active measures towards preventing line/systemic sepsis, central venous thrombosis, and hepatic vascular or parenchymal decompensation. With surveillance protocols, malignant, cardiovascular, and other life-threatening diseases can be diagnosed early and treated promptly with better overall outcome. Further refinement of the UNOS/OPTN allocation system will allow better access to the national donor pool, with shortening of waiting time and subsequent improvement in wait list outcome.

For the liver-free allografts, a national policy allowing better HLA match through a new allocation system is essential to reduce time on the waitlist, particularly for those with DSAs and positive virtual cross-match. In addition, future translational research is

Table 42.2. Risk factors for mortality while on the waitlist for visceral transplantation

- Degree of liver damage (histologic and biochemical) [15 – 18,20,22]
- Hospitalization [19]
- Cause of intestinal failure [16,20,22]
- Narcotic dependency [20,22]

required to identify, validate, and ameliorate donor risk factors (Table 42.2) in the hope of increasing organ availability.

For liver-contained allograft candidates, broader access to the UNOS deceased donor national pool is essential to improve outcome at the present time. Similar policies should be adopted worldwide, particularly with the observed increase in the clinical activities of visceral transplantation shown in the recent report of the intestinal transplant registry [40].

CHAPTER 43

Intensive Care in Hepatic Failure

Jenny E. Han and Ram M. Subramanian

Division of Pulmonary and Critical Care Medicine, and Division of Gastroenterology and Hepatology, Department of Medicine, Emory University School of Medicine, Atlanta, GA, USA

Introduction

During the diagnosis, treatment, and management of liver failure in critical care, a rapid distinction needs to be made between acute liver failure (ALF) and acute on chronic liver failure (ACLF). Both types of liver failure can cause multiorgan failure, sepsis, and death. However, their pathophysiology differs, which manifests with distinctive hepatic and extrahepatic organ dysfunction that needs to be anticipated, closely monitored, and treated. In particular, a crucial distinction between ALF and ACLF in the context of hepatic encephalopathy is the potential complication of intracranial hypertension and the risk of herniation in ALF. In the setting of multiorgan failure in advanced ALF or ACLF, an optimization of hepatic and extrahepatic derangements, including cardiopulmonary, renal, and neurologic dysfunction, is essential to the successful transition of the critically ill patient to liver transplantation.

This chapter provides a multiorgan system-based description of the intensive care management of ALF and ACLF. It complements the content in Chapter 38, dealing with the management of patients awaiting liver transplant, and also relates to Chapter 47, which details the use of hepatic assist devices in liver failure.

Acute liver failure

ALF is defined as the onset of hepatic encephalopathy within 8 weeks of the onset of symptoms of hepatic dysfunction in a patient without pre-existing liver disease. A distinct feature of the encephalopathy of ALF is the risk of progression to *intracranial hypertension and cerebral herniation.* The encephalopathy is typically accompanied by a coagulopathy, and the progression of these two parameters is suggestive of worsening hepatic insufficiency, thereby necessitating the need for liver transplantation. The incidence is approximately 2000 cases of ALF a year in the US [1]. In 15% of adult cases, a cause may not be identified [2]. Approximately 45% of patients with supportive care alone will survive, approximately 25% proceed to transplant, and 30% die without transplantation. There are various causes of ALF that portend various prognoses (Table 43.1). The most favorable outcomes are for acetaminophen overdose, hepatitis A, and ischemia, where approximately 60% will survive with supportive therapy. Drug-induced ALF and hepatitis B have a poorer prognosis, with only 25% of patients surviving with supportive therapy alone.

Pathophysiology

The pathophysiology of ALF is massive hepatocellular necrosis. The characteristic clinical manifestations of encephalopathy and coagulopathy are secondary to hyperammonemia from a dysfunctional hepatic urea cycle and the absence of hepatic coagulation factors, respectively. ALF has been delineated into three types depending on the timing of progression from jaundice to encephalopathy: hyperacute (0–7days), in which rapidly fatal cerebral edema may develop, but this has the best overall prognosis; acute (8–28 days); or subacute (5–12 weeks), which has a lower rate of cerebral edema but poorer prognosis [3].

Diagnosis

When a patient presents with possible ALF, a careful and expedited evaluation should be performed to determine the etiology of liver failure (Table 43.1) and to rule out the presence of chronic liver disease that would preclude a diagnosis of ALF. Early in the diagnosis and management of these patients, transplant evaluation should be considered, and any barriers to transplantation such as lack of social support, co-morbidities, and active neoplastic or infectious etiologies should be identified.

A detailed work-up for potential etiologies of ALF (as outlined in Table 43.1) should be performed, and serial assessments of mental status are crucial. Serial measurements of liver enzymes, coagulation parameters including international normalized ratio (INR), arterial pH, and arterial lactate should be followed. Expedited cross-sectional abdominal imaging with computed tomography (CT) or magnetic resonance imaging (MRI) is invaluable in ruling out chronic liver disease, which would manifest as radiographic signs of chronic portal hypertension such as a cirrhotic hepatic contour, splenomegaly, and varices. In addition, the imaging study provides valuable information to the transplant surgeon with regard to assessing vascular patency in preparation for a potential liver transplant. If the patient is insufficiently stable to be transported to the radiology suite for CT or MRI, an abdominal ultrasound with Doppler measurements can provide useful data at the bedside. The utility of liver biopsy in ALF is limited, but may be of use if lymphoma is suspected or if a patient has subacute liver failure of uncertain etiology.

Given the possibility of rapid deterioration in clinical and biochemical status following an initial stable presentation of ALF, early

Table 43.1. Causes of acute liver failure

Drug-induced (acetaminophen toxicity most common)	
Prescription medications:	Most cases are idiosyncratic and often occur within 6 months of initiating therapy
Antimicrobials	
Anticonvulsants	
Antidepressants	Mechanisms of injury include hepatocellular necrosis, cholestasis, mixed pattern, steatosis, autoimmune, hypersensitivity, phospholipidosis, mitochondrial toxicity, sinusoidal obstruction syndrome
Lipid-lowering agents	
Antihypertensive agents	
Glucose-lowering agents	
Chemotherapeutic agents	
HIV medications	
Over-the-counter analgesics	If hypersensitivity suspected, steroids may have a role
Recreational drugs	
Viral (12% of cases in US; hepatitis A and B are most common)	Hepatitis A
	Hepatitis B (may treat with antiviral)
	Hepatitis D (super- or co-infection)
	Hepatitis E (20% mortality if pregnant)
	Hepatitis C (rare)
	Herpes simplex (treat with acyclovir)
	Varicella zoster (treat with acyclovir)
	Cytomegalovirus (treat with antiviral)
	Epstein–Barr virus
Toxins	*Amanita phalloides* (mushrooms)
	Organic solvents
	Herbal medicines
	Bacterial toxins (e.g. *Bacillus cereus*)
Wilson's disease	May have findings of chronic disease
	May have hemolytic anemia and renal failure
	May have low–normal alkaline phosphatase
	May have low uric acid
	Nearly 100% mortality without transplant
Pregnancy related (often treated with delivery of fetus)	Acute fatty liver of pregnancy
	HELLP syndrome
Autoimmune hepatitis	Treat with steroids
	May have findings of chronic disease
Malignancy	Lymphoma
	Diffuse metastatic disease
Hepatic ischemia	Shock
	Cocaine
	Acute arterial thrombosis/injury
Heat stroke	Clinical history important
Acute Budd–Chiari syndrome	Hypercoagulable states
Post extensive hepatic resection	Based on percentage volume removed as well as state of remaining hepatic parenchyma
Indeterminate (15–20% of cases)	Up to 20% of these cases may be due to undiagnosed acetaminophen toxicity
	Liver biopsy may or may not be helpful

transfer of patients to a liver transplant center is recommended. A detailed communication between the transferring and receiving facility should address the existing neurologic, cardiopulmonary, hepatic, hematologic, and renal status. Prior to transfer, it may be necessary to electively intubate a patient for airway protection, as advancing encephalopathy can occur unexpectedly in transit. Since patients with advanced ALF present with multiorgan system failure, management should follow an organ system-based, goal-directed approach.

Management

Cerebral edema and intracranial hypertension

A crucial feature of the management of ALF involves the assessment and therapy of *cerebral edema and intracranial hypertension*. In contrast to ACLF, the acuity of hyperammonemia in ALF carries the risk of causing cerebral edema and intracranial pressure (ICP) elevation due to astrocyte swelling. Of ALF patients, 20–30% will develop intracranial hypertension [4]. Serial neurologic assessments are essential to detect the onset of progressively worsening intracranial hypertension, which will manifest as worsening encephalopathy. The West Haven criteria for grading hepatic encephalopathy (Table 34.2) are useful in assessing and documenting serial neurologic exams, and in decision-making regarding elective intubation and the placement of ICP monitors. Advanced grades of encephalopathy (grades III and IV) are associated with cerebral edema and require emergent intubation for airway protection, and ICP monitoring and management to aggressively lower ICPs. It must be emphasized that brain imaging with CT or MRI is not sensitive enough to assess for cerebral edema and elevated ICP associated with ALF and therefore, should not be used to rule out intracranial hypertension.

Intracranial monitoring and management

ICP monitoring practices vary across institutions. There are no randomized trials studying the efficacy of ICP monitoring in ALF. However, the utility of ICP monitors is supported in the general neurointensive literature, extrapolation of these concepts to the context of ALF is being applied in certain centers in Europe and the US, though widespread use has been limited by the risk of intracranial bleeding in the setting of coagulopathy. In the presence of advanced encephalopathy requiring intubation and mechanical ventilation, the presence of sedation limits the utility of the neurologic exam and therefore, a more accurate and objective measure of ICP using a monitoring device would enable determination of intracranial hypertension and guide decisions regarding therapy, prognosis, and candidacy for liver transplantation. The intraparenchymal monitor appears to offer the optimal balance between accuracy and safety, and is the most widely used ICP monitor in ALF.

Intraparenchymal monitoring can be placed rapidly and safely at the bedside by trained specialists. The coagulopathy of ALF can be corrected rapidly with recombinant Factor VIIa at a dose of 40 μg/kg, thereby minimizing the risk of procedure-related bleeding. Elevated ICP is defined as an ICP of >25 mmHg for over 10 min. Monitoring the ICP also allows calculation of cerebral perfusion pressure (CPP), which is the mean arterial pressure (MAP) minus ICP (CPP = MAP – ICP). Therapeutic targets for the ICP and CPP are <25 mmHg and >60 mmHg, respectively. The optimization of CPP, especially in the setting of an elevated ICP, involves the pharmacologic induction of a therapeutic hypertension (elevated MAP) with a vasoactive agent such as norepinephrine. With regard to the management of elevated ICP, Figure 43.1 outlines an algorithm for pharmacologic therapy, which includes mannitol, hypertonic saline, hypothermia, and barbiturate coma [5].

Prior to the initiation of pharmacotherapy, patients with grade III or IV encephalopathy should be intubated for airway protection. Endotracheal or intravenous lidocaine prior to intubation may be helpful in reducing increases in ICP. Any seizure activity should be treated with dilantin; prophylactic dilantin is not currently recommended. In the intubated patient, patient–ventilator synchrony with adequate sedation and analgesia should be maintained to prevent surges in ICP due to tracheal irritation.

Pharmacotherapy for elevated intracranial pressure

The use of mannitol is efficacious in the initial correction of elevated ICP in ALF, with repeated dosing limited by serum osmolality and renal function (since the drug is renally cleared). Mannitol increases blood osmolarity, which creates an osmotic gradient that

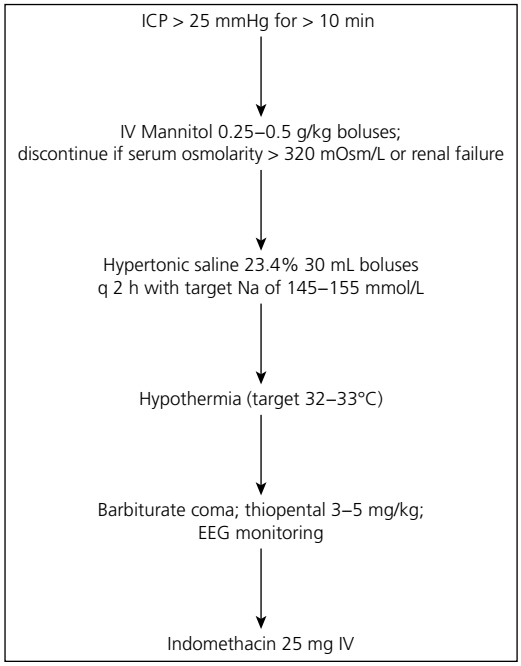

Figure 43.1. Algorithm for the management of intracranial hypertension in acute liver failure. EEG, electroencephalography. (Reproduced from Ford et al. [19], with permission from Elsevier. Copyright ©2010, Elsevier.)

draws fluid from the brain to the blood. Its ability to lower cerebral edema is associated with increased survival [6]. Bolus doses of 0.5–1 g/kg may be given to achieve correction of elevated ICP as long as the serum osmolarity does not exceed 320 mOsm/L and the patient is not in renal failure. Hypernatremia and hyperosmolarity resulting in pulmonary edema and hypervolemia can ensue; therefore, frequent vigilant monitoring of osmolarity and chemistries are essential.

Following initial intervention with mannitol, hypertonic saline is used repeatedly to decrease and maintain ICPs by increasing blood osmolarity. This intervention has been shown to successfully decrease ICPs in ALF [7]. Intravenous 23% hypertonic saline in 30-mL aliquots can be given as often as every 2 h to target a serum sodium level between 145 and 155 mmol/L. In addition, moderate hypothermia, with a goal core body temperature of 32–34 °C, can also effectively reduce ICP, especially in the setting of ICP elevations refractory to the above pharmacologic interventions [8]. Furthermore, in the authors' experience, the combination of hypertonic saline and hypothermia is effective in most cases of elevated ICP in ALF. In cases of refractory intracranial hypertension despite the above therapies, the induction of barbiturate coma can be used. Continuous electroencephalogram (EEG) monitoring is needed to titrate the barbiturate to achieve burst suppression on the EEG tracing. This treatment has the potential side-effects of myocardial suppression and hypotension, which limit its use [9]. A form of salvage therapy is intravenous indomethacin, which is a cerebral vasoconstrictor and should be used only as the last line of therapy due to its transient effects on lowering ICP [10]. It should be noted that the above interventions to optimize ICP and CPP are typically implemented for a finite time period in order to stabilize the neurologic status while the patient awaits definitive therapy with liver transplantation. In the event that an ICP monitor is placed pretransplant, it should be kept in for 24 to 48 hours post-transplant to confirm the presence of normal intracranial pressures.

Hematologic derangements

Coagulopathy as manifested by an elevation in the prothrombin time/INR) is a characteristic feature of ALF. Since hepatically synthesized factors (e.g. Factors V and VII) and the INR are the most sensitive biochemical indicators of hepatic synthetic function and recovery, the INR should be used as a *measure of potential hepatic recovery*, and *should not* be corrected with blood products in the absence of bleeding. Also, in addition to the loss of procoagulant factors, the synthesis of hepatic anticoagulant proteins, such as protein C and S, is decreased; hence, an elevated INR does not translate to an increased risk of bleeding. If the INR needs to be corrected for invasive procedures or bleeding, activated recombinant Factor VIIa can temporarily correct the INR. A minimum dose of 40 μg/kg is recommended to achieve transient reversal of coagulopathy, with a therapeutic window of approximately 2 h to perform invasive procedures. The transient effect of recombinant Factor VIIa is ideally suited to the context of ALF, since the temporary correction of coagulopathy to facilitate invasive procedures safely is followed by a return of the intrinsic INR to its uncorrected value; this can be used as a biochemical marker to trend hepatic function.

Thrombocytopenia is often present in ALF. Despite the low platelet count, patients do not typically exhibit signs of bleeding. Since ALF does not manifest the derangements of chronic portal hypertension, the risk of variceal bleeding is minimal. If the patient does not show active signs of bleeding, routine platelet transfusion is not recommended unless the count is $<10\,000/mm^3$. If a procedure is planned, a platelet count of $>50\,000/\ mm^3$ is commonly recommended.

With regard to the correction of hematologic derangements, the risk of transfusion-related acute lung injury (TRALI) should be recognized. The risk is greatest with fresh frozen plasma (FFP), but has been associated with platelet and packed red blood cell (pRBC) transfusions as well. The characteristic of TRALI is the onset of acute lung injury within 6 h of product administration; therapy is supportive.

Cardiopulmonary derangements

Cardiovascular

As the course of ALF progresses, the systemic inflammatory response induces the physiology of a hyperdynamic circulation and a low systemic vascular resistance. Given a compromised hepatic reticuloendothelial system, the patient with ALF is an immunocompromised host and is at risk for infectious complications that can worsen existing hypotension. Vasoactive agent support includes agents typical for septic shock, including norepinephrine and low-dose vasopressin. In the setting of cardiac dysfunction, ionotropic support with dobutamine or milrinone may be considered. As mentioned previously, there is a role for vasoactive agents such as norepinephrine in the setting of an elevated ICP in order to induce an iatrogenic hypertension to optimize CPP.

Pulmonary

The presence of advanced encephalopathy necessitates elective intubation for airway protection, and adequate short-acting analgesia (e.g. fentanyl) and sedation (e.g. propofol, dexmedetomidine) to ensure patient–ventilator synchrony. There are no evidence-based guidelines regarding the optimal mode of mechanical ventilation;

a volume-controlled or pressure-controlled mode can be used. With respect to pulmonary derangements, patients with ALF are at risk for acute lung injury due to infectious and non-infectious causes. TRALI is a non-infectious form of acute lung injury that the patient with ALF may be at particular risk for, given the need for correction of coagulopathy and thrombocytopenia with blood products. With respect to prophylactic measures, the routine intensive care unit (ICU) practice of head of bed elevation at 30º serves to decrease the risk of ventilator-associated pneumonia, and assists in decreasing ICP as well. With regard to ventilator settings, maneuvers to decrease intrathoracic pressures will facilitate venous drainage from the CNS circulation, thereby favorably influencing ICP values; therefore, tidal volumes in the range of 6–8 mL/kg of predicted body weight, and the lowest positive end-expiratory pressure (PEEP) to maintain adequate oxygenation should be utilized.

Renal failure

Acute kidney injury (AKI) is commonly seen in ALF and is associated with a poor prognosis [11]. The work-up for AKI should address pre-, intra-, and post-renal etiologies. It must be noted that AKI in the setting of ALF is unlikely to be hepatorenal syndrome (HRS), since the physiology of HRS requires the pathophysiologic derangements of chronic portal hypertension. AKI in the setting of ALF often necessitates renal replacement therapy, especially for the indication of a rapidly worsening anion-gap metabolic acidosis due to hyperlactatemia. If renal replacement therapy is initiated, the *continuous mode* of dialysis therapy with a bicarbonate bath should be used, even in hemodynamically stable patients, since intermittent hemodialysis can induce significant fluid shifts and cause dramatic rises in ICP [12]. In addition, high-volume hemofiltration has been shown to reduce serum lactate, base deficits, and vasopressor requirements [13].

N-Acetylcysteine therapy

For treatment of hepatic dysfunction in acetaminophen- or non-acetaminophen-induced liver failure, N-acetylcysteine (NAC) can be used, especially if given within the first 12 h of acetaminophen ingestion. NAC increases glutathione production, which is an antioxidant that ameliorates hepatoxicity. It is useful for up to 48–72 h from ingestion [14]. For non-acetaminophen liver failure, studies have shown that NAC improves end-organ oxygen delivery and hemodynamic stability [15]; therefore, all patients with ALF should receive NAC independent of etiology. NAC may be given orally or intravenously, and it is well tolerated with minimal side-effects. The oral loading dose is 140 mg/kg, followed by 70 mg/kg every 4 h for 17 doses. The intravenous dose is 150 mg/kg (in 5% dextrose solution) followed by 50 mg/kg over 4 h, followed by 100 mg/kg over 16 h [16]. NAC therapy can be discontinued when there is clinical improvement in hepatic dysfunction as evidenced by an improvement in encephalopathy and coagulopathy (INR <1.5).

In summary, the management of ALF involves addressing derangements in multiple organ systems, with specific attention to the management of hepatic encephalopathy and coagulopathy. In multiple prognostic models, these two factors have demonstrated utility for predicting spontaneous hepatic recovery or the need for liver transplantation.

Acute on chronic liver failure

The pathophysiology of ACLF involves the splanchnic and systemic derangements induced by chronic portal hypertension. Multiple organ systems can be involved that can lead to life-threatening derangements such as variceal bleeding, shock, abnormalities in gas exchange, and HRS-induced AKI. Early recognition of these disease states and anticipatory critical care support are lifesaving interventions prior to definitive therapy with transplantation.

Portal hypertension

Portal hypertension in cirrhosis is a consequence of the combined effects of intrahepatic resistance to portal flow and increased portal inflow. The resistance to portal flow consists of both fixed and functional components. The fixed component occurs from sinusoidal fibrosis and compression by regenerative nodules. The functional component is secondary to vasoconstriction, resulting from both decreased intrahepatic nitric oxide and increased intrahepatic vasoconstriction. The paradoxical decreased intrahepatic nitric oxide and overproduction of extrahepatic nitric oxide produces splanchnic vasodilation and increased portal inflow. Combined, the effects of the intrahepatic resistance to flow and increased portal inflow result in portal hypertension [17]. In addition, the pathologic splanchnic vasodilation results in a shunting of the cardiac output to the splanchnic circulation, and an associated decrease in effective systemic arterial blood volume perfusing other organs. These hemodynamic derangements in the splanchnic and systemic circulation form the basis for current management strategies in decompensated cirrhosis prior to liver transplantation. A central theme in the management of splanchnic and systemic derangements in ACLF is the reversal of splanchnic vasodilation with splanchnic vasoconstrictors (e.g. octreotide, terlipressin).

Hepatic encephalopathy

Hepatic encephalopathy is a serious complication of portal hypertension occurring in ACLF. Its neuropsychiatric clinical presentation ranges widely from mild cognitive impairment to frank coma. The pathophysiology is accepted to be a result of impaired hepatic clearance of toxins from the gastrointestinal tract, particularly ammonia.

While the debate continues over which toxins mediate the development of hepatic encephalopathy, elevated ammonia levels have long been implicated to play a role in its pathogenesis. Specifically, ammonia's effect on brain astrocytes is suspected in the development of hepatic encephalopathy. The astrocytes in chronic liver disease take on an Alzheimer's type morphology known as Alzheimer type II astrocytosis. In chronic liver disease, excess serum ammonia levels alter astrocytic neuronal proteins, leading to abnormal glutamate trafficking. This alteration in glutamate is thought to be partially responsible for the abnormal neurotransmission seen in hepatic encephalopathy. Other studies have suggested the involvement of seratoninergic and GABA receptors, manganese, as well as catecholamine pathways in the pathogenesis of hepatic encephalopathy [18].

Patients may present with symptoms ranging from subtle changes in the sleep–wake cycle, to lethargy, to worse levels of consciousness, including somnolence and coma. The West Haven criteria grades hepatic encephalopathy from grade I to grade IV based on varying levels of consciousness, intellectual function, and behavior (Table 43.2). Neurologic abnormalities on physical exam may be seen in more advanced presentations and include asterixis, hyperactive deep tendon reflexes, and hemiplegia.

Initial management of hepatic encephalopathy involves determining the grade of encephalopathy with prompt ICU transfer and elective intubation for airway protection in grades III and IV. The

Table 43.2 West Haven criteria for semi-quantitative grading of mental state

Grade 1	Trivial lack of awareness
	Euphoria or anxiety
	Shortened attention span
	Impaired performance of addition
Grade 2	Lethargy or apathy
	Minimal disorientation for time or place
	Subtle personality change
	Inappropriate behavior
	Impaired performance of subtraction
Grade 3	Somnolence to semi-stupor, but responsive to verbal stimuli
	Confusion
	Gross disorientation
Grade 4	Coma (unresponsive to verbal or noxious stimuli)

requirement for sedation during mechanical ventilation is typically minimal. Potential sedative agents include propofol and dexmedetomidine; benzodiazepines should be avoided given their risk of exacerbating hepatic encephalopathy. Imaging of the brain should also be considered to rule out other etiologies of altered mental status, including cerebrovascular accident (CVA), intracranial bleed, or masses. The *precipitating factor* of hepatic encephalopathy must be identified and treated. These include gastrointestinal bleeding, infection, electrolyte disturbances, dehydration, recent placement of a transjugular intrahepatic portosystemic shunt (TIPS), constipation, medication non-compliance, sedatives, or progressive hepatic dysfunction. Supportive care with intravenous fluid hydration, correction of electrolyte disturbances, and aspiration, and fall precautions should be instituted.

In contrast to ALF, the risk of developing cerebral edema and intracranial hypertension in the setting of hepatic encephalopathy in ACLF is negligible; therefore, ICP monitoring and osmotherapy are not indicated. A putative rationale for the lack of cerebral edema in ACLF is that the chronicity of hepatic dysfunction provides time for extrahepatic tissues such as muscle to up-regulate ammonia fixing mechanisms; therefore, in the setting of an acute insult that results in a hyperammonemic state, the central nervous system circulation is not subject to elevated ammonia levels that would lead to astrocyte edema (as seen in ALF).

Non-absorbable disaccharides such as lactulose are the main pharmacologic agents to aid in the clearance of ammonia in the treatment of hepatic encephalopathy. These drugs work by decreasing ammonia production in the gastrointestinal tract and increasing fecal nitrogen excretion. Specifically, when oral lactulose reaches the cecum, it is metabolized by enteric bacteria, causing a drop in the pH. This leads to a shift in bacteria favoring uptake of ammonia, leaving fewer for mucosal absorption. If the patient is unable to take oral lactulose, then a nasogastric tube must be placed for luminal administration or lactulose enemas. The dosage should be titrated to approximately three bowel movements per day. Antibiotics, including flagyl, rifaximin, and vancomycin, have also been studied and shown to be effective in the treatment of hepatic encephalopathy. These work primarily by eliminating urease-producing bacteria flora. While these agents can reduce blood ammonia levels and improve mentation, it is important to note that the degree of encephalopathy has not been shown to correlate with specific ammonia levels. Other treatment methods, including zinc administration and protein restriction, are also used, but lack strong clinical supporting evidence. In addition to the above agents targeted at elimination of ammonia, the treatment of the inciting factor is essential; in particular, the identification and treatment of a potential infectious etiology is critical.

Hemodynamic derangements

Due to the systemic vasodilatation from cirrhosis, which leads to low systemic vascular resistance, cardiac output is increased to facilitate end-organ perfusion. The hemodynamic pathophysiology mimics the features of septic hypotension, with characteristic features of a low MAP, a wide pulse pressure, and tachycardia. In the setting of worsening hepatic function or an active infection, this septic physiology can be exacerbated, leading to rapid progression to severe shock. With regard to vasoactive agent support, norepinephrine is typically the first agent of choice, since it acts on α and $\beta 1$ receptors, causing increased vascular tone and preserving cardiac output. Low-dose vasopressin can be added for distributive shock refractory to initial norepinephrine therapy. Dopamine should be used judiciously since it causes splanchnic vasodilatation, which can worsen portal hypertension. Volume resuscitation should be monitored closely since it can exacerbate ascites, which in turn can induce an abdominal compartment syndrome and subsequent hypovolemic hypotension due to inferior vena cava (IVC) compression and decrease in cardiac preload [19].

Pulmonary complications

Hepatopulmonary syndrome

Hepatopulmonary syndrome (HPS) is characterized by hypoxemia, and is defined as an increase in the alveolar-to-arterial oxygen gradient (A–a) and pulmonary vasodilatation in the setting of liver disease [20]. The frequency of HPS has been reported to range from 4% to 29%, with approximately 20% of patients with HPS awaiting transplant [21]. HPS is caused by pulmonary vasodilatation or pulmonary arteriovenous malformations. Proposed experimental models implicate pulmonary endothelin B receptor stimulation, which increases nitric oxide and in turn causes pathologic pulmonary vasodilatation. The dilated pulmonary vasculature induces hypoxemia due to a diffusion-impeded transfer of oxygen from the alveolus to the hemoglobin molecule in the capillary.

Clinical manifestations are tachypnea, hypoxemia, clubbing, cyanosis, platypnea (shortness of breath while upright), and orthodeoxia (hypoxemia while upright). The rationale for an exacerbation of the hypoxemia in the upright position is a basilar preponderance of the pathologic pulmonary vasodilation; therefore, in the upright position, since more blood flow is diverted to the lung bases, the hypoxemia associated with HPS is exacerbated. Patients with HPS typically have normal chest imaging studies, and the presence of hypoxemia in the absence of a radiographic shunt lesion should raise the possibility of HPS.

Diagnosis is based on a PaO_2 of <70 mmHg on room air with an increased A–a gradient of >20 mmHg [22], and diagnostic evidence of intrapulmonary shunting either by echocardiogram with a bubble study or a perfusion scan. The former evaluates for a right-to-left shunt with respect to the right and left heart. Agitated saline bubbles are introduced into the right heart via a peripheral vein. The appearance of delayed bubbles in the left heart after three to six cardiac cycles indicates an intrapulmonary shunt, with the bubbles having traversed the entire pathologically dilated pulmonary circulation; this finding of delayed bubbles needs to be contrasted with an "early bubbles" result, which would occur in the setting of an intracardiac shunt. Apart from echocardiographic data, a scintigraphic perfusion scan can be used to diagnosis intrapulmonary shunting. In a normal patient, technetium-99-labeled macroaggregated albumin is large enough to be trapped in the pulmonary vascular bed, but in patients with dilated pulmonary

vasculature, it can pass through the lungs and appear in the kidneys and brain.

Treatment is supportive with oxygen therapy. For patients who have an arteriovenous malformation on thoracic imaging, embolization may be curative. Patients with HPS who have a PaO_2 of <60 mmHg on room air are eligible for Model for End-stage Liver Disease (MELD) exception points, and transplantation can be curative, with a complete resolution of the hypoxemia. Patients with severe HPS, defined as a room air PaO_2 of <50 mmHg, have been reported to be at increased risk for perioperative mortality [23], although more recent evidence suggests that patients with this severity of HPS can be transplanted without increased mortality and therefore, it should not be a contraindication to transplantation [24].

Portopulmonary hypertension

Another distinct pulmonary entity seen only in cirrhotic patients is portopulmonary hypertension (PPH), which is a form of pulmonary arterial hypertension. It is estimated that 2–10% of cirrhotic patients are at risk of developing pulmonary hypertension, and in those referred to transplantation, 16% have pulmonary hypertension [22]. The diagnostic criteria of PPH include a mean pulmonary arterial pressure (mPAP) of ≥25 mmHg, peripheral vascular resistance (PVR) of ≥120 dynes·s/cm^5, and pulmonary capillary wedge pressure (PCWP) of ≤15 mmHg [22].

The pathogenesis is linked to portal hypertension, although the mechanism is not clearly elucidated. Impaired hepatic clearance of putative endotoxins and cytokines leads to the passage of these factors into the pulmonary circulation, which triggers pulmonary arterial endothelial proliferation. Proliferation of the pulmonary arterial endothelial cells and smooth muscle cells results in pulmonary vasoconstriction and pulmonary artery medial hypertrophy, causing obliteration of the vessel lumen and formation of plexiform lesions, which are the hallmark features of pulmonary hypertension [25]. Severe cases of PPH can lead to cor pulmonale and right heart failure. Patients with moderate-to-severe PPH, defined as a mPAP of ≥35 mmHg and a PVR of ≥250 dynes·s/cm^5, have a >50% mortality during liver transplantation due to the development of acute right heart failure following reperfusion of the hepatic graft; therefore, a mPAP of ≥35 mmHg in the setting of a PVR of ≥250 dynes·s/cm^5 is a contraindication to liver transplantation [23].

Typical symptoms include dyspnea on exertion, palpitations, syncope, and chest pain, with possible progression to symptoms of right heart failure. An echocardiogram is a useful non-invasive screening diagnostic tool for pulmonary hypertension. An estimated pulmonary arterial pressure of >50 mmHg on echocardiography is an indication to obtain more objective data with right heart catheterization. With respect to therapy, intravenous epoprostenol has been studied in the setting of PPH [22], with the demonstration of favorable effects on decreasing the mPAP to levels that are compatible with liver transplantation. Other agents currently being evaluated for the treatment of PPH include sildenafil, a phosphodiesterase-5 inhibitor, and endothelin receptor antagonists (e.g. bosentan). In contrast to HPS, PPH is less reversible following transplantation; most patients with pretransplant PPH require continued pharmacologic therapy in the short term, with potential weaning off therapy over time.

Hepatic hydrothorax

Hepatic hydrothorax is ascitic fluid accumulation in the pleural space, which causes dyspnea and potential respiratory failure. Fluid accumulation in the abdomen migrates through small diaphragmatic defects, and can rapidly accumulate in the pleural space given the relatively negative intrathoracic pressure compared to the peritoneal space. Most commonly, the effusion is right sided (seen in up to 66% of patients with hydrothorax). The mainstay of therapy is diuretic therapy. In the setting of acute dyspnea, thoracentesis can be performed. A large-bore chest tube is not recommended given the risk of inducing hypovolemia and hypovolemic shock. Pleurodesis is not a viable option for recurrent hepatic hydrothorax, since persistent accumulation of fluid prevents optimal apposition of the visceral and parietal pleura. In the setting of a recurrent hepatic hydrothorax process that is refractory to maximal diuretic therapy and thoracentesis, a TIPS may be curative.

The pleural fluid is most commonly transudative. A pleural fluid analysis that demonstrates exudative characteristics should raise the possibility of a para-pneumonic effusion. A hepatic hydrothorax can become infected and develop spontaneous bacterial pleuritis (defined as a transudate with an absolute polymorphonuclear cell count of >250/mm^3 or a positive fluid culture) and should be treated like spontaneous bacterial peritonitis [26].

Respiratory failure

Cirrhotic patients in the ICU often require mechanical ventilation due to an altered mental status, acute lung injury, sepsis, or multiorgan failure. Cirrhotic patients are at risk of developing acute lung injury/acute respiratory distress syndrome [27] due to pulmonary or extrapulmonary insults. Although there are no evidence-based guidelines on the optimal ventilator strategy for cirrhotic patients with acute lung injury or acute respiratory failure [acute respiratory distress syndrome (ARDS)], it is commonly recommended to extrapolate from the Acute Respiratory Distress Syndrome Network study and use a low tidal volume of 6 mL/kg predicted body weight [28]. In addition, ascites, pleural effusions, and chest wall edema commonly seen in cirrhotic patients can further compromise lung mechanics, thereby increasing the risk of barotrauma and volutrauma during mechanical ventilation. In the setting of prolonged mechanical ventilation for airway protection due to persistent hepatic encephalopathy, tracheostomy may have to be considered using a percutaneous or surgical technique.

Variceal bleeding

Gastroesophageal variceal bleeding is a life-threatening complication in cirrhotic patients. Portal hypertension causes increased vasodilatation of the splanchnic circulation, resulting in increased portal inflow. This increased flow, coupled with intrahepatic resistance, causes the formation of portosystemic variceal collaterals in gastroesophageal venous plexus. The development of varices is directly related to the hepatic sinusoidal resistance as measured by the hepatic venous pressure gradient (HVPG), and develops at pressures of around 10–12 mmHg [29]. These varices are at risk for rupture and can cause massive gastrointestinal hemorrhage.

Initial management includes the placement of two large-bore intravenous (18 G and higher) or large-bore central venous access catheters, and fluid and blood resuscitation. Careful hemodynamic monitoring is needed because overly aggressive fluid resuscitation can lead to increased portal pressure and worsening hemorrhage. In the setting of hematemesis or shock, elective intubation is indicated, which also facilitates the performance of endoscopy. It is critical that the patient's anemia and coagulopathy is aggressively managed, with a combination of pRBCs, platelets, and FFP to reverse the hematologic derangements. In addition, prophylactic

antibiotics should be administered to decrease the rate of bacterial infection from the variceal bleeding; either a quinolone or cephalosporin should be initiated and continued for 7 days. The initiation of antibiotics in this setting has been associated with a decrease in the rates of rebleeding and mortality [30].

The prompt initiation of pharmacologic therapy with a splanchnic vasoconstrictor such as octreotide (somatostatin analog) or terlipressin (vasopressin analog) is recommended. In addition, emergent endoscopy with therapeutic intent should be performed. In the setting of esophageal variceal bleeding, endoscopic band ligation can be successful in achieving hemostasis. In the setting of isolated gastric variceal bleeding or esophageal variceal bleeding that is refractory to endoscopic hemostasis, TIPS therapy by interventional radiology can be lifesaving. While awaiting TIPS therapy after a failed endoscopic approach, balloon tamponade therapy with gastric and esophageal balloon insufflation can provide a successful temporizing measure to stabilize active variceal bleeding.

Renal dysfunction and hepatorenal syndrome

Renal failure is a common complication of ACLF. The etiology of renal dysfunction can be pre-, intra-, or post-renal. Standard work-up to identify the cause of kidney injury includes an analysis of the urine sediment and indices, and imaging with ultrasound. The causes of AKI in ACLF include, shock, nephrotoxic drugs, and intrinsic renal disease. HRS is a unique prerenal etiology seen in cirrhotic patients and carries an increased mortality. HRS occurs due to splanchnic vasodilatation in advanced portal hypertension, which results in a reduction in the effective arterial blood volume. This arterial hypotension causes renal hypoperfusion, a compensatory renal vasoconstriction, and a consequent reduced glomerular filtration rate (GFR) [31].

HRS is classified into two types. Type 1 HRS is rapidly progressive AKI characterized by a doubling of the serum creatinine to >2.5 mg/dL or a 50% reduction of the initial 24-h creatinine clearance to a level <20 mL/min in <2 weeks. Type II HRS is defined as renal insufficiency (serum creatinine of 1.5–2.5 mg/dL) without rapid progression, and is typically associated with refractory ascites. HRS is a diagnosis of exclusion, and needs to be distinguished from prerenal azotemia by the lack of a renal response to a fluid challenge with crystalloid or colloid [32]. Combination therapy targeting splanchnic and systemic vasoconstriction with the use of octreotide (somatostatin analog) and midodrine (α-adrenergic agonist), respectively, is a potential treatment option for HRS. Terlipressin is a potent splanchnic vasoconstrictor, and has been shown to improve renal function in HRS [33–35]. It is currently in phase III clinical trials in the USA, and not yet FDA approved for use. In the setting of AKI due to HRS that is refractory to pharmacologic therapy, renal replacement therapy may have to be initiated. HRS and especially prolonged renal replacement therapy beyond 6 weeks should trigger a consideration for combined liver and kidney transplantation [36].

Ascites and spontaneous bacterial peritonitis

Ascites

Ascites is caused by portal hypertension and the derangement of the renin–angiotensin–aldosterone system, which leads to the pathologic renal absorption of sodium and water. New-onset or worsening ascites should trigger an evaluation for acute mesenteric venous thrombosis, and in particular portal vein and hepatic vein thrombosis. In the setting of preserved renal function, combination diuretic therapy with spironolactone and furosemide can be optimized to decrease ascites. If ACLF is complicated by AKI, pharmacologic therapy with diuretics is contraindicated, and large volume paracentesis (LVP) is indicated. If >5 L of fluid is removed during the paracentesis, albumin at a dose of 5 g/L of ascites removed should be administered to help prevent post-paracentesis circulatory dysfunction, which can lead to hypotension and renal impairment. If recurrent LVP is required for the management of persistent ascites, definitive therapy with a TIPS may be considered.

It must be noted that in the critical care setting, tense ascites can induce intra-abdominal hypertension, and the associated physiology of abdominal compartment syndrome (ACS). ACS is characterized by hypotension due to decreased venous return secondary to IVC compression, oliguria due to renal vascular compression, elevated peak and plateau pressures on the ventilator due to decreased chest wall compliance, and potentially, mesenteric ischemia due to compromise of splanchnic blood flow. Bladder pressure measurements using the Foley catheter can provide some objective evidence for intra-abdominal pressures, with a value of >20 mmHg being pathologic. Therapeutic interventions for ACS include large-volume paracentesis and gastrointestinal luminal decompression with nasogastric and rectal tubes.

Spontaneous bacterial peritonitis

Patients with persistent ascites can develop bacterial spontaneous peritonitis (SBP). It has been reported that up to 12% of cirrhotic patients requiring inpatient management for ACLF have SBP; therefore, cirrhotic patients admitted to the hospital should undergo evaluation for SBP with paracentesis [32]. The diagnosis of SBP is made if the ascitic fluid absolute neutrophil count is >250 cells/mm^3 or if the ascitic fluid culture is positive for an organism. Treatment is with a third-generation cephalosporin (e.g. cefotaxime 2 g/every 8 h). With regard to duration of antibiotic therapy, a randomized controlled study found that treatment for 5 days was just as effective as treatment for 10 days [37]. Of note, in addition to bacterial SBP, there is a rising incidence of fungal SBP and therefore, a lack of response to empiric antibacterial therapy should raise the possibility of a fungal infection.

In addition to antibacterial therapy, co-administration of albumin at a dose of 1.5 g/kg within 6 h of detection of SBP and 1 g/kg on day 3 following diagnosis, has been shown to decrease the incidence of renal impairment and death compared to antibiotic treatment alone [38].

Sepsis

Patients with cirrhosis are at increased risk of developing sepsis, severe sepsis, and septic shock. It has been reported that cirrhotic patients with septic shock have an inhospital mortality of up to 70% [39]. Although the mechanisms for increased risk of bacterial and fungal infection in cirrhotic patients are not clear, there has been evidence that cytokine deficiency and macrophage dysregulation play a role. The most common infection is SBP followed by urinary tract infection, pneumonia, bacteremia, and cellulitis. Cultures are positive in about 50–70% of cases and are normally due to Gram-negative bacilli, especially *Escherichia coli*. Gram-positive cocci are seen in 30–35% of cases. Given the increased use of empiric antibacterial therapy, the incidence of nosocomial fungal infections appears to be increasing. Due to the baseline low MAP and systemic vascular resistance, infectious triggers can precipitate rapid hemodynamic deterioration and florid septic shock. Furthermore, cirrhotic patients with septic shock have a higher incidence of adrenal

insufficiency (51–68%), which may be due to chronically decreased adrenal perfusion [40].

Treatment for sepsis and septic shock in cirrhosis is similar to the established management strategies for septic shock in general intensive care; these interventions include early goal-directed therapy aimed at ensuring adequate end-organ perfusion with volume resuscitation and vasoactive agent support, empiric broad-spectrum antimicrobial therapy, and a lung protective ventilatory strategy for acute lung injury.

Summary

The critical care management of patients with liver failure requires a detailed multiorgan, system-based approach to critical illness. The differing pathophysiology of ALF and ACLF requires specific management strategies to address hepatic and extrahepatic derangements. Clinical decision-making involves a team-based approach that incorporates the input of the transplant hepatologist, transplant surgeon, and intensivist, with a goal to stabilize the patient prior to liver transplantation.

Introduction

Cardiovascular disease increasingly complicates the care of transplant patients regardless of the organ system considered. Many indications for non-cardiac transplantation, such as hypertensive nephrosclerosis or insulin-dependent diabetes, represent serious risk factors for concomitant ischemic heart disease, and the generally aging recipient population adds cardiovascular risk as a general concern in most transplant settings. Brain death also markedly impacts cardiac function and thus, the issue of cardiac support impacts the procurement of essentially all organs. The hemodynamic alterations of advanced heart failure frequently compromise the function of vital organs, and result in the need for critical care interventions. In this chapter, we review the approach to a critically ill heart failure patient in need of vasoactive therapies, as well as the role of intra-aortic balloon counter-pulsation and mechanical ventilation in this clinical setting. The chapter complements Chapter 39, which covers waitlist management of critically ill patients awaiting heart transplantation, and provides companion information for Chapter 48, which covers the use of ventricular assist devices. The pathophysiology and approaches to management of disturbances of other organ systems that result from compromised cardiac function, such as pulmonary hypertension, the cardiorenal syndrome, and liver failure, are also discussed. As such, the information contained herein is applicable to most areas of transplantation that deal with critically ill patients and advanced cardiovascular co-morbidities.

Intravenous vasoactive drugs

Patients with advanced heart failure may develop hemodynamic instability and present critically ill with hypotension, respiratory distress, or progressive end-organ dysfunction. In these clinical scenarios, vasoactive agents are often required to improve hemodynamics and preserve end-organ function.

The selection and dosing of vasoactive agents should be based on careful assessment of the patient's hemodynamics. The main parameters of interest are systemic blood pressure, volume status, cardiac output, and systemic vascular resistance. Physical examination can provide a good estimate of these parameters, and objective data can be obtained through right heart catheterization (using a pulmonary artery, Swan-Ganz, catheter). The benefit of pulmonary artery catheter placement in critically ill patients has been questioned. In fact, randomized studies have shown that the routine use of pulmonary artery catheters does not provide a mortality benefit or reduce hospitalizations [1–3]. However, there are scenarios where the use of a pulmonary artery catheter would be reasonable. Typically, right heart catheterization should be considered in a critically ill heart failure patient, especially in the presence of progressive end-organ dysfunction, in whom physical examination does not provide an unequivocal indication of hemodynamic status, or in whom therapy instituted based on clinical assessment does not lead to the expected results [4–7]. Hemodynamic measurements obtained through right heart catheterization are then used to select the appropriate vasoactive agents.

Classes

Inotropic agents

Marked reduction of cardiac output is often the reason for severe symptoms and end-organ dysfunction in patients presenting with heart failure exacerbation. Dobutamine and milrinone are the two most common inotropic agents used to improve cardiac output in heart failure. Both act by increasing cyclic AMP (cAMP) in myocardial and vascular smooth muscle cells (Figure 44.1) [8–11]. In myocardial cells, this leads to a Ca^{2+}-mediated increase in contractility and enhanced chronotropic response. In vascular smooth muscle, cAMP leads to enhanced Ca^{2+} uptake by the sarcoplasmic reticulum and vasodilation.

Dobutamine, a synthetic catecholamine, is a strong agonist of $beta_1$ and $beta_2$ receptors. Binding to the $beta_1$ receptors in the myocardium leads to an increase in cAMP synthesis and a strong inotropic, as well as weaker chronotropic, effect [12]. The effect of binding to $alpha_1$ and $beta_2$ receptors on the vascular smooth muscle cells is dependent on the dose used—at lower doses ($\leq$5 μg/kg/min) the net effect is mild vasodilation, at moderate doses (up to 15 μg/kg/min) peripheral resistance is unchanged, and at higher doses (>15 μg/kg/min) vasoconstriction predominates [13].

Milrinone increases cAMP by inhibiting phosphodiesterase 3 (PDE 3), an enzyme that breaks down cAMP into AMP in the myocardium and vascular smooth muscle (Figure 44.1) [14]. In the myocardium, milrinone produces a potent inotropic effect and improves diastolic relaxation (lusitropy) [15–17]. Vasodilation in

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

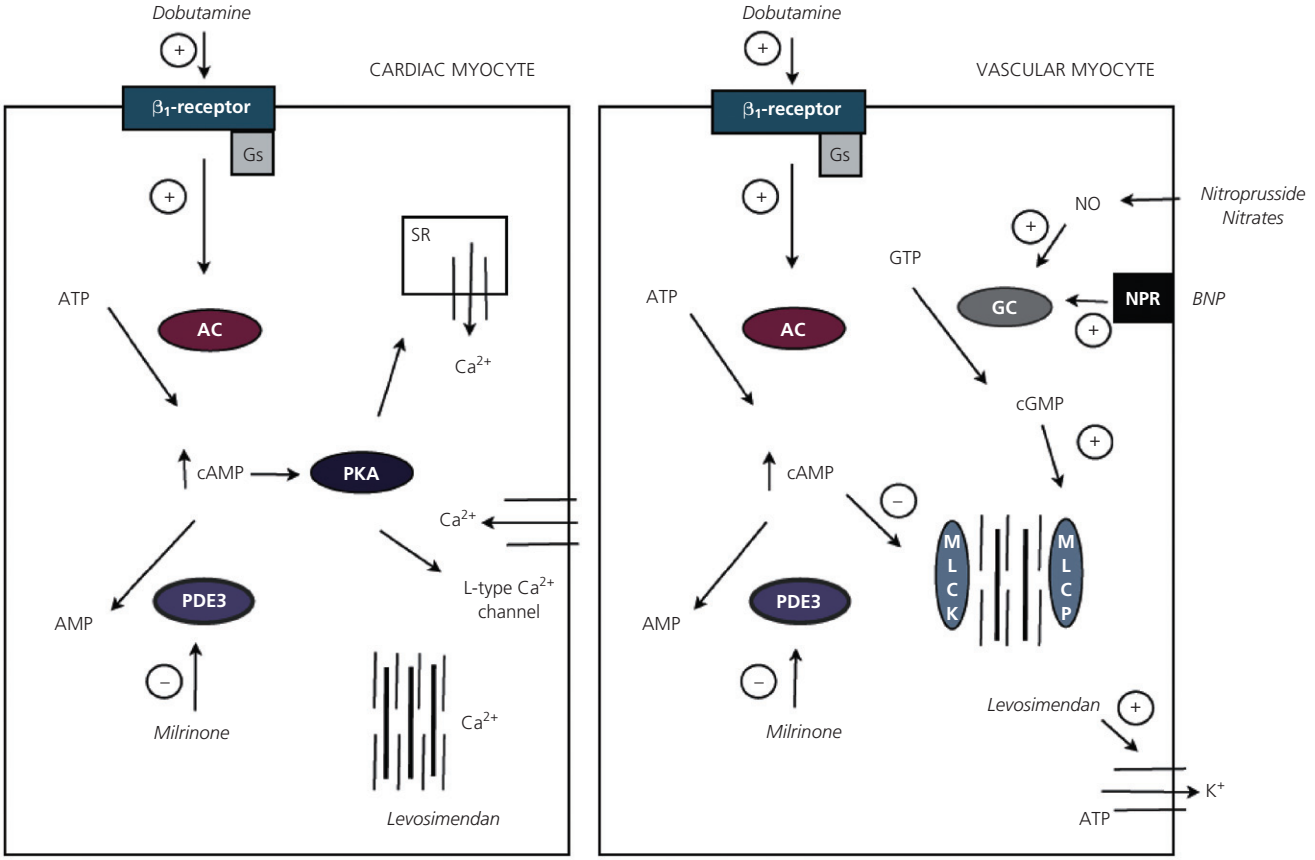

Figure 44.1. (A) Beta-agonists such as dobutamine activate the adenylcyclase (AC) system via G proteins (Gs), leading to an increase in cyclic AMP (cAMP) concentration. Milrinone increases cAMP by inhibiting phosphodiesterase 3 (PDE3) and the breakdown of cAMP into adenosine monophosphate (AMP). In cardiac myocytes, cAMP activates protein kinase A (PKA), leading to phosphorylation of L-type calcium channels and increased Ca^{2+} entry and greater release of Ca^{2+} from the sarcoplasmic reticulum (SR). Ca^{2+}-mediated activation of the actin–myosin–troponin system results in increased contractility. Levosimendan increases contractility by increasing the sensitivity of the myofilaments to Ca^{2+}. (B) In vascular smooth muscle, cAMP inhibits myosin light chain kinase (MLCK) and leads to relaxation. Nitric oxide (NO) and the natriuretic peptide receptor (NPR) act through guanylylcyclase (GC) to increase cyclic GMP (cGMP), activating myosin light chain phosphatase (MLCP) and causing relaxation. Levosimendan activates ATP-dependent K^+ channels, inducing vasorelaxation.

the systemic and pulmonary vasculature is more pronounced than with dobutamine [18,19]. Milrinone is cleared renally, so its dose may need to be adjusted in patients with renal dysfunction.

Direct comparisons of dobutamine and milrinone have shown similar clinical outcomes, including similar hemodynamic efficacy and arrhythmogenic potential [20]. There are situations, however, where one agent may be preferred over the other. Dobutamine leads to less systemic vasodilation and may be preferred in a hypotensive patient, particularly when the systolic blood pressure is $\leq$85 mmHg. Due to blunted beta-adrenergic receptor responses, or due to treatment with beta-blockers, some heart failure patients show diminished efficacy with dobutamine therapy [21]. As milrinone acts through non–beta-adrenergic pathways, these factors do not blunt the response to milrinone. In addition, due to more potent pulmonary vasodilation and greater right ventricular (RV) afterload reduction, milrinone may be preferred in patients with pulmonary arterial hypertension and/or RV dysfunction, as discussed later in this chapter. No mortality differences have been found in the chronic use of dobutamine versus milrinone. While acute administration of these inotropic agents leads to predictable improvement of hemodynamics, chronic administration of both dobutamine and milrinone is associated with increased myocardial oxygen consumption and possibly increased mortality [22–27].

Calcium-sensitizing agents

Calcium sensitizers represent a newer class of inotropes, with levosimendan being the most widely studied agent. In the myocardium, levosimendan binds to troponin C, sensitizing the myofilaments to calcium, which results in increased contractility. In vascular smooth muscle, levosimendan opens ATP-dependent potassium channels, resulting in vasodilation and decrease in preload and afterload [28,29]. Studies have shown improved symptoms in patients with acute decompensated heart failure treated with levosimendan, but survival was no different compared to patients treated with continuous dobutamine [30,31].

Other sympathomimetic agents

Dopamine is a norepinephrine precursor with cardiac and vascular effects that differ according to the dose [32,33]. At low doses (1–3 μg/kg/min), stimulation of dopaminergic receptors in the kidney and splanchnic arteries promotes vasodilation and increases blood flow through these vascular beds. At intermediate doses

(3–10 μg/kg/min), dopamine binds to $beta_1$ receptors, resulting in increased cardiac contractility and chronotropy and a mild increase in peripheral resistance. At higher doses (10–20 μg/kg/min), $alpha_1$-adrenergic stimulation in the peripheral vasculature predominates, resulting in peripheral vasoconstriction and an increase in blood pressure.

Norepinephrine is a potent $alpha_1$ receptor agonist with weaker beta-receptor binding. Norepinephrine administration results in intense vasoconstriction with less pronounced inotropic and chronotropic effects. It may be used temporarily in the setting of significant hypotension; however, prolonged use may be associated with direct myocardial toxicity and arrhythmias.

Epinephrine acts as a strong agonist of cardiac and vascular alpha and beta receptors. At low doses the beta-adrenergic effects predominate, while at higher doses alpha-adrenergic stimulation is greater and results in pronounced arterial and venous vasoconstriction. Epinephrine is often used in the setting of low cardiac output following heart transplantation. Its use in heart failure patients is more limited, as it is associated with a marked increase in myocardial oxygen consumption, an increase in afterload, and increased arrhythmias; it may be used temporarily when severe hypotension is present.

Isoprotenerol is a non-selective beta-receptor agonist with minimal effect on alpha-receptors. It has potent inotropic and chronotropic effects, and is often used immediately following heart transplantation where maintenance of a higher heart rate is desirable [34]. The use of isoproterenol in advanced heart failure patients outside of this setting is limited.

Arginine vasopressin

Vasopressin is an agonist of vasopressin V1 receptors in the vascular smooth muscle. Vasopressin administration results in peripheral vasoconstriction and increases the response of vascular smooth muscle to catecholamines [35]. The use of vasopressin can be considered in patients with heart failure and hypotension believed to be due to marked peripheral vasodilation. Unlike many other vasopressor agents, vasopressin does not have significant arrhythmogenic effects.

Intravenous vasodilators

Chronic heart failure results in activation of the sympathetic nervous system and peripheral vasoconstriction. This increase in peripheral vascular resistance and afterload limits cardiac output and leads to progression of cardiac dysfunction. As long as systemic blood pressure is not too low, intravenous vasodilators may favorably alter hemodynamics.

Sodium nitroprusside is a potent arterial and venous dilator in both the systemic and the pulmonary vasculature. The vasodilation results from reduction of nitroprusside by intracellular glutathione, a reaction that produces nitric oxide (NO). In patients with reduced cardiac output but without hypotension, nitroprusside might be preferable to inotropes as it does not increase myocardial oxygen uptake and is not arrhythmogenic [36,37]. However, the use of nitroprusside may be limited by hypotension. Other adverse effects are related to its metabolites. Cyanide, a product of nitroprusside metabolism, can accumulate in patients with hepatic dysfunction, but cyanide toxicity has also been described in patients with normal liver function. Manifestations of cyanide toxicity include lactic acidosis, nausea, restlessness, and methemoglobinemia. Thiocyanate (a metabolite of cyanide) toxicity is seen in patients with renal dysfunction, and presents as weakness, tremor, confusion, nausea, hyperreflexia, and rarely coma [38,39].

Nitrates are NO donors and their primary effect is venodilation, although arterial dilation can be seen at higher doses. Patients with decompensated heart failure refractory to diuretic therapy, particularly those with disproportionate right-sided failure, may benefit from intravenous nitroglycerin administration. Its use is limited primarily by a rapid onset of tolerance [40,41].

Nesiritide is a recombinant form of human B-type natriuretic peptide (BNP) and mimics the effect of endogenous BNP. It produces arterial and venous dilation and lowers pulmonary capillary wedge and right atrial pressures. Studies of nesiritide in acute decompensated heart failure have shown improvements in symptoms, but no mortality benefit [42–44]. In heart transplant candidates, nesiritide has occasionally been used to bridge critically ill patients unresponsive to other therapies to transplant [45]. The main adverse effect of nesiritide is hypotension.

Clinical application

The use of vasoactive agents in patients with heart failure has been contentious. Clinical trials examining the benefit of inotropic agents in advanced heart failure patients presenting in cardiogenic shock are lacking. Clinical trials evaluating inotropic therapy in less sick patients with advanced heart failure not awaiting heart transplantation have shown increased morbidity and mortality with both short-term and chronic use [24,46,47]. The mechanisms for these undesirable effects are believed to be an increase in intracellular calcium concentration and calcium overload of the sarcoplasmic reticulum, leading to arrhythmias and maladaptive remodeling [48,49]. Clinical guidelines recommend against routine use of these agents in patients hospitalized with acute decompensated heart failure, but note that chronic use is appropriate in inotrope-dependent patients awaiting heart transplantation, or as palliative therapy for severely symptomatic patients as part of end-of-life care [50].

Vasoactive agents are often initiated in heart transplant candidates who present in acute heart failure exacerbation. The specific agents are selected based on the patient's hemodynamics and the attributes of the individual agents reviewed above. Patients with marked systemic hypotension require the use of agents without vasodilatory effect, such as dopamine, epinephrine and norepinephrine. Studies comparing outcomes of the different agents with vasopressor properties in heart failure patients are limited [51]. In patients with low cardiac output without marked hypotension, milrinone or dobutamine are the most frequently used inotropes. Compared to dobutamine, milrinone is associated with less drug tolerance and more vasodilation of pulmonary vasculature; however, in the absence of compelling comparative clinical trials, the two drugs are believed to provide similar results [52]. When used in combination, the beta-agonist effect of dobutamine and the PDE 3 inhibition of milrinone may produce benefit in patients with an inadequate response to either agent alone.

Once hemodynamics are improved, the goal is to transition the patient to oral therapy. In a subset of patients, however, withdrawal of the intravenous vasoactive support will again lead to hemodynamic instability, worsening heart failure, and end-organ dysfunction [48]. In the absence of other reversible factors, these patients are deemed inotrope dependent, and may require continuous inotropic support as a bridge to transplant. This clinical scenario is frequent; between 2002 and 2010, 45% of the 27 387 patients registered in the Scientific Registry of the International Society for Heart

& Lung Transplantation (ISHLT) were on inotropic support at the time of transplant [53]. Patients bridged with inotropes while awaiting transplant require close follow-up. Given the arrhythmogenic properties of inotropes, an implantable cardiac defibrillator should be placed before discharge to outpatient care [54–56]. As inotrope dependency represents a truly advanced stage of heart failure and is associated with higher risk of mortality on the transplant waitlist [57], some organ allocation systems afford these patients a higher urgency status. In the US, for example, patients on a continuous infusion of a single high-dose intravenous inotrope (dobutamine $\geq$7.5 μg/kg/min, milrinone $\geq$0.5 μg/kg/min, dopamine $\geq$7.5 μg/kg/min, or epinephrine $\geq$0.02 μg/kg/min) or two or more intravenous inotropes, and with continuous hemodynamic monitoring, are eligible for the highest urgency 1A status. Patients receiving a continuous infusion of intravenous inotropes, including those maintained on a single agent and as outpatients, will qualify for the next urgency status 1B [58].

Inotrope-dependent patients whose waiting time for transplant is expected to be prolonged, as well as patients with progressive hemodynamic deterioration on inotropic therapy, should be considered for mechanical assist support as a bridge to transplant, either using a ventricular assist device or a total artificial heart. These topics are discussed in more detail in Chapters 48 and 49, respectively.

Intra-aortic balloon counter-pulsation

Intra-aortic balloon pump (IABP) counter-pulsation is often considered in patients with heart failure refractory to medical therapy. The concept of intra-aortic counter-pulsation was first developed by Moulopoulos and colleagues in the early 1960s [59], and applied clinically by Kantrowitz in 1968 [60]. Current applications for the IABP include support in cardiogenic shock, use in high-risk coronary interventions, treatment of intractable angina, and support during weaning from cardiopulmonary bypass [61,62]. The IABP remains the most widely used form of mechanical circulatory support.

Hemodynamic effects

The IABP consists of an inflatable balloon placed percutaneously, usually through the femoral artery, into the descending aorta. An external console controls inflation and deflation of the balloon at precise time intervals during the cardiac cycle: the balloon is inflated at the onset of ventricular diastole and deflated just before the onset of ventricular systole. Balloon inflation in diastole displaces blood from the descending aorta, resulting in increased diastolic pressure and coronary perfusion, as well as enhanced blood flow to other organs during diastole. In systole, balloon deflation creates a vacuum effect, reducing afterload and improving forward blood flow. Many believe it is this reduction in afterload that is most beneficial to a failing left ventricle (LV) [63,64]. Scheidt et al. reported that in a patient with cardiogenic shock, the average result of IABP counter-pulsation was a 20% decrease in systolic pressure, a 30% increase in diastolic pressure, a 20% increase in cardiac output, and a 20% decrease in mean pulmonary capillary wedge pressure (PCWP) [65]. For optimized hemodynamic results, inflation and deflation of the IABP must be synchronous to a patient's cardiac cycle. Technological advancements have allowed for IABP control systems to automatically optimize balloon inflation and deflation timing.

Clinical application

The IABP has been successfully used to bridge approximately 7% of patients to transplant over the past two decades [53]. Patients bridged to transplant with the IABP do not have an increase in post-transplant mortality [53,66].

The IABP has been used most frequently in patients who present with cardiogenic shock due to acute ST-segment elevation myocardial infarction (STEMI). As opposed to inotropes and vasopressors, an IABP does not increase oxygen consumption in the ischemic myocardium. The efficacy of the IABP has been undergoing some renewed scrutiny. A meta-analysis of nine studies of STEMI and cardiogenic shock found that the IABP was associated with a reduction in 30-day mortality in patients treated with thrombolysis, but no significant benefit in the overall cohort (n = 10 529) [67]. Observational data from the National Registry of Myocardial Infarction 2 did not show a mortality reduction with IABP use associated with primary percutaneous coronary intervention (PCI), although a benefit was found in hospitals with a higher volume of IABP use [68]. Most recently, a multicenter randomized trial assigned 600 patients with cardiogenic shock due to acute myocardial infarction, and plan for revascularization, to IABP vs. no IABP. This study has not shown a difference in 30-day mortality in the two treatment groups [69]. Despite the lack of unequivocal clinical efficacy data, the predictable favorable hemodynamic response to IABP counter-pulsation in this clinical scenario is such that STEMI clinical guidelines recommend use of an IABP in cardiogenic shock that is not quickly reversed with pharmacologic therapy [70]. The IABP can then be used as a bridge to revascularization, other mechanical circulatory support, or heart transplant.

The IABP also has a role in patients with non-ischemic cardiomyopathy who present with decreased cardiac output and end-organ dysfunction. While IABP will favorably influence the oxygen supply-to-demand ratio in the myocardium, its ability to improve cardiac output is limited by overall myocardial reserve and contractility [71]. The benefits might be less in patients without coronary artery disease and myocardial ischemia. In a series of patients supported with IABP counter-pulsation, non-survivors were more likely to have chronic heart failure, a LV ejection fraction of $<$30%, New York Heart Association (NYHA) functional class IV heart failure, and acute myocardial infarction [72]. Therefore, in cardiomyopathy patients with profound shock, end-organ dysfunction, or significant arrhythmias, an IABP may be helpful, but plans for more definitive support with other mechanical assist devices should also be made.

IABP counter-pulsation, in combination with vasoactive drugs, has also been used to decrease elevated pulmonary artery pressures in patients awaiting heart transplantation. Newer therapies that include the use of phosphodiesterase 5 (PDE 5) inhibitors and profound unloading with LV assist device (LVAD) implantation, which will be discussed later in this chapter, make this approach less practical.

Contraindications to the IABP use include significant peripheral vascular disease and greater than moderate aortic insufficiency. Potential complications include vascular events such as limb ischemia, bleeding, and vessel laceration, as well as infection and stroke. A major limitation of the IABP is that the patient is immobile, which makes this therapy attractive only for a relatively short duration of time. While IABP placement through the left axillary artery allows the patient to be ambulatory, this method is not widely used [73]. As more permanent ventricular assist devices are now available, it appears reasonable to limit the use of the IABP to

approximately 1 week in patients who have alternative mechanical assist options.

Mechanical ventilation in a transplant candidate

Patients with advanced heart failure may present with respiratory insufficiency requiring mechanical ventilation. The goals of mechanical ventilation include improved gas exchange, decreased work of breathing, and decreased myocardial demand. The interactions between the cardiac and pulmonary systems in the setting of mechanical ventilation are complex [74,75]. Here we briefly review important basic principles relevant to the heart failure patient.

Hemodynamic effects

In normal spontaneous breathing, alveolar and pleural pressures are lowered with inspiration, augmenting venous return of blood to the heart [76]. The application of positive pressure ventilation increases the intrathoracic pressures relative to the extrathoracic vascular beds and alters the pressure gradients for both systemic venous return and LV outflow [77]. The result is a decrease in systemic venous return of blood and a reduction in LV afterload. The net effect is an overall decrease in intrathoracic blood volume and decreased myocardial work [75]. These hemodynamic changes are theoretically beneficial to patients with cardiogenic pulmonary edema. Further benefits of mechanical ventilation occur through improved arterial oxygenation and reduced respiratory muscle oxygen demand [78].

The effect of mechanical ventilation on RV function is less well described and has been best studied in patients with acute respiratory distress syndrome (ARDS). Initiation of positive pressure ventilation is accompanied by a drop in RV preload. During mechanical ventilation, high plateau pressures and high positive end-expiratory pressure (PEEP) may result in increased RV afterload [79,80]. These effects should be considered in patients with RV dysfunction in need of mechanical ventilation.

Clinical application

A common indication for mechanical ventilation in a patient with acute decompensation of heart failure is cardiogenic pulmonary edema. In this setting, the increase in left atrial pressure causes transudation of fluid into the interstitium and the alveoli, leading to increased lung stiffness and ventilation–perfusion mismatch causing hypoxemia, CO_2 retention, and an increased work of breathing. In addition to diuretics and vasodilators, initial treatment may include non-invasive positive pressure ventilation (NIPPV), which has been shown to improve oxygenation and reduce the need for invasive ventilation in patients with cardiogenic pulmonary edema [81–85]. When these treatments fail, however, or if a patient has hemodynamic instability or respiratory muscle fatigue, endotracheal intubation and invasive mechanical ventilation may be necessary. Other indications for mechanical ventilation in a patient with advanced heart failure include mechanical complications of myocardial infarction, refractory arrhythmias, pulmonary infection, and multisystem organ failure. Benefits of mechanical ventilation in these settings include maximal oxygen delivery to the tissues, correction of acid–base disturbances, and a decrease in myocardial demand.

Regardless of the specific indication, the need for mechanical ventilator support at the time of heart transplant remains a strong risk factor for increased mortality, and only a small number of patients are considered for heart transplantation while requiring mechanical ventilation. Of the 10 271 patients in the ISHLT Registry who underwent heart transplant between 2004 and 2009, <3% were supported with mechanical ventilation at the time of transplant. Mechanical ventilation was associated with a 60% increase in 1-year mortality, a risk that persisted after adjustment for other clinical co-variates in a multivariate analysis [53]. Therefore, activation of mechanically ventilated patients for transplantation should be discouraged. If the primary reason for mechanical ventilation is hemodynamic instability due to exacerbation or progression of heart failure, then considerations for inotropic support or mechanical circulatory support should be made to allow for stabilization, extubation, and functional recovery of the patient prior to transplant whenever possible. If the respiratory failure is not caused by hemodynamic instability, outcomes with either transplant or permanent mechanical circulatory support are likely to be poor.

Lungs in end-stage heart failure

Pulmonary hypertension due to LV dysfunction has been referred to as pulmonary hypertension with left heart disease, secondary, pulmonary venous, or postcapillary pulmonary hypertension [86]. Pulmonary hypertension is present in as many as 60% of patients with severe LV systolic dysfunction and an even greater proportion of patients with diastolic dysfunction [87], and is associated with increased morbidity and mortality [88,89]. In one study, mortality of patients with heart failure and moderate pulmonary hypertension was three-fold that of patients without pulmonary hypertension [90].

Up to 50% of patients referred for cardiac transplant evaluation have elevated pulmonary vascular resistance [91,92]. A transpulmonary gradient (TPG) of >16 mmHg carries an increased risk of RV failure and early mortality after transplant [91–93]. Patients with a pulmonary vascular resistance (PVR) of >2.5 Wood units (WU) and/or TPG of >15 mmHg despite vasodilator therapy have a three-fold higher risk of death early post transplant and also have compromised late post-transplant outcomes. Patients who demonstrate significant reversibility of pulmonary hypertension (PVR <2.5 WU) without the development of systemic hypotension have a post-transplant outcome similar to that for those with a PVR of <2.5 WU at baseline [92].

Pathophysiology of cardiopulmonary disease

The pathogenesis of pulmonary hypertension due to left heart disease is complex (Figure 44.2) [94]. Elevated left heart pressures due to systolic [88,90], diastolic [95], or valvular heart diseases [96] can result in a passive increase in pulmonary venous pressure and elevated mean pulmonary artery pressure. Two hemodynamic profiles have been described in patients with postcapillary pulmonary hypertension [97]. The first pattern, passive pulmonary hypertension, involves elevation in mean pulmonary artery pressure as a reflection of elevated PCWP with a minimal increase in TPG. This postcapillary pulmonary hypertension likely represents a compensatory response necessary to maintain forward blood flow against increased downstream pressure [97]. Reduction of PCWP in patients with passive, postcapillary pulmonary hypertension results in a decrease in mean pulmonary artery pressure [98]. The second pattern of pulmonary hypertension in left heart disease involves reactive pulmonary arterial vasoconstriction, superimposed on passively elevated pulmonary artery pressure. The exact mechanisms by which pulmonary venous congestion leads to a reactive increase in PVR are not known. The endothelium plays a central role in vascular

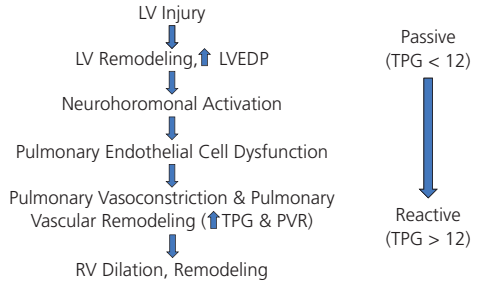

Figure 44.2. Pathobiology of pulmonary hypertension due to left heart disease. Chronic heart failure leads to neurohormonal dysregulation, an imbalance between the vasodilatory effects of nitric oxide (NO) and the vasoconstrictive effects of increased endothelin-1 (ET1). Left ventricular (LV) dysfunction, either systolic or diastolic, results in increased left ventricular end-diastolic pressure (LVEDP), which is passively transmitted to the pulmonary vascular bed, leading to elevated pulmonary artery pressures. Transpulmonary gradient (TPG) is initially low and pulmonary artery pressures are elevated proportionately to LV pressure elevation. Endothelial dysfunction may lead to reactive pulmonary arteriolar vasoconstriction and pulmonary vascular remodeling, where pulmonary artery pressure rises disproportionately to the degree of elevation of LV pressure (TPG increases). Pulmonary hypertension will lead to compensatory remodeling of the right ventricle (RV) and eventual RV dysfunction.

tone through the regulation of nitric oxide and endothelin pathways [94]. Nitric oxide-dependent vasodilation is impaired in patients with heart failure [99], while endothelin release is up-regulated [94]. Abnormalities in pulmonary vascular reactivity in heart failure are believed to be, at least in part, due to endothelial dysfunction and the imbalance of these pathways [94]. In patients with reactive pulmonary hypertension, TPG and PVR remain high even after LV filling pressure is reduced. Reactive pulmonary hypertension over time results in remodeling of the pulmonary vascular bed [100]. Thickening of both the alveolar and capillary basal laminae [101,102] reduces capillary filtration and microvascular permeability. Vascular remodeling likely serves initially to decrease the development of pulmonary edema; however, similar to the neurohormonal cascade in heart failure, these compensatory changes become maladaptive and lead to reduced lung compliance, increased PVR, reduced gas diffusion, and inefficient ventilation [101,102]. Acute reversibility of reactive pulmonary hypertension can be tested with vasodilator therapy. The lack of reduction of pulmonary hypertension, TPG, and PVR with acute hemodynamic tests has been termed "fixed pulmonary hypertension;" however lack of acute response does not necessarily indicate a permanent change. Some patients who do not show decrease in pulmonary pressures with acute testing will show gradual improvement of pulmonary hemodynamics over weeks or months when appropriate medical therapy is introduced [97]. More recently, the profound unloading that a LVAD exerts on the LV has been shown to predictably reduce pulmonary hypertension in most patients where the abnormal hemodynamics are due to left heart disease [103,104].

In a study of patients hospitalized with acute decompensated heart failure, 51% had passive and 25% had reactive pulmonary hypertension [105]. Compared to passive pulmonary hypertension, reactive pulmonary hypertension was more strongly correlated with death (adjusted hazard ratio 4.8 for reactive and 2.8 for passive pulmonary hypertension, compared to normal pulmonary pressures; $P = 0.0001$) [105].

The pulmonary circulation is the major determinant of RV afterload, and mortality due to cardiopulmonary disease is strongly related to RV dysfunction [106–108]. RV failure leads to a reduction in cardiac output and backwards congestion with resultant organ failure (see Kidney and Liver sections). The thin-walled RV can accommodate large increases in venous return and still pump blood through the typically low-resistance pulmonary circuit [109]. Increased RV afterload leads to distension of the RV, increased oxygen consumption, and reduced contractility [110]. Due to ventricular interdependence, RV distension also leads to paradoxical intraventricular septal motion with transmission of elevated right-sided filling pressures to the LV, potentially impairing LV filling [111–114]. Furthermore, increased wall tension from volume overload and myocardial distension may increase fiber length beyond a point where the Frank–Starling mechanism is active, and ventricular contraction may fail [115]. Pulmonary artery pressure further depends on RV function. A normal RV can generate peak systolic pressures up to 40–50 mmHg, but with gradual hypertrophy, much higher pressures can be generated [94]. When the RV begins to fail, the mean pulmonary artery pressure may fall despite a markedly elevated PVR [113].

Diagnosis of pulmonary hypertension

Echocardiography may be used as a screening test to assess right-sided pressures, as the tricuspid jet can be used to estimate RV systolic pressure. Echocardiographic findings suggestive of LV diastolic abnormalities include left atrial enlargement, LV hypertrophy, an abnormal mitral inflow profile, and abnormal mitral annular tissue Doppler signals [116,117]. However, invasive hemodynamic evaluation with right heart catheterization remains the objective diagnostic standard for pulmonary hypertension [87,116]. Right heart catheterization measures right- and left-sided filling pressures, pulmonary arterial pressure, PCWP, and estimated cardiac output. With this information, TPG and PVR can be calculated. In the presence of pulmonary hypertension, its pre- or post-capillary etiology can be determined. Vasoreactivity testing with pulmonary vasodilators is recommended to assess for reversibility of pulmonary hypertension in patients undergoing cardiac transplant evaluation. Vasodilators, including sodium nitroprusside, inhaled nitric oxide, or prostanoids, are typically administered to patients who have a systolic pulmonary artery pressure of >50 mmHg, a TPG of >15 mmHg, or PVR of >3 WU, with the goal of achieving a systolic pulmonary artery pressure of <40 mmHg, a TPG of <12 mmHg, and a PVR of <3 WU, without a drop in cardiac output and while maintaining a systolic blood pressure of >85 mmHg [118].

Management of pulmonary hypertension

Management should be directed at the underlying cause of disease and optimization of LV filling pressures [116]. The overall goal should be to improve physiologic coupling between the RV and pulmonary artery to improve pulmonary blood flow. A number of pharmacologic (diuretics, nitrates, hydralazine, angiotensin-converting enzyme inhibitors, angiotensin II receptor blockers, nesiritide, milrinone) and mechanical (valve surgery, LVAD implantation) interventions may lower mean pulmonary artery pressures via a reduction in left-sided filling pressures. Additionally, a number of therapies target improvement in RV function. Specific therapeutic approaches are described below.

Vasodilators

Both non-selective and pulmonary vasodilators can reduce PVR and augment RV output via reduction in RV afterload. Inhaled

nitric oxide and prostanoids are pulmonary vasodilators with acute, favorable hemodynamic effects [119–121]. Nitric oxide needs to be continuously delivered into a ventilator circuit and rebound pulmonary hypertension may occur upon weaning [122]. Trials of selective pulmonary vasodilators in pulmonary hypertension with left heart failure have not yielded favorable effects on clinical outcomes. Epoprostenol resulted in higher mortality compared to standard therapy in a large, randomized controlled trial [123]. The endothelin antagonist bosentan failed to demonstrate beneficial effects in patients with chronic heart failure, although patients with postcapillary pulmonary hypertension were not specifically selected [124]. Pulmonary selective vasodilators may increase right-sided cardiac output to a poorly compliant LV and precipitate acute pulmonary edema [119,125–127].

Sodium nitroprusside reduces both pulmonary and systemic vascular resistance, leading to a reduction in LV afterload, which may offset any increase in LV filling due to improved RV function. Sodium nitroprusside has been used for acute hemodynamic testing of pulmonary hypertension reversibility, as well as for short-term treatment in acute decompensated heart failure [128]. The recombinant brain natriuretic peptide nesiritide also reduces pulmonary artery pressures and PVR in patients with postcapillary pulmonary hypertension [43,129]; however, benefit beyond improvement of hemodynamics has not been confirmed.

Sildenafil, a PDE 5 inhibitor, is a partially selective pulmonary vasodilator [130–132]. Some clinical investigations suggest that sildenafil may improve hemodynamics, exercise capacity, and quality of life in patients with chronic heart failure due to reduced LV function [133–135]. It has also been demonstrated to improve measures of diastolic function [136]. Sildenafil may also exert a milrinone-like effect through PDE 3 inhibition, augmenting RV function [137]. However, in a randomized trial, compared to placebo sildenafil did not improve exercise capactiy in patients with diastolic heart failure [138]. The efficacy of sildenafil in the management of acute postoperative RV dysfunction has been reported [139,140]. While routine use of PDE5 inhibitors for the management of postcapillary pulmonary hypertension cannot be recommended without more robust data, they are frequently used to reduce pulmonary pressure in heart transplant candidates [140–142].

Management of right ventricular dysfunction

There is lack of effective therapies for the management of RV dysfunction due to pulmonary hypertension. Management strategies include optimization of RV preload and systolic function, and reduction in RV afterload [115]. Attempts to also correct any reversible causes of elevated PVR such as hypoxia should be made. Sleep apnea is prevalent in heart failure patients and its treatment may reduce pulmonary hypertension and improve RV function. RV contractility can be optimized with inotropic agents, including dobutamine and milrinone, which are discussed earlier in this chapter.

Aggressive volume loading for RV failure may adversely affect LV filling by inducing septal shift and reducing LV volume [143–145]. Unmonitored fluid challenges are not advised in the setting of RV dysfunction [115]. Invasive hemodynamic monitoring may be employed to target an initial central venous pressure of 10 mmHg.

Transplant and mechanical support

In patients with end-stage heart failure and pulmonary hypertension that is not reversible with medical treatment, LVAD therapy may be considered [146]. This commonly results in a decrease in PVR over time due to normalization of LV filling pressures [103,104]. In cases of severe RV failure, a RV assist device (RVAD) may be necessary in conjunction with a LVAD to bridge patients to cardiac transplantation. Intra-aortic balloon counter-pulsation and extracorporeal membrane oxygenation have been used as rescue therapies in biventricular failure while awaiting more definitive therapy [147,148]. Protective lung strategies should be employed in patients requiring mechanical ventilation to reduce plateau pressures and avoid further strain on RV function [149]. Carefully selected patients with truly fixed pulmonary hypertension despite medical and device therapy may be candidates for combined heart–lung transplantation [150].

Kidneys in end-stage heart failure

The cardiorenal axis is important for regulation of fluid and electrolyte balance, blood pressure, and systemic perfusion. Acute or chronic dysfunction in either the heart or the kidneys can alter the function of the other organ, which is commonly referred to as the cardiorenal syndrome [151]. In patients with acute heart failure, the cardiorenal syndrome may result in a scenario where therapy aimed at relieving congestion results in further worsening of kidney function. The challenge of successful heart failure management lies in addressing fluid overload while avoiding further impairment in glomerular filtration rate (GFR).

Avoiding progressive renal dysfunction is critical, as reduced GFR in this patient population is a stronger predictor of mortality than reduced LV ejection fraction [152], and this risk is independent of the severity of heart failure symptoms [153–159]. In a systematic review of >80 000 heart failure patients, the mortality rate at 1 year was 24% in those with a normal GFR compared to 38% in patients with mild and 51% in patients with moderate-to-severe reductions in GFR [160]. Increase in serum creatinine during treatment for heart failure is also associated with worse outcomes, including longer length of hospital stay, more frequent readmissions, and increase in both inhospital and long-term mortality [157–159,161–167].

In patients with heart failure and elevated serum creatinine, it is important to distinguish between the cardiorenal syndrome, a result of hemodynamic derangements associated with heart failure, and underlying intrinsic chronic kidney disease. This distinction may be difficult given that in many heart failure patients both conditions can be contributing to abnormal renal function [168]. Findings suggestive of intrinsic kidney disease include significant proteinuria (>1 g/day), an active urine sediment (hematuria, pyuria, or cellular casts), and/or structural abnormalities on kidney imaging.

Pathophysiology of the cardiorenal syndrome

The cardiorenal syndrome is a complex vasomotor nephropathy with an array of factors contributing to the development of worsening kidney function [161,162,169,170]. Known pathophysiological mechanisms include neurohormonal activation, reduced renal perfusion, increased renal venous pressure, RV dysfunction, and systemic inflammation.

Neurohormonal activation

The decreased stroke volume and cardiac output seen in heart failure result in decreased effective arterial blood volume and arterial under-filling, producing decreased triggering of mechanoreceptors in the LV, aortic arch, carotid sinus, and baroreceptor-like

juxtaglomerular apparatus. This in turn results in compensatory activation of a number of neurohormonal pathways—increased sympathetic outflow, activation of the renin–angiotensin–aldosterone system, and the release of arginine vasopressin and endothelin-1, all aimed at restoring organ perfusion via systemic vasoconstriction and salt and water retention [171–173]. Over time, these processes become maladaptive and overwhelm the counter-regulatory vasodilatory and natriuretic pathways of natriuretic peptides, nitric oxide, prostaglandins, and bradykinin [162,169,174]. The effects of these mechanisms in the kidney are attenuated due to down-regulation of natriuretic peptide receptors, renal vasoconstriction, and reduced delivery of sodium to the distal nephron [172,175], which cause sodium and water retention despite elevated filling pressures in the heart [171,176,177].

The use of loop diuretics in heart failure produces increased sodium delivery to the distal tubule, which results in increased adenosine secretion [178]. Elevated serum adenosine levels stimulate afferent arteriolar constriction and proximal tubular sodium reabsorption [163,179]. These actions further reduce GFR, promote sodium and water retention, and may contribute to diminished diuretic responsiveness.

Thus, neurohormonal activation in heart failure results in vasoconstriction, increased afterload, reduced cardiac output, and reduction of renal blood flow.

Reduced renal blood flow

Worsening kidney function during heart failure exacerbation is often attributed to reduced cardiac output and renal hypoperfusion. This is certainly the case in patients who are hypotensive or in cardiogenic shock; however, the correlation between cardiac output and kidney function is not linear [164,165], as renal autoregulatory mechanisms maintain renal blood flow until the cardiac index falls below 1.5 L/min/m^2 [166]. As the majority of patients hospitalized for heart failure with kidney dysfunction are neither hypotensive nor in shock [153,180,181], it appears that factors other than low cardiac output likely play a greater role in the pathogenesis of the cardiorenal syndrome.

Venous congestion

Most patients admitted for acute heart failure exacerbation have signs and symptoms of systemic venous congestion [153]. However, even in the absence of peripheral edema, patients may have an increase in blood volume and elevated intracardiac filling pressures [167].

Ascites, visceral edema, and engorgement of the splanchnic circulation lead to increased intra-abdominal pressure, extrarenal compression, and a decline in kidney function [181]. As renal perfusion pressure is determined by the difference between the mean arterial pressure and renal venous pressure [182], progressive venous congestion may impede forward blood flow through the kidney [183,184], reduce urine generation, and decrease sodium excretion [185]. This explains why systemic venous congestion has been shown to be independently associated with decline in GFR [168,186,187] and why inadequate reduction of systemic venous pressures during treatment of heart failure exacerbation correlates more closely with decline in kidney function than reduction in cardiac output [168]. In the ESCAPE Trial [1] right atrial pressure was the only hemodynamic variable associated with baseline renal function [164].

Because the renal capsule is not distensible, interstitial edema will further increase interstitial and renal venous pressures (Figure 44.3) [182]. Increases in renal venous pressure also stimulate local

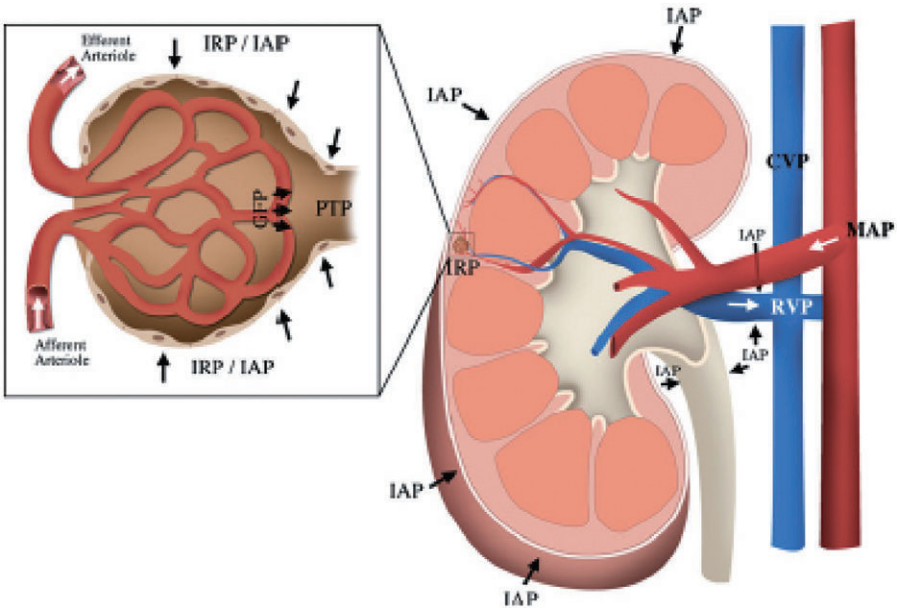

Figure 44.3. Hemodynamic determinants of glomerular filtration rate (GFR). In addition to the number and quality of nephrons, GFR is dependent on multiple hemodynamic factors. The mechanical force driving fluid from the glomerular capillaries to the capsular space is the (renal) filtration gradient (FG), which is equal to: glomerular filtration pressure (GFP) – proximal tubule pressure (PTP). PTP is dependent on the interstitial renal pressure (IRP) and intra-abdominal pressure (IAP), both of which are increased by venous congestion. GFP is dependent on renal blood flow (renal perfusion pressure; mean arterial pressure [MAP] – renal venous pressure [RVP]/renal vascular resistance). RVP is closely related to central venous pressure (CVP) and thus, is increased when venous congestion is present. GFP is further regulated by the complex interplay between afferent and efferent arteriolar vasoconstriction and vasodilatation. (Reproduced from Dupont et al. [182], with kind permission from Springer Science+Business Media.)

sympathetic nerve activity, causing intrarenal arterial vasoconstriction and a further decline in GFR [188–190].

Right ventricular function

Patients treated for acute heart failure exacerbation who have echocardiographic evidence of RV dysfunction typically have greater impairment in renal function compared to patients with normal RV function [191]. Dysfunction of the RV contributes to elevation of systemic venous pressures, which can affect renal function, as described above. In addition, due to pericardial constraint, RV dilatation impairs LV filling, and limits stroke volume and cardiac output [192]. Through both of these mechanisms, RV dysfunction likely plays an important role in progression of the cardiorenal syndrome.

Inflammation

Heart failure is known to result in endothelial activation [193–195]. In response to changes in circumferential stress, endothelial cells produce inflammatory mediators such as endothelin-1, interleukin-6, and tumor necrosis factor-alpha [182,196–199]. Oxidative stress further reduces nitric oxide bioavailability [182], which impairs endothelial nitric oxide-mediated regulation of venous tone, and may contribute to the cardiorenal syndrome [197].

Factors that may affect the response to therapy

Plasma refill rate

Plasma refill refers to fluid shift from the extra- to intra-vascular compartment in response to reduced blood volume, e.g. from diuresis or fluid removal by ultrafiltration. Plasma refill rate is dependent on oncotic and hydrostatic pressure gradients between the extra- and intra-vascular compartments [200]. If plasma refill rate is exceeded, worsening of renal function and hypotension may result. Therefore, a rise in serum creatinine with diuresis may not indicate sufficient decongestion; rather, it may be a result of excessive fluid removal from the intravascular space not matched by plasma refill [201].

Diuretic resistance

Diuretic resistance is defined as a diminished pharmacologic response to a given diuretic dose [202]. A number of mechanisms contribute to diuretic resistance. Often, drug bioavailability is reduced due to reduced gut perfusion and visceral edema [203]. Advanced heart failure may also lead to protein wasting and hypoalbuminemia [204], decreasing intravascular oncotic pressure, increasing the volume of distribution of loop diuretics, and impairing their delivery to the proximal tubule. Reduced renal blood flow may also impair tubular drug delivery [205]. Kidney dysfunction results in the accumulation of organic acids that inhibit tubular secretion of loop diuretics [185]. The pharmacodynamic effect of diuretics may be impaired even in the presence of adequate drug absorption and delivery. Impaired renal perfusion reduces sodium filtration, limiting the diuretic response. Chronic blockade of the proximal $Na^+/K^+/Cl^-$-transporter by loop diuretics also leads to increased sodium delivery to the distal tubule and eventual hypertrophy of the distal tubular cells [185], and a "braking effect," where increased sodium delivery causes a rebound increase in distal sodium reabsorption [206]. The effects of neurohormonal activation also counteract the effects of the diuretics in the kidney; conversely, decreases in norepinephrine levels in response to heart failure therapy have been shown to improve diuretic responsiveness [207].

Management of the cardiorenal syndrome

In the absence of specific therapies directed at increasing the GFR, the goal of therapy in heart failure with the cardiorenal syndrome is relief of systemic congestion and restoration of end-organ perfusion. Favorable hemodynamic changes may re-establish an effective renal arterial venous pressure gradient and improve the GFR [168]. Fluid removal with diuresis, ultrafiltration, or paracentesis may lower intra-abdominal pressure and improve kidney function [208].

Modification of sodium and fluid intake

While not tested in randomized trials, salt restriction is essential in avoiding worsening congestion [209] and it is recommended that sodium intake be limited to 2 g/day. A total fluid intake of <2 L/day is also frequently recommended, especially for patients with hyponatremia (<130 mEq/L) or those who have become diuretic resistant [209].

Diuretics

Diuretics remain the mainstay of managing congestion despite a lack of data regarding their safety and efficacy [209]. Patients with heart failure frequently have an unpredictable dose–response curve to loop diuretics, and these agents require careful titration until the desired response is achieved (Figure 44.4) [210]. Excessive diuresis can lead to hypovolemia, hypotension, reduced cardiac output, and neurohormonal activation, resulting in further decline in kidney function, and higher doses of diuretics have been associated with increased mortality [211–213]. In patients with diuretic resistance,

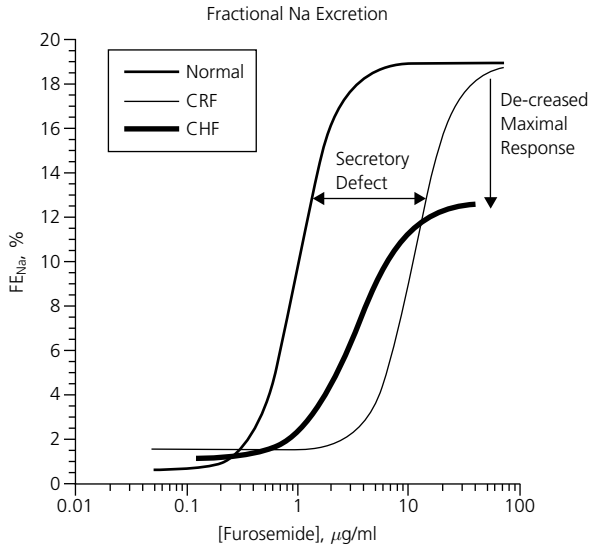

Figure 44.4. Dose–response curves for loop diuretics. Fractional Na^+ excretion (FE_{Na^+}) as a function of loop diuretic concentration. Compared with healthy controls, patients with chronic renal failure (CRF) show a rightward shift in the curve, owing to impaired diuretic secretion. The maximal response is preserved when expressed as FE_{Na^+}, but not when expressed as absolute Na^+ excretion. Patients with chronic heart failure (CHF) demonstrate a rightward and downward shift, even when the response is expressed as FE_{Na^+}, and thus are relatively diuretic resistant. (Reproduced from Ellison [210], with permission from S. Karger AG, Basel.)

diuretic responsiveness may be restored by increasing the diuretic dose. Continuous diuretic infusion or intermittent bolus dosing appear to result in similar volume loss at an equivalent daily dose [214]. Addition of thiazide diuretics can also decrease diuretic resistance. Thiazide diuretics act on the distal tubule and function synergistically with the more proximally-acting loop diuretics. Combined use of thiazide and loop diuretics overcomes the tubular hypertrophy and rapid sodium reabsorption that occur in response to chronically increased distal sodium delivery from long-term loop diuretic use [215].

All diuretics can alter serum electrolyte concentrations, with the potential for cardiac rhythm and neuromuscular disturbances. Careful electrolyte monitoring and replacement is warranted with all diuretic therapy, especially when loop and thiazide diuretics are used in combination. Potassium supplementation and potassium-sparing diuretics act to counter-balance potassium loss. The goal should be to maintain a potassium level at >4.0 mEq/L and a magnesium level of at least 1.5–2.0 mEq/L.

Ultrafiltration

Ultrafiltration has been proposed as a treatment option in patients with heart failure and volume overload with suboptimal response to diuretics. Although diuretics achieve increased sodium excretion, the urine is hypotonic relative to the plasma, with the average urinary sodium concentration following administration of a loop diuretic being 60 mEq/L, compared 140 mEq/L in the plasma [210]. Ultrafiltration has the theoretical advantage of removing greater amounts of salt by isotonic fluid removal. By controlling the rate of fluid removal, ultrafiltration also has the potential advantage of being able to tailor fluid removal to the estimated plasma refill rate. Initial experience with veno-venous ultrafiltration in heart failure suggests that this therapy is well tolerated, and unlikely to cause adverse hemodynamic effects [216,217]. In comparison with intravenous diuresis, ultrafiltration was associated with greater weight loss and fluid removal, with similar changes in serum creatinine [216,218]. If fluid removal does not exceed the plasma refill rate of approximately 12–14 mL/min, further activation of the renin–angiotensin–aldosterone system is avoided [200].

Whether ultrafiltration could aid in resolution of the cardiorenal syndrome remains to be seen. Some studies have shown that the weight loss achieved with ultrafiltration resulted in improved diuretic responsiveness and decongestion was better maintained compared to in patients who were treated with loop diuretics [207,218–220]. Excessive ultrafiltration may result in increased neurohormonal activation, decreased renal perfusion, and deterioration of renal function [183]. In a randomized trial of patients hospitalized with acute heart failure, persistent congestion and worsened renal function, while weight loss at 96 hours was similar, compared to a stepped pharmacologic-therapy algorithm, ultrafiltration was associated with greater rates of worsening renal function and increased adverse events [221]. Currently, ultrafiltration is typically reserved for patients who have failed to achieve a negative fluid balance with aggressive diuresis [209,222,223]. Patients with severe kidney dysfunction may require hemofiltration or hemodialysis rather than veno-venous ultrafiltration. Ultrafiltration should also be avoided when venous access cannot be obtained, in the presence of hypercoagulable states, or when shock or hypotension requiring vasoactive therapy is present [183].

Vasoactive therapies

Data regarding the role of vasoactive therapies in the management of the cardiorenal syndrome are limited. Many commonly used vasoactive drugs, including nitroglycerin, nitroprusside, nesiritide, and dobutamine, have shown variable results as far as improvement of kidney function, despite predictable improvement in cardiac output [224–227]. Many of the agents reduce preload and afterload through combined arterial and venous dilation [228]. By increasing renal blood flow and reducing renal venous pressures, vasodilators may improve kidney function. However, depending on a particular agent's relative effects on the renal vasculature (afferent versus efferent glomerular arteriolar tone) and the particular hemodynamic circumstances of the individual patient, the net effect on the renal blood flow and GFR may not be easily predictable. Systemic hypotension could offset any favorable effects of vasodilators on venous pressure and cardiac output [229]. Among patients with acute heart failure and renal dysfunction, compared to placebo, low-dose nesiritide (0.005 mcg/kg/min) did not enhance decongestion or improve renal function when added to diuretic therapy [230]. Although routine use of a pulmonary artery catheter has not been shown to improve outcomes, its use prior to implementing vasodilator therapy in patients in whom volume status and cardiac filling pressures are uncertain based on clinical assessment is warranted [209].

The utility of low-dose dopamine in preventing worsening of renal function in patients with heart failure and cardiorenal syndrome is uncertain as clinical investigations have shown inconsistent results [231,232,233]. In one study, a combination of low-dose dopamine (5 μg/kg/min) and a low-dose furosemide infusion (5 mg/h) has been shown to be as effective as a high-dose furosemide infusion (20 mg/h) at relieving congestion, with less kidney dysfunction and improved potassium homeostasis [234]. However, in a separate study of patients with acute heart failure and renal dysfunction, compared to placebo, low-dose dopamine (2 mcg/kg/min) did not enhance decongestion or improve renal function when added to diuretic therapy [230]. Additional well-powered investigations are needed and are currently in progress.

Use of intravenous inotropes in patients with acute heart failure may improve symptoms and kidney function by augmenting cardiac output and reducing cardiac filling pressures. Evidence from a number of clinical investigations raises concerns of increased mortality with inotropic treatment [27,235]. While milrinone leads to minor improvements in kidney function, this benefit does not translate to decreased rates of death or readmission [236]. As a result, routine use of intravenous inotropic agents in patients with chronic heart failure is generally not recommended. In heart transplant candidates with kidney dysfunction, intravenous inotropes can be used to stabilize hemodynamics and bridge these patients to implantation of mechanical circulatory support or transplantation.

Transplant and mechanical support

In patients with advanced heart failure and irreversible kidney disease, combined heart–kidney transplantation can be considered. According to data from the United Network for Organ Sharing (UNOS), between 1995 and 2005, 1.4% (n = 264) of heart transplant recipients in the US received a simultaneous kidney transplant [237]. While there are no professional society-endorsed guidelines to inform patient selection for combined heart–kidney transplantation, patients with an estimated GFR (eGFR) of <33 mL/min and no expected improvement in renal function may be good candidates for this therapy and gain a survival benefit compared to heart transplant alone [237]. Expected survival for heart–kidney transplant recipients is similar to that for patients who receive an isolated heart transplant [238]. In contrast, survival following heart transplantation alone in dialysis-dependent candidates is subopti-

mal and end-stage renal disease is therefore considered to be a contraindication to heart transplant, unless a kidney transplant is also planned [238].

In patients with advanced heart failure and cardiorenal syndrome, mechanical circulatory support often results in improvement of kidney function [239,240]. Other reports indicate that improvement in renal function following LVAD implantation may largely be transient [241]. However, LVAD insertion should be avoided in patients whose kidney function is unlikely to recover despite improved hemodynamics, with the exception perhaps in patients who are candidates for combined heart–kidney transplantation.

Liver in end-stage heart failure

There are two clinical syndromes that comprise the "cardiohepatic" syndrome. The first, ischemic hepatitis or "shock liver," is associated with acute heart failure and cardiogenic shock. The second, congestive hepatopathy, is more closely associated with chronic heart failure. However, there is significant clinical overlap between these syndromes. There is considerable interpatient variability such that some patients with mild heart failure have liver function test (LFT) abnormalities, while others with severe hemodynamic derangements do not have evidence of liver dysfunction [242]. What underlies this heterogeneity is unclear. When heart failure patients present with LFT abnormalities, one should also investigate the possibility of concomitant, intrinsic liver disease. Infectious, autoimmune, and biliary processes should always be excluded when evaluating LFT abnormalities in heart failure patients.

Ischemic hepatitis

Ischemic hepatitis or "shock liver" is characterized by a marked and reversible elevation in serum aminotransferase levels to at least 20 times the upper limit of normal in the absence of other causes [243,244]. The most common causes of ischemic hepatitis are cardiogenic—cardiogenic shock resulting from acute myocardial infarction, acute exacerbation of chronic heart failure, dysrhythmia, cardiac tamponade, etc. [243]. Less commonly, ischemic hepatitis may be caused by hypovolemia. The incidence of acute ischemic hepatitis in patients with cardiogenic shock is estimated to be around 20% [245].

Pathophysiology

The pathophysiology of ischemic hepatitis is not fully understood. The liver is highly vascular with a dual blood supply. Approximately 80% of hepatic perfusion is derived from the portal vein and the remaining 20% from the hepatic artery [244,246]. With hypotension, compensatory neuroendocrine and sympathetic nervous system responses redistribute cardiac output, with priority given to perfusion of the heart and brain [244]. Splanchnic vasoconstriction decreases portal vein flow; however, the liver is able to maintain normal oxygen uptake by increasing oxygen extraction [246]. This compensatory mechanism makes the liver relatively resistant to ischemic injury and may account for the relatively low incidence of liver injury in other forms of shock [247,248]. Additionally, ischemic injury is typically self-limited and reversible, unless the liver had been previously damaged [246]. Ischemic hepatitis presents with centrilobular necrosis [243,249], as the centrilobular areas are the most sensitive to oxygen deprivation [244]. The most commonly proposed mechanism is a sudden impairment in hepatic perfusion from hypotension and reduced cardiac output leading to hepatocyte hypoxia [243], with hepatic venous congestion also playing an important role [243]. Indeed, patients with low cardiac output and elevated central venous pressure are more likely to develop ischemic hepatitis than patients with low cardiac output alone [245], and patients with severe shock from trauma seldom develop LFT abnormalities [243]. It is therefore believed that passive congestion may predispose hepatocytes to hypoxic injury, as central venous congestion results in portal hypertension, which may alter hepatic blood flow [243]. The already abnormal hepatic blood flow may be further reduced in the setting of hypotension. Alternatively, hepatocytes chronically exposed to increased pressure may be more susceptible to injury. In addition, hepatocytes in the livers of patients with chronic heart failure may be subject to chronic recurrent injury from unrecognized episodes of underperfusion and hypoxia [243]. Thus, ischemic hepatitis likely requires derangements in both forward and backward blood flow [242].

Management

Supportive therapies targeting the underlying hemodynamic derangements should be employed to improve hepatic perfusion and relieve hepatic congestion. These therapies, which include pharmacologic (vasopressors, inotropes, vasodilators, diuretics) and mechanical support (IABP, ventricular assist devices, ultrafiltration), are discussed in greater detail earlier in this chapter.

Chronic congestive hepatopathy

Congestive hepatopathy is characterized by heart failure, abnormal LFTs, and the exclusion of alternative etiologies of liver dysfunction [250]. Congestion from right heart failure, restrictive cardiomyopathy, or constrictive pericarditis may all lead to congestive hepatopathy. Right heart failure is common in patients with LFT abnormalities [249] and hepatomegaly is commonly found on physical examination in patients with right heart failure [251]. LFT abnormalities due to heart failure most commonly demonstrate a cholestatic rather than a hepatic profile [250,252]. Of the 2679 patients randomized in the Candesartan in Heart Failure Assessment of Reduction in Mortality and Morbidity program (CHARM), 13% had elevations in total bilirubin levels, 14% had elevations in alkaline phosphatase, and 18% had low serum albumin [252]. Direct bilirubin was elevated in 4% of patients, and only 3% and 4% of patients had elevations in alanine aminotransferase and aspartate aminotransferase levels, respectively [250,251]. Total bilirubin is typically higher in patients with volume overload [252]. The severity of tricuspid regurgitation is also associated with LFT derangements and patients with moderate-to-severe tricuspid regurgitation often have a significant increase in cholestatic LFTs [250]. Total serum bilirubin level is a strong predictor of death in patients with heart failure [204,252]. When elevated preoperatively, total bilirubin is also a marker of reduced survival following LVAD surgery [253,254].

Pathophysiology

Backward congestion of hepatic venules and pulsatile injury from tricuspid regurgitation may cause liver injury in patients with chronic heart failure [250] and result in hepatocyte dysfunction and elevation in both direct and indirect bilirubin [255]. Histopathologic studies describe hyperemia and congestion of the central zone of the hepatic lobule, sometimes described as "nutmeg liver" [250,255]. Congestive liver fibrosis may ensue, ranging from mild deposition of sinusoidal collagen to more severe fibrosis [246]. These changes are thought to result from a combination of increased venous pressure, hypoxia, and/or hepatocellular necrosis [256]. Congestive liver fibrosis can progress to cirrhosis. Interestingly,

synthetic function may be preserved in cardiac cirrhosis and patients can present without any perturbations in LFTs. The diagnosis of cardiac cirrhosis is suggested by right heart failure with hepatomegaly and ascites refractory to diuretic treatment [246]. The ascitic fluid protein content of cardiac cirrhosis is usually high (>2.5 g/dL), with a serum–ascites albumin gradient of >1 g/dL, as is common with disorders characterized by portal hypertension [246,257].

Management

The treatment of congestive hepatopathy is similar to the management of chronic heart failure. Congestion is managed with vasodilator therapy, diuretics, and salt restriction. Paracentesis can be performed for refractory ascites; however, because synthetic function is preserved in cardiac cirrhosis, albumin replacement is not necessary [246].

Patients with ascites who are undergoing cardiac transplant evaluation should have hepatic imaging with ultrasound or computed tomography, and if cirrhosis is suggested, a liver biopsy should be done. If cirrhosis is present, combination heart–liver transplant may be considered in eligible patients. Heart transplant alone is not recommended in the setting of cirrhosis. There are no professional society-endorsed guidelines for combined heart–liver transplantation, which is an uncommon procedure, with only 51 recorded in the registry of the ISHLT between 2005 and 2010 [53]. Reported 1- and 3-year survival rates following combined heart–liver transplant (80% and 70%, respectively) approach those for heart transplant alone [258]. Mechanical support may be an option for patients ineligible for cardiac transplantation due to cirrhosis; liver function abnormalities frequently improve following implantation of a LVAD [239]. However, elevated LFTs have been associated with the need for RV support after LVAD implant [254].

Summary

Cardiac failure plays a role in most aspects of transplantation, either as a direct indication for heart replacement or as a consequence of co-morbid conditions. Similarly, cardiac failure can present with numerous adverse effects on non-cardiac end organs, and cardiac failure remains in the differential diagnosis of hepatic, pulmonary, and renal system failure. As such, cardiac support and intensive care remain important topics of which all transplant professionals should have cognizance. Numerous cardioactive drugs are available to support the failing heart, and sophisticated mechanical devices ranging from IABP counter-pulsation to totally artificial hearts exist to bridge patients across episodes of heart failure. The ubiquity of heart failure across the spectrum of transplantation and the ever-increasing complexity of its management make robust cardiology and cardiothoracic surgery programs important parts of even non-cardiac transplant programs.

CHAPTER 45

Intensive Care in Pulmonary Failure

John Adam Reich[1] and Richard Eliot Fagley[2]

[1] Post Anesthesia Care Unit, Tufts Medical Center, Boston, MA, USA
[2] Virginia Mason Medical Center, Seattle, WA, USA

Introduction

Respiratory failure may be acute, chronic, or a combination of the two, and has the potential to proceed to end-organ failure necessitating lung transplantation. As the outcome of a transplant is intimately dependent on the condition of the recipient at the time of the procedure, attention to the proper care of critically ill patients in respiratory failure is necessary. Indeed, respiratory failure is also part of the spectrum of disease seen in critically ill patients requiring other transplants, particularly heart and liver. This chapter will review the physiology and pathophysiology of acute and chronic respiratory failure. Pharmacologic and non-pharmacologic means of optimizing lung function will be discussed. Mechanical ventilation will be reviewed briefly with special consideration given to ventilator strategies specifically designed to avoid further injury to the lung or other end organs. In addition, a disease-specific review will cover the most common diseases of the lung that benefit from solid organ transplantation.

Respiratory physiology and pathophysiology

The adequacy of oxygen and carbon dioxide exchange is determined by inspired gas transit into alveolar units, ventilation (V), and blood flow into alveolar capillaries [perfusion (Q)]. The ideal situation in the lung occurs when the ratio of ventilation to perfusion equals 1 ($V/Q = 1$) [1]. Perfusion without adequate ventilation is known as shunt ($V/Q < 1$). Ventilation without adequate perfusion ($V/Q > 1$) is known as dead space [1]. Anatomic dead space (V_{Danat}) is the volume of gas in the large, non-exchanging airways, i.e. trachea, bronchi, and conducting airways [2]. A portion of tidal volume (V_T) makes its way to alveoli that are not perfused with blood ($Q = 0$), which is known as alveolar dead space (V_{Dalv}) [2]. In most individuals, this volume is minimal, but in the diseased lung V_{Dalv} can rise rapidly [2]. The anatomic and alveolar dead space together are known as the physiologic dead space ($V_{Dphysiol}$) [2]. The physiologic dead space is what is relevant to the patient. The dead space relationships are summarized by the following equation:

$$V_{Dphysiol} = V_{Danat} + V_{Dalv}$$

In the normal person, the sum of anatomic and alveolar dead space represents approximately 20–30% of the tidal volume [1]. When the $V_{Dphysiol}$ reaches 100%, the V/Q ratio approaches infinity ($V/Q = \infty$). Disease processes that decrease the available surface area of lung parenchyma increase dead space, e.g. emphysema. Processes that limit or alter pulmonary blood flow also can increase dead space, as in pulmonary embolism or during hemorrhagic shock. An increase in dead space can result in both hypercarbia and hypoxia.

Complete equilibration between the alveolar and pulmonary capillaries occurs in each perfused alveolus. This means that the arterial gas tension should be equal to the alveolar gas tension. Making these assumptions allows for calculation of dead space. The equation for physiologic dead space is known as the Bohr equation [2]:

$$V_{Dphysiol}/V_T = PaCO_2 - PECO_2/PaCO_2$$

It is important to note in this equation that $PECO_2$ is the mean exhaled PCO_2 and is not the same as end-tidal CO_2 on capnography [1]. $PaCO_2$ is the tension of CO_2 in arterial blood.

Perfusion without ventilation is known as shunt ($V/Q < 1$). Much like dead space, shunt can be divided into true shunt (total absence of gas exchange) and venous admixture (partial gas exchange between alveoli and pulmonary capillary blood). In the true shunt, the V/Q ratio equals zero ($V/Q = 0$). Disease processes that obstruct gas exchange regions or cause excessive blood flow through pulmonary capillaries increase shunt fraction. Examples include acute respiratory distress syndrome (ARDS), pneumonia, hepatopulmonary syndrome, and pulmonary edema. Any alveolar filling process that is accompanied by incomplete hypoxic pulmonary vasoconstriction will also result in some degree of shunt. Shunt results in hypoxemia with either an increase in $PaCO_2$, or no significant change in $PaCO_2$. The higher the shunt fraction, the less responsive the patient will be to oxygen therapy. In fact, at approximately 50% shunt fraction, PaO_2 will be essentially independent of changes in inspired oxygen concentration (FiO_2) [3]. Figure 45.1 shows examples of V/Q abnormalities from shunt (Figure 45.1b) to dead space (Figure 45.1c). Ideal V/Q matching (Figure 45.1a) is 1:1.

Shunt fraction can be calculated using the following equation, where CcO_2 is the oxygen content in the end-pulmonary capillary blood, CaO_2 is the oxygen content in the arterial blood sample,

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

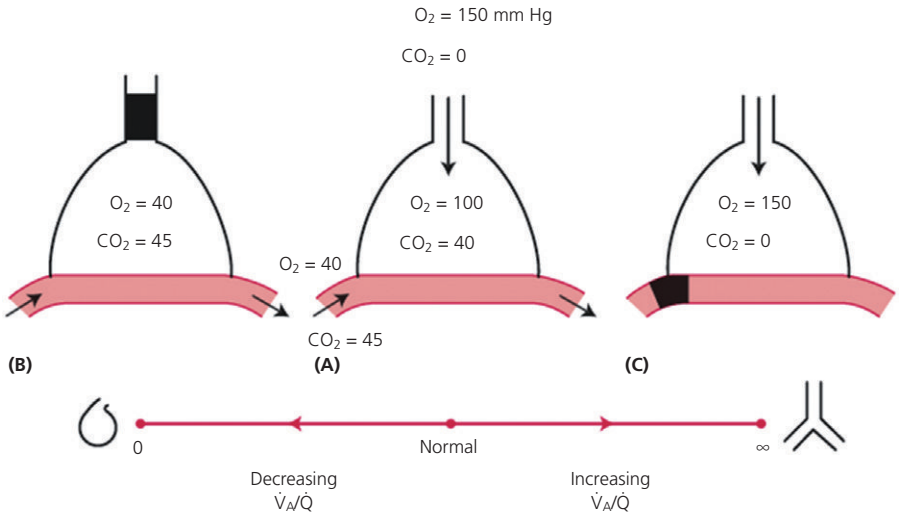

Figure 45.1. (A) Ideal *V*/*Q* matching. (B) Pure shunt. (C) Pure dead space where V/Q = infinity. (Adapted From West JB. Respiratory Physiology: The Essentials, 9th ed. 2011. Reproduced by permission of Wolter Kluwer Health.)

and Cvo_2 is the oxygen content of the pulmonary mixed venous blood:

$$Qs/Qt = (Cco_2 - Cao_2)/(Cco_2 - Cvo_2)$$

This is a somewhat cumbersome appearing equation. The denominator (Cco_2 – Cvo_2) represents total pulmonary blood flow and the numerator represents non-gas exchanging blood flow. In other words, shunt is a comparison between the systemic (Cao_2), the mixed venous (Cvo_2), and the pulmonary capillary blood oxygen content (Cco_2). Although interesting, the clinical applicability of this equation is limited due to the inability to sample post-pulmonary capillary blood. In practice, the more popular Pao_2/Fio_2 ratio can be used to estimate shunt fraction in disease states like ARDS [4]. A Pao_2/Fio_2 ratio of <200 is suggestive of a shunt fraction of >20% (*Q*s/*Q*t) [4].

In clinical practice, *V*/*Q* abnormalities can also be estimated by calculating the gradient between alveolar partial pressures (A) and arterial oxygen tension (a), known as the A–a gradient. The alveolar gas equation is as follows:

$$PAo_2 = PIo_2 - (Paco_2/RQ)$$

where PAo_2 is the partial pressure of oxygen in the alveolus, PIo_2 is the partial pressure of oxygen in inspired gas, $Paco_2$ is the carbon dioxide tension in arterial blood gas, and RQ is the respiratory quotient that defines the relative rate of gas exchange. At sea level and breathing room air, the normal A–a gradient would be 10 mmHg. Age increases the A–a Po_2 gradient because as the human lung ages, small airways lose their architectural strength, resulting in collapse at progressively higher lung volumes, thus causing shunt during normal tidal breathing. There is significant increase in *V*/*Q* heterogeneity due to this increase in closing volume with aging [5]. In addition, the A–a Po_2 gradient increases as the Fio_2 increases. This is thought to be due to the attenuation of hypoxic pulmonary vasoconstriction in local areas of blood that are poorly ventilated. In this way, an increase in alveolar oxygen partial pressure may worsen *V*/*Q* matching. This can increase shunt fraction and widen the A–a gradient [1].

Pharmacology of the lung

Respiratory failure is treated by correcting underlying pathology and by optimizing pulmonary function and mechanics. The goal in doing so is to allow the patient to resume his/her normal quality of life upon discharge. The following provides a focused review of the mechanisms of action of both intravenous and inhaled therapies used to treat the patient in respiratory failure.

Vasodilators: oxygen, nitric oxide, and epoprostenol

Oxygen therapy is the first line of therapy for respiratory failure. As noted above though, in certain pathologies, such as a high percentage of shunt, oxygen therapy does little to increase the arterial partial pressure of oxygen in blood. It is also important to remember that partial pressure of oxygen in arterial blood does little to increase oxygen content in the blood as long as the patient has a normal amount of functional hemoglobin. This is demonstrated by the following equation:

$$Cao_2 = (Hgb \times 1.36 \times Sao_2) + (0.0031 \times Pao_2)$$

where Cao_2 is the oxygen content, Hgb is the hemoglobin concentration in g/dL, and Sao_2 is the percentage saturation of the hemoglobin in arterial blood.

Oxygen decreases hypoxic pulmonary vasoconstriction (HPV) in the lungs, which, in turn, decreases pulmonary vascular resistance. This effect is beneficial in diseases such as pulmonary arterial hypertension, but may result in an increased A–a gradient in other cases by promoting more *V*/*Q* mismatch. Attenuation of hypoxic pulmonary vasoconstriction resulting in worsening *V*/*Q* mismatch during the use of oxygen therapy is especially evident in patients with chronic obstructive pulmonary disease (COPD) [6]. The premise of providing supplemental oxygen is to avoid end-organ damage by providing adequate oxygen delivery. However, even in patients with severe pulmonary insufficiency at rest (arterial Pao_2 in the 20s–30s of mmHg), blood levels of lactate were not elevated [7]. Organs and tissues at rest have extremely low oxygen tension, so the preoccupation with oxygen delivery in the setting of pulmonary insufficiency may be overemphasized in clinical medicine [1].

Oxygen therapy may not be benign either. Oxygen toxicity may occur, probably caused by the generation of peroxides and other reactive oxygen species that cause inflammatory damage to cells [8]. Neonates especially have been shown to be at risk of complications such as retinopathy of prematurity [9]. For these reasons, oxygen therapy should be minimized when possible. Reducing Fio_2 to <60% seems to be a reasonable goal.

Nitric oxide (NO) is produced in the body and in the lung itself by a host of cells, including vascular endothelial cells, epithelial cells, smooth muscle cells, and inflammatory cells among others [10]. In the vascular endothelium, NO acts to increase levels of cyclic guanosine monophosphate (cGMP), which in turn causes relaxation by means of decreasing calcium availability in vascular smooth muscle [10]. Administration of inhaled NO (iNO) is thought to be advantageous because it is preferentially delivered to ventilated alveoli, thus limiting systemic side-effects. This in turn causes more of the cardiac output to preferentially flow towards the adequately ventilated portion of lung. Most patients who are given iNO demonstrate improved *V*/*Q* matching and increase in oxygenation; however, the therapy has not been shown to reduce mortality in ARDS [11]. NO is especially appealing because it is rapidly metabolized in the blood stream and its vasodilatory effects are localized to the lung [10]. Common clinical uses for iNO include management of pulmonary artery hypertension and right ventricular failure [10].

Epoprostenol occurs in the body naturally as a product of arachidonic acid metabolism. Its effect on the vascular endothelium is to increase intracellular levels of cyclic adenosine monophosphate (cAMP), which then decrease levels of available calcium, causing vessel relaxation [10]. It can be given in both intravenous and inhaled forms. Delivery of the intravenous form requires a special pump. The inhaled form has gained popularity recently as a treatment for refractory hypoxemia by improving *V*/*Q* matching, largely due to the cost advantage over iNO. There have been no randomized controlled trials of epoprostenol in ARDS [12].

Bronchodilators: beta$_2$-agonists and anticholinergics

Beta$_2$-agonists

Beta$_2$-agonists can be given intravenously (epinephrine, isoproterenol), but when treating bronchospasm and elevated airway resistance, aerosolized preparations are the most efficacious. In addition, inhaled administration minimizes unwanted side-effects in distant organs. Beta$_2$-agonists act on G-protein receptors and increase levels of cAMP, thus decreasing the availability of intracellular calcium and causing relaxation of airway smooth muscle [13]. Short-acting agents (albuterol, levalbuterol) are used for acute bronchospasm, whereas long-acting agents, such as fometerol and salmeterol, are used for long-term management in patients with asthma or COPD. Long-acting agents have been proven effective in decreasing exacerbations and symptoms in patients with asthma, but there are safety concerns in some patients with a trend towards increased mortality [14]. As such, many clinicians discontinue long-acting bronchodilators in the acute setting in favor of short-acting beta-agonists. The side-effect profiles of beta-agonists are often problematic. This is especially true of the tachycardia they often cause. One particular drug, levalbuterol, has been marketed as an alternative to albuterol to avoid tachycardia and tachyarrhythmia. However, this has not been shown in clinical studies in patients with asthma [15].

Anticholinergics

Intravenous anticholinergic agents (glycopyrrolate and atropine) are rarely used for bronchodilation. Inhaled anticholinergic agents work on the muscarinic receptors (M_1, M_2, and M_3) of the bronchial airway smooth muscle. The inhaled anticholinergic agents ipratropium and tiotropium are quaternary ammonium compounds. Ipratropium is a non-selective muscarinic antagonist, blocking all three M receptors. Tiotropium also antagonizes all three muscarinic receptors in the lung, but the half-life is longer on M_1 and M_3 receptors, which may result in more bronchodilation (M_2 antagonism causes bronchoconstriction) [16]. Because inhaled anticholinergics are quaternary compounds, they are charged and lack the ability to cross the blood–brain barrier, so anticholinergic syndrome is unlikely [16]. Ipratropium is used as second-line therapy in acute asthma exacerbations, but tiotropium is used only in chronic COPD treatment [16].

Anti-inflammatory treatments: steroids and leukotriene inhibitors

Steroids

Steroid therapy for lung failure is a heavily studied and oft debated topic. Lung tissue may be damaged by the inflammatory cascade set in motion by many diseases, infectious and non-infectious alike. Steroids decrease the body's inflammatory response and spare the tissues from further damage. Systemic steroid therapy has proven beneficial in COPD and asthma exacerbations [17]. "Doubling dosing" of inhaled steroids in an asthma exacerbation, however, has not been shown to be beneficial in preventing rescue dosing with systemic steroids in asthma exacerbation [18]. Corticosteroids have also been extensively studied in ARDS in adults, but they have not been shown to have a significant mortality benefit [19].

Leukotriene inhibitors

Leukotrienes are by-products of arachidonic acid metabolism during the inflammatory cascade. As such, they play a significant role in inflammatory conditions of the lung, most notably asthma. Leukotrienes are potent bronchoconstrictors. Antagonism of this action has proven to be a beneficial adjunct in the treatment of exercise- and aspirin-induced asthma. In addition to their role in bronchoconstriction, leukotrienes play an important role in the modulation of pulmonary capillary permeability, mucus production, and neuronal input [20]. Despite their benefit in the chronic treatment of inflammation-mediated pulmonary disease, leukotriene inhibitors have very little role in the acute setting. Rather, their main utility is as an adjunct in the chronic treatment of atopic asthma.

Phosphodiesterase inhibitors

Phosphodiesterases (PDEs) are enzymes that catalyze cyclic nucleotide hydrolysis. There are 11 identified isoforms, each with varying effects on target tissues. Generally speaking, PDEs modulate smooth muscle constriction. Variable expression of the different isoforms of PDEs in different tissues has allowed for targeted drug development in the hope of achieving specific ends [21]. Theophylline is one of the oldest PDE inhibitors still in use for its bronchodilator effects, despite its weak inhibition of PDE [21]. PDE 3 inhibition results in positive ionotropy, but it also has effects on pulmonary and systemic vascular smooth muscle, resulting in vasodilation [21]. For example, milrinone, a PDE 3 inhibitor, is used in the treatment of end-stage pulmonary hypertension with

secondary right heart failure for its inotropic and vasodilatory effects, particularly in the pulmonary vascular bed. The PDE 5 inhibitor sildenafil has been safely and successfully used in the treatment of end-stage pulmonary hypertension [22]. PDE 5 inhibitors can be added in the intensive care unit (ICU) setting as de-novo therapy or to support weaning from inhaled pulmonary vasodilators, like epoprostenol or iNO.

Mucociliary drugs

N-acetylcysteine, guaifenesin, and iodinated glycerol represent a class of drugs that over the years has been used to alter mucus quality or production to allow improved clearance of pulmonary secretions [23]. Interestingly, there are little to no data supporting their use in the critically ill. Illustrative of this point, N-acetylcysteine has well-known antioxidant properties, but in a series of studies, no statistically significant effect on mortality has been shown [24].

Mechanical ventilation for respiratory failure

Command of mechanical ventilator management is important in properly supporting patients with respiratory failure until their underlying condition can be reversed or improved. Mechanical ventilation is not a therapy for the lungs. Rather, mechanical ventilation provides support for the pulmonary system by providing ventilation and oxygenation when the patient is incapable of doing so to a sufficient extent to allow survival. It is important to bear in mind that mechanical ventilation exposes the patient to ventilator-mediated injury, however, and prompt liberation from mechanical ventilation is paramount.

A detailed discussion of the inner workings of the modern mechanical ventilator is beyond the scope of this chapter. Suffice it to say that mastery of ventilator terminology is necessary for the modern clinician to successfully manage a patient in respiratory failure. Modern ventilators are best understood in terms of *trigger variables*, *limit variables*, and *cycle variables*. A *trigger variable* is the input the ventilator microprocessor uses to register patient initiation of a breath, and it is determined by the mode selected by the operator. The specific trigger variable values are often preset, but may be altered if necessary. For example, a patient may trigger a supported breath from the ventilator by achieving a flow rate (in L/min) or a negative pressure deflection (in cmH_2O). A *limit variable* is what the ventilator tries to achieve during the breath, much as a driver tries to achieve the speed limit for maximum efficiency during a trip. The limit variable is generally an inspiratory pressure or a flow rate. The positive pressure breath is ended by the *cycle variable*. The cycle variable can either be a time (in seconds), a volume (in mL), or a flow rate (in L/min).

The most commonly used ventilator modes are *assist-control mode*. In this mode, the clinician sets the respiratory rate. If the patient is apneic, the ventilator will supply positive pressure breaths to achieve that set rate. If the patient initiates a breath, the ventilator will assist the patient by giving the patient a breath at the set tidal volume. Both the control breath and the assisted breath will abide by the limit variable and cycle variable set by the clinician. The clinician selects whether to give a set volume during each breath or a set pressure during each breath. Hence, the full name of the ventilation mode will be assist control-volume (ACV), or assist control-pressure (ACP). ACV is volume limited and time cycled. ACP is pressure limited and time cycled.

Synchronized intermittent mandatory ventilation (SIMV) is a modification of assist control. Like assist-control ventilation, SIMV may be volume or pressure controlled. In this mode, the clinician sets a respiratory rate. If the patient's respiratory drive is blunted and he/she is breathing at a rate less than the set rate, his/her respiratory rate will be the same as the set respiratory rate. If the patient breathes faster than the set respiratory rate, then the ventilator will assist the patient with a predetermined pressure support breath. Pressure support breaths are pressure limited and flow cycled. This support is designed to allow a patient to use more of his/her respiratory muscles to support ventilation. It has been postulated that SIMV with pressure support could be used for patients with prolonged respiratory failure who are difficult to wean from mechanical ventilation. However, review of the existing literature does not show any clear benefit in weaning [25]. Pressure support may be used as a stand-alone mode of ventilation. In this setting, the patient determines the respiratory rate and minute ventilation by triggering support. An important safety feature is a back-up mode of ventilation that provides ventilation in case the patient becomes hypopneic or apneic.

Pressure-regulated volume control (PRVC) is a mode of ventilation that is pressure limited and time cycled. However, the clinician sets a tidal volume goal. The microprocessor evaluates whether the tidal volume was reached, and then changes the pressure limit to attain the set goal. This mode is representative of a movement toward "smart ventilators," though it remains imperative that clinicians understand ventilator modes. As an example of the dangers of PRVC, imagine that a spontaneous pneumothorax occurs with some degree of tension. In this case, the PRVC-programmed ventilator will continue to increase the delivered pressure to achieve the tidal volume set by the clinician. This feedback loop will continue until dangerously high pressures are used to deliver volumes, thus worsening the pneumothorax and eventually resulting in fulminant cardiopulmonary collapse. These "smart ventilator" modes have alarm values to mitigate these situations, but clinicians must be keenly aware of the ways in which the ever-changing limit variable may result in changes in respiratory compliance without immediate changes in tidal volume.

Airway pressure release ventilation (APRV) is a novel ventilator strategy aimed at maintaining a relatively high mean airway pressure (MawP), thus maximizing oxygenation. It is a time triggered, pressure limited, and time cycled type of ventilation [26]. In this mode, a high pressure (P_{high}) and a time high (t_{high}) are set, as well as a low pressure (P_{low}) and time low (t_{low}). A normal starting point for settings could be 6–10 cycles/min with the following settings: $P_{high} = 30$ mmHg, $t_{high} = 5.2$ s, $P_{low} = 0$ mmHg, and $t_{low} = 0.8$ s. In the interest of comparison with conventional ventilator modes, most alveolar recruitment occurs as a result of distension of alveoli with positive end-expiratory pressure (PEEP) at low lung volumes. By contrast, in APRV, the t_{low} is the more important determinant of recruitment. A short t_{low} allows for incomplete expiration and the development of intrinsic PEEP. The clinician thus uses the intrinsic PEEP to recruit lung near to its closing pressure. What makes APRV particularly attractive is the avoidance of alveolar atelectatic shearing trauma. This mode is advantageous because it supports spontaneous ventilation throughout the respiratory cycle with no closing of valves, i.e. the patient can take many small breaths during P_{high} or P_{low}. Because of this, it is thought that patients are more comfortable as they can breathe at any time during the cycle without resistance and without setting off alarms. Spontaneous breathing

improves *V*/*Q* matching and hemodynamics as well. APRV can improve oxygenation in hypoxemic patients because of the prolonged time spent at higher inflation, thus increasing the MawP versus in conventional modes of ventilation. APRV has been shown to increase lung aeration in patients with ARDS more than pressure support ventilation [27]. Importantly, this mode of ventilation can be dangerous in patients with obstructive lung disease requiring a prolonged expiratory phase. Another potential disadvantage of this mode is that the clinician cannot control volumes achieved while at P_{high}. This has the theoretic potential to result in hyperinflation of the lung, resulting in volutrauma [26]. Overall, this mode of ventilation is compatible with the open lung model, which assumes that, by recruitment and maintenance of alveoli, more efficient oxygenation and ventilation will translate into gains for the patient. However, no studies have shown outcome benefits from this mode of ventilation [26].

High-frequency oscillatory ventilation (HPOV) is a mode used in patients with non-compliant lungs in ARDS. A piston oscillator moves a diaphragm, much like a speaker vibrates on a stereo. The rates are 3–10 Hz, which is equal to 180–600 breaths/min [28]. Fresh gas inflow, known as bias flow, is at 40–60 L/min to achieve an FiO_2 of 0.8–1 [28]. An expiratory valve allows for gas escape and for the mean airway pressure to be set [29]. One advantage of HFOV is the ability to separate oxygenation and ventilation [28]. Parameters that affect oxygenation are FiO_2, mean airway pressure, and bias flow [28]. Parameters that affect ventilation are frequency and amplitude (power) [28]. More rigorous study is needed, but there may be a 30-day mortality benefit from using HFOV versus conventional mechanical ventilation in patients with acute lung injury/ARDS [30].

As already mentioned, mechanical ventilation is not therapeutic for the lungs during respiratory failure. With that in mind, the medical team should be constantly assessing the patient's ability to be liberated from mechanical ventilation. It is well documented that, without good vigilance, patients have the tendency to remain mechanically ventilated for longer than necessary. Daily cessation of sedating drugs has been shown to shorten the amount of time patients are mechanically ventilated [31]. The Awakening and Breathing Controlled Trial paired daily sedation interruption with a spontaneous breathing trial and showed a decrease in ICU length of stay and hospital length of stay [32]. Incorporating sedation interruptions and spontaneous breathing trials into protocols will limit the time spent on mechanical ventilation and the complications of mechanical ventilation.

Acute respiratory distress syndrome

ARDS was first described in a case series in 1967. Since then, ARDS has been the focus of many clinical investigations. From an initial mortality of above 60%, the rate has decreased to about 30% [33]. The characteristics of the syndrome were codified in a consensus definition in 1994 that included: (1) acute onset; (2) PaO_2/FiO_2 <200; (3) bilateral infiltrates on chest radiograph; and (4) pulmonary capillary wedge pressure (PCWP) of <18 mmHg [34]. Because of the overall decline in the use of pulmonary artery catheters, a lack of evidence of a cardiac cause of pulmonary edema is an acceptable substitute for a PCWP of >18 mmHg. ARDS is generally caused by a disruption of the alveolar–capillary membrane.

Three phases of pathology have been described (though not all patients traverse through all three): the exudative, proliferative, and fibrotic phases [35]. The exudative phase involves disruption of the alveolar–capillary membrane, which then allows a significant quantity of protein-rich fluid and neutrophils to flood the alveoli. The proliferative phase refers to hyaline membrane reorganization. This phase is followed by the fibrotic phase, classically occurring around the 2-week mark in the disease process, and resulting in scarring that causes a fibrotic appearance of the lung. Starting in the first phase, diffuse alveolar damage means that gas exchange does not take place normally because of the development of a large functional shunt, resulting in hypoxemia. As discussed earlier, when the shunt becomes large, the patient may no longer be responsive to oxygen therapy. In addition, a vast increase in dead space ventilation early in the course of ARDS is associated with higher mortality [36].

Causes of ARDS include direct insults to the lungs, like aspiration, near drowning, pneumonia, toxic inhalation, or pulmonary contusion [34]. Causes may also be indirect or remote from the lungs, such as non-thoracic trauma, sepsis, blood product transfusion, and cardiopulmonary bypass [34]. Once the alveolar–capillary membrane has been disrupted, the inflammatory cascade results in further damage to the lungs.

Numerous pharmacologic interventions have been tried with limited success. For example, surfactant therapy should theoretically provide benefit because the action of surfactant is lost during the flooding of the alveoli during the exudative phase. However, no mortality benefit has been shown for broadly defined groups of ARDS patients. That said, meta-analysis has shown potential benefit for patients who develop ARDS from aspiration or pneumonia [37]. iNO improves oxygenation, but no decline in mortality has emerged as a result [38]. Corticosteroids have not been shown to change mortality, but they may reduce the number of ventilator days [39].

A landmark study published in 2000 by the Acute Respiratory Syndrome Network (ARDSNet) compared patients with ARDS ventilated with "conventional" tidal volumes (12 mL/kg predicted body weight) versus low tidal volumes (6 mL/kg predicted body weight). The study was stopped on ethical grounds after enrollment of around 800 patients because the low volume ventilation group had a mortality reduction from 39% to 31% [40]. This study built upon many prior studies in animals and humans that pointed toward decreasing lung injury when smaller tidal volumes were used.

In ARDS, the damage to the lungs when viewed on chest computed tomography is fairly heterogeneous, with areas of good lung interspersed with areas of damaged lung [41]. As referenced above, the capillary leak of fluid in the alveolus causes regional changes in compliance. When a positive pressure breath is administered to a patient, the volume preferentially goes to the healthier, more compliant regions of the lungs. This redistribution causes more stretch and shear force on the previously healthy lung parenchyma, causing more inflammation and a worsening of lung injury. A lower tidal volume ventilation strategy is likely protective because it mitigates ventilator-induced injury to the healthy regions of the lung.

The lung in ARDS is under constant assault at the hands of inflammatory mediators and it is at significant risk for ventilator-associated lung injury (VALI). There are several types of injury that can happen during mechanical ventilation: barotrauma (high volume trauma), atelectatic trauma (low volume trauma), and biotrauma (distant trauma to organs other than the lung) [41]. *Barotrauma* is caused by overstretching of the alveoli at high tidal volumes, resulting in damage to the alveolar–capillary membrane.

The bedside strategy for minimizing barotrauma includes use of lung protective ventilation with smaller tidal volumes and maintenance of plateau pressures (a surrogate for alveolar pressures) at or below 35 cmH_2O [41]. It is important to keep in mind that peak pressures are not reflective of pressure transmitted to alveoli, but rather are a function of resistance between non-exchanging airways and the ventilator circuit itself [41]. *Atelectrauma* occurs when the closing capacity is greater than the functional residual capacity. With each positive pressure breath, the smaller exchanging airways and alveoli collapse and then reopen, resulting in sheer stress and injury as those units open and close [41]. Application of PEEP stents open lung units that would otherwise close. This has been shown to be beneficial in animal models. However, large randomized controlled trials comparing higher and lower PEEP strategies utilizing low tidal volume ventilation showed no difference in mortality or other clinical endpoints in the comparison groups [42]. Therefore, it seems that minimization of tidal volume is more important in the prevention of VALI [42]. Utilization of a PEEP sufficient to allow adequate oxygenation can be recommended, though the specific strategy should be left to the clinician's discretion. *Biotrauma* is the third type of injury that can be associated with mechanical ventilation in patients with ARDS. Mechanical ventilation can induce the release of some inflammatory cytokines from the lungs and these travel to other distant organs, and are possibly a cause of multiorgan system failure [41]. Additionally, inflammatory mediators released by other organs may result in damage to the lungs. The ARDSNet trial found lower levels of serum interleukin (IL)-6 in the low tidal volume ventilation group [40]. Low tidal ventilation may minimize IL-6–mediated injury.

In summary, ARDS is a clinical syndrome that most likely represents the final common pathway of several different pathologies. Multiple pharmacologic and mechanical ventilatory interventions have been studied with a few generalizable successes. Few patients with ARDS die from irreversible lung injury; rather, mortality is associated with other causes, most notably sepsis [43]. The one "treatment" that we do have for ARDS is treatment of the underlying cause, with supportive care until the patient can recover and the use of lower tidal volume lung protective ventilation in the interest of mitigating VALI.

Diseases of chronic respiratory failure

As mentioned above, most patients with ARDS die from causes other than irreversible lung injury. However, diseases of chronic respiratory failure are often progressive, marked by steady deterioration with intermittent acute exacerbations brought on by infection or inflammation. Most are relatively manageable until the respiratory failure becomes such a threat to life that lung transplantation offers the only hope of prolonged survival with reasonable quality of life.

Lung transplantation is reserved for high mortality conditions that are progressive and will not recur in the donor lungs. A worldwide survey of lung transplantation reveals that the greatest percentage of lung transplants were performed for the following indications: COPD (31%), idiopathic pulmonary fibrosis (21%), cystic fibrosis (16%), and alpha-1 antitrypsin deficiency (7%) [44]. We will briefly review the pathology and management of the diseases for which the majority of lung transplantation is done. Additional discussion of these conditions can be found in Chapter 31.

Chronic obstructive pulmonary disease

The disease burden of COPD, both in the US and worldwide, is great [45]. By 2020, COPD will be the fifth leading cause of death worldwide [46]. The term COPD encompasses both chronic bronchitis and emphysema. Both diseases have an obstructive pattern of airflow on spirometry. Chronic bronchitis is characterized by small airways disease that causes obstruction during the expiratory phase. Emphysema has a similar pattern, but is further complicated by the loss of elastic tissue in the lung parenchyma, resulting in further functional impairment of the expiratory phase.

The diagnosis of COPD can be suspected from clinical history and confirmed with the spirometry values. In practice, manifestations of both emphysema and chronic bronchitis frequently are seen in the same patient. In addition, asthma may be present in some patients, complicating the diagnosis. Pulmonary function testing before and after the administration of $beta_2$-agonists can help to define the amount of reversibility of bronchoconstriction. COPD can been divided into mild, moderate, severe, and very severe based on the forced expiratory volume in 1 s (FEV_1)/forced ventilatory capacity (FVC) ratio and symptoms. Each level of severity is accompanied by an additional therapy. Mild COPD, defined as an FEV_1/FVC of <0.70 and an FEV_1 of $>80\%$ predicted, is managed by reducing risk factors, providing appropriate vaccinations, and using short-acting bronchodilators when necessary. As mild progresses to moderate disease, defined as an FEV_1/FVC of <0.70 and an FEV_1 of between 50% and 80% predicted, one or more long-acting bronchodilators is added, and pulmonary rehabilitation should be considered. Further progression from moderate to severe disease, defined as an FEV_1/FVC of <0.70 and an FEV_1 of between 30% and 50%, inhaled glucocorticoids may be added for exacerbations. Finally, as severe disease progresses to very severe disease, defined as an FEV_1/FVC of <0.70 and an FEV_1 of $<30\%$ predicted or FEV_1 of $<0\%$ complicated by chronic respiratory failure, then consideration should be given to chronic oxygen therapy or surgical treatment options [47].

Because of the combination of obstruction to expiration and loss of elastic tissue, multiple complications occur in COPD, including pneumothorax, cor pulmonale, giant bullae, and pneumonia [48].

The pathogenesis of COPD involves multiple proposed mechanisms of damage to the lungs. Most often, an environmental pathogen, such as cigarette smoke, induces inflammatory changes in the lung. In large airways there can be an increase in the production of mucus. This results in goblet cell hyperplasia, a characteristic of chronic bronchitis [49]. Despite the increase in the production of mucus and goblet cell hyperplasia, the airway obstruction of COPD is not large airway obstruction, but rather smaller airway obstruction, especially of airways of <2 mm in diameter [49]. The exact cascade of factors is not completely understood, but neutrophilic infiltration into bronchioles and lung units clearly occurs [50]. Hypertrophy of smooth muscle may also contribute to resistance to airflow. There is also destruction of the architecture of the lung, leading to deterioration in elastic recoil and increased dead space. The relative contributions of airflow deficit from emphysema and from airway obstruction are still unknown, and likely vary among patients. In addition to the elastic changes in the lung, there is loss of pulmonary capillary blood flow due to parenchymal remodeling, further contributing to a decrease in the diffusion capacity of carbon monoxide [51].

Treatment now is directed toward smoking cessation, bronchodilator therapy, and specific pulmonary rehabilitation therapy. In severe cases, inhaled corticosteroids are added. Threats to life

occur when patients have "COPD exacerbations," defined as acute worsening of symptomatology. The first step in the care of the COPD patient is the prevention of COPD exacerbations. Inhaled corticosteroids have been shown to reduce exacerbations by 20% [47]. Tiotropium has been shown to improve the COPD patient's quality of life and reduce COPD exacerbations by 24% over ipratropium [52]. A combination of salmeterol and fluticasone has been shown to reduce COPD exacerbations by 25%. Bronchodilator therapy with short-acting and long-acting beta$_2$-agonists can be used to improve FEV_1 by about 100–150 mL [48]. Empiric treatment with antibiotics with the onset of COPD exacerbation has been shown to decrease treatment failure by 46% and inhospital mortality by 78% [53]. A short course of 14 days or fewer of systemic steroids has also been shown to reduce treatment failure by 46% [53]. Oxygen therapy should be directed to keep saturations to >88–90% [49]. For hypoxemic patients with COPD, long-term oxygen therapy improves survival and has better results when administered for 24 h rather than for part of the day [54].

Further discussion is warranted with respect to ventilatory support in patients with COPD exacerbations. During COPD exacerbations, total lung volumes expand due to restriction of airflow in the small airways [55]. This hyperinflation strains respiratory muscles and increases the work of breathing. Furthermore, the inability to exhale completely during the respiratory cycle leads to a respiratory acidosis, which further impairs ventilation [55]. A review of randomized controlled trials has shown that use of non-invasive positive pressure ventilation (NIPPV) for support of the patient with a COPD exacerbation reduced mortality by 48% compared to the usual medical care [55]. In addition, the rate of endotracheal intubation was reduced by 59% [55]. The profound benefit of NIPPV is unique to this group of patients and to patients with acute congestive heart failure. In most other groups, the benefit of NIPPV could not be shown, and at times caused harm by delaying the inevitable placement of the endotracheal tube. The striking reduction in mortality in COPD and congestive heart failure (CHF) may be due to the avoidance of endotracheal intubation and its associated risks to the patient, which include decreased secretion clearance, increased requirements for sedation and analgesia, and ventilator-associated pneumonia.

Cystic fibrosis

Cystic fibrosis (CF) is an autosomal recessive disease caused by mutation of the cystic fibrosis transmembrane conductance regulator (CFTR). The disease has variations in its severity, but it is primarily characterized by chronic infection, airway obstruction, deficiency of the exocrine pancreas, and gastrointestinal tract dysfunction [56]. It is most common in descendants of northern Europeans, with between 2% and 5% of Caucasians being carriers for the CF gene mutation [56]. In CF, the lung epithelia are dysfunctional. CFTR protein is important in chloride transport and defects in the protein result in a depletion of airway surface water [57]. The remaining mucus is thicker and more adherent to the cells, which causes airway obstruction and provides a nidus for infection [56]. The mucus is more difficult for the mucociliary elevator to clear. Because of chronically obstructed airways, the patient becomes colonized with potentially pathogenic bacteria.

Treatment of the patient with a CF exacerbation focuses on: (1) antibiotic therapy to reduce bacterial burden; (2) airway clearance; and (3) maintenance of proper nutrition [58]. The most common organisms cultured include *Staphylococcus aureus* and *Pseudomonas aeruginosa* [56]. Patients who present to the hospital with respiratory insufficiency secondary to CF exacerbation should have special CF sputum cultures sent to determine species and sensitivities of each bacterial culture. Because patients receive courses of antibiotics with each exacerbation, multidrug-resistant Gram-negative cultures, such as *Burkholderia cepacia*, are found in approximately a third of CF patients [59]. Initial antibiotic selection is based on the patient's prior cultures and involves two classes of antipseudomonals [58]. Consulting infectious disease specialists can help to guide therapy. Suppressive antimicrobial therapy with inhaled tobramycin as an outpatient has become prevalent and has been shown to decrease rates of CF exacerbation [58]. Macrolide (mainly azithromycin) therapy has been shown to improve lung function, particularly in those patients with pseudomonal infections [60]. Since it does not have activity against *Pseudomonas*, it is thought that modulation of inflammation and immunity may be the mechanism by which azithromycin improves lung function [60].

Airway clearance is achieved by physical drainage assistance and inhaled expectorants. Postural drainage, percussion, and vibration are associated with an increase in sputum expectoration [61]. When postural drainage, precussion, and vibration are used in combination with exercise, a measurable increase in FEV_1 can be achieved [61]. Therapeutic apparatus include vibrating beds and special vests. In terms of expectorant therapy, recombinant human deoxyribonuclease I (rhDNase I) is a biologically manufactured copy of the human enzyme. Extracellular DNA contributes to the viscous nature of mucus in patients with CF. When used twice daily by inhalation, rhDNase reduced CF exacerbations by 37% versus placebo [62]. There is less convincing evidence that nebulized hypertonic saline increases mucus clearance in CF. The purported mechanism for the benefit of hypertonic saline is that the inhalation of salt increases osmotic flow of water, resulting in rehydration of mucus with the resulting reduced viscosity allowing for expectoration [63].

Maintaining nutritional status should be a cornerstone of CF treatment, as poor nutrition and low body mass index (BMI) have been linked to poor outcomes [58]. No specific diet is recommended, but high calorie foods are encouraged, along with appropriate pancreatic enzyme supplementation [58]. Low BMI can even be a barrier to lung transplantation.

Supportive care of the pulmonary system in CF is much the same as in other etiologies of respiratory failure. Oxygen therapy likely has benefit by reducing pulmonary hypertension and cor pulmonale, but studies in the CF population are lacking, and much of the data are extrapolated from the COPD population [58]. Short-term non-invasive ventilation for hypercarbia has been described, but it is unclear whether this is beneficial or harmful in this population [64]. Support of other failing organ systems is necessary because of the expression of CFTR in other tissues, especially the gastrointestinal system. Pancreatic insufficiency is managed by replacement of digestive enzymes. Hyperglycemia generally presents in the second or third decades of life [56]. Patients often have renal insufficiency due to multiple exposures to aminoglycosides. Hepatic cirrhosis may occur as well, in concert with all of its associated complications [56].

Idiopathic pulmonary fibrosis

Idiopathic pulmonary fibrosis (IPF) generally has an insidious onset with non-productive cough and exertional dyspnea. It is

characterized as a restrictive lung disease due to the loss of lung compliance associated with fibrosis. Diagnosis of IPF is generally accomplished with a surgical biopsy of the lung [65]. IPF is fatal unless remission is achieved. At diagnosis the 5-year survival rate is 20–30% [66]. Mortality from progression of disease is 39%, 24% from cardiovascular causes (especially cor pulmonale), 10% bronchogenic carcinoma, and 7% pulmonary embolism [67].

Corticosteroids are the mainstay of treatment, but there is no evidence to support their use as sole therapy [68]. The diagnosis of IPF should prompt an immediate referral of the patient to a center with treatment protocols and consideration for lung transplantation. The lung allocation score was implemented in 2005 with the aim of reducing the number of patients who die on the lung transplant waitlist. It has resulted in a significant increase in the number of patients with IPF who receive transplants [69]. At this time, treatment involves experimental protocols of anti-inflammatory drugs and support. There are currently multiple trials ongoing testing antifibrotic and anti-inflammatory drugs.

It is important to note that pulmonary hypertension is prevalent in this population, and should be investigated with right heart catheterization and treated as appropriate [70]. Intubation should be avoided in patients with advanced IPF where possible unless an immediate treatment can be initiated [71]. In a series of patients with IPF intubated and ventilated for acute respiratory failure, only one survived by having a lung transplant 6 h after mechanical ventilation [71].

Pulmonary arterial hypertension

The definition of pulmonary artery hypertension is a mean pulmonary artery pressure of $\geq$25 mmHg and a pulmonary artery occlusion pressure of $<$15 mmHg during right heart catheterization [72]. The World Health Organization divided pulmonary artery hypertension into groups (Table 45.1) [73]. Idiopathic pulmonary artery hypertension (IPAH) is attributable to group 1. There is much still unknown about this disease process, but current evidence points to the growth and proliferation of cells in all three layers of the blood vessel [73]. Dyspnea is the most common presenting symptom and, though echocardiographic findings are helpful, diagnosis should be made with the aid of a right heart catheterization [73]. Treatment consists of supportive therapy, light physical exercise as tolerated, anticoagulation with warfarin, diuretic therapy, and pulmonary vasodilator therapy [73]. After classification of the patient's functional status, a graded approach to pulmonary vasodilation therapy is recommended [72]. By following these general guidelines, pulmonary hypertensive patients are surviving longer with a better quality of life with vasodilator therapy, making them less likely need a lung transplant in the future.

Table 45.1. World Health Organization categorization of pulmonary artery hypertension

Group 1	Pulmonary arterial hypertension
Group 1′	Pulmonary veno-occlusive disease
Group 2	Pulmonary hypertension from left heart disease
Group 3	Pulmonary hypertension from chronic lung disease or hypoxia
Group 4	Chronic thromboembolic pulmonary disease
Group 5	Pulmonary hypertension with unclear multifactorial mechanisms

Extracorporeal life support

Patients may have such respiratory failure that mechanical ventilation is no longer able to provide sufficient oxygenation to their end organs. In this case, additional support may allow the lungs time to recover or provide a bridge to lung transplantation [74]. Most pulmonary support is given by extracorporeal membrane oxygenation (ECMO) (see Chapter 50). There are two main types of ECMO: veno-venous (V-V) and veno-arterial (V-A). V-V ECMO drains deoxygenated blood from a central venous cannula, oxygenates it, and then returns it into the central venous circulation for delivery to the pulmonary circulation and beyond. This serves as a pulmonary support device in patients who have no evidence of right heart failure associated with their respiratory failure. In contrast, V-A ECMO removes blood from a central vein and returns oxygenated blood under pressure into the arterial system. V-A ECMO serves as cardiopulmonary support and is similar to cardiopulmonary bypass used during heart surgery. Any mortality benefit conveyed by ECMO likely depends upon patient selection, the underlying disease process, and the expertise at the ECMO center. There have been a few recent randomized controlled trials evaluating ECMO that demonstrate benefit. Prior studies failed to find a survival benefit. A recent, well-publicized study found that patients with severe ARDS who were referred to an ECMO center had a survival benefit when compared to a cohort who remained on mechanical ventilation in a non-ECMO center [75]. It is unclear whether the intervention of ECMO was integral in the survival benefit or if transfer to a center of excellence was more important.

Summary

The lung is an integral organ necessary for the maintenance of homeostasis by providing oxygenation, ventilation, and hormonal input. A healthy pulmonary system has a large amount of intrinsic reserve, as evidenced by the body's ability to tolerate single lung ventilation. However, because of their direct exposure to the environment, the lungs are subject to severe injury by aspiration, inhalation, and aerosolized exposure to infectious agents. The advent of mechanical ventilation has allowed for maintenance of tissue oxygenation and ventilation when a patient is no longer capable of doing so to a sufficient extent to allow survival. At times, the lungs may be so damaged that ECMO must be employed to support the body until sufficient recovery or transplantation can be accomplished.

CHAPTER 46

Dialysis

Myriam Farah[1] and John S. Gill[1,2]
[1] Division of Nephrology, University of British Columbia, Vancouver, BC, Canada
[2] St. Paul's Hospital, Vancouver, BC, Canada

Introduction

The current state of kidney transplantation is inextricably entangled with the practice of dialysis. Unlike other life-sustaining areas of organ transplantation, where reliable, long-term surrogates for end-organ failure are either absent (e.g. liver and lung) or only recently gaining a reliable foothold (heart and intestine), kidney transplantation has emerged in parallel with the emergence and refinement of techniques for dialysis. Indeed, it is reasonable to say that the bulk of kidney transplantation exists because of the ability to mitigate the immediate consequences of renal failure and in so doing allow the medical team to attend to the logistics of transplantation. Similarly, the fiscal management of renal failure has been greatly influenced by policies related to the coverage of dialysis (as discussed in detail in Chapters 140 and 143). As such, an understanding of essentially all aspects of kidney transplantation requires some understanding of the current practice of dialysis, and the techniques of achieving and maintaining dialysis access are an accepted part of the repertoire of all clinicians with specialty certification in transplantation.

The chapter will provide the reader with a general understanding of dialysis as it relates to transplantation. It is divided into three sections: a review of epidemiological data regarding the impact of dialysis exposure and dialysis modality on kidney transplant outcomes; an overview of dialysis and related extracorporeal therapies; and a detailed discussion of dialysis management considerations in renal and extrarenal transplant recipients. The chapter can be viewed as a companion to Chapters 28 and 37, which cover patient selection and indications for transplantation, and the management of patients awaiting transplantation, respectively.

Epidemiology

Impact of dialysis on kidney transplant outcomes

Dialysis provides limited clearance of metabolic waste products. Chronic uremia and hypervolemia together with other metabolic abnormalities (e.g. anemia, abnormalities of calcium and phosphate metabolism) cause accelerated progression of pathological conditions, including atherosclerotic disease, vascular calcification, and left ventricular hypertrophy, which lead to excess morbidity and mortality in dialysis patients. Advances in dialysis and medical therapies have improved dialysis survival; however, the annual death rate among waitlisted transplant candidates remains in the range of 3–5% per year [1]. Patient tolerance of uremia is variable, and diabetic and elderly patients have the highest risk of mortality on dialysis.

A longer duration of pretransplant dialysis treatment is associated with decreased allograft survival, presumably because the progression of co-morbid disease during dialysis is not reversed after transplantation [2]. This is in part due to the fact that the patients with a functioning allograft have decreased kidney function, and continue to be at risk for chronic kidney disease-related complications [3]. Complete avoidance of dialysis with pre-emptive transplantation is associated with the best post-transplant outcomes [4]. To what extent the survival advantage of pre-emptive transplantation is due to differences between pre-emptive and non–pre-emptive recipients, rather than a detrimental effect of even relatively short exposures to uremia, cannot be discerned from available observational studies.

The timing of pre-emptive transplantation remains a subjective science. In a study of adult pre-emptive transplant recipients in the US between 1994 and 2000, there was no difference in post-transplant outcomes between the patients who had an estimated glomerular filtration rate (GFR_ of less or greater than 15 mL/min at the time of transplantation [5]. In clinical practice, pre-emptive transplantation may be considered at any time when the GFR is $<$20 mL/min, with avoidance of uremic signs and symptoms being the overriding consideration. The rate of kidney function decline as well as signs and symptoms of uremia should be closely followed in pre-emptive transplant candidates. A short course of dialysis to correct uremia may be necessary in pre-emptive candidates who develop symptoms or biochemical abnormalities that cannot be managed medically (Table 46.1).

Impact of dialysis modality on kidney transplant outcomes

The ability to determine an association between dialysis modality and post-transplant outcomes is limited by the fact that the existing single-center studies have inadequate power to detect a difference in transplant outcomes, and registry analyses are prone to residual confounding. Peritoneal dialysis (PD) is self-administered and

preferred by patients who require flexibility in their dialysis treatment schedule and/or the ability to travel. Accordingly, PD patients may be more active, have a higher functional status, and have a lower burden of co-morbid disease than hemodialysis (HD) treated patients, and such differences are likely inadequately accounted for in registry analyses. Consistent with this view is the finding that PD patients are more likely to receive a transplant than HD patients [6].

In an analysis of United States Renal Data System (USRDS) data, there was no difference in long-term allograft survival or death between PD and HD patients despite a small but significant increased risk of death-censored allograft failure among PD patients [6]. The long-term increased risk of death-censored graft loss was driven by a higher risk of graft failure during the first 3 months after transplantation. This high early risk of death-censored graft loss in PD patients was observed despite a lower rate of delayed graft function (presumably due to higher levels of residual native kidney function in PD patients). The reason for increased early allograft failures in PD treated patients could not be determined. However, in a subset of patients with available information regarding the cause of allograft failure, a higher rate of graft thrombosis was noted [6,7]. No differences in acute rejection were observed. An increased risk of allograft thrombosis in PD patients has been noted in other studies and in theory could be related to an acquired thrombophilic state from loss of anticoagulant proteins across the peritoneal membrane [7]. A small retrospective single-center study found that institution of a prophylactic aspirin protocol reduced the observed incidence of renal vein thrombosis [8]. However, larger and controlled studies are necessary to recommend any specific intervention in PD patients.

Existing studies do not suggest a difference in acute rejection between PD and HD patients. In the setting of delayed graft function, previous studies have suggested a higher clearance of mycophenolic acid (MPA) in PD patients [9]; however, more recent analyses have failed to show any difference in clearance between HD and PD patients, and no adjustment of MPA dosing appears to be necessary to maintain therapeutic efficacy in dialysis patients. However, MPA glucuronide (MPAG) does accumulate in dialysis patients and may lead to increased gastrointestinal intolerance [9,10].

A higher rate of bacterial intra-abdominal, bloodstream, surgical wound, or catheter site infections in PD patients is inconsistently reported in the literature, and it is unclear whether there is a higher risk in PD compared to HD patients [11,12].

No studies have examined whether the dialysis prescription (i.e. increased clearance of metabolic waste products with nocturnal hemodialysis, daily hemodialysis, or hemodiafiltration) mitigates the impact of uremia on post-transplant outcomes.

Dialysis and related extracorporeal therapies

Indications for dialysis

Acute dialysis is indicated to correct the potentially life-threatening complications of uremia (Table 46.1) that cannot be medically managed. The indications for acute dialysis are the same as for chronic dialysis patients, patients with advanced chronic kidney disease not yet initiated on chronic dialysis, and patients with acute kidney injury, including delayed graft function.

Hemodialysis

Procedure

During HD blood is circulated through an extracorporeal circuit containing a dialysis membrane where solute and water are removed, and subsequently returned to the patient [13]. Blood and dialysis fluid (dialysate) are pumped in a counter-flow direction on either side of the dialysis membrane. Solute removal is achieved through diffusion of molecules across the dialysis membrane, while fluid removal is achieved through application of hydrostatic pressure across the membrane. In conventional HD, diffusion is the main form of solute clearance, while in hemodiafiltration, solute clearance is also achieved by convection.

Circuit

Components of the dialysis circuit include a vascular access to extract blood from the patient, dialysis tubing to connect the patient to the extracorporeal circuit, the dialysis machine, dialysate, and the dialysis membrane (Figure 46.1). Modern dialysis machines allow for tight control of fluid removal, and the ability to provide isolated fluid removal without diffusive clearance (isolated ultrafiltration). Anticoagulation is usually required to prevent clotting in the extracorporeal circuit, commonly in the form of heparin.

Prescription

The dialysis prescription specifies the duration and frequency of each treatment, the blood and dialysate flow rates, the type of dialysis membrane, and the composition of the dialysate. The frequency and duration of treatments can be increased to enhance clearance of metabolic waste products and fluid, with a number of demonstrable clinical benefits in chronic HD patients [14–16]. In the acute setting, the frequency and duration of dialysis treatment is dependent on the indication for treatment. Table 46.2 shows a typical dialysis prescription along with common variations in the prescription.

Vascular access

The principal types of vascular access in chronic HD patients are native arteriovenous fistulas (AVF), arteriovenous grafts (AVG), and central venous catheters (CVC) that are typically tunneled under the skin prior to entering the central circulation (tunneled cuffed catheter).

AVFs are created through direct anastomosis between an artery and a vein, while AVGs use synthetic material to connect an artery and vein (Figure 46.2). Both AVFs and AVGs require time for maturation (4 –8 weeks) before use. During dialysis, needles are inserted directly into the AVF or AVG for blood removal and return. CVCs are double-lumen catheters that are usually inserted in the internal jugular, subclavian, or femoral veins (Figure 46.2). CVCs can be used immediately after placement. Between treatments, CVCs are locked with anticoagulants.

Complications

Due to fluid and solute removal

Dialysis disequilibrium syndrome is the occurrence of neurological signs and symptoms due to cerebral edema [17]. The exact cause is unclear, but is related to rapid removal of fluid and solutes. Cardiac

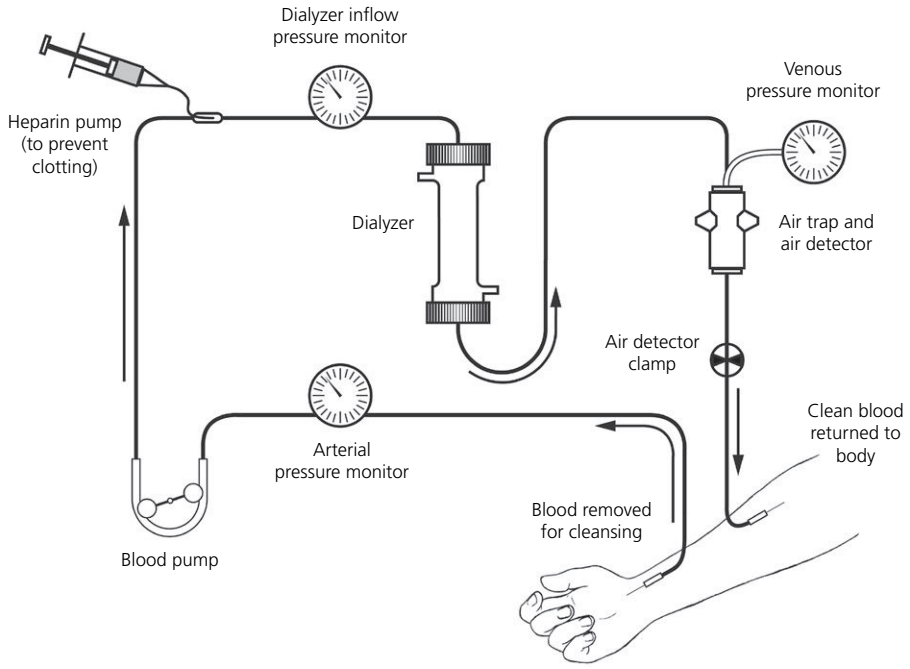

Figure 46.1. Hemodialysis circuit. Components of the dialysis circuit include a vascular access to extract blood from the patient, dialysis tubing to connect the patient to the extracorporeal circuit, the dialysis machine (not shown), dialysate (not shown), and the dialysis membrane (dialyzer). Blood and dialysis fluid (dialysate, not shown) are pumped in a counter-flow direction on either side of the dialysis membrane. Solute removal is achieved through diffusion of molecules across the dialysis membrane, while fluid removal is achieved through application of hydrostatic pressure across the membrane. The circuit is commonly anticoagulated with heparin to prevent clotting. (Reproduced from http://www.catalog.niddk.nih.gov/imagelibrary.)

Table 46.2. Hemodialysis prescription

	Typical prescription	Potential variations
Dialysis membrane	Synthetic hollow fiber High flux Surface area 1.8 m^2	Cellulo-synthetic hollow fiber Low flux Surface area 1.8–2.5 m^2
Dialysate:		
Sodium (mEq/L)	138–140	130–155
Potassium (mEq/L)	2	0–4
Bicarbonate (mEq/L)	35	28–40
Calcium (mmol/L)	1.25	1.25–1.75
Magnesium (mmol/L)	0.75	0.5–1.0
Glucose and chloride	Standard	
Dialysate flow rate (mL/min)	500	300–800
Blood flow rate (mL/min)	350	200–400
Anticoagulation	Heparin 500-U load/500 U/h maintenance infusion	Heparin 500–1500-U load/500–1500 U/h maintenance Other alternatives: no heparin, regional citrate, regional heparin with protamine reversal, citrasate dialysate, danaparoid
Duration of run (h)	4	2—8
Frequency of runs (number/week)	3	3–7
Fluid removal (L/treatment)	2 L per treatment	0–5L per treatment
Dialysate temperature (°C)	36.5	35–37

arrhythmias due to rapid changes in serum potassium and calcium concentrations, seizures due rapid alterations in serum sodium and calcium concentrations, and hypotension due to rapid or excessive fluid removal are other common complications [18].

Due to exposure of blood to the extracorporeal circuit

Despite technologic advances, the removal of blood from the central circulation together with the contact of blood with components of the dialysis circuit can lead to a variety of problems, including bleeding, clotting, thrombocytopenia, infection, and air embolism. Cytokine release and complement activation occur when blood comes into contact with the dialysis membrane. Cytokine release is decreased with modern dialysis membranes made from more biocompatible synthetic materials, compared to that with the earlier cellulose-based membranes; however, dialyzer reactions still occur. The severity of dialyzer reactions ranges from mild allergic reactions to anaphylaxis [19].

Dialysate-related complications

HD patients are exposed to vast quantities of water, which is mixed with dialysate concentrate to create dialysate. Water must be filtered, softened, temperature and pH adjusted, and purified by reverse osmosis, and organic solutes must be absorbed prior to entering the dialysis circuit. Patients may be exposed to trace mineral contaminants, chemical contaminants, and bacterial endotoxins leading to infection or hemolysis [20].

Vascular access-related complications

The major complications with AVF/AVGs are infection, thrombosis, and steal syndrome. Infections can present with local signs of

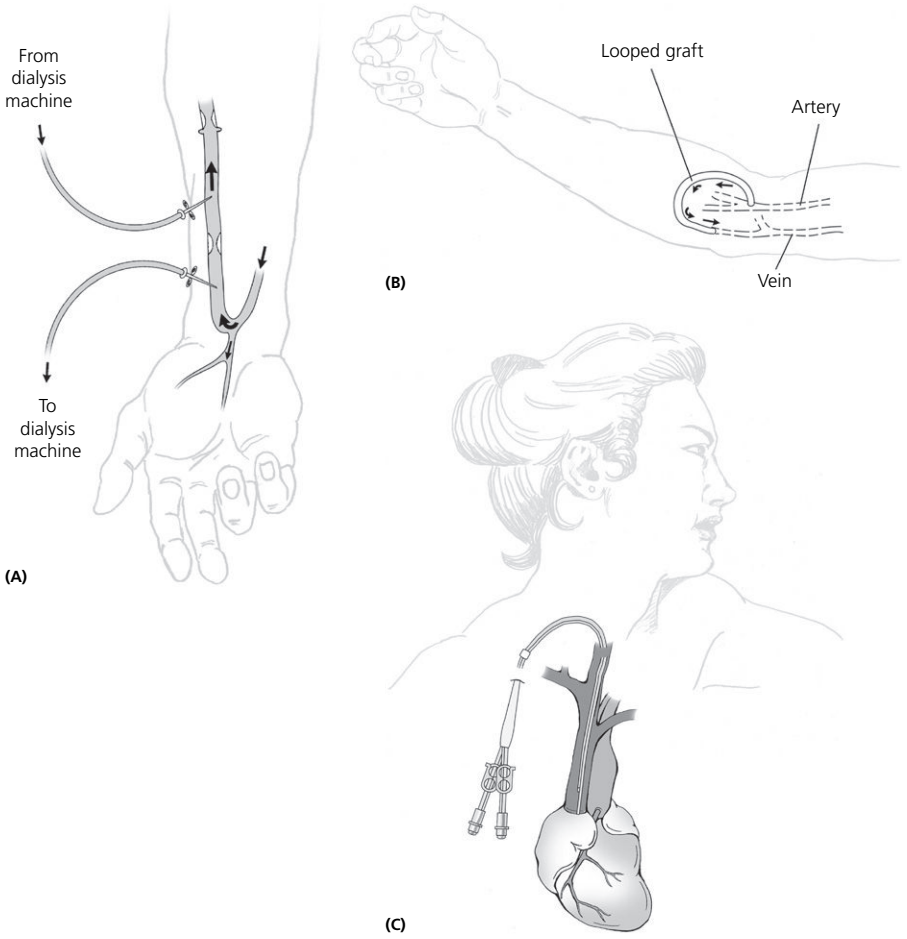

Figure 46.2. Types of vascular access used in hemodialysis. The principal types of vascular access in chronic hemodialysis patients are (A) native arteriovenous fistulas (AVF), (B) arteriovenous grafts (AVG), and (C) central venous catheters (CVC) that are typically tunneled under the skin prior to entering the central circulation (tunneled cuffed catheter). (Reproduced from http://www.catalog.niddk.nih.gov/imagelibrary.)

inflammation, septicemia, or peripheral seeding (endocarditis, osteomyelitis). Management includes investigation (cultures of blood and local drainage), antibiotic therapy, and occasionally surgical intervention [21]. Thrombosis can result from stenosis or poor flow due to local or systemic hypotension. Blood pressure measurements, phlebotomy, and insertion of peripheral intravenous lines should be avoided in the extremity where an AVG or AVF is present. Avoidance of systemic hypotension and local compression are additional important considerations [22]. Diversion of arterial blood flow through an AVF/AVG may lead to ischemia in the distal extremity (steal syndrome). Evidence of ischemia or pain in the extremity, particularly during dialysis, is suggestive of steal syndrome. Signs and symptoms suggestive of steal syndrome should be assessed prior to surgery to inform the need for pre-emptive surgical correction or interventions to protect the extremity during the transplant surgery [23].

CVCs have a higher rate of infection than AVF/AVGs. Infections can be localized or systemic. Investigation and treatment of suspected infections are similar to those for AVF/AVG infections. The decision to remove the catheter is based on patient hemodynamic instability, microbiologic culture results, extent of response to treatment, and whether co-existent tunnel or exit site infection are present [24]. Catheter dysfunction manifests as the inability to reach appropriate blood flow rates during dialysis and a decrease in clearance of metabolic waste products due to high rates of recirculation within the catheter. The main causes of catheter dysfunction are improper positioning, kinking, and intraluminal fibrin sheaths. A variety of interventions including repositioning of the patient or catheter, intraluminal thrombolytics, and even catheter replacement may be required [25].

Development of central vein stenosis can occur with all types of vascular access [26]. This usually manifests as swelling of the upper extremity; other presentations include pleural effusions, development of collateral veins across the trunk, difficult cannulation, and superior vena cava syndrome.

Peritoneal dialysis

Procedure

An indwelling PD catheter is used to instill and remove dialysate from the peritoneal cavity. The patient's own peritoneal membrane acts as the dialysis membrane and allows for diffusion and convection of molecules and fluid into the dialysate, which is drained after a specific dwell period. PD solutions contain osmotic molecules, which promote movement of fluids out of the peritoneal vasculature across the patient's peritoneal membrane into the dialysate. Through repeated fill–dwell–drain exchanges, PD achieves gradual and continuous solute and fluid removal [27].

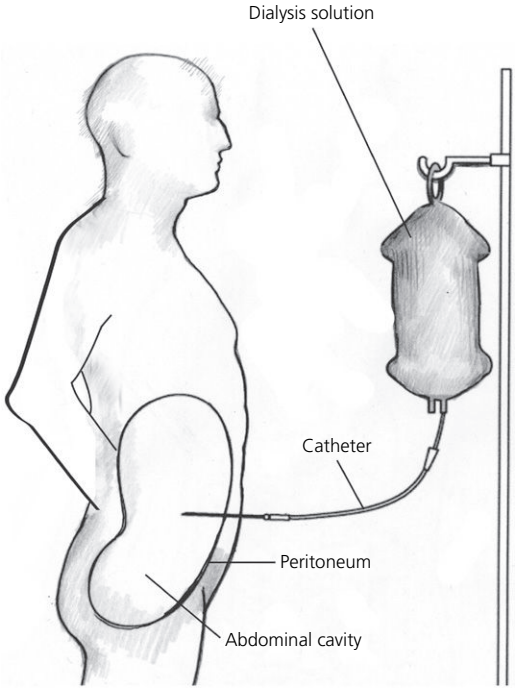

Figure 46.3. Peritoneal dialysis (PD) procedure. The PD set-up includes the catheter, dialysis solution, connection, and transfer sets. An indwelling peritoneal dialysis catheter is used to instill and remove dialysate from the peritoneal cavity. The patient's own peritoneal membrane acts as the dialysis membrane and allows for diffusion and convection of molecules and fluid into the dialysate, which is drained after a specific dwell period. (Reproduced from http://www.catalog.niddk.nih.gov/imagelibrary.)

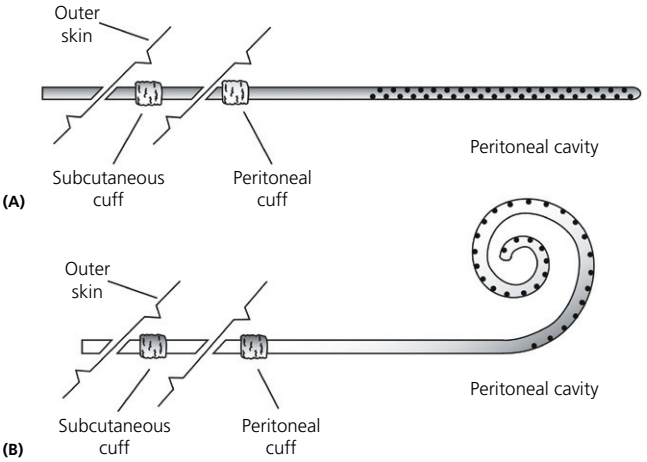

Figure 46.4. Two-cuff Tenckhoff peritoneal dialysis catheter, the most common catheter in use. The peritoneal dialysis catheter consists of a distal intraperitoneal portion, a mid-portion that is implanted into the abdominal wall, and a subcutaneous track. (Reproduced from http://www.catalog.niddk.nih.gov/imagelibrary.)

Table 46.3. Peritoneal dialysis (PD) prescription

	Typical prescription	Range of variations
Frequency of exchanges	3 per day	3–5 per day (CAPD) 3–5 per night (CCPD)
Fill volumes per exchange (L)	2	1.0–2.5
PD solution	1.5% dextrose based	0.5%, 1.5%, 2.5%, or 4.25% dextrose based Variations: bicarbonate based, amino acid based
Long dwell	Overnight 7.5% icodextrin based	Overnight dry abdomen (no fluid) Long day dwell if CCPD
Anticoagulation	None	Heparin injection into PD solution bags
Standard electrolyte composition	Sodium 130–137 mEq/L Potassium 0–2 mEq/L Calcium 1.25–1.75 mmol/L Magnesium 0.5–1.5 mmol/L Lactate 35–40 mEq/L	

CAPD, continuous ambulatory peritoneal dialysis; CCPD, continuous cycler peritoneal dialysis.

Patients are trained to perform PD daily at home, either manually [continuous ambulatory peritoneal dialysis (CAPD)], or using a cycler machine [automated peritoneal dialysis (APD)]. During times when no exchanges are being performed, the peritoneal cavity can be left empty ("dry abdomen") or filled with solution ("wet abdomen"). Patients on CAPD typically perform three to four exchanges during the day using dextrose-based solutions, followed by an overnight dwell. Patients on APD typically perform several exchanges during the night, followed by a day dwell. The choice of initial therapy is usually based on patient preference and suitability. Systemic anticoagulation is usually not required.

Apparatus

The PD set-up includes the catheter, dialysate solution, and connection and transfer sets (Figure 46.3). Dialysate solutions are supplied in prepackaged bags of sterile fluid with fixed concentrations of osmotic agents, electrolytes, and buffers. The type and concentration of the osmotic agent and the duration of the dwell determines the amount of fluid and solute removed during an exchange. Higher osmotic strength solutions remove more fluid and solute. The most common osmotic agents used are dextrose and icodextrin, a high molecular weight glucose polymer. The PD catheter consists of a distal intra-abdominal portion, a mid-portion that is implanted into the abdominal wall, and a subcutaneous track [28]. Variations of the catheter include the nature of the distal end of the intra-abdominal portion (straight vs. coiled), the number of cuffs used for implantation into the abdominal wall (one vs. two), and the design of the subcutaneous track (straight vs. permanently bent). The most common catheter in use is the two-cuff Tenckhoff catheter (Figure 46.4).

Prescription

Components of a typical PD prescription and variations are summarized in Table 46.3. The dialysis prescription requires frequent re-evaluation because the transport characteristics of the peritoneal membrane and the amount of residual native kidney function vary over time, leading to alterations in the amount of fluid and solute removal [29]. Peritonitis can also cause acute changes in membrane characteristics, requiring alteration in the PD prescription.

Complications

Infectious complications

PD catheter-related infections can be in form of an exit site infection, tunnel infection, or peritonitis. Exit and tunnel track infec-

Table 46.4. Diagnosis of peritonitis

tions present with local signs of inflammation and/or drainage. Peritonitis usually results from contamination of the peritoneal cavity during instillation or drainage of dialysate. Suggestive features and diagnostic criteria for peritonitis are shown in Table 46.4. Distinction from peritonitis due to intra-abdominal pathology should particularly be considered in the perioperative setting and usually requires abdominal imaging studies. Isolated and uncomplicated exit site infections can be eradicated with careful exit site care and antimicrobial (topical and oral) therapy. If the exit site infection progresses or concurs with peritonitis or a tunnel infection, the PD catheter must be removed [30]. Peritonitis is usually treated with intraperitoneal antimicrobial therapy, but catheter removal is necessary for fungal, mycobacterial, polymicrobial, refractory, or recurrent peritonitis.

Mechanical complications

The presence of an intraperitoneal catheter with a subcutaneous track and cutaneous exit site may weaken the abdominal wall, resulting in hernia formation. Pericatheter leaks manifest as subcutaneous swelling, reduced outflow volumes, or fluid accumulation around the catheter site. In some patients, abdominal or genital wall edema can develop and may require surgical intervention and/or cessation of PD [31]. The presence of a unilateral pleural effusion may indicate communication between the peritoneal and pleural space. Outflow failure is a common problem related to constipation or catheter-related problems, including malposition, kinking, intraluminal occlusion by thrombus, or compression by the omentum. The intra-abdominal portion of the catheter may rarely cause contusion or laceration to intra-abdominal organs, resulting in a bloody dialysate. Other causes of hemoperitoneum include cyst rupture in polycystic kidney disease patients, ovulation, endometriosis, or retrograde menstruation.

Peritoneal dialysis solution-related complications

Traditional PD solutions are lactate buffered, slightly acidic in pH, and contain dextrose which when metabolized leads to the production of glucose degradation products. All these factors render PD solutions somewhat bio-incompatible which may contribute to loss of peritoneal membrane function over time. Dextrose-based solutions can lead to systemic absorption of glucose with resultant metabolic abnormalities, including caloric loading, hyperglycemia, and dyslipidemia [27].

Continuous renal replacement therapies

The main types of continuous renal replacement therapies (CRRT) are continuous veno-venous hemodialysis (CVVHD), continuous veno-venous hemofiltration (CVVH), and continuous veno-venous hemodiafiltration (CVVHDF). The addition of hemofiltration allows convective clearance of larger molecules that are not removed by diffusion during HD alone.

Table 46.5. Comparison of typical continuous renal replacement therapy (CRRT) [continuous veno-venous hemodiafiltration (CVVHDF)] and conventional intermittent hemodialysis (HD) prescriptions

	CRRT	Intermittent HD
Prescribed daily duration (h)	24 (continuous)	4
Blood flow rate (mL/min)	100–200	250–350
Dialysate flow rate (mL/min)	15–45	300–800
Replacement fluid flow rate (mL/min)	15–45	N/A
Hourly ultrafiltration rate (mL/h)	50–150	100–1500
Dialysis membrane surface area	Usually smaller ($0.9–1.2\,m^2$)	Usually bigger ($1.8–2.5\,m^2$)
Anticoagulation options	**1** Regional citrate **2** Heparin **3** None	**1** Heparin **2** Citrasate dialysate **3** Danaparoid **4** Normal saline flushes
Composition of dialysate	Fixed (several available solutions)	Modifiable
Composition of replacement fluid	Fixed (several available solutions)	N/A

Compared to conventional HD, CRRT operates at lower blood and dialysate flow rates using smaller HD membranes, thereby making it a less efficient form of dialysis [32]. The inefficiency of the dialysis procedure is compensated for by prescribed continuous treatment over a 24-h period so that total daily solute and fluid removal can approximate that achieved with intermittent dialysis.

Technique

While the basic set-up of a CRRT circuit is similar to a conventional HD set-up, some noteworthy distinctions exist (Table 46.5). Most CRRT machines use prepackaged bags of sterile dialysate and replacement fluid. The electrolyte and buffer content within these bags is fixed and cannot be altered as can be done during conventional HD. Resultant derangements in patient electrolyte or acid–base balance therefore require systemic correction. The continuous nature of therapy usually precludes use of a pre-existing AVF/AVG and a dialysis catheter is preferred. Regional or systemic anticoagulation is required. Regional citrate anticoagulation is preferred in most critically ill patients.

Advantages, disadvantages, and indications

CRRT is better tolerated in hemodynamically unstable patients than conventional dialysis. CRRT provides slow but continuous removal of solutes and fluid, which can be adjusted in real time in response to changes in clinical and fluid status. In most patients, this facilitates administration of blood products, total parenteral nutrition, and medications by avoiding volume overload and electrolyte abnormalities.

The delivered dialysis dose is often much less than the prescribed dose in CRRT. Transient CRRT interruptions may be necessary for a variety of reasons, and it is difficult to compensate for this lost time with this slow modality. Despite advances in anticoagulation, the half-life of a CRRT dialysis filter is limited and filter replacement is typically required every 48–72 h [33]. The avoidance of systemic heparin administration with regional citrate anticoagulation requires frequent monitoring to avoid hypocalcemia, hypernatremia, and alkalosis. Therefore, CRRT is an expensive and labor-intensive dialysis modality [34].

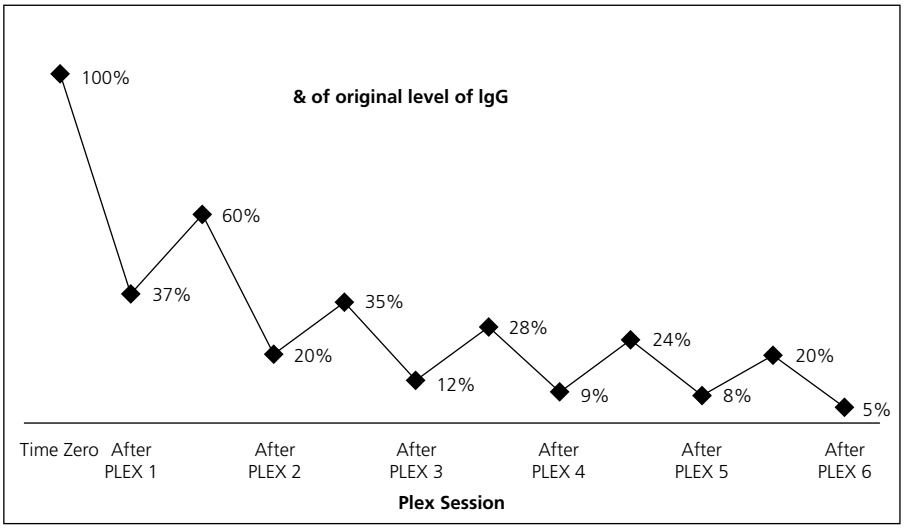

Figure 46.5. Serum levels of immunoglobulin G (IgG) after consecutive therapeutic plasma exchange (TPE; PLEX) treatments. The exchange of one plasma volume will typically lower plasma IgG levels by 65%. The removal of macromolecules with plasma exchange is limited by redistribution from the extravascular space after each treatment (rebound). Typically three to five treatments are required before a sustained reduction in antibody levels is achieved.

Despite its advantages, CRRT does not improve survival or renal recovery in critically ill patients [35]. Nonetheless, it is often the most feasible method to deliver dialysis in hemodynamically unstable patients. CRRT should not be used in clinical settings requiring rapid fluid or solute removal, including in patients with toxic ingestions and life-threatening hyperkalemia.

Therapeutic plasma exchange

Therapeutic plasma exchange (TPE) is an extracorporeal treatment designed to remove large molecular weight substances (e.g. antibodies, para-proteins) from the plasma or to replace deficient plasma factors.

Technique

Separation of plasma from blood can be performed by centrifugation or by membrane filtration [36]. Centrifugation is usually performed using a specialized centrifugal device. Advantages of centrifugation include the ability to remove and return blood from the peripheral venous circulation using two large-bore intravenous catheters and the ability to selectively remove cells from blood (cytapheresis). Disadvantages of this low-efficiency technique include longer treatment times, an increased frequency of thrombocytopenia, and complications related to use of citrate for anticoagulation. In contrast, membrane filtration uses a highly permeable membrane and a standard dialysis machine operating in ultrafiltration mode. Membrane filtration requires placement of a double lumen CVC to allow adequate blood flow rates. Although anticoagulation can be performed with citrate, heparin is commonly used.

When plasma is removed, the intravascular volume must be repleted to prevent hypotension. The choice of replacement fluid depends on the indication for TPE [37]. Fresh frozen plasma (FFP) replaces the normal plasma proteins and avoids depletion of coagulation factors or immunoglobulins. Disadvantages of FFP include increased risk of blood-borne disease transmission, transfusion-related lung injury, citrate-induced hypocalcemia, and urticaria, and rarely anaphylactoid reactions. FFP is only recommended when replacement of plasma factors is required, as in cases of HUS/TTP or bleeding risk. Albumin is favored as replacement fluid in most other conditions because it carries no risk of blood-borne disease transmission and minimizes the risk of allergic reactions. Saline in combination with albumin may be used when hyperviscosity or cost is a consideration. The rapid removal and infusion of protein-containing solutions during plasma exchange primarily involve the intravascular compartment; therefore, even small mismatches between removed and infused volumes can have a large impact on blood pressure. Accordingly, the amount of saline infused, which is distributed both intra- and extra-vascularly, should be limited to 20–40% of the total replacement volume.

The exchange of one plasma volume will typically lower plasma immunoglobulin G (IgG) levels by 65%, while an exchange of 1.5 $\times$ plasma volume lowers plasma levels by 75% [38]. The plasma volume that is exchanged is dependent on the patient's body weight and hematocrit (hct), and can be estimated using a simplified equation:

$$\text{Plasma volume} = 0.07 \times \text{weight (kg)} \times (1 - \text{hct})$$

The number of therapeutic exchanges is dictated by the indication for plasma exchange, patient tolerance, and clinical response. The removal of macromolecules with plasma exchange is limited by redistribution from the extravascular space after each treatment (rebound). Typically, three to five treatments are required before a sustained reduction in antibody levels is achieved, as shown in Figure 46.5. Table 46.6 shows a typical plasma exchange prescription along with common variations.

Complications

Reported rates of minimal reactions, including minor allergic symptoms (e.g. pruritus, hives), are between 5% and 10%. Rates of moderate reactions such as hypotension or cardiac arrhythmias (due to hypokalemia or hypocalcemia) are around 5%, while rates of severe anaphylactoid reactions are $<3\%$, with procedure-related mortality rates being very low ($<0.05\%$) [39].

Table 46.6. Therapeutic plasma exchange prescription

	Typical prescription	Alternatives
Mode	Centrifugal or membrane filtration	
Exchange volume	1 × plasma volume	1.0–2.0 × plasma volume
Replacement fluid	Albumin plus crystalloid (normal saline or Ringer's lactate)	Fresh frozen plasma
Plasma removal rate (mL/min)	60	30–100
Anticoagulation	Citrate (with prophylactic calcium infusion)	Heparin
Treatment regimen	Individualized based on indication and response to therapy	

Table 46.7. Pretransplant assessment of dialysis patients

Dialysis history	Date of first chronic dialysis treatment Timing and reasons for change in modalities
Dialysis access	Hemodialysis vascular access Peritoneal dialysis catheter
Dialysis adequacy	Clinical assessment of adequate dialysis Measurements of adequate dialysis
Residual renal function	Estimation of residual renal function Preservation of residual renal function
Management of chronic medications	Before transplantation After transplantation

Complications during TPE are more common when FFP is used as the replacement fluid, and include anaphylactoid reactions, severe bronchospasm, and transfusion-related lung injury. Allergic reactions may be more frequent in patients prescribed angiotensin-converting enzyme (ACE) inhibitors. Citrate contained within FFP or used for anticoagulation binds to calcium and reduces the ionized but not total calcium concentration, leading to a variety of symptoms including paresthesias, muscle cramps, nausea, vomiting, prolongation of QT and arrhythmia, hypotension, and tetany. Prophylaxis with intravenous calcium may be used (e.g. 10 mL of 10% calcium chloride infused over 30 min, beginning 15 min after initiation of plasma exchange). Citrate may also cause alkalemia, especially in patients with concomitant renal failure. Volume-related complications include hypotension and pulmonary edema due to a mismatch between fluid removal and replacement. Hypotension and dyspnea may also be due to complement activation owing to contact between the blood and filter in the extracorporeal circuit, or sensitivity to ethylene oxide that is used to sterilize the filter. Arrhythmias due to hypokalemia are observed with albumin replacement. Potassium is often added to albumin to minimize the risk of hypokalemia. Removal of clotting factors may predispose to bleeding. In patients at risk of bleeding, FFP may be indicated as a replacement fluid. Removal of immunoglobulins and complement can lead to an increased risk of infection, which may be aggravated by concomitant use of immunosuppressant agents. Plasma exchange removes drugs very efficiently; therefore, medications are typically administered following plasma exchange and increased monitoring of critical dose medications may be necessary.

Dialysis management considerations in renal and extrarenal transplant recipients

Kidney transplant candidates

Pretransplant evaluation

The initial pretransplant evaluation of kidney transplant candidates may occur anywhere from a few days to years before the date of transplantation. Table 46.7 shows the dialysis-related issues most relevant for transplantation.

Dialysis history

Knowledge of the date of first chronic dialysis treatment is essential to project the anticipated date of transplantation, and to devise an appropriate waitlist management plan. Although the timing of transplantation cannot be precisely determined for deceased donor candidates, knowledge of ABO blood group and panel reactive antibody (PRA) can provide a reasonable estimate of waiting time. Based on anticipated waiting time and co-morbid disease history, a waitlist management strategy, including need for longitudinal investigations and repeat medical or surgical evaluation, should be determined. Waitlist management is not covered in this chapter and the reader is referred to published literature on this topic [40–42].

Dialysis access

The site, type, and health of the current HD and PD access should be determined.

HD patients with multiple or prolonged use of CVCs are prone to the development of scarring and central vein stenosis, which may complicate establishment of central venous access at the time of transplantation. A history of frequent AVF/AVG thrombosis should be ascertained and may require further evaluation. It is unclear how patients with a history of recurrent vascular access thrombosis should be managed at the time of transplantation. Most commonly, the cause of thrombosis can be ascribed to vascular access stenosis, and no specific management prior to transplantation is necessary. In some cases, however, a thrombophilic work-up may be necessary to exclude a systemic clotting disorder, which may lead to allograft thrombosis. In cases where the only indication for anticoagulation is maintenance of vascular access and no thrombophilic disorder is identified, anticoagulants should not be required during or after transplantation.

In PD patients, details of previous PD catheter-related complications and reasons for previous PD catheter loss should be established. Removal of previous PD catheters due to serious peritoneal infection together with ongoing symptoms suggestive of intermittent abdominal obstruction or hemoperitoneum may suggest the presence of encapsulating peritoneal sclerosis, an infrequent condition that can complicate transplant surgery or lead to intermittent bowel obstruction after surgery [43].

Dialysis adequacy

An assessment of the dialysis adequacy consists of clinical assessment of signs or symptoms of uremia, supplemented by mathematical formulas to estimate the clearance of waste products during dialysis (Table 46.8). Various methods to estimate the clearance of metabolic waste products with either PD or HD are available but their description is beyond the scope of this chapter [44,45]. Inadequate dialysis can suggest problems with the dialysis access or dialysis membrane (in the case of PD patients) or non-adherence with the dialysis prescription. Modification of the dialysis prescription may be necessary to optimize patient management prior to transplantation.

Residual kidney function

Knowledge of residual native kidney function and urine output is necessary to assess immediate allograft function after transplantation. Because of the non-linear relationship between serum creatinine and GFR, a small change in GFR will cause a large change in serum creatinine in patients with advanced kidney disease. Residual kidney function should not be monitored by serum creatinine alone. A 24-h urine collection for urea and creatinine clearance can provide a more accurate assessment of residual kidney function. However, the usefulness of this test is limited because it is inconvenient for patients and prone to collection error. Further, tubular secretion of creatinine may result in overestimation of kidney function by this method.

A variety of serum creatinine-based equations have been developed to estimate kidney function, as detailed in Table 46.9 [46]. The Cockcroft–Gault equation predicts creatinine clearance based on age, weight, height, and plasma creatinine. The requirement for weight and height somewhat limit the use of this equation in clinical practice. Equations derived from the Modification of Diet in Renal Disease (MDRD) study do not require height and weight measurements and are now the most commonly used in clinical practice. The original six-variable MDRD equation required measurement of serum albumin and urea, and was surpassed by the simpler four-variable equation. The MDRD equation has not been validated in morbidly obese patients and in ethnic minority groups other than African–Americans. To overcome biased GFR estimates related to the method of serum creatinine measurement in the MDRD study, a unified effort to standardize creatinine measurements to the reference isotope-dilution mass spectrometry (IDMS) method was encouraged in laboratories around the world. With this, a new factor of "175" (as opposed to "186") was subsequently recommended in the MDRD equation for creatinine assays that are IDMS aligned. MDRD equations perform poorly in patients with near-normal kidney function, and in these situations the more recently developed Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation is preferred [47]. Either the Cockcroft–Gault equation or the MDRD equation may be used for monitoring kidney function in patients with advanced chronic kidney disease, including pre-emptive transplant candidates.

Residual kidney function is an important predictor of survival in dialysis patients [48]. Every effort should be made to preserve residual kidney function, especially in pre-emptive and PD patients. This includes avoidance of potentially nephrotoxic medications, hypotension, and radiocontrast agents. Expert consultation with the nephrologist should be sought when these insults are unavoidable as prophylactic measures to mitigate the nephrotoxicity of these insults may exist.

Medication management

The majority of medications prescribed to chronic dialysis patients are discontinued after surgery. However, there are certain chronic medications that will require dose adjustment after transplantation because of drug interactions with immunosuppressant medications or because of the establishment of kidney allograft function

Table 46.8. Assessment of dialysis adequacy

	Hemodialysis patients	Peritoneal dialysis patients
Clinical signs of symptoms suggestive of inadequate dialysis	Refractory hypertension Refractory congestive heart failure Progressive left ventricular hypertrophy Refractory hyperphosphatemia Refractory acidemia Confusion, altered cognition Nausea, vomiting Pruritus Unexplained fatigue	
Mathematical indicators of inadequate dialysis	Kt/V < 1.2 (target in clinical practice > 1.4) URR < 65% (target in clinical practice > 70%)	Weekly Kt/V < 1.7 Daily ultrafiltration volume achieved by PD <750 mL (or <250 mL if no residual renal function)

Kt/V, dialysis dose, where K is the dialyzer clearance (mL/min), t is the duration of dialysis treatment (min), and V is the volume of distribution of urea (mL)
URR, urea reduction ratio

Table 46.9. Equations used to estimate native kidney function

Equation	Formula	Variables
Creatinine clearance (mL/min) *Requires adjustment for body surface area*	$GFR = [U_{Cr} \times V]/S_{Cr}$	U_{Cr} = urine creatinine concentration (μmol/L) S_{Cr} = serum creatinine concentration (μmol/L) V = 24-h urine volume (L)
Cockcroft–Gault [creatinine clearance, (mL/min)] *Requires adjustment for body surface area*	[(140 – Age) × W (kg)/Cr × 72] × 0.85 (if female)	W = lean body weight (kg) Cr = serum creatinine concentration (mg/dL)
Original six-variable MDRD [GFR (mL/min/1.73 m^2)]	$170 \times S_{Cr}^{-0.999} \times Age^{0.176} \times BUN^{-0.170} \times Alb^{+0.318} \times 0.762$ (if female) x 1.18 (if black)	S_{Cr} = serum creatinine concentration (mg/dL) Age in years BUN = blood urea nitrogen concentration (mg/dL) Alb = serum albumin concentration (g/dL)
Modified four-variable MDRD [GFR (mL/min/1.73 m^2)]	$186.3 \times S_{Cr}^{-1.154} \times Age^{-0.203}$ x 0.742 (if female) x 1.21 (if black)	S_{Cr} = serum creatinine concentration (mg/dL) Age in years
Modified four-variable MDRD IDMS [GFR (mL/min/1.73 m^2)]	$175 \times S_{Cr}^{-1.154} \times Age^{-0.203} \times 0.742$ (if female) x 1.21 (if black)	S_{Cr} = serum creatinine concentration (mg/dL) Age in years
CKD-EPI [GFR (mL/min/1.73 m^2)]	$141 \times \min(S_{Cr}/\kappa, 1)^{\alpha} \times \max(S_{Cr}/\kappa, 1)^{-1.209} \times 0.993^{(age)}$ x 1.018 (if female) x 1.159 (if black)	S_{Cr} = serum creatinine concentration (mg/dL) κ = 0.7 for females and 0.9 for males α = –0.329 for females and –0.411 for males min = minimum of Scr/κ or 1 max = maximum of Scr/κ or 1 Age in years

GFR, glomerular filtration rate; MDRD, Modification of Diet in Renal Disease, IDMS, isotope-dilution mass spectrometry; CKD-EPI, Chronic Kidney Disease Epidemiology Collaboration.

Table 46.10. Peritransplant medication management

Medications that are usually stopped	Continued medications where dose adjustment may be necessary
Phosphate binders (e.g. calcium carbonate, sevalemer, lanthanum)	Insulin and oral hypoglycemic agents
Coumadin (if sole indication for vascular maintenance of vascular access)	Anticonvulsant medications
Platelet $P2Y_{12}$ receptor blockers* (clopidogrel, ticlodipine, prasugrel)	Aspirin
Vitamin D analogs (e.g. 1-α calcitriol)	Antiarrhythmic medications
Diuretics	Antidepressant medications
ACE inhibitors	Beta-blockers
Statins	Clonidine

*Depends on indication. Bare metal coronary stents require dual antiplatelet therapy with aspirin and $P2Y_{12}$ blocker for a minimum of 1 month and preferably 6 months. Drug-eluting stents usually require a minimum of 6 months and preferably 12 months of dual antiplatelet therapy. Consultation with a cardiologist is recommended.
ACE, angiotensin-converting enzyme.

(Table 46.10). A discussion of all potential medication adjustments is beyond the scope of this chapter, and consultation with the hospital pharmacist is advised to ensure patient safety.

Perioperative management

Dialysis in the immediate pretransplant setting

It is easy to overlook dialysis-related management issues at the time of transplantation. The absolute indications for dialysis immediately preceding transplantation are shown in Table 46.1. In the absence of absolute indications, dialysis is administered based on the timing of the last dialysis treatment, clinical evaluation of the patient, or when delayed graft function is anticipated based on donor characteristics or cold ischemic time.

Modifications to the pretransplant prescription

Heparin is typically eliminated from the HD prescription to minimize the risk of operative bleeding. Measurement of the serum potassium immediately prior to HD and adjustment of the potassium concentration in the dialysate minimize the risk of intraoperative hyper- or hypo-kalemia. Depending on the timing of surgery, the duration of HD may be lengthened to achieve target goal weight in hypervolemic patients. Concerns regarding activation of inflammatory mediators with pretransplant HD treatment, particularly with bio-incompatible membranes, remain theoretical. The widespread use of biocompatible membranes has diminished the relevance of this issue and biocompatible membranes are preferred for pretransplant dialysis treatments if possible.

PD can be continued until the time of surgery. Should acute correction of volume overload or hyperkalemia be necessary, rapid PD exchanges can be performed every 30–90 min if necessary, either manually or using a cycler machine [49]. Icodextrin should not be used during rapid PD exchanges. The peritoneal cavity should be emptied completely prior to surgery.

Patients on prolonged or more frequent dialysis regimens, including nocturnal dialysis, may have lower perioperative blood pressures, although rates of delayed graft function have not been shown to be higher in these patients [50,51]. Some centers routinely switch nocturnal dialysis patients to a conventional HD schedule for a period of 1 week prior to living donor transplantation to avoid the risk of post-transplant hypotension (personal communication, Chris Chan, Toronto General Hospital).

Dialysis access management

Preventative measures to protect AVF/AVGs should be prioritized in the perioperative period (see above) [52], and CVC catheters should be locked with anticoagulant preparation as per local dialysis unit practice prior to surgery. The PD catheter can be either removed or left in situ at the time of surgery for later removal. It is advantageous to maintain the PD catheter as this allows for the provision of dialysis after transplantation if required, while the major disadvantages of doing so are the risk of catheter-related infection, the need for catheter care after transplantation, and the need for a further procedure to remove the catheter [53]. This decision to maintain or remove the PD catheter should consider the likelihood of post-transplant dialysis and risk of PD catheter-related infection. The risk of peritonitis may be informed by history of peritonitis and clinical exam of the PD exit site prior to surgery [54].

Postoperative management

Determination of the need and timing of post-transplant dialysis

The absolute indications for dialysis after transplantation are shown in Table 46.1. In the unstable post-transplant patient, the overriding priority is patient safety, and the need for urgent dialysis may supersede the performance of diagnostic imaging tests to establish the cause of allograft dysfunction.

The presence of severe postoperative hyperkalemia is a medical emergency that requires temporizing medical management while preparations are made for urgent dialysis. This includes administration of intravenous bicarbonate, calcium, insulin, and glucose. Rectal administration of sodium polystyrene sulfonate (Kayexalate) may cause colonic dilatation or even perforation and is best avoided in the immediate postoperative period.

Oliguric or anuric patients are often volume expanded as a result of repeated volume challenges in the intraoperative or postoperative setting. Tolerance of hypervolemia is influenced by preexisting cardiopulmonary status, including history of congestive heart failure, valvular heart disease, chronic pulmonary disease, and sleep apnea, as well as body habitus (obesity). In such patients it may be advisable to limit volume resuscitation in the absence of hemodynamic instability. In situations where urine output is tenuous, it may be prudent to avoid extubation until urine output is established or until after dialysis is completed. Urgent volume removal may be achieved by conventional HD or isolated ultrafiltration.

The immediate postoperative physical evaluation should include confirmation of a functioning dialysis access. Fistula patency may be compromised and dialysis catheters may be displaced during surgery. Clinical exam of the fistula and radiographic confirmation of the location of a new or pre-existing central venous dialysis catheter is required prior to initiation of HD. Rarely, it may be necessary to access the dialysis catheter for infusion of critical medications, and the location of any indwelling dialysis catheter should be confirmed prior to use for non-dialysis indications. In the case of PD catheters, direct discussion with the transplant surgeon is necessary to confirm the integrity of the peritoneal membrane prior to performing PD.

Knowledge of pretransplant residual kidney function and urine output, as well as the timing of dialysis prior to transplantation is needed for the evaluation of allograft function in the oliguric patient. The anesthetic record should be reviewed to determine the

volume and type of intravenous solutions or blood products administered, the occurrence of hypotension or arrhythmia, amount of blood loss, and amount of intraoperative urine output. Review of the surgical record and discussion with the transplant surgeon is essential to understand any donor-related or surgical issues that may impact decision-making regarding the need or timing of dialysis in the immediate postoperative period.

The decision to proceed with dialysis may be informed by knowledge of allograft characteristics and intraoperative events. Specifically, transplantation from an expanded criteria deceased donor, prolonged cold or warm ischemic times, and a complicated vascular anastomosis may provide important prognostic information. Knowledge of the presence or absence of delayed graft function in the mate kidney may also be helpful.

Dialysis management of delayed graft function

In the absence of absolute indications, the decision to proceed with dialysis is often subjective and variable between transplant programs. Therefore, defining delayed graft function (DGF) by the use of dialysis in the first post-transplant week is problematic and contributes to variability in both the incidence and associated consequences of DGF in the literature. Further, because DGF has been associated with decreased allograft survival in some studies, defining DGF by the requirement for dialysis leads to the perception that dialysis itself is harmful to the allograft.

Experimental and clinical observations suggest that DGF may be prolonged by the exposure of blood to bio-incompatible dialysis membranes. Three small randomized trials in the late 1990s failed to show a difference in DGF between patients treated with biocompatible and bio-incompatible membranes [55–57]. Although none of these studies had sufficient power to definitively answer the question, the widespread use of biocompatible membranes has obviated the need for further studies.

Intradialytic hypotension may lead to hypoperfusion of the allograft, prolongation of DGF, or even graft thrombosis. In HD patients, more frequent and longer dialysis sessions as well as a cool temperature dialysis can prevent development of intradialytic hypotension [58]. Alternatively, isolated ultrafiltration can be performed to achieve isolated fluid removal, which is generally better tolerated. In patients with a functional PD catheter and no surgical contraindications, PD may be continued in the setting of DGF as this modality is generally associated with a lower risk of hypotension compared to HD. In hemodynamically unstable patients, CRRT is preferred and is recommended in patients requiring inotropic support.

Careful assessment of volume status and limiting or avoiding the use of medications known to aggravate hypotension are important management considerations. In particular, it may be beneficial to administer lymphocyte-depleting antibodies and HD on alternate days in patients with established DGF.

Post-transplant management

Hemodialysis catheters

In successful transplant recipients who do not require ongoing dialysis, arrangements are made for removal of the catheter within the first few weeks after transplantation to avoid the risk of catheter-related infection. While the catheter is in situ, the health of its tunnel and exit site should be regularly assessed and the catheter should be flushed and locked weekly with an anticoagulant until removal.

Hemodialysis, arteriovenous fistulas, and grafts

Spontaneous AVF/AVG closure occurs in the minority of patients [59]. There is no consensus on routine surgical closure of functioning AVF/AVGs in patients with established allograft function [60]. Advantages of maintaining the fistula include access for future dialysis and avoidance of surgery. Fistula maintenance may be favored in patients who have exhausted vascular access options in the past. Disadvantages include a potentially deleterious effect on cardiac function [61]. Cardiac failure has been reported in dialysis patients with pre-existing cardiac disease after fistula creation [62].

Studies examining the impact of surgical fistula closure in transplant recipients have produced conflicting results. Two small prospective observational studies have shown improved echocardiographic cardiac dimensions, but it is unknown whether these changes will result in improved patient outcomes and routine surgical closure of AVFs cannot be recommended [63,64]. Potential indications for surgical closure of AVFs include worsening cardiac hemodynamics, fistula-related complications (e.g. infection or steal syndrome), and safety considerations in patients involved in high-risk activities [60].

Peritoneal dialysis catheters

PD catheters should be flushed and inspected weekly for signs of infection until removal. Timely removal is indicated to minimize the risk of exit site infection or peritonitis [65].

Heart transplant candidates

Chronic dialysis patients awaiting transplantation

A complex interplay of factors, including decreased cardiac output, deranged neurohormonal pathways leading to salt and water retention, and medication effects make it difficult to remove fluid in dialysis-dependent patients awaiting heart transplantation [66]. Conventional HD is particularly poorly tolerated due to the rapid shifts in fluid and solute. An increase in the frequency and/or duration of dialysis treatments may be required to manage these patients. PD may be the ideal dialysis modality because fluid and solute removal is achieved gradually and is generally better tolerated [67].

Patients with decompensated heart failure not requiring dialysis

In heart failure patients without end-stage kidney disease but with diuretic resistance or acutely decompensated heart failure, peripheral veno-venous ultrafiltration (UF) and slow continuous UF can facilitate fluid removal. In a non-blinded study, 200 patients with acute decompensated heart failure were randomized to treatment with UF or diuretics. There was no difference in the primary endpoint of 48-h weight loss and improved dyspnea. However, there was a greater reduction of mean weight and net fluid loss, as well as lower rates of rehospitalization within 90 days in the UF group as compared to the diuretic group. There was no difference in kidney function and less hypokalemia in the UF group. Proposed mechanisms for the sustained improvements in the UF group include removal of isotonic fluid with UF compared to hypotonic fluid removal with diuretics [68]. UF may provide an important alternative to high doses of diuretics for decompensated heart failure, especially in patients with some degree of kidney dysfunction or diuretic resistance. However, further studies are needed before UF can be routinely employed as a management strategy for advanced heart failure patients.

Critically ill patients in need of acute dialysis

In the setting of cardiogenic shock, CRRT is the preferred dialysis modality. When CRRT is not available, the conventional HD circuit and prescription can be modified to simulate the technical characteristics of CRRT. Performance of frequent (ideally daily) and long (>8 h) dialysis sessions with low blood and dialysate flow rates can approximate the operating characteristics of CRRT. This technique [slow, low efficiency dialysis (SLED)] has been shown to be as well tolerated as CRRT in hemodynamically unstable patients [69].

Patients with mechanical assist devices

Dialysis-specific considerations in patients requiring cardiac support by intra-aortic balloon pump or ventricular assist devices include knowledge of the intravascular location of the device, site of percutaneous access, and type of anticoagulation [70]. A potentially dangerous interaction between a continuous veno-venous hemodialysis (CVVHD) system and an intra-aortic balloon pump (IABP) counter-pulsation device has been reported [71]. Electrical interference created by the roller pump action of the CVVHD system was identified by the balloon pump as cardiac in origin, and it responded by inflating and deflating. Interference between different electrical support systems may occur, and systems should be tested for compatibility before their combined use.

Patients on extracorporeal membrane oxygenation

Patients in refractory cardiogenic shock with hemodynamic collapse may require complete cardiopulmonary bypass in the form of veno-arterial extracorporeal membrane oxygenation (VA-ECMO) [72]. During conventional VA-ECMO, a large volume of blood is extracted from the femoral vein, circulated by a mechanical pump through an oxygenator and heat exchanger where hemoglobin is saturated with oxygen and carbon dioxide is removed, and subsequently returned into the femoral artery. Initial blood flow rates through the ECMO circuit are between 4 and 5 L/min. The ECMO circuit requires continuous systemic anticoagulation and is associated with significant risk of both hemolysis and bleeding.

ECMO patients in cardiogenic shock frequently develop acute kidney injury requiring renal replacement therapy. This may be delivered using one of three methods [73–75]. The first method is to establish a separate vascular dialysis access and run the CRRT circuit independently from the ECMO circuit. This may be challenging in the face of limited venous access and systemic anticoagulation during ECMO. The second method is through the in-line inclusion of a HD membrane after the membrane oxygenator. A limitation of this method is that it does not allow dialysis parameters to be controlled separately from ECMO parameters. The third method is to siphon off a portion of blood from the ECMO circuit, process it through a CRRT circuit, and subsequently return it back into the ECMO circuit to undergo membrane oxygenation. Local center and physician experience should dictate which method is used.

Intraoperative dialysis

Hemodialysis can be performed intraoperatively by connecting a HD circuit in series with a cardiopulmonary bypass pump (CBP). This allows for control of electrolytes (especially potassium) and fluids during surgery and may avoid the need for urgent HD immediately after surgery [76].

Dialysis after cardiac transplantation

Patients requiring dialysis after cardiac transplantation can be treated with either CRRT or conventional HD. Special attention should be paid to anticoagulation of the dialysis circuit and volume assessment, which can be difficult due to the presence of right ventricular strain or failure. Patients established on PD may continue with this modality after transplantation as long as volume status and ventilation parameters can be managed. Rapid PD exchanges (every 30–90 min) using low fill volumes may be required to manage volume overload.

Liver transplant candidates

Patients with liver disease who develop kidney dysfunction are at high risk of death [77]. As discussed in Chapter 43, their management is challenging and often requires support for concomitantly failing kidneys. Dialysis should only be offered to liver failure patients who have acute kidney injury that is expected to recover, and liver transplant candidates or patients undergoing evaluation for liver transplantation [78]. Dialysis is technically difficult due to systemic vasodilation and shunting leading to systemic hypotension, reduced plasma oncotic pressure due to malnutrition and decreased hepatic function, and coagulopathy and thrombocytopenia leading to increased risk of bleeding [79]. Reduced hepatic clearance of vasodilatory molecules leads to decreased effective circulating volume and increased salt and water retention. The resultant volume overload with ascites and peripheral edema is difficult to remove during HD in the face of systemic hypotension.

The decision to treat patients with intermittent dialysis or CRRT is based on hemodynamic stability and tolerability. Theoretic advantages of CRRT include more gradual correction of hyponatremia, and less fluctuation in intracranial pressure [78]. Regional citrate anticoagulation of the CRRT circuit should be avoided as it can lead to citrate toxicity in patients with impaired liver function [33]. Alternatives include high-flow CRRT without anticoagulation and regional heparin–protamine anticoagulation. CRRT is favored in patients with fulminant hepatic failure because in contrast to conventional HD it does not increase intracranial pressure [80].

While achieving reasonable small solute and uremic toxin removal, conventional HD modalities do not provide adequate clearance of larger and protein-bound toxins that accumulate in hepatic failure. In patients with severely impaired hepatic function, there may be a benefit to maximizing clearance of larger molecules that accumulate due to impaired hepatic clearance, and modalities that utilize hemofiltration may be of value, but these require further study [81,82].

PD may be the most feasible dialysis modality in some liver failure patients. Advantages over HD include no need for anticoagulation, more gradual and better tolerated fluid removal, continuous solute clearance, drainage of ascitic fluid, and caloric loading with dextrose-based PD solutions. Disadvantages include potential protein losses into the dialysate [83]. Historic concerns regarding higher rates of peritonitis and patient drop-out due to impaired manual dexterity to perform exchanges remain unproven.

A number of new techniques have been developed to provide support for patients with combined liver and kidney failure. These include membrane- and adsorbent-based systems to provide dialysis and detoxification (e.g. hemoperfusion, hemodiabsorption, plasmapheresis, and selective plasma filtration therapy), as well as

cell-based therapies to replicate the metabolic functions of the liver. None of these approaches has been rigorously tested and should be considered experimental. The MARS (molecular adsorbent recirculation system) removes albumin-bound toxins by albumin dialysis and CRRT [84]. Albumin dialysate is regenerated using a combination of charcoal adsorption and an anion exchange resin. MARS has been studied in a small number of patients with hepatorenal syndrome and was associated with improved survival and hemodynamics compared to hemodiafiltration [85]. Other studies have failed to show any benefit in patients with hepatorenal syndrome that is resistant to vasoconstrictor therapy [86]. A similar but less complex system, single pass albumin dialysis (SPAD) uses a conventional HD circuit, but infuses albumin as the dialysate. Albumin is passed once through the dialysis circuit and then discarded. Preliminary comparisons of SPAD to MARS suggest similar efficacy [87].

During liver transplantation, the inferior vena cava and portal vein are cross-clamped during hepatectomy, which reduces venous return and cardiac output by 40–50%. Following completion of the portal anastomosis, portal unclamping results in large amounts of desaturated blood, potassium, and lactic acid entering the main circulation, which induces hypotension, hyperkalemia, metabolic acidosis, and coagulopathy (the post-reperfusion syndrome) [88,89]. Commonly, large amounts of blood and plasma products may be required intraoperatively. In an effort to mitigate the impact of these factors, intraoperative dialysis (administered as CRRT) has been performed in patients undergoing liver transplantation, with successful intraoperative fluid, acid–base balance, and electrolyte management. This may apply in particular to patients with severe renal dysfunction or who require renal replacement preoperatively. There is considerable experience with intraoperative CRRT in selected centers; however, studies are needed to clarify the indications for intraoperative CRRT [89,90].

Summary

Dialysis provides limited but reliable and sustainable clearance of metabolic waste products, and in doing so controls the uremia, acute electrolyte disturbances, and volume overload associated with renal failure. Numerous forms and methods of dialysis exist. These have been adapted to various settings of renal failure, from the temporary support of a critically ill patient awaiting renal recovery, to the long-term support of a patient awaiting a kidney transplant or in whom transplantation is not an option, to a destination therapy. Given that renal failure often accompanies liver and heart failure, the use of dialysis is a critical supportive modality influencing not only kidney transplantation, but also heart and liver transplantation. The practice of dialysis, and the myriad methods of access required for dialysis, remains a critical part of any transplant clinician's armamentarium.

CHAPTER 47

The Artificial Liver, in vivo Tissue Engineering, and Organ Printing

Igor M. Sauer, Nathanael Raschzok, and Peter Neuhaus
General, Visceral, and Transplantation Surgery, Experimental Surgery and Regenerative Medicine, Universitätsmedizin Berlin, Berlin, Germany

Introduction

Liver transplantation has evolved since 1963 from an experimental procedure to the standard treatment for the life-threatening syndrome of liver failure. Success in liver transplantation is increasingly limited because of donor organ scarcity. To address the growing disparity between the numbers of suitable donor organs and patients waiting for transplantation, efforts have been made to optimize the allocation of organs, find alternatives to deceased donor liver donation, and develop extracorporeal methods to support or replace the failing organ. Clinicians and basic scientists earnestly look for alternative procedures and technical substitutes for conventional transplantation. To expand the donor pool, the procurement of marginal organs and donation after circulatory death have become more widely accepted. However, organ and patient survival is reduced with these alternatives. Liver support devices are used to improve outcome by providing an environment for regeneration of the patient's organ ("bridging to regeneration") or to support the patient until liver transplantation can be performed ("bridging to transplantation"). Liver cell transplantation (LCT) was developed as a therapeutic alternative to solid liver transplantation in the management of liver-based metabolic disorders and may be useful for the treatment of acute or chronic liver failure. Bioprinting, or the layer-by-layer additive biofabrication of tissue and organoid constructs, and the decellularization of donor organs to provide an acellular, natural three-dimensional biologic scaffold are emerging technologies that promise to transform tissue engineering. This chapter will summarize the latest developments in extracorporeal liver support, LCT, and highly innovative bioengineered alternatives to conventional orthotopic liver transplantation (OLT). It complements Chapters 38 and 43, which discuss the care of patients awaiting liver transplantation and the intensive care of patients in liver failure, respectively.

Extracorporeal liver support

Liver support devices are intended to improve the clinical course of the patient in liver failure by providing an environment for regeneration of the patient's organ ("bridging to regeneration") or to support the patient until liver transplantation can be performed ("bridging to transplantation"). Therefore, a liver support device should provide the three main functions of the liver: detoxification, synthesis, and regulation.

The most critical issue of the clinical syndrome in liver failure is understood to be the accumulation of toxins not cleared by the failing liver. Based on this hypothesis, the removal of lipophilic, albumin-bound substances, such as bilirubin, bile acids, metabolites of aromatic amino acids, medium-chain fatty acids, and cytokines, should be beneficial to the clinical course of a patient in liver failure. This theory has led to the development of artificial filtration and adsorption devices—so-called *artificial liver support* devices. The complex tasks of regulation and synthesis remain to be addressed by the use of liver cells—made available in *bioartificial liver support systems*.

Artificial liver support

Artificial liver support systems intend to support or replace the detoxification functions of the liver. Plasma exchange, widely performed in the 1980s, has recently re-emerged as a treatment option. A large multicenter trial by Larsen et al. demonstrated a significant improvement in transplant-free survival when patients with (hyper) acute liver failure (ALF) were treated with three sessions of high-volume (10 L) plasma exchange [1]. Conventional hemodialysis (HD) and continuous veno-venous hemodiafiltration (CVVHDF) have been shown to be effective in the removal of water-soluble toxins. To clear the blood of albumin-bound, hydrophobic substances, additional adsorber or acceptor substances are necessary to enhance mass exchange. Most artificial liver support devices are based on membrane separation associated with sorbents, including charcoal and anion or cation exchangers. Because albumin is the predominant carrier of toxins in the patient's blood, it may also serve as an appropriate acceptor substance. Based on this idea, albumin has been added to the dialysate of modified HD systems. Stange and Mitzner from Rostock, Germany introduced a detoxification system based on albumin dialysis, the *molecular adsorbent recirculation system* (MARS; Gambro, Stockholm, Sweden) [2]. An albumin solution, which is separated from the patient's blood by a high-flux HD filter, is circulated in a closed circuit (Figure 47.1A). The albumin acts as the acceptor substance for albumin-bound toxins and is partly regenerated by passing an anion exchanger and a charcoal adsorber in a closed circuit. *Single-pass albumin dialysis* (SPAD) is a simple method of albumin dialysis using standard renal replacement therapy machines without an additional perfusion pump system, in which the patient's blood flows through a circuit with a high-flux hollow-fiber hemodiafilter. The other side of this

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

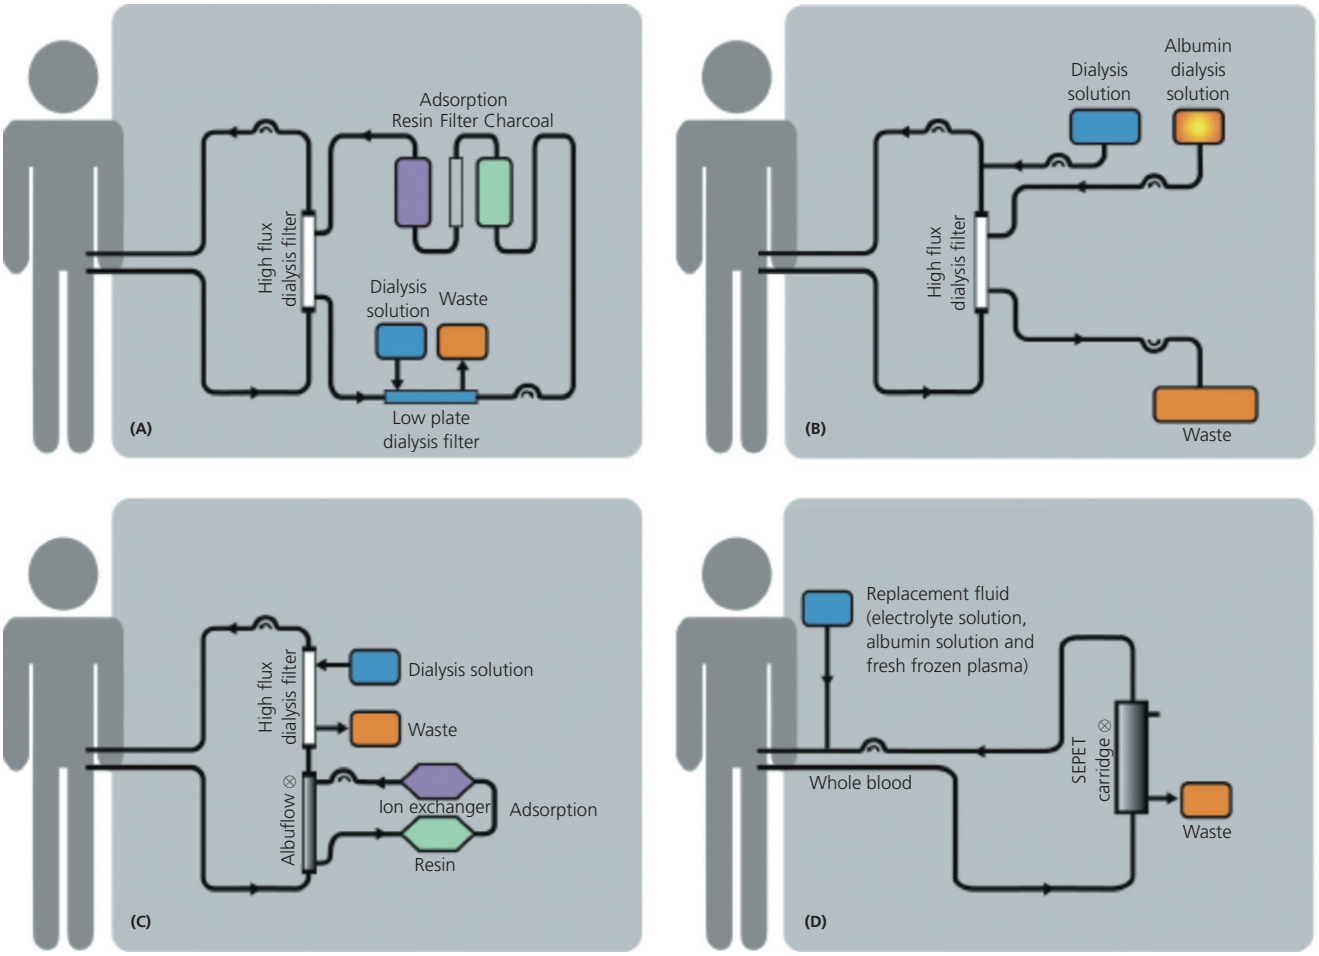

Figure 47.1. Artificial liver support systems. (a) The molecular adsorbent recirculation system (MARS); (b) single pass albumin dialysis (SPAD); fractionated plasma separation and adsorption (FPSA, Prometheus), and (d) the selective plasma filtration therapy (SEPET). (Reproduced from Jörres A, Ronco C, Kellum JA. (2009) Management of acute kidney problems: Extracorporeal liver support, with kind permission of Springer Science + Business Media.)

membrane is cleaned with an albumin solution in counter-directional flow, which is discarded after passing through the filter (Figure 47.1B) [3].

The use of membranes with larger pores, separating a certain fraction of plasma proteins, including the toxin-loaded albumin from the patient's blood, is a second approach. *Fractionated plasma separation and adsorption* (FPSA; Prometheus, Fresenius Medical Care, Bad Homburg, Germany) allows the patient's own albumin to be regenerated via passage through two adsorption matrices in a secondary circuit (Figure 47.1C). In contrast to SPAD and MARS, an albumin-permeable polysulfone membrane is used to filter the patient's albumin fraction into the secondary circuit, where direct purification from albumin-bound toxins by different adsorbers takes place. Afterward, conventional high-flux dialysis is performed inside the primary circuit [4].

Selective plasma-exchange therapy (SEPET; Arbios Systems, Allendale, NJ, USA), developed by Rozga et al., attempts to combine the advantages of SPAD with the advantages of Prometheus (Figure 47.1D). As in the Prometheus system, the fractionated plasma passes through an albumin-permeable, size-selective membrane. Substances with a molecular weight (MW) of <100 kDa are removed, whereas larger molecules (MW >100 kDa), including immunoglobulins, complement system proteins, most blood-clotting factors, and stimulators of hepatic regenerative response, are largely retained in the blood circulation. However, as in the SPAD system, there is no regeneration. Instead, the albumin fraction containing the patient's toxins is discarded and replaced by an electrolyte solution, albumin solution, and fresh frozen plasma [5].

The *BioLogic-DT* system developed by Ash et al. combines hemodiabsorption with push–pull, sorbent-based pheresis that is based on a cellulosic plate dialyzer with a suspension of powdered charcoal and cation exchangers as dialysate. The system was redesigned and renamed the *liver dialysis device* (HemoCleanse, Lafayette, IN, USA), but is no longer marketed [6].

Bioartificial liver support

Artificial liver support devices only support the failing detoxification function of the diseased liver. As the liver does more than detoxify, the clinical syndrome of the failing liver will most likely also be determined by the failing regulatory (e.g. acid–base status, amino acids) and, even more importantly, synthetic functions (e.g. albumin, glucose, lipids, coagulation factors, even unknown substances). These tasks have to be addressed with the use of liver cells.

Extracorporeal liver perfusion, initially performed in the 1960s, requires complex logistics because the organ has to be freshly explanted prior to the treatment session and then connected to the patient's blood circulation under sterile conditions. To address these problems, several different liver support bioreactors were developed, which enabled the cultivation of isolated liver cells in a more suitable mode for integration into clinical perfusion systems and for prolonged cell culture times.

The *HepatAssist* system developed by Demetriou et al. is based on 5–7 $\times$ 10^9 cryopreserved porcine hepatocytes within the intercapillary space of a device resembling a modified dialysis cartridge. The patient's plasma ultrafiltrate is passed through the cartridges via an activated charcoal adsorber and an oxygenator [7].

The *extracorporeal liver assist device* (ELAD), developed by Sussman et al., uses approximately 200 g of cells of a cell line originating from human hepatoblastoma (C3A, derived from HepG2) in a similar setting. The cells are separated from the patient's plasma by hollow-fiber membranes, and an integrated charcoal adsorber and a membrane oxygenator support detoxification and maintain the oxygen supply of the cells [8].

A bioreactor introduced by Gerlach et al. in the 1980s was later integrated into the *modular extracorporeal liver support* (MELS) system. The bioreactor consists of two hydrophilic polyethersulfone membrane bundles and a hydrophobic multilayer hollow-fiber bundle for oxygenation. The bioreactor is charged with primary porcine [9] or human liver cells [10]. MELS combines this bioreactor with CVVHDF and SPAD for the removal of water-soluble and albumin-bound toxins, respectively.

The *Academisch Medisch Centrum bioartificial liver* (AMC-BAL), developed by Chamuleau et al., differs from other clinically applied systems in one major aspect: the patient's plasma is in direct contact with the cells rather than separated from the extracorporally applied liver cells by a membrane. Within a cylindrical housing, a nonwoven polyester matrix offers a large surface area to which the inoculated primary porcine cells can attach and form aggregates between the fibers [11].

Evaluation

The design of clinical studies with respect to liver failure is difficult. ALF and acute on chronic liver failure (AoCLF) are very heterogeneous diseases with respect to the capacity for parenchymal regeneration and prognosis. In ALF, liver support treatment will usually be terminated within 24–48 h of the patient being listed for high urgency liver transplantation due to organ availability. Additionally, sensible clinical endpoints are lacking [12].

There is a lack of appropriate randomized controlled and adequately powered studies because most clinical studies are nonblinded and uncontrolled. There are significantly more clinical data available for artificial liver support systems than for bioartificial concepts.

A Cochrane systematic review of extracorporeal liver support systems for clinical use in ALF and AoCLF, which reviewed articles published before September 2002, concluded that these systems had no significant effect on mortality, but there appeared to be a survival advantage in AoCLF [13]. More recently, Stutchfield et al. published a meta-analysis with more stringent criteria for selection of randomized controlled trials (RCTs) concerning the effect of extracorporeal liver support on survival in both ALF and AoCLF. A systematic review of the wider effects of extracorporeal liver support on clinical and biochemical parameters was also undertaken [14]. Stutchfield et al. included 74 clinical trials (17 RCTs, five case–controlled studies, and 52 cohort studies). Eight RCTs investigating the effects of extracorporeal liver support in ALF (three studies, 198 participants) and AoCLF (five studies, 157 participants) were suitable for inclusion. In six studies, artificial liver support devices (five for MARS, one for Biologic DT) were used; two studies evaluated bioartificial systems (ELAD and HepatAssist). None of the included trials reported a significant difference in adverse events between the group treated with extracorporeal liver support devices and the group treated with standard medical therapy. No specific biocompatibility issues were raised by any of the trials. Interestingly, overall extracorporeal liver support therapy significantly improved survival in ALF (risk ratio 0.70; $P = 0.05$). No significant survival benefit was demonstrated in AoCLF (risk ratio 0.87; $P = 0.37$).

The results of the HELIOS trial, a randomized controlled European multicenter trial of Prometheus/FPSA therapy in a total of 145 patients with AoCLF, were not included in the above meta-analysis. In the HELIOS trial, there was no statistically significant difference in the overall survival between the study groups. However, a significant survival benefit was observed with FPSA therapy in two predefined subgroups, namely patients with hepatorenal syndrome type I and those with a Model for End-stage Liver Disease (MELD) score of >30 [4].

Compared with the large clinical effects of liver grafting after transplantation, these results appear limited and ask a number of questions. Are the concepts being evaluated inadequately? Are the concepts right but their scale too small and performances too low? Most studies have evaluated artificial liver support systems—are biological components mandatory? Cell-based, bioartificial liver support systems address all of the complex tasks of detoxification, regulation, and synthesis, but have some biological and physical limitations in common: most of these systems use hollow-fiber membranes, which limit the mass exchange between the patient's blood and extracorporeal liver cells. For technical reasons, the perfusion of bioreactors is limited to 100–300 mL/min of plasma, which is rather low compared with the blood flow rate of the natural human liver in situ of approximately 1500 mL/min. Therefore, the maximum clearance rate for any substance in the bioreactor, which involves the plasma volume passing through the bioreactor, must be expected to be much lower than in the human liver. Another characteristic of current bioreactors is the absence of functional biliary excretion into a dedicated compartment. Liver cells in three-dimensional culture conditions can form functional bile canaliculi, but it is unknown to what extent biliary compounds still accumulate intracellularly and whether these will shorten the vitality of the cells [15]. However, this concern can be addressed by the addition of certain detoxification components, such as SPAD in the MELS concept or the charcoal adsorber in the ELAD concept.

Finally, liver cell mass and source appear to be limited. Usually, bioreactors in liver support systems are charged with 100–200 g (some bioreactors even contain 600 g) of hepatic parenchymal cells, which seems to be insufficient. In living donor liver transplantation (LD-LTx), a graft size of 40% or less of the recipient's ideal liver mass (approx. 1500 g) is likely to be insufficient to meet the recipient's metabolic needs, and the recipient is at risk of suffering graft failure [16]. An even higher number of cells must be provided when they are applied within an extracorporeal circuit—especially with respect to the limitations of plasma flow and mass exchange [17].

The dominant limitation of all bioartificial support systems is still the cell source. Widely available cells, unfortunately, are associated with the metabolic incompatibility and risk of xenozoonosis

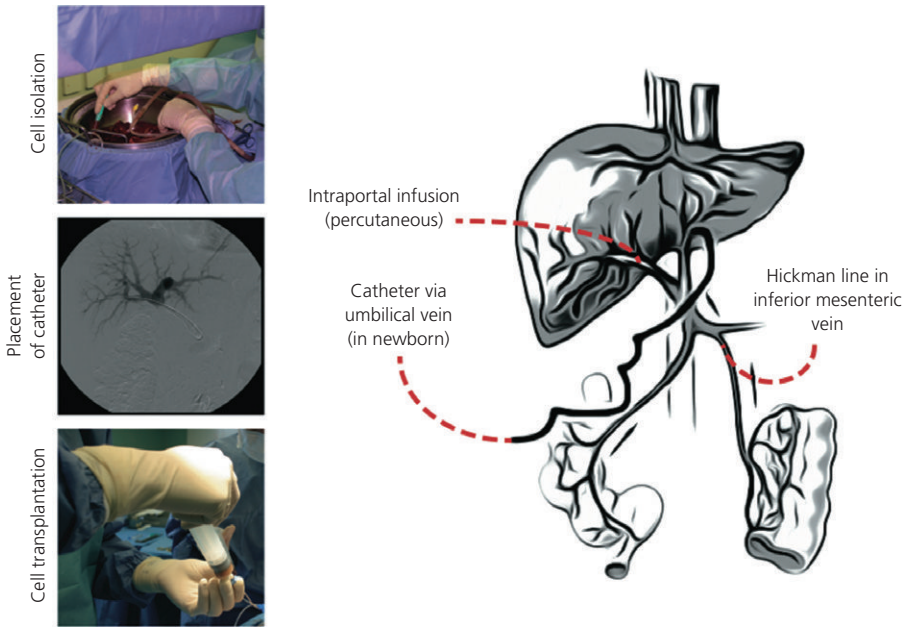

Figure 47.2. Liver cell transplantation. Hepatocyte transplantation is based on the administration of isolated liver cells in suspension. Liver cells are isolated from donor livers using enzymatic perfusion technique. Hepatocytes are infused into the liver of the recipient through the portal circulation. Vascular access to the portal system is performed by percutaneous or transjugular hepatic puncture, umbilical vein catheterization, or insertion of a Hickman line in the inferior mesenteric vein.

(porcine cells) or with the risk of metastases and a lower liver-specific metabolic performance (tumor cell lines). The use of primary human liver cells is increasingly favored for clinical application. Discarded donor organs might serve as a source for the isolation of primary human hepatocytes. However, in addition to their limited availability, primary human liver cells originating from these organs are impaired with respect to their metabolism and regenerative capacity because of histological alteration, preservation, and isolation processes. Until we can establish a reliable, safe, highly metabolically active and easily expandable human cell source, a successful breakthrough in bioartificial liver support systems appears to be unlikely.

Liver cell transplantation

LCT was developed as a therapeutic alternative for solid liver transplantation in the management of liver-based metabolic disorders and acute or chronic liver failure [18]. LCT is based on the administration of isolated liver cells in suspension (Figure 47.2). Liver cells are isolated from donor livers or liver lobes rejected or unused for whole organ transplantation [19]. Cell isolation is performed using collagenase perfusion techniques, followed by centrifugation for cell purification. Hepatocytes are transplanted immediately following isolation or after cryopreservation and thawing. Isolated hepatocytes are infused into the liver of the recipient through the portal circulation or transplanted to an ectopic implantation site, e.g. the spleen or peritoneum. Intraportal infusion is currently the main cell delivery route, with the liver serving as a biological matrix for the transplanted hepatocytes. Vascular access to the portal system is gained by percutaneous or transjugular hepatic puncture, inferior mesenteric vein catheterization, or, in infants, revascularization of the umbilical vein. Hepatocytes that accumulate in the portal periphery, which causes transient local hypertension and ischemia-reperfusion injury, adhere to the activated endothelium, translocate through the sinusoidal fenestration, and engraft in the liver plates. Under the appropriate conditions, e.g. in the presence of a regenerative stimulus or survival advantage, donor hepatocytes proliferate and replace the recipient liver. The infusion of up to 10^8 cells/kg of body weight can be safely performed under continuous monitoring of the portal pressure and lead to a replacement of 5% of the recipient liver cell mass [20].

From a conceptual point of view, cell transplantation offers various advantages compared with whole organ transplantation:

1. Liver cells can be cryopreserved and stored in cell banks, which enables timely and scheduled applications.
2. Cell infusions are less invasive than whole-organ transplantation, offering the chance to treat critically ill or very young patients who are not suitable for whole organ transplantation.
3. The native liver is left in place, allowing its potential recovery and meaning that graft failure need not be life threatening.
4. Cell infusions can be dosed according to the individual needs of the recipient, and the cells can be genetically modified or labeled with a contrast agent prior to their transplantation.

Based on preclinical studies in animal models of ALF or metabolic disorders, which have demonstrated improved survival or improvements in biochemical abnormalities, clinical LCT has been developed over the last 10 years, and current reviews list over 80 case reports of clinical human hepatocyte transplantation from approximately 13 centers [21]. This section will discuss the current status of clinical LCT for the treatment of metabolic liver disorders, ALF, and chronic liver diseases, and highlight the conceptual and practical limitations.

Treatment of metabolic liver diseases

Among all indications, LCT is currently most effective in the treatment of inborn metabolic liver disorders. In cases where a specific

gene is missing, donor hepatocytes expressing the gene are transplanted to replace the missing function without the need to replace the whole organ. The transplanted cells integrate into the normal host liver and improve specific functions of the failing liver, without the need to replace all hepatic functions. Approximately 35 children and adults who received LCT for liver-based metabolic liver disease have been reported in the literature, with the majority of studies performed within the last few years [21–24]. In all cases, LCT was performed through intraportal infusion, by single or repeated infusion, using both fresh and cryopreserved cells. As a first attempt to treat metabolic liver disorders with hepatocytes, Grossmann et al. described LCT for the treatment of familial hypercholersterolemia in 1994 [25]. They isolated autologous hepatocytes from liver tissue resected from five adult patients, transduced the cells in vitro with an LDL receptor expressing retroviral vector, and infused these intraportally 3 days after resection, taking advantage of the regeneration stimulus after partial hepatectomy. The authors observed an approximately 20% reduction in LDL cholesterol levels, but transgene expression declined early after transplantation. Today, patients with urea cycle defects are the most common group of patients to undergo LCT [21]. Among them, 10 children (aged 1 day to 5 years) with ornithine transcarbamylase (OTC) deficiency showed decreased ammonia levels after LCT and could be successfully bridged to OLT in most cases. Two patients with citrullinemia and one patient with arginine succinylase deficiency were metabolically stabilized. Eight cases of Crigler–Najjar syndrome type 1 treated with hepatocytes have been reported. The patients showed a 30–60% decrease in bilirubin levels after the intraportal infusion of 5% of their calculated liver mass. However, OLT was necessary after a few months in most of these cases. Other conditions under which individual patients have been successfully treated with LCT are glycogen storage disease, Refsum syndrome, and Factor VII deficiency.

In conclusion, the published cases indicate that LCT is safe and feasible for at least the temporal treatment of metabolic liver disorders. Major medical complications associated with LCT for the treatment of metabolic disorders have not been described in the literature. However, the correction of metabolic deficiency has been temporary in most cases, indicating declining activity of the transplanted cells due to insufficient engraftment [26] or graft rejection [27]. Moreover, the lack of controlled trials makes the interpretation of these findings difficult.

Treatment of acute liver failure

Based on small animal studies with D-galactosamine poisoning, in which splenic, portal, and peritoneal hepatocyte transplantation was shown to reverse the disease, LCT has been investigated in humans with ALF as a bridge to recovery of the native liver or to OLT [28,29]. Fisher et al. reviewed 37 patients with ALF who were allotransplanted with human hepatocytes [30]. Among them, 10 children were treated with intraportal hepatocyte infusion. Three children were successfully bridged to OLT and two children recovered without OLT. Of the 27 adults transplanted with hepatocytes, four could be bridged to OLT and five showed full recovery without organ replacement. Of the 13 adult patients who received cells into the spleen, three were successfully bridged to OLT and one recovered fully. Cell infusion-associated complications, such as hepatocyte lung emboli, splenic and mesenteric vein thrombosis, or bleeding due to interventional hepatic access, were observed in the critically ill ALF patients [31,32]. LCT in patients with ALF resulted in the reduction of ammonia and bilirubin levels and improvements in hepatic encephalophathy in some patients, but the reported morbidity and mortality were relatively high; this may be because an insufficient mass of cells to rescue the patients was transplanted by intraportal or intrasplenic infusions. Because both the treatment protocols (e.g. number of cells or implantation site) and the patients transplanted with hepatocytes vary among the published reports and because RCTs are not available, the efficiency of LCT for the treatment of ALF cannot be truly assessed.

Treatment of chronic liver disease

In chronic liver disease, LCT has been performed to replace the function of the diseased liver by hepatocyte transplantation to ectopic implantation sites or to repopulate the diseased liver with transplanted cells. Published data are available on 20 patients with chronic liver disease and transplanted hepatocytes [21]. Small animal studies have shown that the deranged liver architecture prevents successful hepatocyte engraftment and intrahepatic shunts caused a systemic distribution of intraportal transplanted cells; thus the spleen was the implantation site in the majority of the published clinical cases [33].

Mito et al. were the first to treat cirrhotic patients with hepatocytes [34]. They resected the left lateral liver segment of cirrhotic hepatitis C patients and isolated and retransplanted the autologous hepatocytes into the spleen of the patients. One patient fully recovered and hepatocytes could be detected by radioisotope imaging 11 months after LCT; however, no clinical benefit of splenic hepatocyte injection could be observed in the other nine patients. In a further 10 cases, allogeneic hepatocytes isolated from non-cirrhotic liver donors were used for transplantation.

While some clinical improvements have been observed, LCT appears to be least successful in those patients with chronic liver disease, which may be due to the low number of cells infused in the majority of the published cases. Cirrhotic liver disease patients may benefit from alternative extrahepatic sites for liver cell implantation, but if the native cirrhotic liver is left in place, the management of co-existing portal hypertension and the risk of development of hepatocellular carcinoma in the native liver will not be resolved [35].

Conceptual and practical limitations

Although the safety and feasibility of LCT has been well demonstrated over the last decade, especially for the treatment of metabolic liver disorders, there are still many questions and barriers regarding the successful treatment of liver disease by hepatocyte transplantation.

Cell source for hepatocyte transplantation

Along with the critical shortage of donor organs for whole organ transplantation, donor organs for hepatocyte isolation are scarce. To provide a sufficient cell supply for LCT, alternative sources, such as marginal organs or livers from non-heart beating donors, must be established for clinical hepatocyte isolation [36]. Another valuable alternative for hepatocyte support could arise from stem cells or induced pluripotent cells [37,38]. Despite the encouraging results regarding the generation of hepatocyte-like cells from such precursor cells, there are still safety concerns, particularly concerning the oncogenic potential of stem cells.

Engraftment and survival of transplanted cells

Another critical aspect in LCT is the insufficient engraftment and long-term survival of transplanted hepatocytes. It is likely that

many cells do not survive long enough to enter the liver structure, and animal studies have shown that up to 80% of the transplanted cell mass is lost within 24–48 h after cell infusion [39]. In-vitro studies have indicated that, as in islet transplantation, isolated hepatocytes induce an immediate blood-mediated inflammatory reaction, which could be responsible for significant cell loss in vivo [40]. Also, due to the innate immune system, hepatocytes face reactions mediated by the adaptive immune system and non-specific mechanisms, such as apoptosis or specific cell-mediated or humoral rejection, even when immunosuppression is used after OLT [41]. Hepatocyte engraftment is also hampered by the need for the cells to translocate through the sinusoidal fenestration to integrate into the liver parenchyma. Histopathological analyses in animal models and explanted livers of humans transplanted with liver cells commonly reveal cells entrapped in distant portal branches [26]. It is likely that these cells are not metabolically active in the long term. Two strategies are currently being discussed to enhance hepatocyte engraftment in clinical LCT: liver irradiation and partial embolization of the liver. Large animal studies have showed that hepatic irradiation could arrest native hepatocyte proliferation, disrupt the sinusoidal endothelium, and inhibit the phagocytic function of Kupffer cells [42]. Partially reversible embolization of the portal vein could stimulate a regenerative response in the liver, which could also be of benefit to the transplanted cells [43]. It is possible that a combination of reversal portal embolization and hepatic irradiation may produce the best effect.

Tracking of transplanted liver cells

Unfortunately, little is known about the processes during and following LCT in humans because investigations of donor liver cell distribution and engraftment in humans are limited to the examination of tissue samples. A clinically applicable method for the visual monitoring of transplanted cells is currently not available. Cell labeling with radioisotopes was used in a patient to demonstrate hepatocyte biodistribution after transplantation [44]. However, radioisotope imaging is limited by the short half-life of the radioisotope and the lack of anatomical resolution. Magnetic resonance imaging (MRI) is currently the main clinically relevant technology for real-time and non-invasive monitoring of cell transplantation. MRI offers high spatial resolution in parenchymal organs, and dynamic imaging is possible. Cells must be labeled with intracellular contrast agents to be detectable by MRI. In-vitro studies have demonstrated the feasibility of labeling human hepatocytes with MRI contrast agents, and animal models have demonstrated the feasibility of tracking transplanted liver cells with MRI under clinical conditions [45,46]. However, further work is necessary to translate this approach to clinical use in LCT.

Implantation sites for liver cells

Ectopic implantation sites for hepatocytes are necessary, especially for the treatment of chronic liver disease [21]. Clinical studies have focused on the spleen, but the long-term survival of hepatocytes has not been conclusively demonstrated, and the hepatization of the spleen remains a mystery. The required mass of cells necessary for support during ALF cannot be safely transplanted into the spleen. Moreover, the exposure of hepatocytes to the immunological environment of the spleen is undesirable. The encapsulation of hepatocytes is a promising approach to immunoprotect them and enable ectopic implantation at the same time. Mei et al. showed that hepatocytes encapsulated in alginate beads could be implanted into the peritoneal cavity in a sufficient mass (50% of the native liver weight) to rescue animals with fulminant liver failure [47]. Further work is necessary to identify and evaluate clinically workable extrahepatic sites or tissue engineering-based constructs enabling in-vivo extrahepatic liver cell support [35].

Bioengineered solutions

Given the scarcity of donor organs and the unresolved issues of extrahepatic liver support and LCT, other solutions are necessary. Bioengineering approaches, which combine in-vitro and in-vivo tissue engineering, could reach the ultimate goal of total bioartificial liver grafting. This section will focus on two of the currently most exciting concepts regarding the bioengineered liver: organ printing and organ recellularization.

Organ printing: biofabrication of human organ constructs

Organ printing is a technology designed for the complete de-novo biofabrication of three-dimensional vascularized functional human organs. Organ printing is based on the layer-by-layer robotic biofabrication of functional three-dimensional tissue [48]. Cells of different origin are placed next to each other in a physiological manner to mimic the cellular distribution in the intact template organ. Robotic bioprinters, which are based on the concept of conventional inkjet printers, and bioreactors are the essential components of an organ biofabrication line (Figure 47.3A) [49].

Compared with other tissue engineering-based approaches designed for the liver, such as the use of scaffolds for ectopic hepatocyte seeding or the transplantation of liver cells, organ printing has certain competitive advantages: it allows for a precise simultaneous three-dimensional positioning of several cell types, ideally as found in nature; it enables the creation of tissue with a high level of cell density; it can solve the problem of vascularization in thick tissue constructs; and it can be automated and offers a pathway for the scalable production of engineered organs [50].

The fabrication of vessels for blood supply and bile removal is usually the limiting issue in tissue engineering-based approaches for the construction of functional liver tissue. Organ printing is capable of addressing these issues, e.g. using the technique of layer-by-layer deposition [51]. As described by Visconti et al., a sheet of biocompatible hydrogel is printed and tissue spheroids are embedded into the hydrogel [52]. Tissue spheroids are prepared from cell suspensions and can be homogeneous or heterogeneous, containing a single cell type or a mixture of several cell types (e.g. hepatocytes combined with endothelial cells or cholangiocytes). The deposition of layers of hydrogel and tissue spheroids is pursued according to the predefined blueprint of the desired three-dimensional structure, e.g. a tubular construct. The fusion of the tissue spheroids and the removal of the hydrogel leads to the generation of a hollow tube after a few days. The living cell-based construct that results from the printing and postprinting fusion process is then placed in an incubator, where it attains its final three-dimensional structure and appropriate biomechanical properties. Proof-of-concept studies have already been performed to show that thick tissue sheets and straight and branched tubes can be "built" [53].

Organ printing is a highly innovative and ambitious technology. To date, only a few successful applications have been published. For example, bone grafts have been generated using a bioprinter-based approach. Fedorovich et al. applied organ printing technology

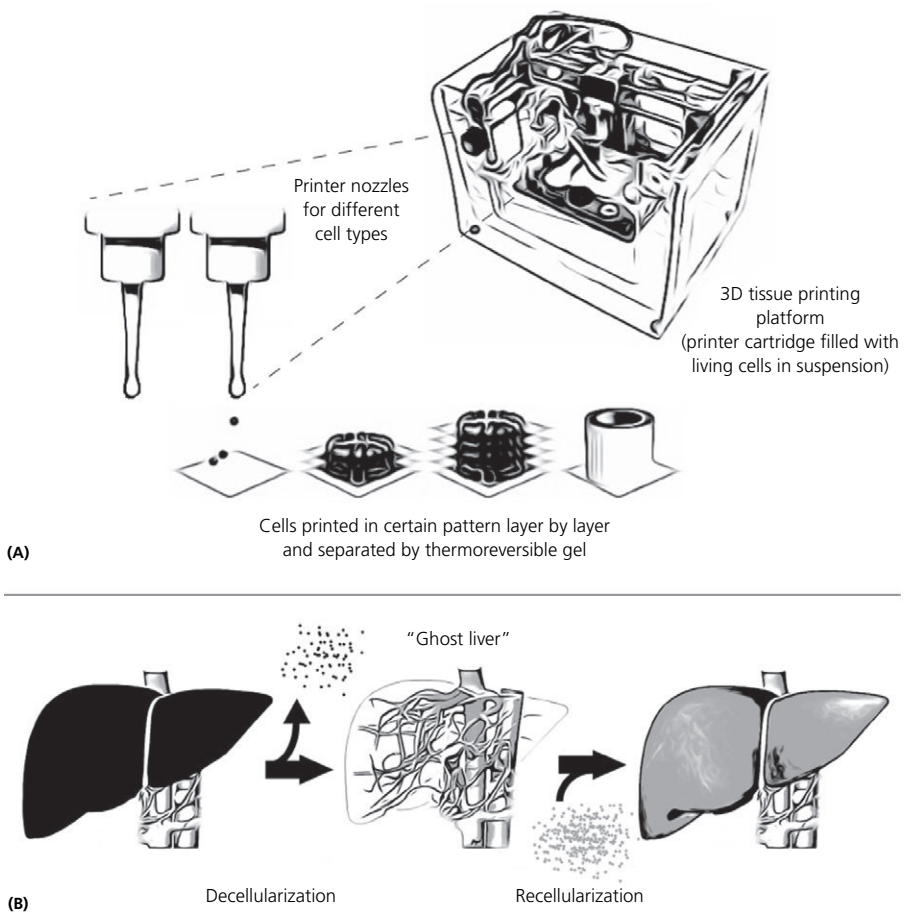

Figure 47.3. Bioengineered solutions for the liver. (a) Organ printing is based on three-dimensional printing of cells or spheroids. Cells are printed in a certain pattern layer by layer and separated by thermoreversible gel to generate tubular structures. A living cell-based construct results from cell printing and postprinting fusion of the cells. (Adapted from Mironov et al. [51].). (b) Decellularization and recellularization of the liver. Livers are recellularized by perfusion with a detergent that lyses cells and solubilizes cytoplasmic components. The decellularized "ghost liver" can then be sequentially recellularized with hepatocytes and endothelial cells or progenitor cells to generate functional liver tissue.

to fabricate porous constructs containing endothelial progenitors and multipotent stromal cells [54]. They showed that these grafts retained heterogeneous cell organization after subcutaneous implantation in immunodeficient mice. Cell differentiation led to tissue formation at the site of the deposited progenitor cells. While perfused blood vessels were formed in the endothelial progenitor cell-laden part of the constructs, bone formation was taking place in the multipotent stromal cell-laden part of the printed grafts. In another example of the successful application of bioprinting technology, Xu et al. showed that automated cell printing systems could be used to print a three-dimensional co-culture model of cancer cells and normal fibroblasts. Bioprinting allowed for high spatial control over the printing of co-cultured cells, which is helpful for investigating specific cell–cell interactions [55]. Moreover, bioprinting was applied for embryoid body formation, providing an effective tool to generate controllable uniform-sized embryonic bodies [56].

Studies on organ printing for the liver have not yet been published. However, it is very likely that this technology will be used to fabricate blood vessels and bile ducts to place hepatocytes and non-parenchymal liver cells in the spaces between these structures. Based on the promising results reported for other cells and tissues and the ongoing development of this young technology, it is conceivable that organ printing may ultimately be successful in the biofabrication of human liver constructs suitable for surgical transplantation.

Recellularization of decellularized organs

Recellularization is another young concept that has rapidly evolved in recent years. This concept is based on the idea of removing all cellular and antigen-presenting components from a donor liver and reseeding this *ghost organ* with cells from a different origin (Figure 47.3B). Decellularization ideally preserves the macrovascular skeleton of the entire organ, including the functional aspects of the native microvasculature, the extracellular matrix, and the three-dimensional architecture, which makes decellularized organs in a biomatrix ideally suited for reseeding with cells [57]. Because organs from non-heart beating donors (and foreseeably organs of xenogeneic origin) can be used for decellularization, this concept is promising in overcoming the issues of organ scarcity [58]. Recellularization could be performed with the patient′s own cells, either using stem cells or induced pluripotent stem cell technology, which might prevent the need for life-long immunosuppression following transplantation.

Following the successful demonstration of decellularized matrices in the tissue engineering of other tissues, including the bladder, arteries, and the trachea, a few groups have started to develop techniques for the de- and re-cellularization of the liver. Uygun et al. were the first to report on the fabrication of a transplantable recellularized liver [59]. They performed whole organ decellularization of rat livers by perfusing them with SDS, an anionic detergent that lyses cells and solubilizes cytoplasmic components. After complete decellularization, the authors restored the parenchyma of the liver with repeated hepatocyte infusions via the portal vein and additionally perfused the liver with microvascular endothelial cells as the non-parenchymal component. As a proof of principle, they connected the bioengineered liver graft to the renal artery and renal vein of a nephrectomized rat and perfused it for 8 h in vivo. Histological analysis of the perfused organ showed that hepatocytes had engrafted around the larger vessels and repopulated the surrounding parenchyma, suggesting that the cells migrated beyond the matrix barrier to reach the decellularized sinusoidal spaces. The endothelial cells were capable of lining the vasculature encircled by hepatocytes. Following implantation, the hepatocytes retained both normal morphology and hepatic function.

Based on these encouraging results, further studies were performed to optimize the decellularization and recellularization procedures for the liver. Baptista et al. showed that livers from mice, rats, and adult pigs could be successfully recellularized with human endothelial cells and human fetal liver cells [60]. Soto-Gutierrez et al. developed a minimally disruptive whole organ decellularization protocol for the liver [61]. Using this protocol, they were able to preserve the native microvascular network, the bile drainage system, and up to 50% of the growth factor content of the liver. Bao et al. modified the decellularized graft with heparin depositions to avoid intravascular thrombosis [62]. Using this internal surface anticoagulant modification, they were able to increase the number of reseeded cells by up to 10% of whole liver equivalents. They implanted the recellularized graft in series with the residual native liver, perfused it with portal vein blood, and demonstrated improved liver function and the prolonged survival of 90% of hepatectomized rats over a period of 72 h. Finally, Barakat et al. engineered a humanized porcine liver by transplanting human fetal hepatocytes co-cultured with fetal stellate cells into the decellularized matrix of a porcine liver [63].

The fascinating results of these pilot studies demonstrate the feasibility of creating recellularized liver grafts. However, tremendous efforts are still needed before recellularized liver grafts are suitable for clinical use. The decellularization protocols need to be further optimized and standardized to enable the efficient removal of all cellular components while conserving the microarchitecture and extracellular matrix of the liver. The number of cells that can be reseeded must be increased, and the reseeded cells need to be stimulated to repopulate the decellularized matrix. Moreover, further investigation is needed to determine whether hepatocytes in recellularized grafts retain their physiological properties and are capable of building functional tissue. Finally, animal studies need to be performed to show that a recellularized liver performs similarly to a native liver graft. Despite these challenges, it is already evident that this technology, if ultimately successful, will have a broad impact on the clinical setting of liver transplantation and has the potential to overcome the organ scarcity facing liver transplantation.

Summary

Liver transplantation remains limited by organ supply and an incomplete ability to prognosticate a patient's ability to recover from ALF. Liver support devices have been used in various forms for several decades, and conceptually remain exceedingly attractive as a means of bridging patients to recovery or to transplantation. However, their efficacy remains to be proven and considerable optimization is needed before these devices reach their conceptual potential. Suitable artificial processes capable of replacing the myriad processes of the liver and a suitable source of hepatocyte biomass for bioartificial hybrid devices remain the limiting factors. LCT has been developed as a therapeutic alternative for solid liver transplantation, particularly for the treatment of liver-based metabolic disorders, and may be useful for the treatment of acute or chronic liver failure. Given the clear need for alternatives to donor transplantation and the shortfalls of other existing technology, numerous novel approaches are being tested, including bioprinting and the use of decellularized organs that are subsequently recellularized to provide a new source of hepatocyte mass.

CHAPTER 48

Ventricular Assist Devices

O.H. Frazier[1] and Steven M. Parnis[2]

Introduction

The use of ventricular assist devices (VADs) to treat patients with advanced cardiac failure and as a bridge to cardiac transplantation has become an accepted and routine practice in clinical cardiovascular medicine. Their prevalence and general incorporation into the care of patients being considered for heart transplantation now necessitates their consideration in tandem with heart transplantation, and indeed, VAD services are frequently combined with transplant services as part of a multidisciplinary care team for patients with cardiac failure. This chapter will cover the origins, development, and modern use of VADs, and serves as a companion chapter to Chapters 30 and 39, which consider the preoperative assessment and waitlist management of patients awaiting heart transplantation, respectively.

History

Research into temporary mechanical support of the circulation was initiated by Gibbon, who was the first to successfully use the cardiopulmonary bypass machine in a clinical setting [1,2]. In addition, Dodrill demonstrated a successful mitral valve repair utilizing a left heart bypass. This technique, however, was envisioned as an approach specific to mitral valve surgery, not as a means for prolonged mechanical left ventricular (LV) support [3]. Observations of these first patients to receive cardiopulmonary support demonstrated that sometimes prolonged support after surgery could allow the heart to recuperate over time. Once function had been restored, these patients could be successfully weaned off the heart–lung machine. This finding was an important impetus to the development of mechanical circulatory support. However, oxygenators in use at the time caused blood damage, which limited the success of cardiopulmonary bypass for ventricular recovery. Therefore, cardiac recovery by use of VADs in this era could be achieved only if the patient's own lungs could be used as an oxygenator and only the circulation required support.

In 1961, Dennis et al. [4] employed an external roller pump to directly assist a failed LV. Following extensive research and detailed anatomic dissections, they were able to place a cannula transseptally into the left atrium via the right jugular vein. Blood was then returned by the roller pump via the common femoral artery. The trans-septal inflow cannula was placed blindly, and this, remarkably, was successful in supporting seven of eight patients with heart failure following extensive myocardial infarction [4]. (This approach, first applied by Spencer and Dennis, formed the basis of the now widely used Tandem Heart.) Likewise, in 1965 Spencer et al. also successfully used roller pumps for temporary circulatory support, allowing ventricular recovery [5].

DeBakey and Spencer simultaneously reported the successful recovery of a patient after prolonged support with partial cardiopulmonary bypass [5,6]. This work evolved in an era of very high mortality following open heart surgery. The initial goal of this research, therefore, was to develop a pump that would temporarily support the heart until sufficient myocardial function had returned to allow pump removal. In 1963, the Baylor group led by Dr. DeBakey reported the first implantation of an intracorporeal, pulsatile left ventricular assist device (LVAD) [7]. Circulation was well maintained and the myocardium showed improvement through the duration of support; however, the patient failed to recover from a neurologic injury that occurred during this procedure. In August 1966, Dr. DeBakey implanted another LVAD, now placed extracorporeally, in a 37-year-old woman who could not be weaned from bypass after a double valve replacement [6]. After 10 days, the pump was successfully removed, and she survived for 6 years with good cardiac function, only to eventually die tragically in an automobile accident.

Work on short-term LVADs continued through the 1960s, but it was soon overshadowed by the beginning of cardiac transplantation: the first successful heart transplant was performed by Barnard in 1967 [8]. However, in spite of the short-term surgical and medical success of heart transplants, the disappointing long-term outcomes led to a general abatement of this program and stimulated a renewed interest in both short- and long-term mechanical circulatory assist devices. In 1972, under the auspices of the National Institutes of Health (NIH), a committee of senior academic clinicians met in Washington and recommended further development of an implantable, long-term LVAD. As transplantation was not considered an option at that time, these devices were to be developed with long-term cardiac support as a goal ("destination therapy"). However, the initial implantable LVADs were once again employed only as a short-term bridge to recovery for patients who could not be weaned from cardiopulmonary bypass following open heart surgery. At the time, the Texas Heart Institute had the largest clinical experience

with intra-abdominal LVADs under the guidance of Dr. John Norman [9]. Although the use of these LVADs did not result in meaningful long-term survival, these devices were successful at providing short-term circulation support, allowing the first bridge to transplant with a LVAD to be performed in 1978 [10].

In parallel with the above efforts to develop the temporary intra-abdominal LVAD, efforts were also underway to develop a long-term, totally implantable LVAD. This research was also supported by the National Heart, Lung, and Blood Institute (NHLBI). Requests for proposals (RFPs) were issued in 1976 and 1978 for the development of the latter with the ultimate goal of returning a terminal heart failure patient to a New York Heart Association (NYHA) class I cardiac functional status. As noted, these were only LV pumps; it was hoped that the right ventricle (RV) could be supported by long-term LV unloading and temporary pharmacologic assistance.

As stated earlier, the emergence of cardiac transplantation was an important stimulus to the clinical application of implantable LVADs. Before the introduction of cyclopsorine, three LVADs were implanted for use as a bridge to transplant (Table 48.1). Unfortunately, although the mechanical support as a bridge to transplantation was effective, these patients all eventually died of overwhelming sepsis secondary to infections resulting from the profound pan-immune suppressive drugs employed at that time to prevent transplant rejection. With the advent of cyclosporine, the use of these pumps as a bridge to transplant could once again be explored. The survival of a patient who underwent cardiac transplantation while suffering from active ongoing staphylococcus, streptococcus, and candida sepsis at our hospital in 1984 showed that even severely infected patients could successfully undergo cardiac transplantation utilizing the new immune suppression drug [11]. Therefore, it was believed that patients receiving LVAD support could also potentially undergo successful cardiac transplantation with cyclosporine immunosuppression, thereby making LVADs a viable option as a bridge to transplant. Shortly after this case was reported, Portner and Oyer described the use of a Novacor LVAD as a bridge to transplant (Figure 48.1) [12]. In addition, the Thermo Cardiosystems, Inc. (TCI) LVAD, also developed with NHLBI support, was first implanted in 1986 as a bridge to transplant [13].

Although bridge to transplant was not the original use envisioned for this technology, the introduction of cyclosporine, which allowed successful transplantation following the use of mechanical assist devices, renewed interest in long-term, implantable circulatory support [14]. As a result, the use of these implantable pump technologies as a bridge to transplant began to see an increase through the 1980s, and the 1990s saw a period of exponential growth in this field [14].

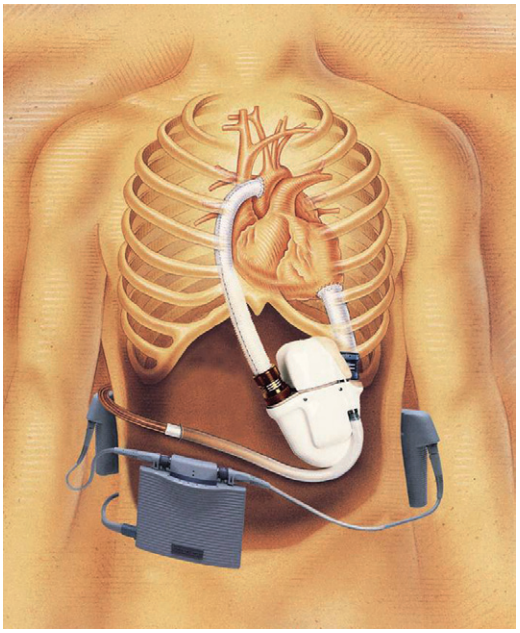

Figure 48.1. Novacor electronically powered implantable left ventricular assist device. Oyer and Portner used it as the first successful bridge to transplant in 1984.

As donor organ waiting times began to increase, the duration of LVAD support also began to increase. Transplant candidates who received the initially available tethered pneumatically powered LVADs were rehabilitated from a NYHA class IV status to a NYHA class I or II status, but unfortunately, they were forced to remain hospitalized until after transplantation. A significant advancement in LVAD technology occurred in 1991, when the first patient received an untethered, wearable, implanted, electric-powered TCI LVAD (Figure 48.2). This patient was eventually discharged from the hospital in 1993, becoming the first such patient to be discharged with an implantable LVAD [15]. In addition to providing patients with the freedom to be discharged from the hospital, these portable devices were also shown to improve end-organ function and exercise tolerance, normalize hemodynamics, and improve quality of life [16–19].

At the time, the two dominant pulsatile implantable pumps were the Novacor and the TCI [19]. The first pump to receive US Food and Drug Administration (FDA) approval was the pneumatic HeartMate (formerly known as the TCI LVAD) in 1994. The electrical versions of both the TCI and the Novacor implantable pumps received FDA approval in 1996.

REMATCH and destination therapy: the end of the beginning

Since the original RFPs for the development of these technologies were initiated in the 1970s as an alternative to transplantation, it was important for the NHLBI to assess these technologies with that goal in mind. Accordingly, under the auspices of the NHLBI, the Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure Trial (REMATCH) was initiated. This study analyzed the use of long-term LVADs in patients who were not candidates for heart transplantation and compared their outcomes to those in a randomized cohort of medically treated patients. This study demonstrated that implanting an LVAD in

Figure 48.2. TCI HeartMate left ventricular assist device (LVAD), which was the first untethered LVAD, allowing patients to be discharged from the hospital.

patients with NYHA class IV symptoms was an acceptable alternative therapy and that the use of LVADs in these patients resulted in clinically meaningful survival benefit and an improved quality of life [20].

These implantable, pulsatile devices played an important role as life-saving technologies when applied to select patients facing imminent death from heart failure. They performed effectively as a bridge to transplant in these patients. The main limitations of these implanted, pulsatile pumps were size and durability. Because of the large size of these pumps, they could only fit comfortably in normal sized adults. In addition, as waiting times for transplantation increased, the greatest limitation for these pumps became durability. A goal of 2 years of functionality was an ambitious one, considering that the pumps required a flexing, non-lubricated membrane to be activated >100 000 times every 24 h or a minimum of 38 million times in a year. Accomplishing the goal of 2 years was a remarkable achievement. However, successful use beyond that time interval was limited, and multiple exchanges were frequently required even to obtain that degree of durability. This durability barrier, thus, prevented the application of pulsatile pumps for meaningful long-term cardiac support. As a result, the main use of this technology remained only as a bridge to transplant.

Rotary blood pump systems

Since the first use of the heart–lung machine in the 1950s, there has been an interest in the use of continuous flow pumps. Saxton et al. [21] introduced the concept of using continuous flow pumps for long-term support as early as 1960. However, at that time this technology was only used clinically for temporary support in an immobilized patient. Rotary blood pump technology as a long-term cardiac support was not pursued at the time because of engineering limitations and the perceived physiologic barriers to this approach.

The Hemopump, introduced by Dr. Richard Wampler in 1986, showed that implantable continuous flow technology could feasibly support a failed heart. To explore the potential for this device, the senior author (OHF) and Dr. Wampler conducted in-vivo research using an implanted Archimedes screw pump rotating at over 25 000 rpm to directly unload the failed ventricle. These studies showed that this pump worked efficiently, could pump up to 4 L against physiologic pressures, and that the rapid rotation of this pump did not cause hemolysis. The first successful clinical application of the Hemopump occurred in 1988. At the same time, our lab was also working with Robert Jarvik to develop a long-term, implantable continuous flow Archimedes' screw-type pump utilizing blood-immersed bearings. Before the above studies were conducted, not only was rapid rotation considered too hemolytic for intravascular application, but the common wisdom was that non-lubricated, blood-washed bearings could not be implanted in the vascular system long term. These experiments were essential to the clinical application of rotary blood pumps for both temporary and long-term cardiac support.

Rotary blood pumps have several advantages over the earlier volume-displacement pumps. They are smaller than their precursors and therefore applicable to small adults and even children. This allows easier surgical implantation and permits a more acceptable anatomic placement. Importantly, they do not require valves, eliminating a large expense because the flow is unidirectional. They usually contain only one moving part, the impeller or rotor, which increases mechanical longevity; and they have smaller drivelines. The percutaneous driveline required in pulsatile pumps as a vent for the negative pressure created by their pulsatility is not necessary in continuous flow pumps, allowing for transcutaneous power delivery and eliminating external contamination completely. Also, rotary pumps have much lower power requirements than the earlier volume displacement pumps to deliver the same level of support [22].

In the late 1990s and early 2000s, the use of clinical implants with rotary blood pumps began in Europe and the US. The initial pumps were axial flow, Archimedes screw pumps utilizing blood-immersed bearings. The MicroMed, Jarvik, and HeartMate II pumps were introduced clinically in 1998, 1999, and 2001, respectively. All of these pumps are similar in operation, the main differences between them being the length or presence (Jarvik) of the inlet cannulas, the anatomic location of the pump relative to the heart, and the type of blood-immersed bearings used. In June 2000, the Jarvik pump was the first of these long-term pumps to be applied as destination therapy, rather than as a bridge to transplantation. This patient was supported by the pump for 7.5 years. At the time of his death, the pump remained in good working order with minimal bearing wear (Figure 48.3).

Continuous flow pumps in current clinical use

Axial flow pumps

HeartMate II

The HeartMate II (Figure 48.4; Thoratec Corporation, Pleasanton, CA, USA) is an implantable axial flow-type LVAD that is basically a long-term application of the Hemopump principle (Figure 48.5).

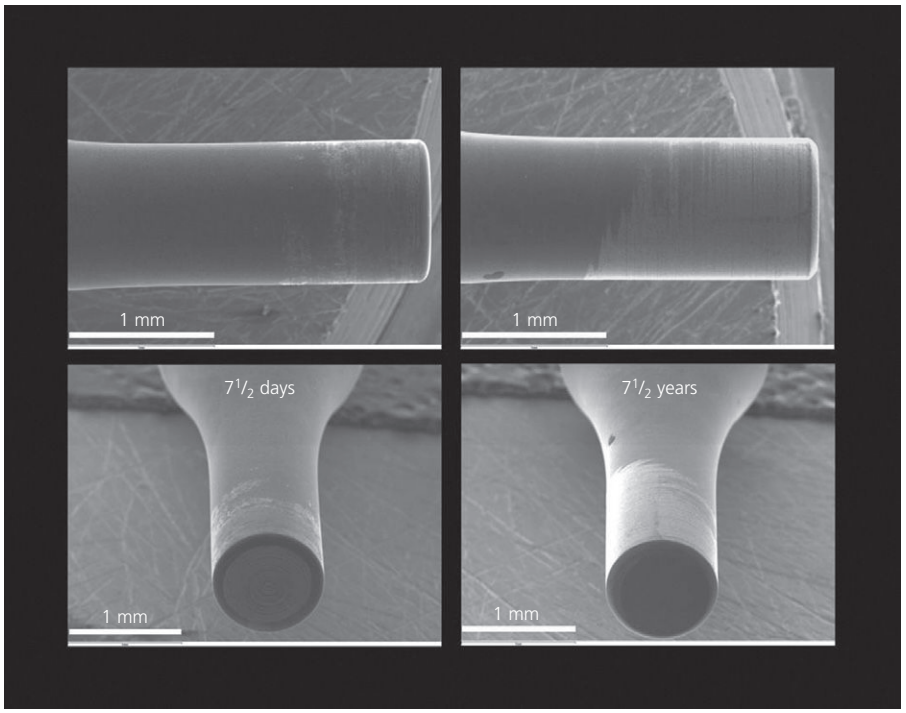

Figure 48.3. Minimal bearing wear of Jarvik 2000 is seen after implant for 7.5 years.

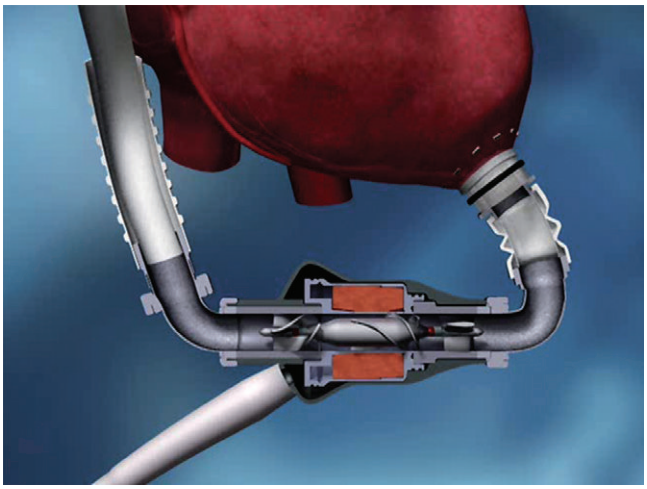

Figure 48.4. HeartMate II. Note its blood-immersed bearings.

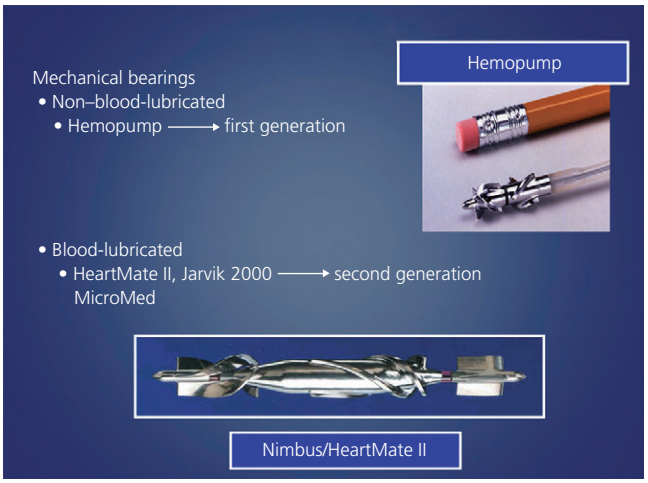

Figure 48.5. Evolution of HeartMate II from Hemopump.

Research on this was initiated in the 1980s with Nimbus and the Texas Heart Institute, and it was further developed in the 1990s by the research group at the University of Pittsburgh led by Bartley Griffith [23].

This battery-powered LVAD is connected to an external controller and batteries via a percutaneous lead. The external system controls the rotational speed, monitors system function, and provides power. The blood pump weighs 375 g and is 4 cm in diameter × 6 cm in length. The impeller, the only moving part of this device, is held in place by blood-lubricated bearings and is controlled by an electromagnetic motor embedded in the pump housing. The impeller rotates at speeds of 6000–15 000 rpm and can generate flows of up to 10 L/min. The system is normally implanted via a median sternotomy with the patient placed on cardiopulmonary bypass, although it can be implanted without cardiopulmonary bypass [24]. The inflow cannula of the device is placed into the LV cavity via a circular sewing ring at the apex or through the free wall of the LV at the diaphragm in such a way that the cannula lies parallel to the ventricular septum. This approach is similar to what we currently use to implant the HeartWare LVAD (Figure 48.6) [25].The outflow from the pump is anastomosed in an end-to-side fashion to the ascending aorta. Postoperative long-term support of patients

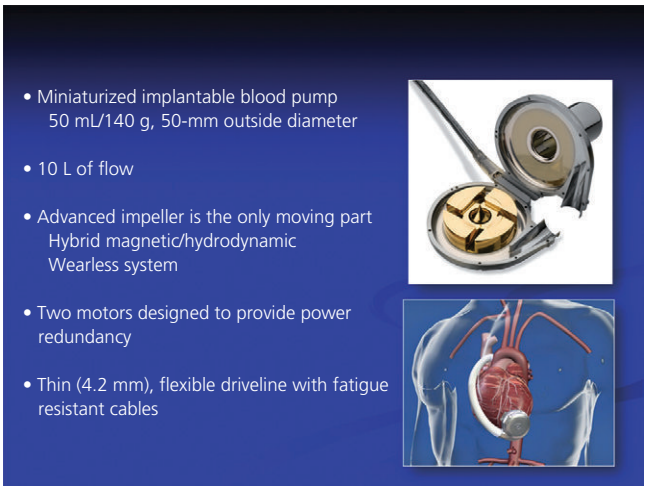

Figure 48.6. HeartWare ventricular assist system.

includes the use of warfarin to maintain an international normalized ratio (INR) of 1.5–3 [26].

Clinical trials began in the US in 2003 [23,27]. By the mid 2000s, excellent results were observed for patients receiving HeartMate II implants. In 2008, the Thoratec HeartMate II axial flow LVAD was approved by the FDA as a bridge to cardiac transplantation, leading to an increase in the number of HeartMate II LVADs implanted. A postapproval prospective study following HeartMate II recipients showed that patients receiving the HeartMate II VADs had further improvement in their survival, particularly if they received the pump earlier in the course of their illness [28]. Currently (August 2012), >11 000 patients have received the HeartMate II blood pump for circulatory support, making the HeartMate II the most widely used implantable LVAD.

Jarvik 2000

The Jarvik 2000 (Jarvik Heart, Inc., New York, NY, USA) is a small (diameter 25 mm, weight 90 g) implantable axial flow-type LVAD, which was also developed throughout the 1990s and 2000s with the support of the NIH [29]. This battery-powered LVAD is connected to an external controller and batteries via either a small percutaneous lead that can exit the abdominal cavity or via a postauricular pedestal [30]. The external portion of the system controls the rotational speed, monitors system function, and provides power. As in other axial flow-type pumps, the impeller, the only moving part of this device, is supported by blood-immersed bearings. The impeller spins at 8000–12 000 rpm. The pump can deliver up to 7 L/min of flow at physiologic pressures [31]. To address potential blood stasis issues, an intermittent speed controller was developed and implemented in 2005. This controller decreases the pump speed to 7000 rpm for 6 s in every minute. By lowering the pump speed, the ventricle is allowed to fill and then eject blood from the aortic valve. The ventricular ejection allows a washout of the aortic root, thereby preventing stasis and thrombus formation [32]. In addition, by opening the aortic valve, aortic valve fusion and resultant aortic insufficiency and stenosis may be prevented.

The Jarvik 2000 can be implanted via a median sternotomy with the outflow anastomosis to the ascending aorta (Figure 48.7). It was originally designed to be implanted via a left thoracotomy [33]. This technique avoids pressure and distortion of the outflow graft by the chest wall–pump interface and avoids repeat sternotomy at the time

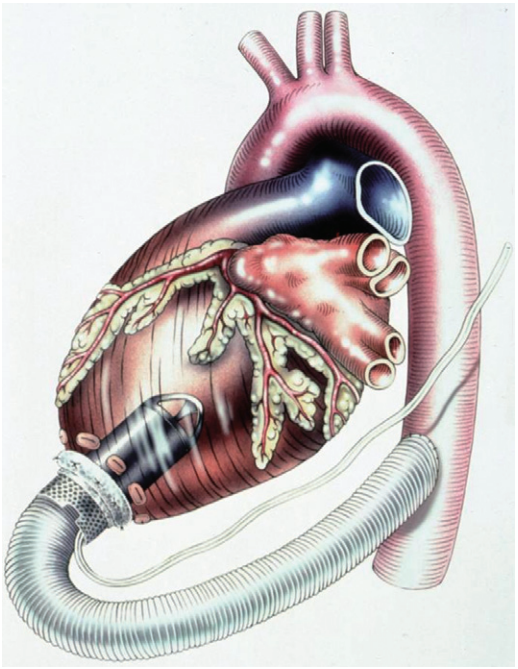

Figure 48.7. Intraventricular placement of the Jarvik pump.

of transplant. Pump implantation can be performed with or without cardiopulmonary bypass [34,35]. A unique feature of this device is that the entire blood pump can be placed into the LV cavity, thereby negating the need for a preperitonial pump pocket. By eliminating the pump pocket, the incidence of infection is greatly reduced [36]. The outflow graft from the pump with the thoracotomy approach is anastomosed in an end-to-side fashion to the descending thoracic aorta. Management of anticoagulation with warfarin depends on aortic valve opening. Another approach to pump insertion is through the diaphragmatic surface of the ventricle by a left subcostal incision. This approach is particularly beneficial in patients with prior median sternotomies, and the device can usually be placed without cardiopulmonary bypass [37]. If aortic valve opening is successfully achieved with the intermittent speed controller (Figure 48.8), INR levels are maintained in the 1.5–2.0 range. If aortic valve opening is minimal, INR ranges of 2.5–3.0 are the goal [32]. Clinical trials of the Jarvik 2000 began in April 2000. To date, the Jarvik 2000 has been used clinically for more than 360 patients according to the manufacturer [33,34].

InCor

The InCor LVAD (Berlin Heart AG, Berlin, Germany) is an implantable axial flow-type LVAD that uses magnetic levitation of the rotor with active axial electromagnetic bearings positioned at each end of the rotor. The pump weighs 200 g. The dimensions for the pump are 30 × 120 mm, and it has a displacement volume of 80 mL [38]. The system is operational at rotational speeds of 5000–10 000 rpm and can provide blood flow of up to 7 L/min [38]. The system is normally implanted via a median sternotomy with the patient placed on cardiopulmonary bypass [39]. The inflow cannula of the device is placed into the LV cavity via a circular sewing ring at the apex. The silicone outflow conduit from the pump is anastomosed in an end-to-side fashion to the ascending aorta. The pump is implanted in the chest inside the pericardial cavity to lie along the

Figure 48.8. Intermittent speed control of the Jarvik pump assures aortic valve opening and is an important contribution to the field.

diaphragmatic border under the heart. A drive cable that exits the patient's right side connects the pump to a small control system that regulates and monitors the system. Batteries are used to allow for patient mobility. The blood-contacting surfaces of the InCor are coated with Carmeda® Bioactive Surface to help reduce the incidence of thrombus formation. For long-term usage, anticoagulants are administered to maintain an INR of 2.8–3.2 [40]. At the present time, this system has been implanted in over 500 patients worldwide [41].

Centrifugal-type pumps

In centrifugal-, or radial-, type pumps, blood enters the pump perpendicular to the pump outflow, is accelerated by the impeller, and is then discharged radially. Although centrifugal pumps are a little larger in diameter than axial flow pumps, the overall geometry of these pumps allows for an anatomic profile design and can fit easily into the pericardial space of a normal sized adult. Centrifugal blood pumps utilize lower rotational speeds than axial flow blood pumps (1400–4000 rpm) and do not require stationary vanes, or stators, in the pump outflow for directional stability of blood flow.

HeartWare HVAD

The HeartWare HVAD (HeartWare International, Miami Lakes, FL, USA) is a centrifugal pump designed to be implanted within the pericardial space [42]. The pump contains a rotating impeller with wide blades and imbedded magnets, a center post with imbedded magnets, and a front and rear housing, each with a sealed motor stator. When the pump is activated, the impeller begins to spin, suspended by hydrodynamic bearings and passive magnetic levitation created by the interaction of the magnets. The impeller can rotate at speeds from 1800 to 4000 rpm and can generate blood flows of up to 10 L/min. The HeartWare HVAD weighs 145 g and has a displacement volume of 50 mL. The front housing incorporates an integrated inflow cannula that allows for device placement into the LV.

The HeartWare HVAD system is normally implanted via a median sternotomy with the patient placed on cardiopulmonary bypass. The integrated inflow cannula of the device is positioned within the LV cavity via a circular sewing ring attached to either the diaphragmatic surface or the apex of the LV. Diaphragmatic placement allows the cannula to reside in the central portion of the LV, oriented towards the mitral valve and parallel to the ventricular septum (Figure 48.9) [25]. The 10-mm outflow graft from the pump is anastomosed in an end-to-side fashion to the ascending aorta. The pump is positioned within the pericardial space, eliminating the need for a preperitoneal pocket and reducing the degree of surgery required for implantation. A thin, flexible driveline exits the patient's side and connects to an external system containing a wearable controller and batteries, which monitors and controls the system as well as provides power to the system. Long-term usage requires patients to be treated with the anticoagulant warfarin to maintain an INR of 2.5–3 [43]. Over 1700 HeartWare HVAD implants have been performed to date.

EVAHEART

The EVAHEART system (EVAHEART Medical USA, Inc., Pittsburgh, PA, USA) is an implantable LVAD that combines the use of a centrifugal blood pump to generate blood flow and pressure with an extracorporeal fluid recirculating system. The pump consists of an open-vaned impeller that is mounted on a shaft and driven by a motor that weighs 420 g [44,45]. A hydrodynamic bearing provides lubrication and support for the rotating impeller shaft. Fluid from the extracorporeal recirculating system is pumped via a percutaneous channel to provide heat transfer and to prevent heat denaturation of blood proteins. The pump is connected to a controller by a percutaneous driveline. The pump can generate a

blood flow of up to 8 L/min against an aortic pressure of approximately 90 mmHg. The surfaces of the EVAHEART pump in contact with blood are coated with 2-methylacryloyloxyethyl phosphorylcholine (MPC), a polymer that mimics the vascular intima to provide a blood-compatible surface. The EVAHEART blood pump is implanted via a median sternotomy. The 16-mm polytetrafluoroethylene inflow and outflow conduits are connected to the LV apex and ascending aorta, respectively. Clinical trials assessing the EVAHEART have been ongoing in Japan and have recently begun in the USA.

Complications

Our ability to manage complications has progressed over the last decade. The use of continuous flow technology has led to a profound change in device management. The complications seen clinically with rotary blood pump LVADs largely mimic those of the earlier pulsatile LVADs. However, the frequency of adverse events from pulsatile pumps is higher in most categories.

Right heart dysfunction

RV function should be assessed during the preoperative LVAD evaluation. Chronic elevation of left-sided and pulmonary pressures can lead to RV dysfunction. LVAD support alone is sufficient to sustain the vast majority of heart failure patients as demonstrated by data from the Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) [46]. The possibility for temporary right-sided support should be available at the time of LVAD implant. Most right-sided heart failure occurs during the intraoperative or the early postoperative period and can be exacerbated by the use of blood products. RV function should be assessed during implant surgery. Upon LVAD initiation, rapid unloading of the LV can cause the interventricular septum to shift from the right to the left, which can reduce the contribution of the septum to RV contraction and decrease right-to-left blood flow. Appropriate adjustment of LVAD flow can help to compensate for this RV dysfunction and can reduce the need for RV assist. A recent paper by Kirklin et al. using the INTERMACS data showed that the use of RV assist increased mortality two-fold [47]. This increased mortality is associated not only with higher blood loss but also the delay of implantation of the RV assist. If needed, the use of a temporary RV assist should not be delayed.

Although the initial development of implantable, long-term mechanical assist devices was limited to the LV, current technologies, particularly the HeartWare pump and in some instances the Jarvik, can be applied to the right side. The first implantation of the right ventricular assist device (RVAD) occurred in 2003 with a Jarvik patient who developed aggressive right-side failure shortly after implant of a VAD on both the right and left [48]. Since this implant, other cases of chronic right-sided support with implantable pumps have been applied. The largest experience has been in the German centers [49]. Excellent outcomes with this approach as a bridge to transplant have been obtained [49].

Infection

Infection is one of the major challenges to the management of the patient with an LVAD and remains one of the major causes of death to LVAD recipients [50]. Despite the decrease in pump and driveline size and the increase in experience leading to improved outcomes with the use of continuous flow LVADs [51], infections and associated sepsis continue to be major complications for patients receiving LVAD implants while awaiting cardiac transplantation [52]. Infections related to the LVAD may include the following: driveline exit site infections, which may or may not track along the driveline and from the exit site to the pump; and pump pocket infections. Complications can also occur in relation to infections not localized to the LVAD itself, such as pneumonia, sternal wounds, urinary infections, and systemic infections.

Gastrointestinal bleeding

Gastrointestinal (GI) bleeding after the immediate surgical period has been a challenge to the management of patients on chronic LVAD support since its inception. The pneumatic HeartMate as well as the HeartMateXVE did reduce the incidence of bleeding because systemic anticoagulation was not required with this technology. The Novacor pump, which required systemic anticoagulation, had an incidence of GI bleeding as high as 19% [53]. The use of continuous flow technology has been accompanied by anticoagulation. This is required not for the pump, as flow through the pump is continuous and no elements of Virchow's triad are present. However, anticoagulation is felt to be necessary, particularly for potential clot formation at the aortic root or around the base of the pump inlet. Early in the course of the LVAD experience, GI bleeding from arteriovenous (AV) malformations was observed [54]. With more widespread use of the HeartMate II pump, the number of patients encumbered by this complication increased. This problem is believed to be related to the diminished pulse pressure imparted by the use of these continuous flow pumps. It was first alluded to in 1958 by Heyde, who described bleeding from AV malformations in patients with severe aortic stenosis [55]. Its etiology remains poorly understood, but it predictably occurs in 10–15% of patients after implant. It can be addressed by decreasing the pump's rotation rate, which allows for an increase in the pulse pressure, and minimizes anticoagulation.

Summary

In the US, heart failure accounts for 34% of cardiovascular-related deaths [32,56]. Because of improved survival of patients following acute myocardial infarction combined with a population that continues to increase in age, heart failure will continue to increase in prominence as a major health problem in the US [57–60]. Long-term mechanical cardiac assistance has become an important and effective tool in the management of patients awaiting cardiac transplantation. It has been demonstrated over the last 5 years that support with rotary blood pumps can improve renal and hepatic function in advanced heart failure patients awaiting cardiac transplantation [61]. As more of these devices are put into use and clinical studies provide stronger evidence to support the safety of these devices, both the medical community and patients are becoming more open to the prospect of implanting these devices earlier in the disease process, before patients become moribund. The improved durability and reduced short- and long-term morbidity associated with the HeartMate II has reduced the need for urgent cardiac transplantation [62].

Because of the unpredictable waiting times for donor organs, which have largely resulted from the increasing numbers of patients on transplant waiting lists and from the plateau in the number of donor hearts available each year, the current use of VAD technology now far exceeds its application as a bridge to transplant. VADs are now primarily used as long-term support of the advanced heart failure patient whose ultimate goal is transplant [46]. Ideally, in the

future, with better medical as well as adjuvant therapies and more suitably designed devices, heart function will improve enough to allow device support to be removed [53].

The increased demand for mechanical assistance reflects modern medicine's success at treating various circulatory issues. Until we can conquer heart disease by finding and treating the underlying processes, VADs will continue to play a crucial role in restoring circulatory function to end-stage heart failure patients so that they may live full and satisfactory lives.

Introduction

The Syncardia CardioWest Total Artificial Heart (TAH) is the only Food and Drug Administration (FDA) approved TAH. It was approved for potential cardiac recipients who have severe biventricular heart failure. Often, these patients have multisystem organ failure and are at risk for death within hours to days. In contrast to left ventricular assist devices, the TAH replaces both ventricles of the heart. The TAH is the first implantable organ replacement with potential for use as a destination therapy. It perhaps represents a view of the future state of transplantation, where organ replacement can be achieved without the concerns of immunosuppressive morbidity and donor organ supply that dominate modern organ transplant practice. This chapter will cover the TAH, considering it separate from ventricular assist devices (covered in Chapter 48), but also within the context of bridge to transplant therapeutic modalities. As such, this chapter complements Chapters 39 and 44, which discuss the management of patients awaiting heart transplantation and the intensive care of patients with cardiac failure, respectively.

History

Early work with the pneumatic TAH included that of Akutsu and Kolff who achieved canine survival for 90 min [1]. Over the following years, work in calves provided encouraging results, and in 1964, Congress passed the National Heart Initiative supporting the creation of a TAH for humans.

Dr. Denton Cooley implanted the "Liotta TAH" in 1969 as a bridge to transplantation. His patient was supported for 64 h and then received a cardiac transplant [2]. The patient died 32 h after transplantation from sepsis. In 1981, Dr. Cooley implanted the Aktusu TAH and the patient was supported for 53 h until transplant [3]. This patient lived for 8 days after transplant but also died of sepsis. Later in 1981, DeVries, Kolff, and Jarvik at the University of Utah received FDA approval for implantation the Jarvik-7 TAH as a permanent heart replacement. Their first patient, Barney Clark, received the Jarvik-7 in 1982 and was supported for 112 days but died after a series of cerebral thromboembolic complications. The procoagulant nature of the TAH and the resultant need for anticoagulation were quickly recognized as central issues in the success of the TAH [4].

In March of 1985, Dr. Jack Copeland at the University of Arizona implanted the Phoenix TAH in 1985 to save a patient with acute cardiac graft failure [5]. The patient was supported for 12 h and then retransplanted, only to die of sepsis 33 h after the second transplant. The use of an unapproved FDA device was controversial but did result in a landmark ruling from the FDA. Since 1985, the FDA allows any physician to use an unapproved FDA device once in order to save a patient's life in a "true emergency."

Copeland and his team then implanted the Jarvik-7 into Michael Drummond on August 29, 1985 [6]. He was successfully bridged to transplantation after 9 days on the TAH and survived for over 5 years post transplant.

The success of the Michael Drummond's bridge to transplant led to subsequent use of the Jarvik-7 (100 mL) and later the Jarvik-7 (70 mL). In 1990, after a few other successful TAH implantations, the FDA decided that Symbion, the company producing the Jarvik-7, was out of compliance and closed the Symbion investigational device exemption (IDE) study that permitted implantation in the US. This paused all US programs as of 1991. In Paris at La Pitie Hospital, Szfener et al. published a report with zero neurologic complications with the Jarvik-7 in 60 consecutive patients with an anticoagulation protocol based upon anticoagulation as well as antiaggregation [7]. Many programs have adopted important features from that original protocol that emphasizes thromboelastography and platelet aggregation studies.

An effort was made to reinstate the Jarvik-7. The device was renamed the CardioWest Total Artificial Heart in 1993 and a new IDE study at five centers was launched. The first patient in that study was implanted in January 1993 at University Medical Center (UMC). She survived 186 days until transplantation and then lived for an additional 6 years. In 2002 the completed trial had included 81 patients over the 9-year period. Later, in 2002, when faced with the financial strains that have bankrupted many small artificial heart companies, and in an effort to "save the technology," the company was refounded with the name SynCardia Systems and eventually the heart was renamed the SynCardia Total Artificial Heart. The IDE study showed that the SynCardia CardioWest TAH could be used as a successful bridge to transplant for severely sick patients with biventricular failure awaiting cardiac transplantation. The data, presented in 2004 [6], resulted in the only approval by the FDA of a TAH as a bridge to transplantation. Four years later, the

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

SynCardia TAH was approved for Medicare funding, and since that time, it has been funded in the US by Medicare and private insurance companies.

A total of over 1000 SynCardia TAHs have been implanted in 50 active centers equally divided between the US and Western Europe. Thirty-nine additional institutions are trained and ready to implant. Small driver consoles are now available for in hospital and out of hospital care, allowing the accumulation of over 25 patient years of out of hospital experience. Most of this experience has been in Europe. The longest bridge to transplant with this device has been 3.75 years. In the past few years, 60–70 TAHs have been implanted per year worldwide. In the first 2 months of 2012, over 20 were implanted. There has been steady growth in the number of implants since the early 1990s, followed by accelerated acceptance and use in the past 5 years.

Patient selection

Choosing among the options of left ventricular assist device (LVAD), biventricular assist device (BiVAD), and TAH implantation in heart failure patients is controversial. Patients appropriate for TAH have been shown to be those with irreversible biventricular failure, acute decompensation after cardiotomy, cardiogenic shock after acute myocardial infarction, stone heart, irreversible cardiac rejection, severe graft coronary vasculopathy, failed LVAD or BiVAD, decompensating heart failure with left ventricular thrombus, acquired ventricular septal defect, and prosthetic or incompetent native aortic valve in cardiogenic shock, or unresponsive ventricular arrhythmias. The last six of those indications are appropriate for TAH only, while the others can be appropriate for LVAD, BiVAD, or TAH. As discussed in Chapter 48, the indications for LVAD or BiVAD include left ventricular heart failure without right heart failure, and potentially reversible heart failure such as with viral myocarditis, in which heart transplantation may be avoidable.

The TAH FDA trial noted a 79% survival for bridge to transplantation with the CardioWest TAH [8]. The inclusion criteria were strict and selective:

- New York Heart Association (NYHA) class IV;
- a body surface area of 1.7–2.5 m^2;
- hemodynamic instability defined as a cardiac index of <2.0 L/min/m^2 and one of the following: systolic arterial pressure of <90 mmHg or central venous pressure (CVP) of >18 mmHg, or two of the following: dopamine at 10 μg/kg of body weight/min, dobutamine at 10 μg/kg/min, epinephrine at 2 μg/kg/min or vasopressor medications at maximal doses, intra-aortic balloon pump or cardiopulmonary bypass.

These criteria translate to the new Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) class 1—the crash and burn patient. In 2001, Copeland et al. published a retrospective study comparing the use of the CardioWest TAH, Novacor, and Thoratec as a bridge to transplantation [7]. The study demonstrated that the CardioWest TAH is the best option for patients with biventricular failure, cardiogenic shock, or multisystem organ failure, or those patients now classified as INTERMACS class 1 ("critical cardiogenic shock") or class 2 ("in progressive decline") [8].

The CardioWest TAH is designed to benefit those patients where an LVAD, right ventricular assist device (RVAD), or BiVAD is not sufficient for the severity of multisystem organ failure such as renal and/or hepatic failure. In a risk factor analysis published in 2008, the risk factors proven to be associated with LVADs such as Novacor, HeartMate I or Thoratec do not increase the risk of implantation and survival in the CardioWest TAH [9]. Control of the left and right side of the circulation is unique to the TAH. It gives the patient a predictably high cardiac output and high perfusion pressure. This may be a life-saving advantage in critical cases and may reduce postimplant morbidity in borderline cases. Also, orthotopic replacement of native ventricles and valves provides a means of salvaging patients with irreversible damage to the valves, ventricles, proximal great vessels, as well as to myocardium.

Patient selection is also dependent upon the fit of the device in the recipient's chest. If the fit is too tight, the inferior vena cava (IVC) and/or the left pulmonary veins may be compressed. Guidelines for adequate fit include the following:

- distance of 10 cm from the posterior sternum to the anterior spine on computed tomography (CT) scan at the level of T10;
- body surface area of ≥ 1.7 m^2;
- cardiothoracic ratio on anteroposterior chest X-ray of >0.5;
- left ventricular end-diastolic dimension on echocardiography of ≥ 70 mm;
- a cardiac volume on CT scan of ≥ 1500 mL.

In addition, there are some general guidelines: a large person with a normal sized heart or a small person with a large heart is most likely a good candidate, whereas a normal or small person with a normal sized heart is most likely a poor candidate. All of these factors need to be considered; with increasing experience, the size issue is recognized as very important and surgeons become proficient at using the guidelines.

One of the most difficult aspects of using the TAH is excluding patients who are at too great a risk of death or incapacitating complications. Unfortunately, in new programs the selection of the first patient is often overly optimistic and the experience ends tragically. This is reminiscent of the early experience with cardiac transplantation when the results were uniformly bad. Once stringent selection criteria were applied and contraindications were respected, survival was obtained. Besides inadequate fit criteria, there are several further contraindications: cachexia, advanced physiologic age, chronic multiorgan failure judged to be irreversible, judgment that the patient will never become a potential cardiac transplant recipient, and situations that are at high risk for massive hemorrhage (ongoing dialysis, multiple previous operations, multiple previous operations and a history of heparin-induced thrombocytopenia, failure to wean from bypass with massive bleeding, etc.).

SynCardia total artificial heart

The SynCardia total artificial heart (TAH-t) consists of two orthotopically placed 70-mL ventricles that together displace 400 mL and weigh 160 g. They are connected to lines brought out through the skin just under the left costal margin and are connected via 6-foot tubing to an external pneumatic console that controls the TAH. Each ventricle has a maximal stroke volume of about 70 mL. The large console consists of two complete pneumatic drivers (one primary and one back-up), two air tanks with enough pressurized air to last for 2 h per tank, and a panel of alarms. There are only 36 of these consoles in the world; thus, the availability of smaller more portable drivers has been long awaited and is just beginning to make an impact.

The pneumatic ventricles are lined with segmented polyurethane, including four layered diaphragms that separate the blood and air,

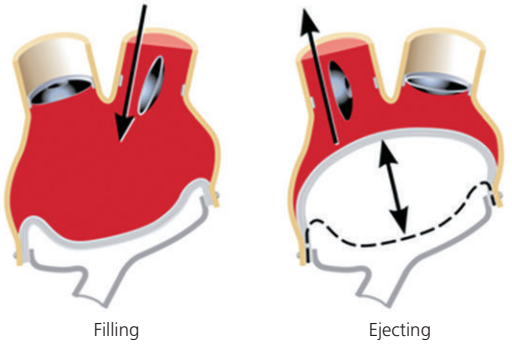

Figure 49.1. Blood flow through the SynCardia TAH-t. Blood and air are separated by a multilayer polyurethane diaphragm. Blood is pumped by air pressure and the ventricle then refills from the atrium under hydrostatic pressure.

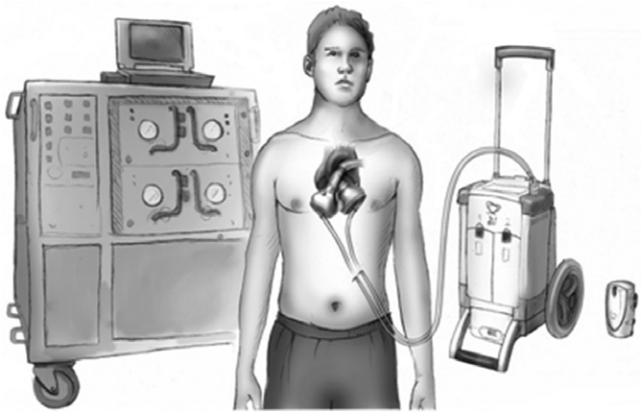

Figure 49.2. Schematic of the implanted device and three drivers. The large console on the left, "Big Blue," weighs 400 lb, the middle console on wheels, "Companion 2," weighs 55 lb, and the smallest pump on the right, "Freedom," weighs 13.5 lb.

and move in response to air pressure for outflow and venous blood filling pressure for inflow. Each ventricle has an inflow and an outflow valve. Thus, during inflow the ventricle has no air pressure on the air side and is filled through the inflow valve; and during device outflow, air pressure displaces the diaphragm, pushing blood out of the outflow valve.

The logic for running the device is very simple—partial fill, full eject (Figure 49.1). This means that the device is set to allow the ventricles to fill with 55 ± 5 mL of blood and then to completely eject that volume. The computer on the console displays ventricular air filling pressure, ventricular rate of blood filling (measured by monitoring the flow rate of air out of the ventricle), ventricular filling volume (from integration of the rate of filling over time), beat rate, output from left and right ventricles approximately every 1–2 s, and the average output over time as well as the trend over the past 8 h. Adjustments that can be made include: maximal air pressure for each ventricle, beat rate (the ventricles "beat" simultaneously), percentage systole (the percentage of the time the ventricles are in systole), and vacuum. The typical settings are: right ventricular pressure of 60 mmHg, left ventricle pressure of 180 mmHg, beat rate of 120–130/min, percentage systole of 50%, and vacuum pressure of –10 cmH_2O. This typically achieves a cardiac output of 7–8 L/min at physiologic blood pressure and a central venous pressure of 10–12 mmHg. The chosen pressure settings of the console are 30 mmHg higher than the anticipated pulmonary artery pressure and 60 mmHg higher than the anticipated systemic pressure, thus allowing for full ejection in the face of increasing vascular resistance. The vacuum never creates a negative pressure in the patient's atria. It is a negative force that is applied to the exit of air from the console (6 feet from the device), which slightly increases the rate of ventricular filling.

The external console weighs about 418 lb and was nicknamed "Big Blue" by a patient. With this console, the patient remains in the hospital until transplantation, but there are two smaller versions of the console that allow the patient to be mobile within the hospital and to be discharged home. The Companion II driver weighs 55 lb. In the US, there is currently a new portable driver for home use, called the Freedom driver. General availability awaits completion of an FDA trial in the US. The Freedom driver weighs 13.5 lb and can be worn as a shoulder case or a backpack, and it has enabled people to go home and be mobile enough to ride a bicycle (Figure 49.2).

Implantation and explantation

Implantation is very similar to transplantation. Explantation can be very difficult if the surgeon fails to "set up" for explantation at the time of implantation.

The first part of the implant operation is explanting the native heart. The native heart should be arrested and the aorta cross-clamped before there is any major manipulation of the native heart, particularly if there is any chance that mural thrombi exist on the left ventricular endocardium. The native heart is explanted just on the ventricular side of the atrioventricular groove. The annuli of the tricuspid and mitral valves are preserved, as is a circumferential 1–2-mm remnant of atrioventricular valve tissue. The purpose of this is to strengthen the base for the atrial quick-connect anastomosis. The great vessels are divided at the sinotubular junction and dissection of the great vessels is minimized to decrease postimplant adhesions.

The outflow conduits are presealed. Then, the atrial connectors and the outflow conduits are anastomosed. We usually cut the aortic conduit to 3 cm above the quick connect and the pulmonic artery to 6 cm. Prior to snapping the ventricles into place, a "neopericardium" [10] is constructed to separate the ventricles from the patient's mediastinal tissues. This prevents severe adhesion formation and facilitates explantation of the TAH at the time of transplantation. We also very loosely sling the superior vena cava (SVC), IVC, and aorta with ribbons of polytetrafluoroethylene (PTFE) or some other material to provide access for control of those vessels at the time of explantation (Figure 49.3).

Deairing and closure of the chest are major concerns at this point. The surgeon must allow the left ventricle to fill after quick-connecting to the left atrium in order to remove air from the left side. The remaining deairing techniques are similar to those in conventional cardiac surgical procedures. Closure of the chest is the time when adequate fit is confirmed. If the device is too large or there is temporarily inadequate space due to pulmonary edema, closure of the chest results in an immediate drop in pump output and reopening the chest restores output. If this is the case, the safest strategy is to leave the sternum open and to close the skin with a large Gortex patch, with the plan to reoperate and make another attempt at closure after some decrease in mediastinal inflammation and increase in pulmonary compliance.

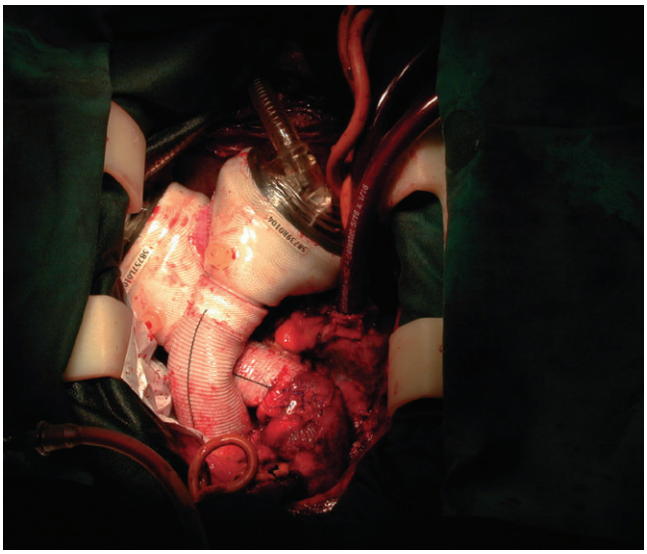

Figure 49.3. A fully implanted SynCardia TAH-t in situ prior to chest closure (viewed from the patient's head).

Anticoagulation

TAH patients are treated with anticoagulants and antiaggregants to achieve normocoagulability and moderate depression of platelet function. If TAH patients were not treated with anticoagulants and antiaggregants, the flow of blood through the device would create an imbalance by stimulating both the chemical coagulation proteins and the platelets, eventually leading to thrombus formation and increased risk of embolism. On the other hand, anticoagulation using current heparin protocols might be too much and lead to bleeding, while current aspirin protocols might not provide enough anticoagulation to inhibit platelet function, particularly in the face of the anticipated postimplantation thrombocytosis. Thus, close monitoring of coagulation tests and platelet function are very important in the titration of doses.

Our approach is based upon monitoring coagulation with thromboelastography (TEG) and platelet function with platelet count, bleeding time, and platelet aggregation studies [11]. The TEG measures the evolution of clot formation by measuring adherence and strength of the clot during its formation. As clots form in the TEG, there is a latent or enzymatic phase of stimulation by a foreign surface. The clot then becomes more adherent and stimulates platelet adhesion. After a period of minutes, the clot strength becomes maximal and then, if the fibrinolytic system is active, it is broken down.

The speed of formation of a sticky clot and the adherence of the clot to a foreign surface are variable and depend upon the excitation of the coagulation factors, the concentrations of the factors for the initial part of the TEG, and the number of platelets and concentration of fibrinogen and activity of the platelets in the later part of the TEG that describes the strength of the clot. By looking at both of these characteristics in a weighted equation, a number called the coagulation index (CI) can be calculated. This is a numerical value for defining the "coagulability" of the blood. Thus, a normal range is determined and called "normocoagulability." Anticoagulation, factor depletion, and thrombocytopenia can lead to hypocoagulability. In TAH patients, hypocoagulability correlates closely with the tendency to bleed. Stimulated coagulation factors and platelets or large concentrations of either, especially in the face of increased inflammation, lead to hypercoagulability and this is associated with a tendency to clot in the device or elsewhere (veins, diseased arteries, areas of blood stasis or turbulent flow).

The goal of anticoagulation is to make the patient "normocoagulable" according to the CI of the TEG. The beauty of this test is that it safely guides the physician in the use of anticoagulants, particularly in the first few weeks post implantation. Doses of heparin monitored by TEG are lower than they would be based on partial thromboplastin time (PTT). When using TEG, the PTT values are not even close to the "therapeutic" levels used conventionally (target PTT is 45 s). Thus, bleeding is rarely seen after the first few days following device implantation. As the patient recovers from multiple organ failure, especially from shock liver, use of oral anticoagulant therapy with coumadin may be preferable to heparin if hospital discharge and a wait of several months for transplantation is anticipated. The conventional guideline of an INR of 2.5–3.5 is reasonable in combination with antiaggregation therapy.

Antiaggregant therapy consists of aspirin and dipyridamole. Dipyridamole in fairly high doses (400–1000 mg/day) is started immediately per nasogastric tube. In selected patients it is given intravenously. Aspirin is not started until the platelet count is at least 150 000/mm^3 Initial dosing is 81 mg/day. It is gradually increased on the basis of platelet count (81–162 mg/day for each additional 150 000/mm^3 on the platelet count), bleeding time (with the aim to keep this 1.5–2 times normal), and the platelet aggregation (with the aim to preserve response to collagen, but depress response to arachidonic acid and epinephrine). As the patient recovers and can dependably take oral medication, we switch to Aggrenox b.i.d. It has been noted that the combination of aspirin and dypyridamole found in Aggrenox (20 mg and 200 mg, respectively) allows for a considerably lower dose of each agent than when aspirin and dypyridamole are administered separately..

We also use pentoxiphylline 400 mg t.i.d. for rheologic effects, prevention of rouleaux formation and decreased fibrinogen.

Postoperative complications

We have recently reported complications, or "adverse events" as they are called, for 101 consecutive patients with 24 patient years of TAH support from one center [12]. The major problems were thromboembolism, hemorrhage, and infection. There were two deaths due to central line entrapment of the tricuspid valve, a preventable event, and one death from device failure (a perforation in one of the four diaphragm layers).

Stroke

In this report, we found eight strokes (defined as neurologic deficit for >24 h). Four of these were related to the implantation and occurred within 2 days after the operation, and four occurred later during the period of support (at an average of 87 days). Two were in stable patients: one expressive aphasia that was transient and one hemiparesis; both patients were transplanted. Two were in patients with internal device infections. One stroke was fatal, three were associated with residual deficits and four patients had deficits that resolved completely within days. Thus, there were two strokes during stable support (0.02 events/patient year) and two strokes in the only two patients with internal device infections (0.02 events/patient year).

Bleeding

Bleeding requiring return to the operating room was seen in 25% of patients and occurred within 12 h of implantation in most cases. While this seems to be an important percentage, experience has shown that in very sick patients, particularly those with thrombocytopenia and liver synthetic dysfunction, this percentage is fairly constant for device implantation.

Our approach to bleeding in these patients is primarily surgical. We attempt to attain optimal hemostasis at the time of implantation, and often spend several hours waiting for adequate coagulation, controlling local bleeding with sutures and cautery as well as topical agents. We are liberal with replacement using blood and fresh frozen plasma, but reluctant to give platelets unless absolutely necessary. Platelet transfusions that may carry passenger white blood cells can cause anti-HLA antibody formation and thus limit subsequent transplantation options. We also are reluctant to use factor concentrates in this setting because of the possibility of over treatment that could result in stroke and systemic arterial and venous pathologic coagulation.

Infection

Infection in this series was defined as any positive culture or any treatment with antibiotics for a suspected infection; 64% were found to have "infection," which again is not an unexpected percentage Only a few of these infections were important, including three mediastinal infections requiring reoperation, drainage, and antibiotic irrigation. One of these patients survived.

Our approach to infections is to use limited prophylactic antibiotic therapy, usually just one or two doses of vancomycin. If infection is diagnosed, specific sensitivity-driven antibiotic therapy is given.

These three complications are intertwined, with anticoagulation increasing the risk of bleeding; reoperation and bleeding increasing the risk of infection; and infection increasing the risk of hypercoagulability and stroke.

Causes of death

In the above-mentioned most recent report of 101 consecutive TAH implants, there were 32 deaths on device support [12]. Seventy percent were in the first 2 postoperative weeks, suggesting a strong impact from the very poor condition of most patients. The causes of death were: 13 from multiple organ failure, six from pneumonia and/or pulmonary edema, five from sepsis, four from neurologic injury (one stroke, one hypoxic damage from hypotension, two intracranial hemorrhage), one from pancreatic abscess, one from small intestinal ischemia, one from disseminated intravascular coagulopathy, and one from disseminated coccidiodomycosis. This spectrum of causes of mortality is similar to that seen in mortality statistics for many types of mechanical support.

Summary

In the multi-institutional trial with SynCardia TAH-t, in which patients were carefully selected for implantation, a survival rate of 80% to transplantation and a survival of transplanted patients of 86% were found [6,8]. In our more recent report [12], using less rigorous selection criteria, the survival to transplantation was reduced to 70% and post-transplantation 1-year survival was 77%. Several large European experiences with liberal selection criteria have reported survival to transplantation of 50–70%. Regardless of the selection bias, patients in the throes of catastrophic decline who are classified as "crash and burn" with only hours to days to survive, as well as many patients who are beyond this classification and for whom there is no other solution than a total artificial heart, have survived in very significant numbers for years with TAH rescue and subsequent cardiac transplantation. Thus, this is a device that should be available in any serious end-stage heart disease program.

CHAPTER 50

Artificial Lungs

Claire A. Watkins and Bartley P. Griffith
University of Maryland School of Medicine, Division of Cardiac Surgery, Baltimore, MD, USA

Introduction

There are an estimated 750 000 patients with respiratory failure in the US, of whom 150 000 die annually [1]. Originally adapted from cardiopulmonary bypass components in 1972, techniques in extracorporeal membrane oxygenation (ECMO) have evolved to improve survival and reduce morbidity from respiratory failure [2]. Artificial oxygenators use porous hollow fibers for gas exchange; bloods flows over the fibers, often with the aid of a pump, while gas flows through the fibers (Figure 50.1). Although initial interest was hampered by poor survival in two randomized clinical trials of ECMO for adult respiratory distress syndrome (ARDS), 10% survival in 1974 [3] and 33% in 1994 [4], technical improvements, including heparin coating of components, polymethylpentene (PMP) diffusion membranes, centrifugal blood pumps, and redesigned cannulas, have improved outcomes and stimulated increased clinical use [5,6]. Studies throughout the 1980s and 1990s [2,7,8] consistently demonstrated survival rates between 40% and 50%. The multicenter CESAR trial in 2009 showed decreased mortality in patients randomized to mechanical ventilation with ECMO for ARDS in comparison to ventilation alone [9]. The benefit of ECMO in acute respiratory failure was re-emphasized in the H1N1 influenza pandemic in the late 2000s as survival with ECMO was >70% [10]. Additionally, recent studies demonstrate survival when ECMO is used as a bridge to transplantation of between 50% and 80%. The success of ECMO and its extension to a variety of indications also served to spur the development of other artificial lung devices. As for most life-supporting mechanical devices, outcomes are significantly improved by the selection of candidates early in their course of mechanical ventilation and without significant co-morbidities. As the bioengineering of artificial respiratory systems evolves, improved results can be expected.

The broad acronym ECMO is generally accepted to include $ECCO_2$-R (CO_2 removal), ECLA (lung assist), and ECLS (life support). However, the original application of ECMO was for hypoxia due to decompensated ARDS, as 3–15% of respiratory failure is attributed to ARDS [2]. With use of the ARDS Network (ARDSNet) ventilator management guidelines, including low tidal volumes (<6 mL/kg), low plateau pressures, permissive hypercapnia, inhaled pulmonary vasodilators, and judicious fluid utilization, survival nears 60% [11], leaving a sizeable population with the potential to benefit from ECMO. In severe cases, this ventilatory approach may not provide adequate gas exchange and may contribute to the progression of ARDS by inducing barotrauma, alveolar damage, increased capillary permeability, pulmonary edema, and inflammation (see Chapter 45) [2].The use of ECMO to allow protective approaches to ventilation with low frequency and tidal volume provides not only lung rest and less ventilator-associated lung damage, but also has led to improved outcomes for ARDS, as revealed in the CESAR trial. This multicenter, blinded clinical trial randomized severe ARDS patients to receive conventional ventilator management with or without ECMO. The significant improvement in 6-month survival without disability (63% vs. 47%) seen in this study served to establish ECMO as a superior therapy for severe ARDS [9].

Before ECMO was used as a bridge to transplantation, it was successfully used in salvaging dysfunctional grafts following transplantation. Primary graft dysfunction (PGD) is the leading cause of early death following lung transplant, occurring after 15–35% of transplants, 7% of which historically have required ECMO support [12,13]. PGD presents as progressive hypoxia, loss of lung compliance, and eventual hemodynamic instability. Contributing factors to PGD may include ischemia–reperfusion injury, rejection, prolonged ischemic time, and perhaps massive transfusion. Although higher survival is seen in lung recipients not requiring postoperative ECMO (82% vs. 40%), studies have demonstrated that in patients weaned from post-transplant ECMO (67%), survival approaches that of no ECMO controls (80% vs. 82%) [12]. Post-transplant ECMO has no effect on long-term lung function in survivors. The ability to wean from post-transplant ECMO following PGD is significantly lower at >14 days of support, and retransplantation must be considered at this point [12]. With mortality rates between 25% [14] and 60% [12], ECMO can serve to rescue failing transplant patients by allowing lung recovery or bridge to retransplant.

As of 2005, waitlist mortality for end-stage respiratory failure patients awaiting lung transplant was 20% at 1 year and 40% at 2 years after listing, indicating a clear need for alternatives both to transplantation and bridging devices that may allow survival to transplantation [15]. As the success of ECMO for ARDS and as rescue from transplant was realized, its use as a "bridge to transplant" grew. However, its use as a bridge to transplant was belated as reported outcomes were isolated and short term. Originally, ECMO was thought to be a contraindication to transplantation due to poor outcomes (estimated at 60% in 2002) [5]. However, case reports of successful use of ECMO as a bridge to primary lung transplantation in young, acutely ill patients, often with influenza-

Figure 50.1. The ECMO circuit.

associated bacteria pneumonias, unveiled the potential of ECMO therapy in this application. This indication for ECMO may serve a large population of patients with irreversible respiratory failure without other organ failures who may not otherwise survive on the transplant waitlist. Patient survival is now reported to be between 50% and 80%; thus, allocation of lungs to ECMO patients is justified and common.

ECMO in support of lung transplantation

Indications for ECMO vary with the clinical urgency of respiratory failure (Table 50.1). Generally, acute or chronic respiratory decompensation without other concurrent organ failure prompts its use as a bridge to transplantation. While guidelines vary among institutions, ECMO is generally considered when Pao_2 is <50 mmHg, $Paco_2$ is >80 mmHg, and/or Pao_2/Fio_2 ratio is <1 [16]. Contraindications generally include a contraindication to anticoagulation, irreversible central nervous system (CNS) damage, sepsis, multiple organ failure, and severe peripheral vascular disease [6]. Acute renal failure, high vasopressor requirements, age, obesity, and extended duration of mechanical ventilation are relatively strong contraindications [16]. The only explicit contraindication is irreversible CNS damage. Recent data suggest that patients with chronic severe pulmonary failure anticipating transplant may benefit from early implementation of ECMO [6]. While bleeding and

thrombosis are always a delicate balance in ECMO patients, the use of heparin-bonded ECMO components has softened the contraindication to ECMO in those who cannot be anticoagulated or have a history of bleeding. Although not a contraindication, when initiated for pneumonia or sepsis, ECMO has markedly decreased survival [10].

The decision to initiate ECMO should be based on the severity of respiratory impairment and the likelihood of successfully bridging patients to recovery or transplant. Additional advancements in the management of acute lung injury, such as inhaled nitric oxide (iNO), low tidal volume ventilator strategies, and prone positioning, may improve some of the parameters and serve to restrict ECMO therapy to more severe cases of respiratory failure [2]. Additionally, as the benefits of both awake and ambulatory ECMO are realized, the timing and use of ECMO in chronic disease is evolving.

Mode of ECMO support for bridge to transplant

Clinical considerations that may be useful to determine the mode of ECMO for a bridge to transplant include hemodynamic stability, degree of oxygenation, or ventilatory failure and presence of right ventricular (RV) or pulmonary artery (PA) failure. Veno-venous (V-V), veno-arterial (V-A), or arterial venous interventional lung assist (iLA) ECMO can be considered (Figure 50.2). Minor hemodynamic decompensation secondary to hypoxia and modest RV failure can generally be stabilized with V-V ECMO, while cardiogenic shock can only be stabilized with V-A ECMO. Both V-V and V-A cannulation strategies improve systemic oxygenation; however, V-A ECMO provides the immediate circulatory support often necessary in decompensated heart failure [17]. In most circumstances V-V cannulation is preferred due to its inherent reduced risk of systemic embolization and absence of injury-related arterial cannulation. Persisting hypoxia in V-V mode is due to recirculation and/or the inability to capture all desaturated venous blood into the ECMO circuit via peripheral V-V cannulation. If severe hypoxia persists (<85% arterial saturation) after repositioning of inflow and outflow cannulas, a central V-V cannulation or switch to a V-A mode is indicated. In the absence of left heart failure, we strongly prefer avoidance of a V-A mode and centrally cannulate the right atrium (RA) for inflow and the pulmonary artery (PA) for outflow via an upper third sternotomy. Cannulas are brought out below the right costal margin to reduce infection at the small sternal incision and to enable mobility of the patient as recovery evolves. Other innovative strategies have been shown to successfully stabilize heart failure while on V-V ECMO, including the creation of an atrial septostomy. A septostomy can unload volume to the left ventricle (LV) and can deliver high saturations through oxygenated venous blood delivered to the left atrium (LA) and LV. An alternative approach is a sternotomy and central recannulation, with inflow from the RA and outflow to the PA, left atrium (LA), or aorta. Pumpless iLA, in addition to traditional ECMO, has successfully bridged patients with PA hypertension to transplant and even allowed extubation and ambulation [16,18].

Cannulation approaches generally utilize the internal jugular vein and femoral vein and/or artery. Although most cannulas can be placed percutaneously, open chest cannulation between the RA and aorta is an option during surgery. V-A cannulation carries an additional threat of distal limb ischemia due to thromboses and requires frequent assessment of limb perfusion [16]. An important consideration in cannulation placement is potential recirculation of blood through the circuit without systemic perfusion. This is prevented by maintaining distance between the ends of the in- and out-flow cannulas. Using V-A ECMO, sufficient systemic oxygenation can be achieved with the tip of a femoral arterial cannula in the lower abdominal aorta [6]. Recirculation should be suspected with high in- and out-flow oxygen content that does not correlate with the oxygenation of the patient. Another concern with femoral vessel outflow cannulation for V-A ECMO is the preferential flow of oxygenated blood to the lower extremities and abdomen, leaving cardiac and cerebral perfusion dependent on cardiac output. Some have suggested axillary artery cannulation to avoid upper body mixed perfusion and sites of severe peripheral vascular disease, and to allow ambulation [19]. Both upper and lower extremity saturations should be followed with any discrepancies treated by adjustments of both ventilatory and circuit blood flow [16]. Cannula-related complications, such as thrombosis, kinking, or malpositioning, should be suspected whenever there is a decrease in previous oxygen saturation levels, increased pressures (negative on inflow and positive on outflow) in circuit lines and hemolysis.

Routine therapeutic goals in ECMO, as defined by the Toronto Transplant Program guidelines, include oxygen saturation of >85%, Pao_2 of >100 mmHg, $Paco_2$ of 35–45 mmHg, and pH of 7.35–7.45. To prevent thrombotic complications, activated clotting times (ACTs) should be maintained between 160 and 200 s for both V-V and V-A ECMO. To prevent bleeding complications, the international normalized ratio (INR) should be <1.8 or <1.5 if bleeding is occurring and platelets should be >80 000/mm^3 or >100 000/mm^3 if bleeding is occurring [16] (Table 50.2). Diuretics are

Pco_2	35–40 mmHg

required to maintain preillness weight. Hemofiltration is useful when necessary.

Complications of bridge ECMO

Disadvantages of ECMO include its limited duration of use and high rate of complications [15]. Complications from ECMO in patients bridged to lung transplant include renal failure (35%), pulmonary infection (52%), sepsis (41%), fatal sepsis (17%), tracheostomy (41%), digital ischemia (11%), gastrointestinal bleeding (6%), and stroke (6%) [20]. Although the development of heparin-coated components alleviates some of the need for high systemic anticoagulation, the major complication affecting mortality is bleeding. Damage to blood cells as a result of shear through the blood pump, such as hemolysis, platelet activation, and depletion and activation of white blood cells with inflammation, requires frequent monitoring (Table 50.2). Hemolysis is followed not only with cell counts but also with lactate dehydrogenase and plasma free hemoglobin levels. Other studies estimate the complication of bleeding occurs in 52%, hemodialysis in 42%, and neurologic events in 12% [13].

Outcomes with bridge ECMO

Despite affirmation of the utility of ECMO in bridging otherwise terminal respiratory failure patients to lung transplantation, reported benefits vary. The largest study examining outcomes included 51 patients throughout the US and reported a 1-year survival with ECMO bridge to transplant of 50% [21]. Additional single-center experiences from large transplant centers demonstrate higher survival rates of 80% (Hannover), 74% (Pittsburgh) [20], and 60% (Vienna) [17]. A study of two high-volume centers in Scandinavia reported 1-year survival of 75% with ECMO intention to bridge and 92% for those receiving transplant, and survival with transplant of 50% at 10 years [22]. Additionally, in this study >60% of transplants used marginal donors by International Society for Heart and Lung Transplantation Society (ISHLTS) criteria. These results suggest important considerations regarding ECMO as a bridge to transplantation. Outcomes of ECMO in transplantation are clearly dependent on the institution's experience with the technique, with higher volume centers having better outcomes and all centers' outcomes improving with time. Additionally, ECMO patients are considerably sicker and more complicated than patients presenting from home for transplant, explaining the poorer outcomes. This is also seen in the higher survival of patients bridged using CO_2 removal devices, which require hemodynamic stability (often lacking in V-V and certainly V-A ECMO patients) [17]. Interestingly, in the Vienna study, the morbidity and mortality of transplant recipients did not differ by duration of ECMO prior to transplant, which has been speculated to be a cause for variation in outcomes. While 60% survival may appear low, it is notable that of patients surviving to 3 months, 78% survived to 1 year, which was not significantly different from the 80% survival in all other lung transplant patients at that institution [17]. The US experience also demonstrated similar findings in that ECMO was a risk for early but not late transplant mortality compared to unsupported transplant patients [21]. This suggests that if moribund ECMO patients survive the initial decompensation that required initiation of support, their outcomes will be similar to those for other lung transplant patients. In a review of outcomes from Pittsburgh, a high-volume transplant center, ECMO before transplantation was associated with increased perioperative mortality, but not 1-year graft function (74%) [20]. The higher survival in this study may be augmented by the exclusion of patients transplanted with any other organ failure or systemic infection as well as use of standard criteria donors. Additional Pittsburgh findings include that ECMO patients were younger, more often repeat transplants, had longer ischemic times and higher rate of PDG, and were more likely (48% vs. 7%) to require post-transplant ECMO rescue [20]. Transplant allocation in the US has recently reclarified the goals of donating organs to patients with both highest urgency and best likely outcomes through the Lung Allocation Score (LAS). This focus serves to prioritize ECMO patients by a high score due to co-existing need for mechanical ventilation.

Novel directions in ECMO bridge to transplantation

Mechanical ventilation prior to lung transplant is a significant risk factor for complications, such as infection, ventilator-associated lung injury, deconditioning, additional organ dysfunction, as well as increased mortality [23,24]. The ability to avoid mechanical ventilation during ECMO therapy postulates improved outcomes and less morbidity when bridged to transplant. As initially reported in five awake patients with pulmonary hypertension and right heart failure, ECMO initiation earlier in the course of end-stage respiratory failure and before mechanical ventilation has demonstrated successful results. In this series, V-A cannulations were done under local anesthesia and without sedation. Two patients died from bleeding complications. Three patients breathed spontaneously, ate and drank without nutritional supplement, participated in passive and active physiotherapy, and made a full recovery [25].

An "awake ECMO" approach has been extended to broader end-stage respiratory failure patients with exciting results. The largest study examining this strategy is from Hannover and included 26 awake ECMO patients compared to 34 patients bridged with conventional mechanical ventilation [6]. Awake ECMO patients (13 V-V and 13 V-A) had significantly higher Acute Physiology II scores and lower oxygen saturations before bridging, but decreased days of mechanical ventilation following transplant and decreased mortality at 6 months. This survival advantage dropped to 43% when awake ECMO patients required intubation (most often secondary to bleeding). In addition, ICU days ($P = 0.07$) and length of stay ($P = 0.06$) trended lower in awake ECMO patients [6]. Interestingly, despite being generally sicker patients, the awake ECMO group did not have a higher mortality while waiting for lung donation. The apparent survival benefit of awake ECMO as a bridge to lung transplantation may be due to avoiding the hazards of anesthesia and mechanical ventilation. Additionally, in the setting of right heart failure, anesthesia induction and intubation carries a high risk of circulatory collapse. The ability of the awake patient to eat, drink, breath spontaneously, and participate in physical therapy likely contributes to improved post-transplant outcomes. Reported difficulties with the awake ECMO approach are the maintenance of not only oxygenation but also the respiratory comfort of severely hypoxemic patients, such as those with interstitial pulmonary fibrosis (IPF) [6].

In parallel with the development of awake ECMO, the creation of a dual lumen venous cannula for single cannulation in V-V ECMO has allowed the progression of bridging techniques to include both awake and ambulatory ECMO [26]. The dual lumen catheter (Avalon Elite Bicaval Dual Lumen Catheter) is placed

under ultrasound guidance with the proximal and distal inflow cannula tips placed in the superior vena cava and inferior vena cava (IVC), and an outflow orifice in the RA. The distal inflow cannula should be positioned far into the IVC, at or past the hepatic veins, to avoid recirculation of blood through the circuit. Outflow should be directed at the tricuspid valve under ultrasound guidance. Cannula sizes include 23-French (Fr), 27-Fr, and 31Fr, and can provide blood flow of up to 3.5–5 L/min. With the Avalon cannula, patients should be fully anticoagulated at the time of ECMO initiation and an ACT of 140–160 s maintained throughout support. In initial reports, the dual lumen catheter was able to maintain oxygenation (median Pao_2 increased from 45 to 115 mmHg), stabilize hemodynamics [median mean arterial pressure (MAP) increased from 48 to 72 mmHg], and wean 72% of patients from support, including those with chronic obstructive pulmonary disease (COPD). There were no mortalities directly associated with ECMO (55% survival), but there were two cases for whom cannulas required emergent repositioning and one case of cannula thrombosis secondary to subtherapeutic anticoagulation [26,27]. Any acute oxygen desaturation or increased oxygen pressure in inflow blood raises concern for cannula complications and the need for repositioning under ultrasound. Similar to awake ECMO, ambulation allows increased pulmonary toilet, decreased pulmonary infection, and added active physical rehabilitation, with patients being able to use treadmills and stationary bikes [27]. In addition to avoiding femoral cannulation, this technique can be useful in patients with previous vascular interventions such as IVC filters. By decreasing the length of tubing and minimizing contact with foreign materials, the dual lumen catheter may also serve to decrease inflammation and thrombosis [26]. Despite exciting initial results, no direct comparisons of single cannulation to traditional V-V ECMO have been done.

Artificial lungs for CO_2 removal

Extending ECMO beyond the indication of inadequate oxygenation, Gattinoni et al. in 1978 first conceptualized using artificial gas exchange to reduce ventilatory requirements and barotrauma through CO_2 removal [28]. They used room air through a silicone coiled membrane lung in lambs, and demonstrated reduced tidal volume, respiratory rate, peak inspiratory and end-expiratory pressures, as well as maintenance of pH, cardiac output, and oxygenation with CO_2 removal in both spontaneously and mechanically ventilated animals. Additionally, this group showed that artificial CO_2 removal can reduce airway pressures significantly enough to allow healing of induced large bronchial air leaks not successfully treated with conventional mechanical ventilation approaches [28]. This work stimulated the expansion of extracorporeal gas exchange to differing clinical scenarios and the development of new and improved devices.

Developed in 1999, the NovaLung is a pumpless PMP membrane capable of normalizing pH, peak inspiratory and positive end-expiratory pressures, as well as significantly improving $Paco_2$ and Pao_2 in severe ventilatory failure with hypercarbia and respiratory acidosis [29]. This approach is similar to ECMO in allowing lung protective ventilatory strategies, but also prevents additional barotrauma and ventilator-associated lung injury that have been identified as a risk for additional remote organ failure [30]. This device was able to remove up to 70% of excess CO_2 in adults with severe ventilatory failure, while maintaining hemodynamic stability. In initial applications as a bridge to lung transplant, 1-year survival with the NovaLung was reported at 80% in 2005 [13]. Additionally, the NovaLung has demonstrated benefit in patients suffering from ARDS following pulmonary resection, improving survival in a clinical state carrying 40–60% mortality to 71.4% [31]. iLA can be helpful in allowing decreased ventilation and sequential lung deflation in those with COPD exacerbation [10]. Use of iLA has been successfully extended to the management of severe chest trauma, ARDS, PA hypertension, pneumonia, and airway obstruction [29].

The low-resistance iLA device is implanted between the femoral artery and vein, and uses cardiac output rather than a pump to generate flows of 0.5–4.5 L/min. The lack of an artificial blood pump component in the NovaLung means less of the cardiac output (about 20%) goes through circuit, and thus allows a smaller circuit and therefore reduces the priming volume and foreign surface contact [31]. Unlike ECMO, the degree of CO_2 removal is dependent on sweep gas flow, not blood flow. While oxygenation is generally maintained by the native lung in the setting of iLA, small increases in oxygenation can be seen with the NovaLung. Contraindications to iLA include severe hypoxia, cardiogenic shock, or peripheral vascular disease [29]. Prior to iLA placement, the diameter of the femoral artery should be measured via ultrasound. An appropriate cannula size will be at least 20% smaller than the arterial diameter [31]. When both cannulas are connected and flushed with heparinized saline, the transition to iLA should be done gradually over >2 min to reduce the hemodynamic effects of the created A-V shunt. Arterial cannulation with an inflow cannula creates an additional risk of low flow limb ischemia and thus requires frequent assessment of peripheral limb perfusion. Gas flow rate is generally started at 1 L/min and titrated with blood gas results. Management principles include periodic reduction of ventilator settings to minimize ventilator-associated lung injury by decreasing rate (<10 breaths/min), tidal volume (<6 mL/kg), plateau inspiratory pressures (<20 mmHg), with an increase in positive end expiratory pressure (PEEP; >10 mmHg) in pressure control modes if necessary. Ventilatory settings can be reduced to minimal lung protective settings within 2 h of iLA initiation without hemodynamic instability. iLA is able to significantly improve respiratory parameters, decrease levels of inflammatory cytokines, and improve Murray ARDS scores. Anticoagulation to maintain a partial prothrombin time of 50–60 s will generally prevent clotting of the NovaLung membrane. Additionally, a MAP of >60 mmHg is required to maintain flow through the NovaLung and should be maintained with intravenous fluid or vasopressors if necessary. Similar to weaning ventilatory support, as respiratory function returns, gas flows can be decreased. Decannulation and removal of the NovaLung should only be considered when the patient can maintain >3 h of respiration with no sweep gas flow either with or without mechanical ventilation [31].

Paracorporeal artificial lungs

As ECMO has proven ability to sustain acute lung injury patients to recovery, rescue transplant patients with PGD, and bridge patients to transplantation, future indications for ECMO may include bridge to a paracorporeal artificial lung (PAL) device capable of extended or "destination" use as modeled in ventricular assist device therapy for heart failure [6]. Various PALs have been developed, with indications in both end-stage respiratory failure not amenable to transplantation and as a bridge to lung transplant. A PAL device has the potential to allow ambulation, rehabilitation,

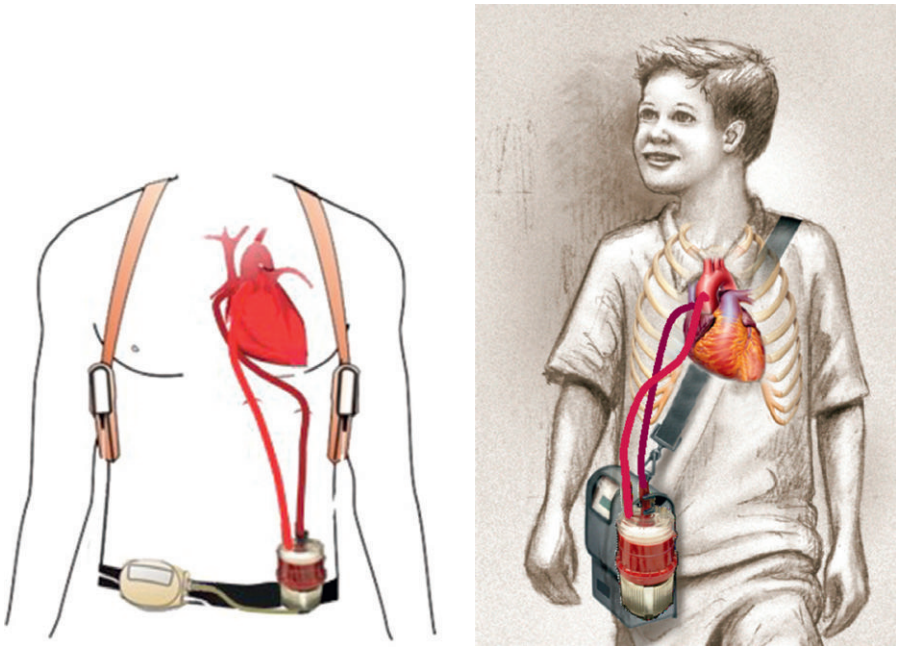

Figure 50.3. Ambulatory paracorporeal artificial lung.

and discharge from the hospital in patients who would otherwise be confined to hospital on ECMO [1].

Factors in the design of new and smaller devices must include maintenance of blood pressures across the device to prevent clotting. While this is most simply achieved with the use of a blood pump, pumpless devices using the heart to generate flow have also been shown to maintain consistent device flows [32,33]. However, the pump or external circuit itself cannot expose the heart to extensive resistive pressures as these will inevitably lead to right heart failure, as seen in animal studies of pumpless devices despite the addition of inflow compliance chambers or valves modifying the degree of cardiac output reaching the device [33]. In the setting of bridge to transplantation, perhaps the best device resistance imposed on the right heart would be that of healthy lungs [34]. Cannulation approaches must also consider the strain put on the right heart, as can happen with in-series cannulation [33]. Concerns regarding an in-parallel cannulation method are bypass of the lung's metabolic and filtering functions, as well as the threat of systemic thromboemboli from the device [32]. Shear stress through the device requires optimization, as high shear stress leads to blood cell damage, hemolysis, platelet activation, and consumption, but low shear stress leads to coagulation activation, fibrin deposition, and thrombosis in the device [32]. Activation of inflammation is a biocompatibility concern that will also require optimization before human use. Additionally, while the paracorporeal position allows device change and maintenance, the goal should be for the device to be used for the entire duration of support.

Various studies in both healthy and disease model sheep have demonstrated the capability of PAL devices to provide respiratory assist, with durability of up to 30 days [32]. Initial animal studies using PAL devices found a high incidence of right heart failure with in-series cannulation (PA-PA). Therefore, parallel (PA-LA) configurations providing lower circuit resistance may be the preferred approach to long-term PAL implantation [33]. Feasibility in long-term gas exchange was seen using PA-LA oriented pumpless systems, similar to iLA, as this technology was extended to human use [34,35]. Risks of this device, as demonstrated in animals, include embolic events and device failure, the latter corrected with relatively easy replacement [34]. These risks have improved with the use of heparin-coated components, but likely derive from the alternating use of a pumpless oxygenator in a low-pressure orientation rather than the systemic atrioventricular (A-V) orientation that is successful in iLA. Initial poor results and incidence of right heart failure with in-series pumpless devices [33] have been improved with both in-parallel cannulation approaches [34] and the incorporation of a centrifugal pump into a PAL device [36] (Figure 50.3). Using an integrated pump lung, 30-day animal studies establish the feasibility of such a device in humans. Implanted between the RA and PA, the artificial pump lung can serve to both unload volume to the right heart while maintaining total flow through the lungs and decreasing the risk of systemic thromboembolus. With a compact size and low priming volume, the integrated pump lung has demonstrated the ability to maintain oxygenation and normal end-organ function without significant hemolysis, or platelet or white blood cell activation [36]. These promising results, as well as the initial success of the pumpless PAL in patients, establish the potential for long-term mechanical respiratory support.

In 2008, initial use of a PAL device as a bridge to transplantation was reported in a patient with severe primary pulmonary hypertension, allowing survival for 62 days until donor lungs became available. Thoracic PA-LA cannulation allowed in-parallel shunting of blood at 2–4 L/min through the pumpless oxygenator (iLA), while avoiding femoral vessel cannulation. The patient was emergently placed on ECMO as a result of ARDS, right heart failure, and cardiac arrest following a cholecystectomy. The paracorporeal device was implanted after 9 days of ECMO and was associated with reversal of liver and kidney failure, and protective ventilation allowed slow normalization of gas exchange, followed

by extubation, ambulation, and thus a bridge to successful double lung transplantation [1]. This novel treatment for decompensating pulmonary hypertension and right heart failure was then successfully extended to four patients with pulmonary veno-occlusive disease (PVOD). With the same PA-LA cannulation and pumpless membrane oxygenator, patients were supported for between 8 and 21 days prior to transplantation and improvements in oxygenation, ventilation, cardiogenic shock, acidosis, and kidney and liver function were seen. Two patients were briefly supported with V-A ECMO through induction of anesthesia, one was able to be extubated with the PAL device, one required device change, and three regained full right heart function. Sepsis and multiorgan failure led to mortality in one patient following transplant; otherwise there were no complications [35]. Given the high mortality of these patients while waiting for transplantation and their reliance on V-A ECMO, these successful attempts at bridge to transplantation demonstrate a novel ability to recover the right heart function and ease refractory pulmonary hypertension using a PAL device. Our own program has been interested in ECMO for ARDS and a V-V or RA-PA central cannulation. Since 2009, we have supported 57 patients with an overall 54% survival. Of interest, eight of 11 who survived once transplanted were discharged from the hospital with an average of 53 days of ECMO support. Clearly, prolonged lung support is increasingly possible and extended bridge platforms are in evolution.

Summary

Artificial lung support has advanced significantly in the past two decades to include traditional ECMO as well as numerous novel devices to assist with oxygen delivery and CO_2 removal. These are important adjuncts to the transplant pulmonologist and surgeon seeking to provide bridge support either to transplantation, transplant recovery, or retransplantation. While not practical as destination therapy, newer devices are allowing for remarkable degrees of ambulation and rehabilitation, and it is likely that permanent artificial lung support will be an emerging option for patients with end-stage lung failure.

Introduction

No treatment has been shown to prevent type 1 diabetes in humans [1]. Without a means to prevent the disease, islet [2] or pancreas/kidney transplantations [3] are thought of as possible cures, but neither option is widely available as there are insufficient organ donors. Engineered cell lines [4], stem cells [5], or xenotransplantation [6] may overcome the islet shortage, but the timeline is unclear and the recipient may still require immunosuppressive therapy, which can have significant associated risks [7]. Although the benefits of good glucose control have been well documented [8–10], studies have shown that achieving the required level of control is difficult [11]. Sensor-augmented pump (SAP) therapy, leading to a closed loop artificial pancreas (AP), has thus emerged as a leading contender in the quest to reduce the burden and improve the health of individuals with this condition. Its consideration in a textbook of transplantation is appropriate as a potential future state for the field, potentially limiting the need for pancreas or islet transplantation or providing an alternative to transplantation for patients in need of glucose control.

The AP is envisioned as a fully automated system that can regulate glycemia through insulin titration based on a glucose sensor feeding information to a control algorithm [12]. This work has been at the forefront of research in the diabetes scientific community for almost four decades [13]. Early closed loop AP systems employed intravenous (IV) glucose sensing and insulin delivery methods. Miles Laboratory (Elkhart, IN, USA) commercialized the first AP in 1979 for intended use in the hospital setting and received US Food and Drug Administration (FDA) approval in 1983. The device, known as the Biostator, performed whole blood measurements by extracorporeal online analysis with an electrochemical sensor [14] and achieved glucose regulation by classical control techniques using a proportional-derivative algorithm. While the system demonstrated tight glycemic control and was extremely effective when used to perform glucose clamp experiments [15], its usefulness was limited to the clinical or laboratory environment. Other types of closed loop AP systems have emerged using the intraperitoneal (IP) insulin delivery route—one being a fully implanted system with a central intravenous glucose sensor placed close to the right atrium [16]. Although the IP system showed fast insulin kinetics, sensor latency affected control performance. The system was used in a hybrid configuration with a fully implanted IP insulin delivery pump and subcutaneous sensor [17]. An alternative to the fully implanted IP delivery pump is the DiaPort® (Roche Diagnostics, Mannheim, Germany) [18]—a port that is surgically implanted in the wall of the abdomen and is connected to an IP catheter that facilitates insulin delivery using an external pump. Although invented in 1999, this system has not been widely used, but has recently been adopted for closed loop AP studies.

Current research in the development effort toward an AP system has been mostly consumer oriented. Such a device must be suitable for ambulation and continuous wear, enabling patients to go about their daily activities. This system will likely employ interstitial fluid (ISF) glucose sensing [19] and continuous subcutaneous insulin infusion (CSII) methods. Developing algorithms for systems that measure ISF glucose and rely on CSII is made difficult by the time delays between ISF and plasma glucose [20], delays in the measuring device per se [21], and delays associated with subcutaneous insulin delivery [22]. Many of the challenges inherent in current commercially available devices have been reviewed in detail [23].

In this chapter, consumer-based AP systems are described for use outside of the hospital setting. The components of the systems include minimally invasive glucose sensing techniques in the interstitial compartment and CSII methods. Each component is described together with the particular system's performance and clinical utility. All references to the AP from this point forward will refer to subcutaneous (SC) glucose sensing and SC insulin infusion (SC-SC). The results discussed with this approach can be compared and contrasted with the results achieved through pancreas or islet transplantation, which are discussed in Chapters 107 and 61, respectively.

Glucose sensing

Minimally invasive SC glucose sensors are typically placed in the abdominal region and are used to continuously measure ISF glucose. This technology is widely believed to be the most likely to be adopted and used in the initial ambulatory systems worn by patients without supervision and outside of the clinical setting. The first commercially available continuous glucose monitoring (CGM) device approved by the FDA was the continuous glucose monitoring system CGMS® System Gold™ [24], launched in mid-1999 by MiniMed Inc., now Medtronic Diabetes. The original CGMS

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

device had the capacity to store 3 days of continuous glucose data measured with a sample acquisition time of 5 min. The data were downloaded to a PC where a software application was used to retrospectively analyze the data in a similar fashion to how electrocardiogram (ECG) signals are analyzed offline with a traditional cardiac Holter monitor. CGM was shown to capture significantly more glycemic variability. One study [25], using a CGM system developed by Roche Diagnostics, showed that 71% of hypoglycemic events were missed by subjects taking four fingerstick blood glucose samples per day and 58% of events were missed by subjects testing up to seven times per day.

This retrospective CGM technology developed by Medtronic Minimed was approved for real-time use in 2005 with the launch of the Guardian® REAL-Time [26], the first commercially available real-time CGM device. It displayed glucose values every 5 min, and provided hypo- and hyper-glycemic alerts. Efficacy of the system was demonstrated in a 12-week multicenter study [27] consisting of 156 stable type 1 patients [hemoglobin $A1_c$ ($HbA1_c$) >8.1%]: it enabled patients to decrease their $HbA1_c$ levels from 8.1% to 7.0%, with 26% of patients decreasing their $HbA1_c$ to below 6.1%. Hypoglycemia occurred once in each study arm and only in one case when the patient was wearing the device, despite a confirmatory fingerstick. The Guardian® REAL-Time system was followed by the approval of the STS™ system developed by Dexcom, Inc. (San Diego, CA, USA) for the US market. A study of that system, which included 91 patients, some with type 2 diabetes, showed that subjects using the system spent 21% less time hypoglycemic, 23% less time hyperglycemic, and 26% more time in the target range [28]. The Abbott FreeStyle® Navigator® (Abbott Diabetes Care, Alameda, CA, USA), which provides glucose samples every minute for a 5-day period and includes the FreeStyle BG meter, was introduced into the marketplace in 2008.

All of the initial studies showing the efficacy of CGM were conducted using sensor technology that has since improved. The clinical accuracy of the Dexcom SEVEN® Plus [29], the Abbott FreeStyle® Navigator® [30], Guardian®, and Paradigm® platforms [31] have been published in a number of scientific journals. However, the accuracy is improving, as are the manufacturing processes, with smaller more comfortable sensors with increased accuracy throughout the glycemic range [32] and better calibration algorithms [33,34]. Still, low error rates do not necessarily guarantee effective therapy and conversely, sensor error may not necessarily lead to unsafe therapy, as many therapy algorithms may be robust to sensor error.

The accuracy of current glucose sensors has been questioned in respect to enough accuracy for closed loop control. Several groups have already reported sufficiently accurate CGM performance to perform closed loop control. In particular, Hovorka et al. [35] demonstrated effective glucose regulation during the nocturnal period in a three-phase study that employed the Guardian® system in one phase and the Navigator® monitor in the following two phases. The study reported accuracies of 10% for the Guardian® monitor with YSI calibrations every 6 h and 12% for the FreeStyle® Navigator® meter using fingerstick calibrations. In a similar study, Castle et al. [36], also utilizing the Guardian® monitor in addition to the Dexcom SEVEN Plus system (Dexcom, San Diego, CA, USA), revealed highly accurate sensor performances during closed loop control. The combined dataset resulted in a mean absolute relative difference (MARD) of 8.7% when calibrating with YSI samples close to every 6 h.

Sensor augmented pump therapy

While no CGM technology has been approved as a replacement for blood glucose monitoring, the technology has been combined with insulin pump technology to create what is now known as SAP therapy. In this technology the sensor is still serving an adjunctive role, sounding alerts that can be verified by the user. The first major step toward the AP was the launch of Medtronic's Paradigm® REAL-Time system, which merged CGM with insulin pump therapy [37]. Although this system has all of the required components for closed loop control [38], the CGM and insulin delivery subsystems operate autonomously. Today, CGM and CSII have been successfully merged with four SAP therapy products sold worldwide—the most recent being the Animas® Vibe™ (Animas® Corp., West Chester, PA, USA), which is built upon the Animas insulin delivery technology integrated with the Dexcom G4™ CGM system with glucose sensing over a 7-day period, and the Medtronic Paradigm Veo™ insulin pump, which provides additional functionality, with increased accuracy at low glucose levels [33] enabling the addition of auto-suspend capabilities [39] that can reduce severe hypoglycemia.

Several landmark trials have successfully demonstrated the efficacy of SAP therapy. The STAR 1 trial [40] compared SAP and conventional CSII therapies in a 6-month randomized multicenter study (n = 146 pediatric and adult subjects) achieving an $HbA1_c$ reduction in both SAP cohorts (0.5% in adult). SAP therapy was compared to multiple daily injection (MDI) therapy in a number of studies, including the REAL Trend with 115 pediatric and adult subjects [41]; the Eurythmics with 83 adult subjects [42]; the ONSET study with 160 subjects aged between 1 and 16 years [43]; and STAR 3, the largest to date with 485 pediatric and adult subjects [44]. The REAL Trend study treatment arm attained close to a 1% reduction in $HbA1_c$, with the greatest improvements in subjects who wore a sensor at least 70% of the time. The Eurythmics trial over 6 months saw a reduction in $HbA1_c$ exceeding 1% with only 0.13% reduction in the control group—34% of subjects in the SAP group lowered their $HbA1_c$ to below the recommended 7%, whereas no subjects in the control arm reached this target. The ONSET trial showed lower $HbA1_c$ levels over a 15-month period for newly-diagnosed pediatric patients undergoing SAP therapy in comparison to MDI, and a lessening in the decline of C-peptide levels. Finally, the STAR 3 trial, demonstrated after a 1-year period $HbA1_c$ reductions of 0.8% (1% in adults) compared to 0.2% in the control group without increased incidence of hypoglycemia.

Paradigm Veo™ semi-closed loop system

A link between subsystems was established with the Paradigm® Veo™ insulin pump. This device was launched in 2009 in Europe and around the world outside of the US. The Veo™ insulin pump employs the same platform as the Paradigm® REAL-Time insulin pump with additional functionality that includes automatic suspension of insulin delivery beyond predefined low glucose thresholds, making it the first product that utilizes glucose sensor feedback to control insulin delivery, or in this case, suspend delivery.

This low-glucose suspend (LGS) capability is illustrated in Figure 51.1, demonstrating the functionality of the sensor in reducing the severity of hypoglycemia. This capability is not intended to prevent hypoglycemia, but to reduce the impact of any episodes missed by the user [45]. Therefore, when a low-glucose event occurs an alarm

will alert the subject and allow rescue carbohydrate to be consumed if necessary. In situations where the subject is not in a state to react to the hypoglycemic event or if an alarm has gone unnoticed, the system will respond by suspending insulin for 2 h, after which time normal basal insulin delivery is resumed.

Two examples of LGS activation are shown in Figure 51.2. In the first example, sensor glucose first crosses a hypoglycemia alert threshold between midnight and 2:00 AM, when two sensor alarms sound. However, the sensor reports glucose levels increasing back into the normoglycemic range. Sensor alarms sound again when the sensor drops below the low alarm threshold at 4:00 AM. Eventually, glucose falls below the LGS threshold, the LGS pump alarm sounds just before 5:00 AM, and insulin delivery is suspended when there is no response to the alarm. This auto-suspend function is for a 2-h period, unless there is user intervention. During this time period, glucose levels increase. With the resumption of basal insulin, glucose levels start to decrease again and a sensor low alert is triggered. Eventually, there is a second LGS activation between 10:30 AM and 11:00 AM for an additional 2-h period. Glucose concentration reaches safer levels following this activation. The effectiveness of this system has been demonstrated by retrospective analysis [46] of data collected from 935 patients totaling 49 867 days and noting 27 216 activations of the LGS feature, with 60% occurring during the afternoon or evening. The Veo™ insulin pump has demonstrated efficacy in a study of 21 patients [47] comparing the LGS functionality with a control arm with the LGS feature disabled: a reduction in the number of hypoglycemic excursions and a decrease in time spent in hypoglycemia were shown.

Closed loop research

Medtronic Minimed approached the closed loop algorithm development problem by developing an algorithm emulating the beta-cell. This approach, termed external physiologic insulin delivery (ePID), was argued to be optimal based on the clinical consequences arising from the loss of various aspects of the beta-cell response [48], e.g. the loss of first-phase insulin release that often precedes type 2 diabetes. Characteristics of the beta-cell thought to be most important include not just first-phase insulin release, but also the slow rise in insulin secretion attributed to second-phase release, the cephalic phase associated with the anticipated consumption of a meal, and the effect of insulin per se to inhibit

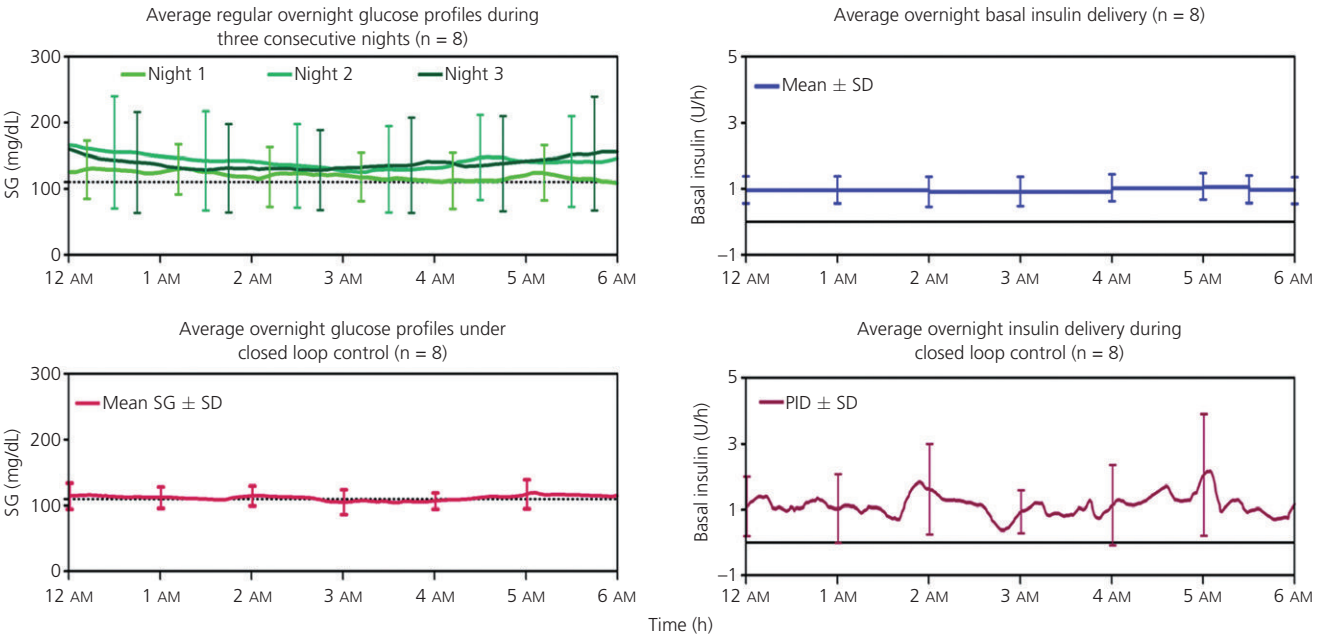

Figure 51.2. Example of the low glucose suspend (LGS) functionality of the Paradigm® Veo™ semi-closed loop insulin pump. SG, sensor glucose; PID, physiologic insulin delivery.

insulin secretion. Other putative beta-cell characteristics, such as the effect of prior exposure to glucose to accentuate the insulin response and pulsatile release, may also play significant—albeit less well understood roles—in maintaining normal glucose tolerance.

Initial attempts to model the beta-cell were dominated by the observation that the beta-cell response to an acute elevation in plasma glucose (hyperglycemic clamp) could be well described by a classical proportional-integral-derivative control algorithm. The beta-cell response when a clamp is applied is broken into three components, and the relative amount of each component is estimated by fitting the data obtained in non-diabetic individuals with healthy beta-cells [48]. Comparing classical control techniques to beta-cell physiology, the first-phase insulin release closely resembles the controller derivative component where insulin is infused at a rate proportional to the positive rate-of-change of the sensor glucose signal. The controller integral component, which is fundamentally a moving average of the difference between the sensor glucose measurement and the target or desired glucose level, mimics the second-phase insulin release or basal rate. The challenge in adapting this response into a closed loop AP utilizing SC insulin delivery was to overcome the long delays associated with the SC site. This was initially achieved by adjusting the relative ratios of each phase—slowing down the rate of rise in the integral component and increasing the relative amount of insulin delivered in the derivative component. Initial studies in a diabetic canine model showed the approach yielded stable overnight control with a reasonable meal response [49]. A subsequent study in adult human subjects with type 1 diabetes [50] also showed good overnight control (defined as percent time at 80–120 mg/dL), but generated higher than desired 2-h postprandial breakfast responses and low nadir values following breakfast.

A cephalic-like phase was introduced into the algorithm by having the user manually administer a small meal bolus in advance of an anticipated meal [51]. The modification was evaluated by Weinzimer et al. [52] in 17 adolescents under closed loop control for 34 h. Subjects who were assigned to the semi-closed loop arm ($n = 9$) received a priming bolus 15 min prior to food intake and the remaining subjects ($n = 8$) underwent fully closed loop control with no meal announcement. A significant reduction in postprandial mean glucose concentration was achieved (194 ± 47 vs. 226 ± 51 mg/dL). Overall mean glucose concentrations were 135 mg/dL in the semi-closed loop arm and 141 mg/dL in the fully closed loop arm. This study demonstrated tight overnight glucose control; however, there were two incidents of hypoglycemia in the semi-closed loop arm and one in the fully closed loop arm, all between the hours of 11:00 PM and 01:00 AM. Insulin feedback was later introduced to emulate the effect of insulin to inhibit insulin secretion, with the mechanism adapted for use with SC insulin delivery using an approach referred to as "pole placement" [53] and subsequently evaluated in a clinical study of adults with type 1 diabetes [54].

With so many choices of methods to improve the response, it becomes difficult to systematically evaluate each one via clinical protocols. One commonly used approach, traditionally employed in control systems to address this problem, is to develop a mathematical model of the system being controlled and then to use the model to evaluate the performance of proposed controller designs—a process now termed silico, or virtual, closed loop research. This requires the dynamics of the system being controlled to be well understood. A review of the metabolic literature in this area reveals that many models have been proposed, but no real consensus has emerged as to which is most appropriate [51]. Also, for any individual model, the model parameters need to be either identified from existing data or assumed using values from a variety of different sources obtained under varying conditions and patient populations. To deal with such issues, approaches that apply a series of reasonably well-accepted submodels such as the Bergman minimal model of glucose kinetics, which is a simple two-compartment model of insulin absorption and meal absorption, were combined with a model of SC–ISF glucose kinetics [54]. The combined model was then identified using the data obtained in the initial University of California, Los Angeles (UCLA) study [50]. The study protocol was then reproduced in silico (computer simulation). This yielded results virtually indistinguishable from the original in-vivo results. Based on the virtual patients ($n = 10$), we then simulated a study in which a premeal bolus was used to aid the control algorithm [55]. This resulted in a substantial lowering of peak postprandial glucose and improvement in post-meal nadir glucose. Silico models have been successfully applied to tuning control algorithms. In fact, the FDA has recognized a simulator developed by researchers at the University of Virginia and University Padova [56] to test closed loop algorithms prior to clinical studies. The University of Cambridge AP group has developed a metabolic model [57] with a number of virtual patients to test its closed loop control algorithm and sensor faults, a necessary step in achieving a reliable system for outpatient studies.

The research groups at the University of Virginia and University of Padova have been testing a closed loop controller in overnight studies with a model predictive control (MPC)-based algorithm employing a Navigator® sensor and Omnipod (Insulet Corp., Bedford, MA, USA) infusion system. This work, collaboration, and its progression have been reviewed by Cobelli et al. [58]. A US study [59] in eight subjects compared closed loop control to standard open loop control (Figure 51.3). The mean overnight blood glucose and time spent in range (70–180 mg/dL) of the closed loop control arm compared to the open loop control arm were 113.16 mg/dL versus 111.89 mg/dL and 81.69% and 96.94%, respectively. Additionally, there was significant reduction in the average number of overnight hypoglycemic events (1.63 vs. 0.13). The same system is being evaluated in two European centers [60] and one in the US that is evaluating 11 adolescents and 27 adults for 22-h in-clinic sessions that include an exercise period. Control algorithms under evaluation use a control-to-range approach with varied levels of optimization. The control-to-range method is not a fully closed algorithm and augments insulin delivery beyond predefined zones. In each implementation, time in control was increased with significant reductions in the incidence of hypoglycemia in comparison to the CSII control arm.

The closed loop control algorithms and systems described thus far have been for single hormone treatment of glycemia with insulin. The only mechanism to prevent hypoglycemia with this approach is to ensure optimal insulin delivery to a safe glucose range, thereby ceasing insulin delivery in time to avert a low glucose event. Should over-delivery happen, the only means of recovery requires human intervention. It has therefore been suggested that a fully endocrine AP should also incorporate an analog of glucagon. While a stable recumbent for the commercially available and one-time use Eli-Lilly glucagon does not exist at the present time, two groups have been successful in developing closed loop algorithms augmented with the glucagon used off-label.

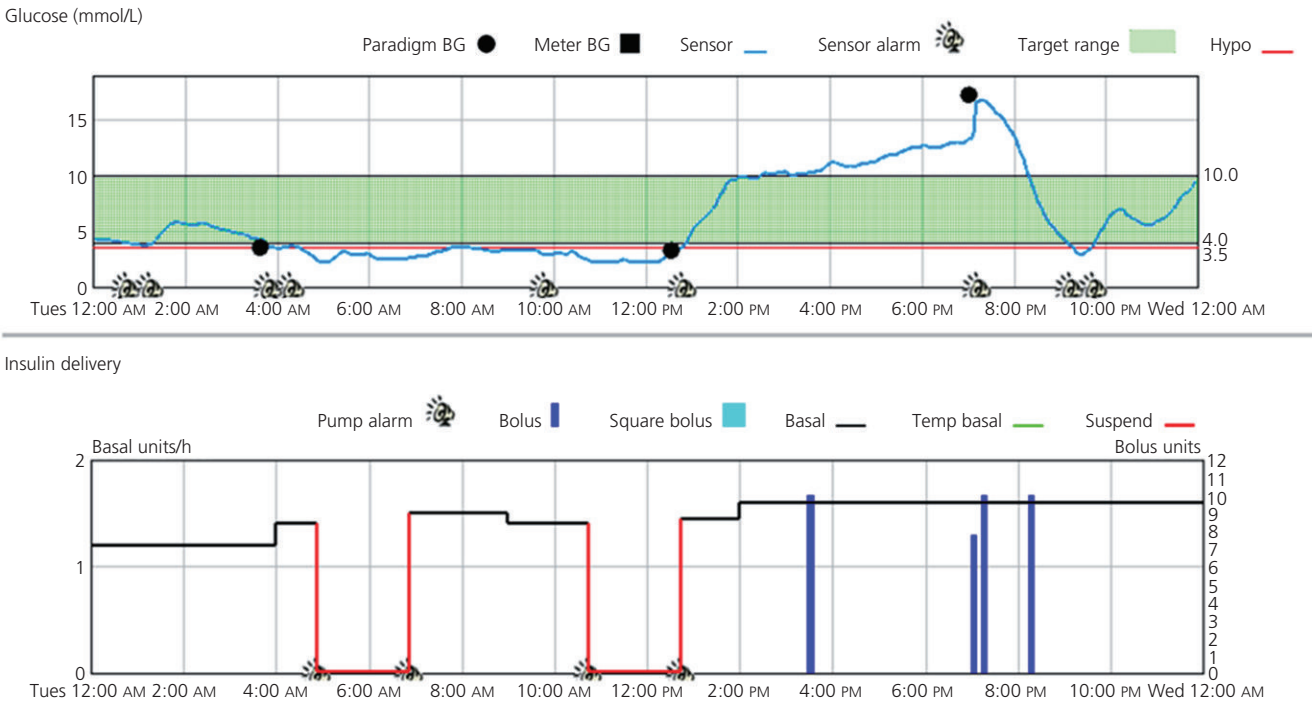

Figure 51.3. Outpatient overnight glycemia and inhospital nocturnal closed loop glucose control.

Researchers at Boston University have developed a glucagon-based controller. This system uses two Cozmo infusion pumps for dosing both insulin and glucagon. The GlucoScout® (International Biomedical, Austin, TX, USA) was used to measure plasma glucose concentrations every 5 min. The control algorithm uses MPC to calculate insulin dose and a proportional-derivative controller to determine the glucagon dosage [61]. In a recent study, 11 subjects were studied under closed loop control for 27 h during which they received three high-carbohydrate content meals [62]. A mean glucose concentration of 140 mg/dL was achieved for six subjects without the need for any intervention; however, five subjects required treatment for hypoglycemia. The control algorithm was then updated, and additional experiments with both groups produced no further hypoglycemic episodes, with a mean blood glucose concentration of 164 mg/dL. The addition of glucagon to help prevent hypoglycemia should also allow for more aggressive treatment with insulin, although the study had no insulin-only control arm; therefore, it is difficult to assess the full benefit provided by the glucagon component in achieving tighter control.

A group at the Oregon Health and Science University are using a Fading Memory Proportional Derivate (FMPD) algorithm [63] to calculate insulin and glucagon doses, basing control on either a Guardian® REAL-Time or SEVEN Plus sensor and insulin infusion with an Animas IR 1000 pump. In a recent paper [64], studies in 13 subjects, seven in whom glucagon was administered in a bolus fashion when required, and six subjects in whom glucagon was infused over a prolonged time period, were compared to insulin-only closed loop and placebo (n = 8). The addition of glucagon delivery when comparing the combined approaches to insulin plus placebo provided a 63% reduction in time spent hypoglycemic (15 ± 6 vs. 40 ± 10 min), with no significant difference in mean blood glucose concentration between the high-gain glucagon delivery and placebo (138 ± 17 vs. 131 ± 17 mg/dL). However, mean glucose was higher (157 ± 24 vs. 135 ± 16 mg/dL) for the low-gain glucagon delivery. Interestingly, the study demonstrated reduced frequency and time spent hypoglycemic with the addition of rapidly administered SC glucagon boluses, which more closely resembles physiology, than the low-gain arm with a higher total glucagon dosage.

The Cambridge AP group published randomized cross-over studies [35] that used the Guardian® REAL-Time system in one study and the FreeStyle® Navigator® CGM system in the proceeding studies, and hand entered new infusion rates into a Deltec Cozmo insulin pump (Smiths Medical, St. Paul, MN, USA) every 15 min. A total of 17 subjects underwent standard closed loop control (n = 12) or closed loop control following exercise (n = 9), and were compared with controls following meals with varied glycemic index (n = 6). The influence of each endeavor in challenging the MPC-based controller was observed during an overnight period. Median time spent in target range for open loop control was 52% versus 39% for standard closed loop, 78% versus 43% for exercise, and 53% for rapidly versus 55% for slowly absorbed meals. Throughout the 33 closed loop control nights, blood glucose only dropped twice to 3 mmol/L, both during the exercise study, in comparison to nine such events in the control arm. This algorithm was further tested with the intake of a large meal and alcohol [65] to further challenge control throughout the night. Compared to the control arm on standard therapy, time in control was increased by a median of 22% under closed loop control. In addition, the ability of the controller to maintain glucose homeostasis for a gestational diabetes cohort was evaluated in well-controlled pregnant women [66,67]. In comparison to CSII, the closed loop control arm experienced less hypoglycemia.

Closed loop systems

The previously described ePID closed loop system was developed using the Medtronic technology. The first version was developed on a laptop computer system capable of receiving glucose sensor signals at 1-min intervals (modified from the 5-min product version), calculating an insulin delivery rate based on a proportional-integral-derivative control algorithm, and transmitting the insulin delivery rate back to the pump as a series of small (0.1 U) boluses. In 2001, a fully automated closed loop was performed in diabetic canines [49] and was subsequently evaluated in humans beginning in 2003 [50], marking the first SC-SC closed loop study and initial step toward an ambulatory consumer-based closed loop AP system. The system was later introduced into the pediatric population in 2005 [52] and into the hospital ICU in 2006 [68]. Insulin feedback was introduced to emulate the effect of insulin to inhibit insulin secretion [69,70].

A number of algorithms were subsequently tested; however, the patient was always tethered to the bedside using this laptop-based system. With the ubiquitous use of smartphones today, it was a natural progression to move the control from the laptop-based system to a BlackBerry. A closed loop study [71] consisting of eight subjects was piloted in 2011. The BlackBerry houses the control algorithm and communicates with a pump and sensor system through a translator device based on Bluetooth technology. All features of the BlackBerry smartphone were enabled, and real-time glucose and insulin data were transmitted every minute to a central server. Remote monitors could log on to the server and monitor closed loop studies in real-time from anywhere in the world. This type of system is intended to provide a bridge to at-home studies. Currently, a number of similar closed loop systems are under development employing smartphone technology such as the Android and iPhone.

Nocturnal closed loop systems

To date two methodological approaches adopted for closed loop glucose control have dominated research into closed loop systems—the classical proportional-integral-derivative algorithms and the more contemporary MPC-based methods [12]. Regardless of the control approach implemented, each technique is challenged by the same disturbances, such as meals and exercise. Therefore, many studies have focused on the overnight period, which is a logical time period to study as an intermediate step toward the fully closed loop for 24-h use. Nocturnal closed loop control could provide significant patient benefit given the prevalence of nocturnal hypoglycemia, with studies reporting 55% of severe incidences occurring during sleep [72] and 75% of pediatric seizures happening at night [73]. Moreover, Buckingham et al. [74] reported 71% of nocturnal CGM alarms elicited no patient response.

Due to the multitude of control challenges inherent in any consumer-based closed loop AP system, most of which are heightened throughout the day, it is probable that the first AP will be labeled for nocturnal use only. Throughout this period when subjects are not ambulatory there are considerably fewer control disturbances to deal with, such as food intake and high levels of activity. Maintaining tight control is therefore less challenging.

Summary

The closed loop AP, with the benefit of current medical device technologies and advances in glucose sensing and insulin delivery, has been shown to achieve normal glycemia, particularly during the overnight hours. While efficacy has been demonstrated in a supervised controlled environment, before such as system can be made available to the consumer, a high level of safety must be demonstrated in outpatient studies. Current efforts have shifted from only focusing on control performance to the inclusion of fault detection and handling routines. Smartphone technology may provide the necessary bridge to outpatient studies, where a subject can be monitored in their home environment. This is a necessary step in advancing current research toward the commercialization of the closed loop AP.

Introduction

Broadly, the goal of regenerative medicine is to harness the body's capacity for complex development, regeneration, and healing to provide therapeutic interventions directed toward diseases of damaged, non-functional, or absent organs and organ systems [1]. Tissue engineering is a subset of regenerative medicine that seeks to build complex biologic structures that can recapitulate the form and function of natural tissues [2]. The building process may employ the cells' own capacity for self-organization into complex structures, or alternatively may involve significant structural organization in the laboratory to obtain the desired tissue configuration.

Given the success of traditional transplant medicine in the treatment of the failure of solid organs such as the liver and kidney, hollow viscera including the small bowel, components of the eye including the cornea, the heart, the airway and lungs, as well as significant recent advances such as hand and whole face transplants, the potential utility of tissue engineering might be questioned. However, as detailed throughout this textbook, transplantation is as defined by its limitations as it is by its triumphs. Indeed, all transplant therapies depend critically upon the availability of donor organs, which are limiting in all applications. Furthermore, once transplant surgery is performed, the graft is prone to rejection by the host, necessitating a lifetime of costly and morbid immunosuppressive drug therapy. Patient non-compliance with an immunosuppression regimen may result in rejection, failure, and loss of the graft, which then requires a relisting for transplant and another long course of bridging therapies. For all these reasons, tissue engineering, as a subset of regenerative medicine, is an attractive alternative, and is appropriately considered in a textbook of transplantation as a future companion or alternative therapeutic option for patients with end-organ failure.

To be successful, tissue engineering requires an interdisciplinary approach that includes input from surgeons, physicians, materials scientists, bioengineers, and others. Since the initial unsuccessful attempt by Green in the 1970s to produce cartilage by seeding chondrocytes onto bone spicules, it has become clear that the materials and scaffold used to build tissue and organs are critical to the success of the tissue engineering approach (Figure 52.1). The first true attempts at generating an appropriate synthetic scaffold from biocompatible materials were undertaken by Vacanti and Langer of Boston Children's Hospital and Massachusetts Institute of Technology (MIT), respectively, who recognized the inherent unpredictability and irreproducibility of biologically-derived materials. In the mid 1980s, they developed scaffolds based upon biodegradable polymers, including polyglycolic acid (PGA) and polylactic acid (PLA).

Tissue and organ-specific approaches

Cornea

The human cornea is a transparent tissue that is critical for vision, as it causes refraction of light rays incident to the eye for focusing and formation of an image on the retina. It is highly organized, with five layers totaling about half a millimeter in thickness. The cornea is lined on the anterior side by a stratified squamous epithelium for protection, and the inner endothelial layer regulates the hydration status of the cornea by continuously pumping fluid out and into the anterior chamber of the eye [3]. Corneal endothelium consists of a terminally differentiated cell population that cannot renew itself with age or after injury [4]. Therefore, in the setting of declining visual acuity secondary to a damaged, diseased, or aged cornea, the only curative treatment is transplantation of a full-thickness corneal allograft [5]. First performed in 1905 by Zirm [6], this procedure is highly successful in the short term, but 5- and 10-year survival of corneal grafts has been reported to be only 74% and 64%, respectively [7]. Moreover, because of the increasing survival of older adults in industrialized nations [8], demand for corneal grafts is predicted to continue to increase over the 21st century. Despite the fact that a single cornea may be divided into up to three portions using a microkeratome for transplantation of the separate components [9], the demand will almost certainly continue to outstrip supply.

Although human corneal endothelial cells (HCECs) do not undergo regeneration in vivo, they have been successfully grown in vitro. Initial isolation techniques entailed explant culture followed by selective migration of the HCECs [10,11], and evolved into a scraping method, by which the HCECs are first removed mechanically from the adjacent Descemet's membrane (DM) of the cornea [12,13]. More recently, this has been further refined into a dissection and digestion strategy, whereby the DM and its attached HCECs are isolated and digested enzymatically with collagenase, dispase, or trypsin/ethylenediaminetetraacetic acid (EDTA) [14–16]. However, this method results in the unwanted introduction of

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

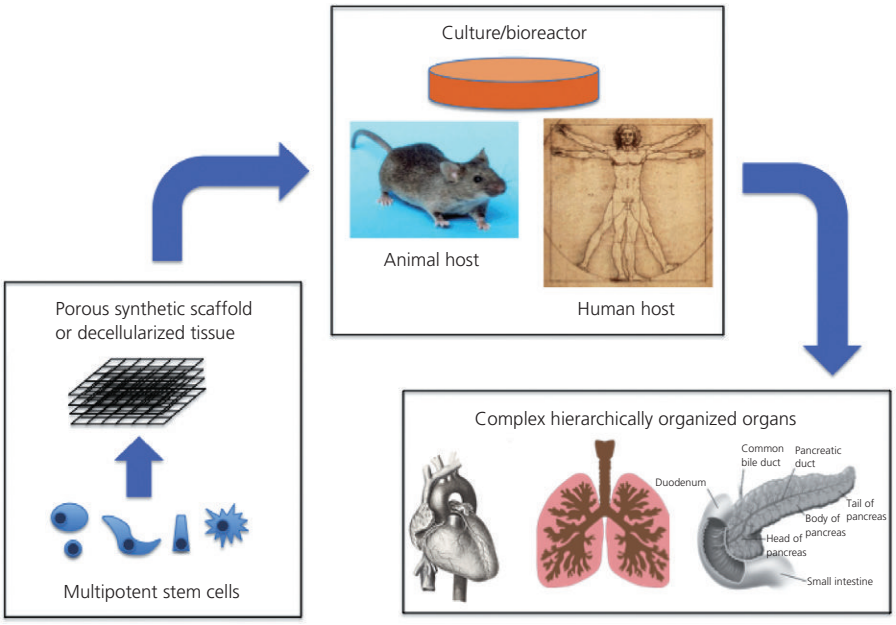

Figure 52.1. Schematic of the process for tissue engineering. In general, a biodegradable porous scaffold or decellularized native tissue is used to support the growth of a multipotent stem cell population. The loaded scaffold is characterized in vitro or implanted into an animal or human host, resulting in tissue ingrowth, proliferation of loaded cells, and the development of a complex organ.

fibroblastic stromal keratocytes into the culture, which must be suppressed with appropriate culture medium [17,18]. Contamination by keratocytes can be minimized with increased dissection skill and techniques such as securing the cornea for dissection with a vacuum suction cup [19,20]. Once isolated, the HCECs are normally grown in plates with an appropriately coated surface for attachment and proliferation. Effective coatings have included collagen [14], laminin/chondroitin sulfate [18], and the commercially available FNC coating mix (Biological Research Faculty & Facility, Inc., Ijamsville, MD, USA), which contains fibronectin, collagen, and albumin [21]. Some authors have suggested that coatings are unnecessary, however [16].

Heart

To perform its function of pumping blood to the systemic and pulmonary circuits, the heart requires a complex structure that facilitates electrical and mechanical coordination between the atria and ventricles, a reliable intrinsic pacemaker that can be regulated by neural and circulating factors, and specialized cell populations to perform these functions [22]. Cardiovascular disease remains the number one cause of death in western industrialized nations, with the majority of deaths attributable to myocardial ischemic disease [23]. Further, congenital heart defects are common, affecting approximately 1% of newborns [24]. It has traditionally been thought that the myocardium consists of terminally differentiated cells with no capacity for regeneration [25]. However, the existence of so-called cardiac progenitor cells (CPCs), that express markers such as c-kit and KI-67, and early cardiac lineage transcription factors such as GATA-4 and Nkx2.5, has been described [26].

Unfortunately, these cells proliferate poorly in vitro [27]. Therefore, other cell sources have been employed in attempts to facilitate myocardial repair and regeneration, including bone marrow-derived angioblasts [28], skeletal myoblasts [29], and neonatal rat primary cardiomyocytes [30]. In addition, stem cells from a number of sources, including embryonic stem cells, adult bone marrow stem cells, and umbilical cord stem cells, have been employed [31]. Another approach has been to place single cells from the various populations that make up the myocardium, including cardiomyocytes, endothelial cells, and fibroblasts, into culture in varying proportions to produce "cardiac organoids" with rudimentary electrophysiologic properties [32]. Some of the initial applications of these cell populations to myocardial tissue engineering have focused on the scaffold materials used [33,34]. Groups have employed a variety of materials, including collagen [35], Matrigel–collagen mixtures [36,37], polyglycolic acid [38], and alginate [39,40].

To move beyond the cell and organoid approach and optimization of in-vitro tissues, animal models for surgical intervention with tissue-engineered myocardium after infarction have been designed and studied. In rats, cardiac patch material was bioengineered from seeded alginate scaffolds that were matured within a host animal's peritoneal cavity. These patches sealed an experimentally created defect in a heterotopically transplanted donor heart in a second host in a separate operation. The patched hearts demonstrated grossly normal echocardiographic wall motion and function [41]. In a further study, the same group implanted a similar alginate material loaded with neonatal rat myocardial cells, Matrigel, and growth factors into a host rat omentum for 5 days to induce neovascularization, after which the patches were grafted to infarcted myocardium in separate host animals. There was decreased ventricular remodeling compared to controls and electrical coupling of the patch to the host animal myocardium [42]. In rabbits, another group seeded porcine submucosa with mesenchymal stem cells (MSCs), cultured it for 5 days, explanted it, and then implanted it as a free graft to the site of an experimentally created myocardial infarction, after which incorporation into the myocardial wall, decreased wall thinning, and decreased left ventricular dilation were seen relative to controls [43].

Airway and lungs

The airway and lungs serve to perform gas exchange and are intimately related to the cardiovascular system. The adult human lung transports about 10^4 L, or 10 m^3, of air per day and has an aggregate surface area of approximately 70 m^2 [44]. The trachea and mainstem bronchi are essentially conductance airways leading to the deeper airways that consist of tubular structures with varying amounts of cartilage and connective tissue. Primary disease of the trachea is rare, but it can be narrowed by mass effects, metastatic ingrowth of neoplastic processes of the thyroid, esophagus, lung, and mediastinum, or injury [45]. About 5 cm of the adult trachea can be resected with primary anastomosis, and in children, the equivalent figure is about a third of the total length. Disease of longer segments may require stenting or management with a tracheostomy. Some attempts have been made at replacement therapy of the trachea, with materials such as collagen scaffolds augmented by silicone stents or cartilaginous tubes grown in vitro [46]. However, these approaches were unsuccessful because of a lack of epithelialization that led to stricture, or inadequate mechanical strength resulting in collapse or tracheomalacia [47]. An additional problem of transplanting tissue-engineered organs is that without native blood supply, necrosis occurs, and cartilage may "melt" as the tissue is resorbed.

Because of these failures and the complexity of the hierarchical organization of cartilage and connective tissue in the trachea and mainstem bronchi, it was first believed that a synthetic scaffold approach would not succeed. Therefore, attention was turned to using the trachea itself as the scaffold. This is accomplished by decellularization, where the cellular components of the tissue are removed by washing with detergent solutions, leaving only the connective tissue skeleton [48]. In theory, all immunogenic properties of the original tissue are removed, allowing it to be used as a biologically derived scaffold supporting the patient's own cells. In a landmark paper in the *Lancet* in 2008, Macchiarini et al. successfully implanted a tissue-engineered tracheal segment to replace the left mainstem bronchus in a human patient with end-stage bronchomalacia (Figure 52.2) [49].

Given this preliminary clinical success with tissue-engineered trachea, other groups are pursuing tissue engineering of the entire human lung. The three-dimensional structure of the lung is complex and exhibits hierarchical relationships at multiple size scales. Grossly, the lungs comprise a defined lobar and segmental architecture with closely related systemic and pulmonary vascular organization. On an intermediate scale, the airways themselves undergo approximately 16 bifurcations from the level of the carina to the most terminal bronchioles. On the smallest scales, alveoli contain gas exchange apparatus in close apposition to specialized pulmonary capillaries to allow oxidation and ventilation. Therefore, engineering of the lung in toto presents a significant challenge. Diseases causing end-stage destruction of lung parenchyma include idiopathic pulmonary fibrosis (IPF), chronic obstructive pulmonary disease (COPD), cystic fibrosis, and chronic lung disease of childhood [50,51]. Although patients with these conditions can benefit from lobar or whole lung transplant, there is a shortage of donor lungs, as is the case with the solid organs and intestine. Regenerative medicine approaches to treatment of end-stage lung parenchymal disease have included both cell-based therapies and tissue engineering. However, the former is beyond the scope of this chapter and we focus here on tissue engineering.

Given the lung's complex structure, preliminary tissue engineering approaches for this organ have focused in large measure upon the scaffold upon which lung stem cells are placed [52]. Stem cells of the human lung have recently been identified and express the putative lung stem cell marker c-kit [53]. Naturally derived materials that have been used for tissue engineering include collagen [54], Matrigel [55], Gelfoam [56], and Englebreth-Holms tumor basement membrane [57]. Synthetic polymers have also been employed, including polyglycolic acid (PGA) [58], poly(lactic-co-glycolic acid) (PLGA), and poly-L-lactic acid (PLLA; Figure 52.3) [59]. Notable results from these approaches include the implantation of somatic lung progenitor cell (SLPC)-loaded PGA constructs into sheep [60]. In this work, SLPC-loaded PGA and Pluronic F-127 (PF-127) scaffolds were implanted into the right upper lobe of wedge-resected and pneumonectomized sheep. After 6 weeks, the scaffolds were noted to support some soft tissue growth, and alveolus-like structures were seen to form from the loaded PF-127

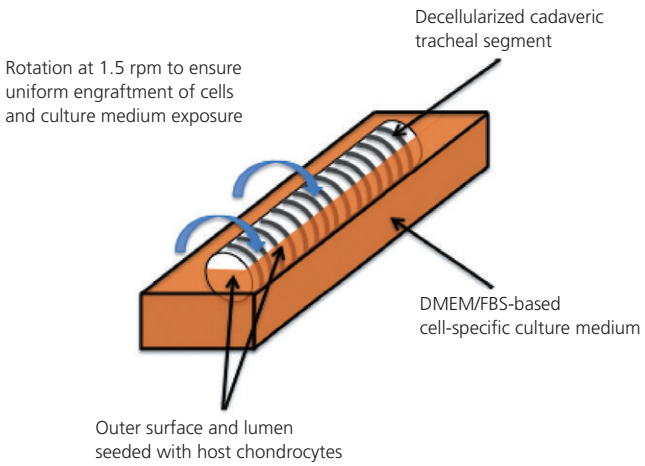

Figure 52.2. Bioreactor system for producing human tissue-engineered trachea from a decellularized cadaveric airway segment. (Adapted from [49]. Copyright © 2008, with permission from Elsevier).

scaffolds. Another study described the implantation of fetal rat-derived cell-loaded Gelfoam into the lung parenchyma of adult rats and harvest after 35–100 days. These authors noted the formation of alveolar-like structures near the edges of the implanted sponges, but fewer in the interior [55]. When fetal pulmonary cells (FPCs) were placed in Matrigel and implanted subcutaneously into the abdominal wall of a mouse host, lung epithelia and vascularization of the construct were seen [54].

Some of the most significant remaining challenges to whole lung engineering include selection of the appropriate cell population for seeding and ensuring its HLA compatibility with a potential patient, construction of a scaffold that combines structural integrity and physiologic stress–strain characteristics with cell compatibility, and the appropriate in-vitro growth factors and culture conditions to cause appropriate differentiation of the chosen precursor cell population into mature lung tissue [52].

Alimentary tract

The function of the alimentary tract, including the oropharynx, esophagus, stomach, duodenum, jejunum and ileum, cecum, and ascending, transverse and descending colon, is to transport and absorb the nutritive value of foodstuffs, which can be consumed orally or can be given as enteral nutrition via surgically placed gastrostomy or enterostomy tubes. It also assists in regulating fluid homeostasis: in an adult human, approximately 1 L of saliva, 1.5 L of gastric fluid, 1 L of pancreatic fluid, 1 L of bile, and 2 L of small intestinal fluid are produced daily, and most of the water content of this secretion is reabsorbed by the colon. When a significant portion of the intestine is lost, whether due to infection, trauma, ischemia, resection for mesenteric neoplasia, or other etiologies, short bowel syndrome (SBS) may result.

SBS is a morbid condition caused by resection of a significant fraction of the total length of the small bowel, usually >50–75%, such that its absorptive capacity is severely reduced and the patient cannot obtain sufficient nourishment from enteral nutrition [61–63]. In children, the most common causes of SBS are massive small bowel resection secondary to necrotizing enterocolitis [64] or malrotation with midgut volvulus [65]. Also, though less common, SBS can occur in adults because of multiple bowel resections in the setting of Crohn's disease [66], or after mesenteric ischemia secondary to vascular disease or trauma such as gunshot wounds [67]. Because SBS patients cannot maintain sufficient nutrition with enteral intake, they may require long-term total parenteral nutrition, which itself can be complicated in children by liver failure and cirrhosis [68]. SBS patients therefore endure significant healthcare costs, recently estimated to be on the order of $1.6 million per patient over 5 years [69]. The current standard of care for intestinal failure secondary to SBS is intestinal, liver/intestinal, or other multivisceral transplantation, but this confers only a 60% 5-year survival and consigns the patient to a lifelong course of immunosuppressive therapy [70]. Further, limited donor organ availability results in an inevitable mismatch between supply and demand as well as long waiting times [71]. For these reasons, autologous tissue engineering of human intestine from the patient's own tissue is an attractive strategy, as it could potentially offer a durable, long-term cure for SBS with none of the drawbacks of existing therapies [72].

Much of the research undertaken toward tissue engineering of the intestine has focused upon the process of normal intestinal epithelial regeneration from proliferative and stem cell populations of the intestinal crypt, the location of the intestinal epithelial stem cell niche. The intestinal mucosal layer regenerates every 3–7 days in humans. Stem cells in the crypt divide, renewing themselves as well as giving rise to transit amplifying cells that travel up the villus axis and differentiate into four mature cell types in the small intestine (enterocytes, Paneth cells, goblet cells, and enteroendocrine cells) and three in the colon (colonocytes, goblet, and enteroendocrine cells). Clevers' group in the Netherlands first identified intestinal crypt-based columnar cells as the mammalian small intestinal stem cell population in the mouse, and demonstrated that they are marked by expression of the G protein receptor leucine-rich repeat G protein receptor 5 (Lgr5) [73,74]. Other markers that have been suggested for mammalian intestinal stem cells include DcamKL-1, Bmi1, Musashi-1, CD133, and mTert [75–79].

Some of the most successful work in intestinal tissue engineering has resulted from the transplantation of organoid units, multicellular units processed from native intestinal tissue that are seeded on a biodegradable scaffold, which is then implanted in a host animal for incubation. In the processing step, which is originally attributable to Evans' lab but has since been modified [80], the intestinal stem cell niche can be preserved despite mechanical and enzymatic digestion of the native intestinal tissue, because the multicellular aggregates formed, termed organoid units, maintain the microanatomic relationship between the stem cells in the crypt and the supporting mesenchyme that surrounds them. This technique has been applied with great success to the tissue engineering of esophagus, stomach, and small and large bowel in the rat [81–85]. The technique has also been transitioned to a mouse model (Figure 52.4) [86,87], in order to employ the extensive transgenic library

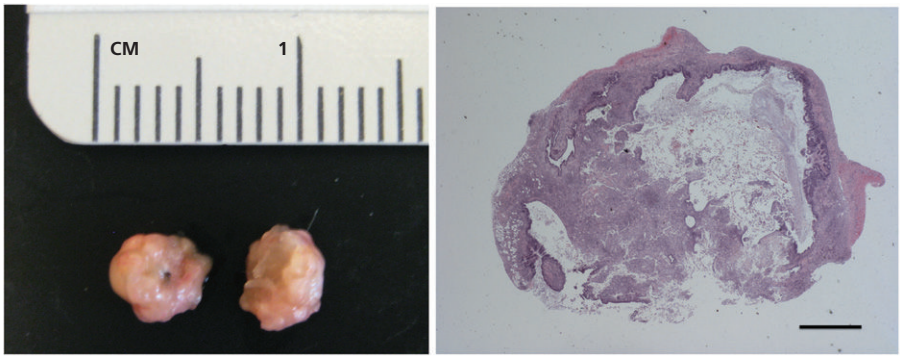

Figure 52.4. Tissue-engineered small intestine (TESI) produced in murine hosts as described in [86]. (A) Freshly-harvested TESI that has been bi-valved to show the mucosa and lumen. (B) Low-magnification H&E histology of a characteristic sample of mouse TESI. Scale bar: 100 μm.

available in *Mus musculus* to better understand the biochemistry and detailed mechanism of the organoid units/scaffold approach to intestinal tissue engineering. Similar results have also been reported in Yorkshire swine, validating this approach's feasibility in a large animal, pretranslational setting [88].

Liver

The human liver has myriad functions in digestion, excretion, detoxification, and protein production that are mediated by a structural–functional relationship of its dual blood supply, portal venous system, and network of lobules and hepatic artery/portal vein/bile duct triads. The supply–demand mismatch for this organ is significant: approximately 7000 liver transplants were performed in 2008, despite >17 000 patients being listed at that time [89]. Indications for transplantation are legion and include advanced chronic hepatic failure with Child–Pugh–Turcotte (CPT) score of >7, advanced Model for End-stage Liver Disease (MELD) score suitable for listing, acute fulminant hepatitis (viral or drug induced), biliary atresia, familial cholestasis, primary hepatic malignancy, biliary cirrhosis, primary sclerosing cholangitis, liver injury of cholestasis, and Budd–Chiari syndrome [90,91].

For adequate performance of its digestive and excretory functions, the liver must have an intact and patent connection to the extrahepatic biliary tree, as well as a functioning connection to the enteric lumen at the sphincter of Oddi in the duodenum. As with the lung, the main challenge in tissue engineering of the liver is therefore recapitulating its hierarchical structure over a wide range of length scales, from the large scale of segmental arteries, portal veins, and bile ducts, to the intermediate scale of lobules, to the smallest scale of the microscopic relationships between bile canaliculi, portal venules, and hepatic arterioles within the sinusoids. To confront this challenge, engineering approaches focus on the specific biomaterials used for scaffolding, as well as the appropriate cell populations for in-vitro expansion that also exhibit functional characteristics of the hepatocyte [92,93]. Three-dimensional microgels seeded with hepatocytes have the desirable properties of control of orientation as well as assembly into larger structures [94,95]. Another approach employs microfluidic channels, which more accurately simulate native liver sinusoids in terms of cell–cell interactions, flowing soluble factors, and three-dimensional mechanical forces, than two-dimensional systems [96]. Decellularized liver scaffolds have also been used to support hepatocytes ex vivo, which exhibited albumin and urea synthesis at levels similar to in-vitro sandwich culture, and expression of drug metabolism genes similar to normal liver tissue [97].

For source cells, both hepatocytes and a variety of stem cells have been investigated. Mature hepatocytes can be prepared either fresh or from cryopreserved tissue, but at least in the case of direct hepatocyte transplantation, cryopreserved cells engraft less well than fresh hepatocytes [98]. Hepatic progenitor cells have also been employed [99]. Stem cell approaches have included human embryonic stem cells (hESCs), which can be reliably expanded in culture [100]. Although differentiation of these cells into hepatocytes initially stops at a fetal hepatocyte stage that lacks mature expression of cytochrome P450 3A4, they can be further differentiated with the appropriate addition of cytokines to the culture medium [101]. Building upon recent advances with induced pluripotential stem (iPS) cells, stem cells that are derived from terminally differentiated somatic cells and have been "reprogrammed" to a pluripotent stem cell state [102], attempts have been made to differentiate human iPS cells into hepatocytes [103]. Finally, some work has focused on using iPS cells derived from patients with diseases including defective low density lipoprotein (LDL) receptor-mediated cholesterol uptake, misfolding of alpha-1 antitrypsin, and abnormally increased lipoprotein or glycogen storage, which can be differentiated into hepatocytes that exhibit in-vitro features of the same metabolic derangements, thereby providing patient-specific in-vitro disease models [104].

Kidney and urinary tract

The kidney is a highly specialized organ that serves to regulate overall fluid status, electrolyte levels, and blood pressure, and to excrete water-soluble toxins that are by-products of diet or metabolism into the urine. Its function is intricately related to the patency and muscular function of the ureters, bladder, and urethra to maintain normal urinary excretion. The incidence of end-stage renal disease (ESRD) continues to increase, with etiologies including diabetes mellitis, hypertension, and various glomerulopathies [105]. Although hemodialysis (HD) constitutes renal replacement therapy, it requires either catheter placement or permanent arteriovenous fistula creation [106], and results in significant complications, including derangements of serum calcium and calciphylaxis [107], cardiovascular disease [108], mechanical complications of extended indwelling catheters [109], and fistula failure and revision [110]. The alternative of peritoneal dialysis allows for increased patient independence as compared with HD [111], but confers the risk of infection and peritonitis [112] as well as dialysis catheter failure and reoperation [113].

In 2007 >90 000 US patients were on the renal transplant waitlist, while only slightly >16 000 transplantations were performed [114]. The ureters are prone to stricture from radiation, or iatrogenic trauma, and can be reconstructed using the bladder [115] or small intestine [116]. Distal to the kidney and ureter, bladder cancer resection can result in significant morbidity with the need for surgical urinary diversion [117].

As with other organ engineering approaches, the differentiation processes of stem cells, including embryonic stem cells (ESC) derived from early human embryos at the blastocyst stage [118], inducible pluripotent stem (iPS) cells [119], and MSCs, which can be isolated from bone marrow stroma [120], have been investigated in order to drive these cells toward a renal lineage. In-vitro culture systems of embryonic rat nephrons have produced branching ureteric buds and metanephric mesenchyme, which are primitive elements of the collecting system and nephron, respectively [121]. Initial efforts to make use of living renal cells incorporated them into extracorporeal synthetic scaffolds [122,123]. This approach has been applied in animals [124], as well as in a small human pilot trial [125]. However, these approaches do not constitute tissue engineering per se, the goal of which would be to construct the entire organ, or enough functioning tissue to replace the failed organ. Because of the complex three-dimensional structure of the kidney, there are significant challenges to using completely synthetic materials to develop a renal scaffold. Therefore, some work has focused upon decellularized scaffolds as candidates for cell engraftment, but to date, these experiments have been performed only in rats and monkeys [126,127]. In the rat experiments, murine pluripotent cells were placed on decellularized kidneys as a xenograft and exhibited rudimentary epithelial differentiation with primitive lumen formation. The Rhesus monkey experiments showed that fetal kidney explants could graft onto and recellularize scaffolds derived from unrelated donor kidneys.

By contrast, tissue-engineered urethras and bladders have already been applied to human therapy. Following early success using polyglycolic acid mesh scaffolds for urethral regeneration in animal models [128–130], attention was turned to bladder- and urethral-derived acellular submucosa matrices [131,132]. After success in animals, bladder submucosa constructs have been used to treat urethral strictures in humans [133,134]. Of note, these stricturoplasties were done in an onlay fashion with a non-seeded matrix, but when this approach was attempted for circumferential replacement of segmental sections of the entire urethra, postoperative strictures ensued [135]. To combat this, more recent efforts have focused upon the importance of the normal wound healing response to these engineered tissues, as well as the effect of first seeding the circumferential segments of matrix with autologous or exogenous cells [136].

Early efforts to augment the human bladder employed synthetic materials, such as polyvinyl sponge, Teflon, collagen, polyglycolic acid, and silicone. However, permanent materials resulted in mechanical failure and urinary stone formation, and biodegradable materials caused fibroblast deposition, scarring, graft contracture, and a reduced bladder volume [135–138]. In addition, when scaffolds of various materials were implanted without cell seeding, the result was preferential regeneration of the urothelial layer with an under-development of the other tissue layers [139]. More faithful reproduction of the muscularis and other layers was obtained when scaffold materials were first loaded or seeded with bladder cells [138,140]. A canine model was then developed where dogs underwent cystectomy followed by implantation of a tissue-engineered bladder prepared from bladder cell-seeded biodegradable polymers. In dogs in which tissue-engineered bladder was implanted, post-implantation bladder capacity and wall compliance were very similar to preoperative values [141]. Finally, the same approach was employed in a pilot study in human patients, but results were preliminary with only seven patients being included, and clinical studies are ongoing [142].

Extremities: bone, tendons, and ligaments

The upper extremities provide human beings with significant dexterity and function for the highly technical and skilled activities humans can perform with intact arms, joints, hands, and fingers. The lower extremities similarly provide us with the often underappreciated capacity for locomotion—walking, running, playing, competing. The axial skeleton, in turn, provides the structural support and points of attachment for the head and extremities. Therefore, since the advent of war and other sources of major trauma, physicians and surgeons have attempted to fashion appropriate prostheses for patients who have lost some of these functions. Tissue engineering approaches for bone, connective tissue, muscle, and the limbs themselves aim to completely restore these functions. Approximately 1 million orthopedic surgeries per year in the US involve bone repair for replacement, trauma, and developmental abnormalities [143]. Traditional reconstructive approaches have relied upon either autogenous or allogeneic bone grafts, and polymeric or metallic implants [144]. However, these approaches are limited by supply–demand mismatch and failures to integrate into surrounding host tissue, and allogeneic grafts in particular carry a risk of infectious disease transmission and rejection [145].

Bone tissue has a remarkable capacity for self-renewal, as it is well-known that multipotent MSCs capable of differentiation into osteoblasts are present in human bone marrow and periosteum [146]. Both skeletal development and fracture repair require a complicated, coordinated process including cell migration, differentiation, and activation, with the formation of a bone microvasculature being critical to the continued survival and regeneration of living bone tissue [147,148]. After these processes, mineralization to a solid bone structure must occur via one of two mechanisms; intramembranous or endochondral ossification [149].

Researchers have attempted to reproduce this natural process by implantation of a variety of materials, with the intent of allowing adjacent bone tissue to incorporate into and remodel the implant. A number of porous scaffold polymers, including collagen [150], PLA, PGA, and poly(lactic-co-glycolic) acid matrices, have been employed [151]. However, these polymers lack sufficient structural integrity to tolerate physiologic loads and shear stress, and have limited osteoconductivity (ability to support the attachment of native bone cells and tissue), so attempts have been made to incorporate ceramic materials such as hydroxyapapatite (HA) and calcium phosphate with PLA or PLGA [152]. When combined with human fetal bone cells, these materials result in constructs with significant osteoconductive and osteogenic potential [153]. Because of the complex spatial and temporal profile of growth factors involved in normal bone development as well as remodeling and repair, it is also thought that the incorporation of methods to deliver such factors, including bone morphogenetic proteins (BMPs), pleiotrophin (PTN), transforming growth factor-beta (TGF-β), and vascular endothelial growth factor (VEGF), may be critical for successful in-situ regrowth of bone [154].

The structures that transmit the forces and torques of human locomotion from bone to muscle and between bones are the tendons and ligaments. In the adult, these tissues have low cell density and poor regenerative capacity, and if the load on the tissue exceeds a critical value, permanent damage results [155]. In terms of material content, both tendons and ligaments consist of 55–70% water, followed by collagen (mostly type I with some type III), elastin, proteoglycans, glycosaminoglycans, and glycoproteins, such as fibronectin and thrombospondin [156]. In humans, tendon injuries can include tendinopathy or rupture, and the healing process occurs in three phases: inflammation (24 h), remodeling (3 days to 6 weeks), and modeling (6–10 weeks) [157]. Ligamentous injuries heal in a similar but slower process; the final phase is referred to as remodeling and may last for years [158].

A number of synthetic and biologic materials have been employed in attempts to reproduce the structure of tendons and ligaments [159]. Fibroblasts derived from rabbit anterior cruciate ligaments were seen to adhere and proliferate on poly(ε-caprolactone) (PCL), PLA, and PLGA two-dimensional substrates at rates similar to attachment rates to culture dish plastic [160]. To more accurately simulate the microstructure of the native tissue, others have employed a three-dimensional braided scaffold approach with PGA, PLGA, and PLLA filaments with human fibronectin coating prior to co-culture with rabbit ACL fibroblasts [161]. Although synthetics offer reproducibility in production conditions and ease of fabrication into desired shapes and sizes, they often lack appropriate functional groups for cellular attachment and can elute non-physiologic substances into the circulation [162]. Therefore, some groups have investigated the possibility of functionalizing non-degradable graft materials to improve cell ingrowth and minimize failures [163]. Other approaches to tendon and ligament engineering have focused upon natural polymerical biomaterials including collagen type I [164], silk fibroin [165], or combinations of these two [166]. In vivo implantation of MSC-seeded silk grafts as replacement therapy for resected rabbit anterior cruciate ligament

(ACL) cells resulted in substantial production of collagen types I and III and stable ligament–bone attachment, but much lower tensile strength than native human ACL tissue [167]. Lastly, preliminary data have shown that decellularized native tendons can be prepared from *Gallus domesticus* donors and subcutaneously implanted in rats to demonstrate host cell ingrowth and lack of immunogenicity [168].

Summary

From this brief survey of tissue engineering of several organs and tissues, it should be apparent that the last two decades have seen an explosion of work in this field. Though these techniques are in the preclinical stage for most organs, with the notable exceptions of the trachea and bladder/urethra, though long-term outcome data have yet to be reported, the pace of advancement and the breadth in the field vis-à-vis the types of organs for which engineering is being attempted suggest that tissue engineering may eventually allow for routine implantation, transplantation, and replacement therapy for diseased tissue in a variety of organ systems. Success of this approach will mean an improvement in the supply–demand mismatch problem and the significant immunologic barriers that still remain for transplant surgeons at the turn of the 21st century.

CHAPTER 53

Organ Assessment and Acceptance for Standard and Expanded Criteria Donors

Matthew Cooper[1] and Stephen T. Bartlett[2]

[1] Medstar Georgetown Transplant Institute, Georgetown University School of Medicine, Washington, DC, USA

[2] Department of Surgery, University of Maryland School of Medicine; University of Maryland Medical System, Baltimore, MD, USA

Introduction

A successful transplant procedure begins with the acceptance of a suitable donor organ. While that decision is rather simple when faced with a stable, young donor with few chronic medical conditions, there has been a strong trend over the past two decades to employ organs from donors of increasing age. Thus, the process of organ acceptance has grown increasingly complex, and despite its intuitive importance in the transplant process, until recently it has been guided by few systematic or data-driven criteria. The transplant clinician is often presented with the decision at odd hours with temporal pressures and incomplete information about both the donor and the prospective recipients. The pairing of a proper organ with a proper recipient has been influenced on both sides of the equation by the progressive aging of the general population and donor pool, juxtaposed with a shortage of deceased donor organs.

This chapter will cover the criteria used to evaluate donors. Cursory attention will be given to standard criteria donation (SCD) donors, as the acceptance of these organs is rather straight forward and a decreasingly common luxury. Substantially more attention will be given to the assessment of donors who fall outside the ideal norms for donation, i.e. those designated as expanded criteria donation (ECD) donors. It will also discuss the outcomes associated with the use of these donors in general terms. Chapter 54 will specifically cover the procedures and outcomes relevant to the procurement and use of donation after circulatory death (DCD) donors. This chapter and Chapter 53 complement the organ-specific considerations outlined in the technical and perioperative management chapters for each organ.

Standard criteria donors: a shrinking source of donor organs

In the early era of transplantation, the typical organ donor was a young trauma victim with a closed or penetrating head injury. Over the past two decades, the spectrum of organ donors has changed dramatically. Among the most dominant changes in organ donor characteristics is the mean age. Data from the Scientific Registry of Transplant Recipients (SRTR) (Table 53.1) show that the percent of transplanted deceased donor kidneys from donors aged over 50 years increased by 216% between 1991 and 2011 [1]. Over that two-decade span the fraction of all transplanted deceased donor kidneys from donors aged over 50 years increased from 18.2% of 4268 donors to 33.1% of 7433 donors. Similarly, donors in the ideal age range of 6–49 years decreased from 76.2% of all donors to fewer than half at 43.4%. The reasons for the aging of the donor population relate to a number of public health interventions impacting the US population.

Among the most dominant public health victories in the US has been the concerted effort to improve automobile safety. Between 1979 and 2010 the number of automobile deaths in the US decreased from 51 093 to 35 498 [2] despite a marked increase in the US population from 225 million in 1979 to 310 million in 2010. Even in the last decade, the incidence of motor vehicle death has fallen from 15.5 per 100 000 to 10.1 per 100 000, a 50% decline. This public health achievement can be attributed to improvements in automobile crashworthiness, electronically enhanced braking systems, and increased automobile conspicuity. Similarly, the human factor has been affected by enforcement of seat belt and driving while intoxicated laws, universal driver education, and improved trauma care systems [3]. The reduction of automobile deaths can be inferred to have led to a reduction of admission to the hospital of individuals who have sustained traumatic head injury leading to the declaration of brain death and organ donation.

During this same time period, the societal diffusion of high kinetic energy weapons (missiles with high velocity or mass) has resulted in a larger fraction of victims dying at the scene of accidental or intentional gunshot wound. Notably, the number of deaths from gunshot wound has not changed in the US in the last decade, with the rate remaining equal to the current rate of deaths from motor vehicle accidents (10 per 100 000). Death at the scene from gunshot wounds to the head approaches 70%. Mortality from gunshot wounds to the head in those reaching trauma centers can be from both cardiovascular (exsanguination) and neurologic causes. High kinetic energy weapons may lead to more cardiovascular deaths at the scene. Marked improvements in the neurosurgical management of traumatic brain injury is dramatically lowering

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

Table 53.1. Changing age of organ donors between 1991 and 2011. Note the shift to a significantly older donor pool. Donors over the age of 50 years have increased from 18.1% to 33.1% of the donor pool

Number Kidney Donors By Age
1991 and 2011

Age	1991			2011
<1	39			87
1–5	197			222
6–10	171			109
11–17	563			425
18–34	1,556	3,255 (76.2%)		2,143
35–49	965			1,987
50–64	653	777 (18.2%)		2,039
65+	124			421
Total	4,268			7,433

Data from www.srtr.org

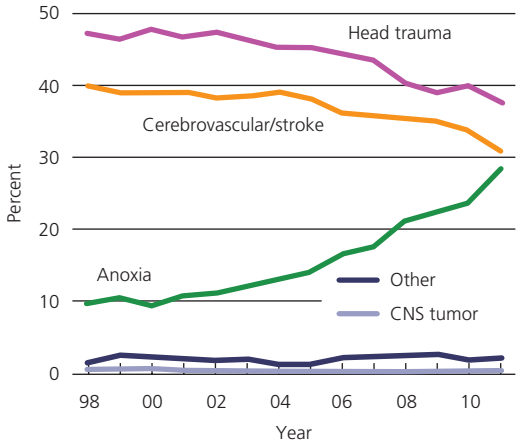

Figure 53.1. Cause of death among deceased kidney donors by year. Note the sharp reduction in the number of donors with head trauma and the dramatic increase in the number of donors with cerebral anoxia. (Data from SRTR Annual Report 2011 [1].)

mortality [4,5]. Management of cerebral edema with decompressive craniotomy combined with recognition and elimination of ongoing shock has revolutionized the care and outcome of patients with closed and penetrating head injury. Finally, it should be noted that in a study of neurosurgical trauma admissions to the University of Maryland Shock Trauma Center, 19% were over the age of 75 years, with many of these cases resulting from falls to which elderly persons are susceptible. These public health developments have led to a substantial reduction in the proportion of donors in the younger age group (Howard Eisenberg, MD, University of Maryland School of Medicine, personal communication).

Coincident with the developments in trauma incidence and management, another major public health trend has led to a rise in the number of potential elderly organ donors. Cardiac arrest is the leading cause of death in the US. Previously, recovery from cardiac arrest was considered a fortuitous event. A major public health effort has been invested in the development of organized response plans for cardiac arrest victims in public locations such as shopping malls and airports [6]. These response plans have included provision of basic instruction on response to cardiac arrest and the use of automatic external defibrillators (AEDs) [7,8]. Widespread training of the public in Basic Life Support has contributed to increased numbers of patients surviving to reach the hospital after cardiac arrest. In a landmark study comparing cardiac arrest at home or in public, survival was dramatically higher when arrest occurred in a public place. In the study, overall survival leading to hospital discharge was 7%. For witnessed cardiac arrest at home, survival for those who received cardiopulmonary resuscitation (CPR) was 10%. When in a public place, a witnessed cardiac arrest had a 20% survival; with application of a shock from an AED, survival after arrest in a public place was 42% [8]. Emergency medical services (EMS) response time was a remarkable 5.6 min for an arrest at home and 5.0 min for an arrest in public. Again, one can infer that among the non-survivors will be those who have sustained irreversible brain injury leading to declaration of brain death or those who have withdrawal of support as a consequence of advanced directives. As a consequence of organized response programs to cardiac arrest in public, increasing numbers of persons who have sustained cardiac arrest with restored circulation are now reaching hospitals. Among the eventual non-survivors, it is reasonable to infer that some may become organ donors. Thus, between 1998 and 2011 (Figure 53.1) the fraction of deceased organ donors with cerebral anoxia as a cause of death has tripled from 10% to 29% of all donors, while the number with head trauma has decreased from 48% to 38% of all donors [1].

The above considerations have characterized a donor population that is progressively aging. With further public health efforts to stem firearm-related deaths, it can be anticipated that the donor population will age further [9].

Characterization of the outcome of SCD, namely donation from those under the age of 55 years, has not been the subject of recent publications as the bulk of the recent kidney transplant literature is focused on strategies and outcomes associated with the aging and marginal donor. Characterization of the outcomes of SCD requires a focus on inferences that can be made from the current literature on ECD donors and the control SCD groups. As will be noted in the concluding section, strategies designed to preserve renal function that are deemed critical to success with ECD donors should be universally applied as even ideal donor kidneys generally function over an insufficient duration to cover a recipient's remaining lifespan.

Understanding the optimal outcome associated with the use of a SCD donor is critical. First, as utilization of higher risk donor kidneys increases, centers will need to remain mindful of outcomes with optimal donors as public perception and to some extent regulatory agencies' perception of expectations may lag behind the reality of the changed and changing donor pool. The most comprehensive review of SCD and ECD kidney outcomes is the exhaustive review by Pascual et al. [10]. This review provides a compendium of the single-center and multicenter comparisons of ECD and SCD kidneys. Nine single-center studies suggest equivalent short-term outcome between SCD and ECD kidneys. In contrast, 39 studies indicate, as is now widely accepted, that the outcome of transplants with SCD kidneys is superior to that with ECD kidneys. Importantly, 20 US and five European multicenter studies were reviewed. Each confirms superior outcome for transplants with SCD kidneys. Among these studies the most contemporary is that by Andreoni et al., which is based on United Network for Organ Sharing (UNOS) cases between 1995 and 2004. SCD kidney transplants have 1-, 3- and 5-year patient survivals of 96%, 90% and 86%, respectively; and graft survivals of 91%, 80%, and 70%, respectively. Among all the

compared series, rates of delayed graft function for SCD donor kidneys ranged from 19% to 50%.

The results of the BENEFIT trial, comparing belatacept- and cyclosporine-based immunosuppression, illustrate the outcome of transplantation in a modern well-controlled series of transplants using optimal donors. In this study, all patients received basiliximab induction, mycophenolate mofetil (MMF), and corticosteroids [11]. The variable treatments were moderate (MI) or low (LI) doses of belatacept versus cyclosporine. Only living donors or SCD donors were included. One-year graft survivals for the three groups were 95%, 96%, and 93%, respectively. The calculated glomerular filtration rate (GFR) in each group was 65, 63, and 50 mL/min/1.73 m^2. The incidence of rejection in each group was 22%, 17%, and 7%, respectively. Although this series included a few living donors, the outcome at 1 year for ideal kidneys with either a calcineurin-based immunosuppression protocol or calcineurin-free protocol can be appreciated. These findings have been subsequently extended to ECD kidneys with diminished but analogous results [12].

The remainder of this chapter will focus on ECD donors, with specific attention given to kidney and liver donors. Understanding the shifting donor demographic away from optimal kidney donors while maintaining a clear grasp of the potential best outcome with ideal kidneys positions a surgeon and transplant physician to use best judgment regarding allocation. Widespread application of nephron-sparing immunosuppression, as noted above, will be needed to obtain optimal long-term outcomes with both ideal and non-ideal donor kidneys.

Expanded criteria kidney donation

The critical organ donor shortage has led transplant professionals to seek additional sources of kidneys for transplantation. What once was considered beyond the limits of acceptable donor demographics has now become a valuable resource and has provided opportunities for many who otherwise would never benefit from organ transplantation.

The number of kidneys transplanted in the US has increased from 13 621 in 2000 to 16 899 in 2010, representing a 19.4% overall increase in absolute numbers. Much of this rise in kidney transplantation is due to a 23.4% increase in deceased donor kidney transplantation over this decade; almost twice that for living donor transplantation (12.4%). During this same time period, however, the number of candidates has increased by almost 35 000 [13]. Similar trends have been seen for other organs, indicating a general trend toward a growing gap between the need for and availability of donor organs [13]. Accordingly, efforts at increasing the numbers of transplants performed and decreasing the refusal rate for what are deemed "transplantable" organs have been intensive and the subject of controversy. It is well recognized that the organ acceptance and transplant rate is as much an overall subjective response to organ quality as it is an objective and measurable criterion. The Health Resources and Services Administration (HRSA)/OPTN-sponsored collaboratives sought to bring together transplant professionals from around the country and across various disciplines to share best practices in an effort to increase organ utilization, primarily via the use of "marginal" or ECDs [14].

The current and accepted definition for ECD stems from the Kidney Work Group at a 2001 Crystal City Meeting to Maximize the Use of Organs Recovered from the Cadaver Donor [15]. Upon conclusion, the working group recommended the development of a distinct and separate allocation system for kidneys that at the time were procured from deceased donors expected to have inferior survival compared to average, although acceptable survival compared to dialysis. This recommendation was eventually developed into a national policy utilizing the definition developed by Port et al.: kidneys from donors with characteristics associated with a relative risk of graft failure at least 70% higher than that of a reference group of non-hypertensive donors, aged 10–39 years, who did not die as a result of a cerebrovascular accident would be distributed under a distinct algorithm [6,7]. This policy was implemented on October 31, 2002 [8]. This new system was designed to decrease cold ischemia time (CIT) by expediting the placement of these organs to centers that not only were aware of the graft survival data but had also consented their recipients in advance to accept such organs for transplantation. ECD kidneys, in counter-distinction to SCD organs, are allocated by waiting time alone and without consideration for HLA matching. In addition, programs were encouraged to perform predonation cross-matching whenever possible.

Following this establishment of a definition for ECD, the number of donated kidneys that met these criteria increased by 36.3%, from 1235 in 1999 to 1683 in 2005. In this same time period, SCDs increased by 13.1%, from 6680 to 7554, reflecting a greater interest in the use of ECDs for transplantation. Currently, however, ECDs represent approximately 19% of all deceased donations in the US, a small increase from 15% in 1999 [13]. A full 40% of all ECD kidneys recovered are eventually discarded despite the implementation of this algorithm to facilitate placement. It is important to recognize that the ECD definition may significantly underestimate the extreme variability in organ quality as the relative risk of >1.7 tends to imply that all organs meeting ECD criteria have the same relative risk of failure. Some ECD kidneys demonstrate adequate long-term survival, while others may have poor outcomes [16–18].

Outcomes compared with dialysis

While a few isolated reports have suggested similar patient and graft survival using ECD kidneys compared to SCD kidneys [19,20], the vast majority of all single-center and all available multicenter and registry reports showed significantly worse 1- and 5-year patient and graft survival rates after kidney transplantation using ECD kidneys compared to SCD kidneys [18,21–23]. A review of the 2007 SRTR report demonstrated the 1-year adjusted graft survival rates for ECD-listed recipients were 83.6% for those who received an ECD organ and 90.4% for those who received a non-ECD transplant [24]. Keeping these data in context, however, Ojo et al. demonstrated in 2001 that the average increase in life expectancy for recipients of an ECD kidney compared to those remaining on dialysis and/or not proceeding to transplantation was 5 years. This benefit was found to be present for certain patient populations but did not extend to high-risk recipients [25]. Kauffman et al. noted a 62% greater 1-year death rate (14.4% vs. 9.1%) in patients aged 60 years or older who received an ECD versus an SCD transplant [26]. Further, Merion et al. studied the benefit of ECD compared to remaining on the waitlist for an eventual SCD kidney [27]. As a result of the increased mortality in the early preoperative period, the authors determined that ECD kidney recipient survival did not reach equality with that observed for SCD kidneys until 3.5 years following the surgery in regards to cumulative mortality. Consequently, ECD transplantation clearly offers a survival benefit over dialysis for almost all designated subgroups, especially those aged over 40 years, non-Hispanics,

sensitized recipients, diabetics, and those with long (>4 years) waiting time, but an SCD transplant offers additionally improved survival compared to an ECD transplant. On average, the adjusted graft survival for an ECD kidney is 8% lower at 1 year and 15–20% lower at 3–5 years after transplantation compared with an SCD kidney [7,17]. Graft outcomes are, in part, due to a recognition that single organ (as opposed to dual) kidney transplant recipients stabilize postsurgical renal function at approximately 60% of the estimated donor creatinine clearance (CrCl), and recipients of an ECD kidney experience a lower initial "baseline" and more rapid loss of function at measured time points compared to SCD [14].

Proper recipient selection

Due to the recognized difference in outcomes with ECD transplantation, various investigators have suggested targeting discrete patient populations as appropriate recipients of these deceased donor organs. SRTR data support that the majority of patients aged 60 years or older are listed for an ECD kidney transplant. Over the last 5 years, the percent of ECD recipients aged 50 years or older has increased from 55% to 81% [13]. Repeat analyses by the SRTR before and after the formal definition of ECD was established have demonstrated significant differences between the demographics of ECD versus SCD recipients, not only in age but also HLA match (ECD transplants were less likely to have zero HLA mismatch than SCD transplants) and cause of end-stage renal disease (ESRD; recipients with ESRD secondary to diabetes or hypertension were more likely to receive an ECD kidney than those whose kidney dysfunction was caused by glomerulonephritis) [17]. Blood type, race, gender, and alloantibody as determined by the panel reactive antibody (PRA) have not been associated with significant differences in ECD allocation [18]. Perhaps the most discouraging results have been seen in retransplant patients. Miles et al. examined the outcome of >9000 patients awaiting retransplantation [19]. Of the almost 3000 who eventually received a new graft, the 10% who received an ECD organ demonstrated similar survival to those remaining on the list, but with far fewer complications related to the treatment of their ESRD. Patients who received an SCD graft, however, experienced a 56% decrease in mortality. These results suggest patients who wish for retransplantation are best served with an SCD kidney if they are not highly sensitized to donor HLA.

Upon exclusion for retransplantation, the main selection criterion for patients to receive an ECD kidney is age >40 years [20]. Importantly, data would suggest there does not appear to be an upper age limit, as recipients older than 70 or 75 years have a demonstrable survival benefit when utilizing ECD donors [25,28,29]. Individual survival benefit is, and always should be, compared with waitlist mortality.

Schold and Meier-Kriesche in 2006 worked to further define appropriate recipients for ECD transplants based upon recipient survival [30]. Critical review of the SRTR data demonstrated the life expectancy for recipients aged under 40 years receiving an SCD transplant following 4 years on the waitlist was significantly greater than following an ECD transplant after 2 years (26.4 vs. 17.6 years). This same analysis did not hold true for recipients aged over 65 years (5.6 vs. 5.3 years). Conversely, diabetic recipients were found to benefit from an ECD transplant. ECD transplantation in a diabetic recipient aged under 40 years and following 2 years of dialysis demonstrated a similar life expectancy to those waiting 4 years for an SCD (9.6 vs. 9 years).

Perhaps as a direct result of the appreciable differences in graft outcomes, the Eurotransplant International Foundation, responsible for the allocation of all organs in Austria, Belgium, Germany, Luxembourg, the Netherlands, and Slovenia, established a renal allocation scheme to provide every patient on the waitlist with a reasonably balanced opportunity for a donor offer [31,32]. The Eurotransplant Senior Programme (ESP) was introduced in which organs from donors aged over 65 years are allocated to recipients similarly aged over 65 years. In its simplest terms, the ESP seeks to identify the best recipient for each available donor organ with the rationale that a kidney graft that outlives the recipient is considered a success, whereas death with a functioning graft is life years lost. The allocation scheme is solely based upon the concept of matching the metabolic demand of the transplant recipient and the excretory capacity of the donor organ. In order to obtain an acceptable degree of success, all efforts were made to minimize the degree of CIT and to reduce immunologic risk, and only non-sensitized (PRA < 5%), first transplant recipients were included. The option of dual transplantation in those in whom the donor CrCl was <70 mL/min was included. At 3 years, 64% and 67% of ESP and control grafts and patients survived ($P = 0.04$), respectively. Death-censored graft survival was also similar at 70% and 71%, respectively.

Numerous authors have described a program for evaluation and selection of appropriate patients for ECD transplantation [21,30,33–35]. In one such review, Stratta et al. described the multidisciplinary approach to the evaluation of such patients [36]. All patients undergo a comprehensive medical, psychosocial, and financial evaluation with a particular emphasis on the cardiovascular system in an effort to optimize and predict operative and early postoperative risk. During committee discussion, patients are assigned a risk assessment for the purposes of management of co-morbidities while on the waitlist as well as follow-up, and a decision is made whether or not to list the patient for an ECD donor. For patients younger than 30 years of age, they recommended against listing for ECD kidneys those who are highly sensitized (PRA > 50%), extremely obese (BMI > 35 kg/m$_2$), or retransplantation candidates. Both the patient and the referring physician may elect to decline such an option, particularly if the patient is predialysis, doing "well" on dialysis, or has a potential living donor. Patients who are either hepatitis B or C positive, and willing to accept a hepatitis B core antibody-positive or hepatitis C-positive donor, respectively, may elect to remain off the ECD list due to the relatively short waiting time for these transplants, particularly in regions where hepatitis-positive donors are more common.

Role of biopsy

There is wide variability in the histologic findings for donor kidneys from different demographic groups, such as those from aged and hypertensive donors. Age alone has a demonstrable effect on the kidney. Autopsy studies show a progressive age-related decrease in the number and size of glomeruli. Older kidneys have a reduced functional mass of nephrons that may be inappropriate for the functional requirements of recipients regardless of age [37]. In addition, grafts from marginal donors may be more sensitive to ischemic and volume insults during all phases of transplantation, resulting in a progressive and sometimes rapid decline in renal function contributing to graft failure (Figure 53.2) [17,38–40].

In a hallmark paper by Sung et al., the authors examined the factors associated with ECD kidney discards. They further evaluated the associations with the development of delayed graft function (DGF). A 6-year analysis of SRTR data demonstrated that 8% (3887) of 48 796 SCD kidneys procured during this time period were discarded versus 41% (5139) of the 12 536 ECD kidneys. ECD

IGF, immediate graft function.

kidneys were more than four times (OR = 4.35; $P < 0.0001$) more likely to be discarded as SCD kidneys using a logistic model. Among all kidneys, those that were biopsied were more likely to be discarded (OR = 2.08) [41]. Odds of discard for all groups increased progressively with increasing percentage of glomerulosclerosis (GS), from 1.5 for those organs with 0–5% GS to 16.92 for those with >20% GS. Separate analysis of ECD kidneys showed that the odds of discard increased from 0.57 for ECD kidneys with GS of 0–5% on biopsy to 7.22 ($P < 0.0001$) for ECD kidneys with GS in excess of 20%. The OR of discard for biopsied SCD kidneys was only 4.21 compared to those not biopsied. Of note, discard rates also increased significantly with the addition of each component of the ECD definition [age above 50 years, death from cerebrovascular accident (CVA), history of hypertension (HTN), serum creatinine >1.5 mg/dL] [42].

Complications

The best described complication is DGF and this may result in a cascade of complications after transplantation of an ECD organ [22,23,26,43–45]. Experimental renal allograft models have demonstrated a strong correlation between prolonged CIT, donor age, and renal allograft dysfunction. It is well established that the ischemia–reperfusion injury associated with organ transplantation contributing to DGF is associated with impaired long-term graft and patient survival. This is particularly true for transplantation of an ECD organ in older recipients. Remuzzi et al. reported the 1-year mortality rates for patients older than 60 years receiving an ECD kidney transplant increased significantly if they developed DGF compared to those with immediate graft function (7.7% vs. 18%; $P < 0.05$) (Figure 53.3) [46].

The overarching intent in the development of an allocation system for ECD organs was to decrease the CIT. UNOS data have shown that the percent incidence of DGF for an equal CIT is greater for kidneys from older donors (51–65 years) compared to younger donors [15]. Analysis of the United States Renal Data System (USRDS), however, do not demonstrate that very short intervals in decreased CIT have had an impact upon the development of DGF in ECD recipients either before or after 2002. However, efforts to significantly decrease CIT have resulted in beneficial outcome in several studies. Valcarce et al. reported the results of a prospective single-center study in which CIT was limited to <10 h (9.3 + 2.5 h for ECD and 8.3 + 3.3 h for SCD) [47]. This study found no significant differences between the two groups (ECD vs. SCD) for outcomes such as primary non-function (4.2% vs. 2%), DGF (16.7% vs. 10%), surgical complications (25 vs. 16%), or acute rejection episodes (8.3% vs. 2%). Although 1-year graft survival rate was similar between the two groups, allograft function as measured by GRF was superior for SCD kidneys (49.4 + 12.5 mL/min vs. 65.8 + 14.9 mL/min for ECD vs. SCD, respectively).

An increased incidence of death has been demonstrated from infection in recipients of ECD kidneys who are aged over 50 years, a group that also has an increased number of co-morbidities. Recipients of ECD kidneys are reported to have an increased number of surgical complications, particularly ureteral necrosis and leak. However, these complications have not resulted in a significant increase in graft loss [34,48]. Danovitch et al. reported the annual death rate for recipients of ECD kidneys was 100 per 1000 patients-years at risk compared to 48 per 1000 patients-years for recipients of SCD. Adjusted patient survival at 1- and 5-years for ECD kidneys was 90.6% and 69% compared with 94.5% and 81.2% for non-ECD kidneys [49].

Specific protocols

Grafts from marginal donors are more sensitive to the ischemia–reperfusion injury inherent in all deceased donor kidneys and have an impaired ability to repair tissue and parenchyma [38,39,50]. Strategies to prevent further loss of the initially reduced nephron mass are critical to the success of ECD kidneys. Elimination of

potential nephrotoxic exposures to the graft are important. In addition, elderly recipients of ECD grafts demonstrate an increased incidence of infections, cardiovascular complications, and malignancies. Of particular concern are the numerous reports of a higher incidence of cytomegalovirus (CMV) infection and polyomavirus-induced nephropathy in recipients of ECD grafts [42]. To that end, physicians have sought not only to reduce CIT, but also to develop specific post-transplantation protocols designed to optimize graft outcome and prolong survival while minimizing immunosuppressive complications. Very few prospective, randomized, multicenter, long-term outcome trials that include ECD recipients have been performed; even fewer randomized trials have focused solely on ECD kidney recipients.

Calcineurin inhibitors (CNIs) are nephrotoxic and may be associated with reduced short- and long-term allograft survival [51–53]. This is particularly true for ECD kidneys, with biopsies demonstrating parenchymal damage. Both CNI minimization and elimination strategies have been proposed to avoid injury. In a US study by Stratta et al. that included 101 ECD recipients, recipients received either antithymocyte globulin or alemtuzumab along with maintenance immunosuppression with MMF and steroids [20]. Tacrolimus was withheld until after the serum creatinine was <4 mg/dL and a moderate dose was instituted with tight control of trough levels. Four-year actuarial patient and graft survivals were noted to be 93% and 74%, respectively, which are far superior to those in published registry data. Several non-randomized European trials have confirmed these results in a cohort of recipients, 54% of whom had DGF [54].

CNI avoidance, however, has not met with similar success. Utilizing antithymocyte globulin and dual therapy of MMF and steroids, European investigators reported acute rejection rates of 25% and 5- year graft survival rates of 65% [55]. Using a similar protocol and recipient inclusion/exclusion criteria, basiliximab induction produced discouraging results (45% rejection rate) and recipients were ultimately converted to CNI therapy [56]. Although CNI-free, sirolimus-based therapy has found some success in SCD transplants in small single-center trials, this has not been confirmed in larger randomized trials. Other single-center, non-randomized trials have confirmed this finding in cohorts of ECD recipient [57]. Diekmann et al. reported the results of CNI-free sirolimus-based therapy in recipients of ECD as associated with "acceptable" outcomes, but with increased levels of proteinuria. Similar immunosuppressive modifications and outcomes have been reported with the use of dual ECD kidneys as well [57].

Most recently, Larsen et al. reported the results of a prospective, randomized, multicenter trial (BENEFIT-EXT) comparing the use of belatacept, a novel biologic agent for maintenance of immunosuppressive therapy, with CNI in recipients of ECD [58]. The protocol evaluated both a more intense (MI) and less intense (LI) belatacept regimen: 347 of 543 (64%) recipients completed 2 years of treatment. Patient and graft survival were similar across all groups, but renal function was improved in the CNI-free groups, with GFR 8–10 mL/min higher compared to those receiving cyclosporine. Post-transplant lymphoproliferative disorder (PTLD), specifically central nervous system PTLD, was observed more frequently in belatacept-treated patients, prompting a warning that belatacept use should be limited to Epstein–Barr virus (EBV) seropositive recipients.

In addition to specific immunosuppression protocols, some advocate aggressive intervention and control of co-morbidities in elderly recipients of ECD kidneys [36,59]. Treatment of hypertension, hyperlipidemia, anemia, diabetes, and other medical conditions to maintain blood pressure at <140/90 mmHg, fasting serum cholesterol at <200 mg/dL, hematocrit at >30%, and fasting blood glucose at <126 mg/dL is recommended. Antiplatelet therapy with oral aspirin should be administered to all patients along with a low sodium, heart healthy diet, and regular evaluation for cardiovascular risk factors/events should be routine. Regular screening for systemic or kidney-specific viral and bacterial illnesses is crucial as is early detection of presumed rejection episodes in an effort to avoid lympho-depleting antibodies in this high-risk group.

Pulsatile perfusion

As covered extensively in Chapter 25, pulsatile perfusion (PP) or "pumping" has become an acceptable method both for organ evaluation and preservation, while providing valuable information informing the transplantation decision of ECD organs. PP involves the ex-vivo hypothermic pulsatile perfusion of the donor kidney, supplying oxygen and nutrients to the organ while removing waste. During perfusion regular monitoring of renal flow and resistance provides information about kidney utility. Attempts to improve renal blood flow and correction of acidosis are important elements of the active monitoring of perfused kidneys. Perfusate often consists of standard perfusion solutions containing (or added) hydroxyethyl starch to prevent interstitial edema; adenosine to increase ATP; phosphate as a proton buffer; gluconate to decrease cellular swelling; glutathione as an antioxidant; and various other agents to reduce metabolism and balance electrolyte composition. PP is mimicked to decrease vasospasm and resistance. Decreased flow rates, increased resistance, and an increase in the calcium concentration measured during PP have been associated with DGF [60,61].

Initial studies from the 1980s failed to demonstrate a decrease in DGF or show a graft survival advantage for PP versus cold storage (CS) [62–64]. Additionally, the increased cost of PP was felt to be prohibitive, especially in the absence of an obvious kidney survival benefit. Several studies, including those performed on paired kidneys from the same donor, with one placed on PP and the other in CS found similar rates of post-transplantation dialysis [61,65].

As the numbers of ECD kidneys offered for possible transplantation continued to increase, the utility of another objective measure of kidney "health" utilizing PP began to generate increased interest. In 2003, 17.2% of transplanted kidneys were from ECD donors. Of those, 28.4% were preserved with PP. In a review of ECD-PP versus ECD-CS kidneys, Matsuoka et al. found that ECD-PP kidneys tended to come from older donors (61.1 vs. 59.8 years; $P < 0.001$) and had increased terminal serum creatinines (1.2 vs. 1.1 mg/dL; $P = 0.03$). The PP donors had a statistically increased incidence of diabetes (12.7% vs. 9.4%; $P = 0.003$) and were more likely to be DCD donors (6.5% vs. 0.9%; $P < 0.001$). Although the CS cohort experienced decreased CIT, this was under 24 h for both groups. Kidneys demonstrating increased degrees of GS (27.3% vs. 18.1%; $P = 0.002$) and interstitial fibrosis (48.5 vs. 40.5%; $P = 0.03$) were more likely to be placed on PP. The authors noted no difference in the incidence of primary non-function, but did observe a 10% higher rate of DGF in ECD-CS kidneys compared to ECD-PP kidneys (37% vs. 26%; $P < 0.001$). There was no difference noted in the incidence of rejection up to 1 year following transplantation despite the decrease in DGF. There was a decrease in DGF in the donation after brain death (DBD) versus DCD donors (34.5% vs. 54.3%; $P < 0.001$). After adjusting for all variables, PP resulted in a 49% decrease in the risk of developing DGF compared to CS (OR = 0.51; $P < 0.001$). As expected, other donor factors predictive

of DGF include DCD, history of HTN, elevated serum creatinine, and "suboptimal" donor histology. Importantly, ECD kidney transplants that experienced DGF were found to have statistically significant lower graft survival rates compared to those with immediate graft function (IGF) at both 1 (70.1% vs. 87.8%) and 3 years (53.0% vs. 74.4%; $P < 0.001$). Preservation method made no difference to survival of kidneys with IGF. Overall, graft survival for the PP and CS groups was similar.

In a separate review, Sung et al. analyzed a later cohort with a similar evaluative process and found that the discard rate for ECD-PP kidneys was 29.7% versus 43.6% for those preserved with CS [41]. Furthermore, ECD-PP kidneys with measured high resistance were associated with a higher odds ratio of discard. ECD kidneys with terminal resistance of <0.18 mmHg/mL/min and with resistance of 0.18–0.25 mmHg/mL/min were discarded 12.6% and 14.0% of the time, respectively. In contrast, ECD kidneys with terminal resistance of 0.26–0.38 mmHg/mL/min had a 25.7% discard rate and those with a resistance of >0.38 mmHg/mL/min had a 53.1% discard rate (OR = 2.50 and 7.88, respectively, compared to a resistance of <0.26 mmHg/mL/min; $P < 0.0001$). Interestingly, the authors also commented on the high variability of ECD discard rate among Organ Procurement Organizations (OPOs), which ranged from 14% to 60%. Their data showed that OPO practices, including local use of PP and ECD kidneys, affected rates of organ recovery and were significant determinants of rates of discard.

The rise in the use of ECD kidneys coincident with the rise in the use of PP by transplant programs can be explained by the need for an additional tool to determine the functional quality of the organ in question. Various measurements and especially the intra-arterial resistance can be used as further valuable data to decide on the suitability for transplantation. It can be argued that the lack of DGF in various reports utilizing PP as a preservation technique is due to the discard of many organs demonstrating poor machine perfusion parameters. Nonetheless, the use of PP in the evaluation of ECD kidneys and in the potential reduction of DGF has led many OPOs and transplant programs to utilize PP.

Dual kidney transplantation

As a result of the greater emphasis placed on the use of ECD for kidney transplantation and the paucity of organs to meet the needs of those waiting, the transplant community has focused on strategies to minimize organ discard, particularly in light of the aging donor population. Dual kidney transplantation (DKT) from kidneys procured from ECD donors has been employed in an effort to alleviate the organ shortage. Initially at the University of Maryland in 1994 [66], surgeons began to utilize both kidneys from a single donor that were often refused by other centers and would have otherwise been discarded because they were judged to be inadequate for single transplantation [67,68]. The overarching principle in DKT is that transplantation of a single kidney with nephron mass recreates experimental models that undergo progressive graft failure. These experimental models demonstrate that initial nephron mass is a determinant of chronic allograft failure. Increasing the number of viable nephron units by simultaneous transplantation of two kidneys effectively prevents the progressive deterioration in renal function that occurs in control subjects given a single kidney [69,70]. While DKT has the theoretical advantage of increasing the effective nephron mass transplanted, there is the risk that kidneys that might be suitable for single kidney transplantation (SKT) might be transplanted as DKT, thus reducing rather than increasing the numbers of transplants performed. Short-term data for DKT from both single-center and registry analyses demonstrated excellent early (1 year) survival, but found a higher incidence of primary non-function when compared to SKT [67,71,72].

A more recent paper by Tan et al. analyzed the results of DKT compared to SKT with over 8 years of follow-up of their recipients [72]. In this review, 113 patients aged 55 years or older underwent deceased donor kidney transplant with either dual (n = 39) or single (n = 72) allografts. Interestingly, the authors noted that all organs used for DKT had previously been refused by other centers prior to transplantation at their center. The most common reasons for exclusion were, as expected, donor age, donor instability, history of HTN, >20% GS on biopsy, or a combination of these factors. The determinant for DKT versus SKT was based on donor admission CrCl estimated by the Cockcroft–Gault equation. If the CrCl was <90 mL/min, both kidneys were used for transplantation into a single recipient. The lower limit for acceptance of these organs was noted to be 45 mL/min. The average donor age was greater in the DKT group (61 vs. 48 years; $P < 0.001$). There were no statistical differences between the groups in terminal serum creatinine of the donor, HLA mismatch, or CIT (15 vs. 18.5 h). Patients who received a DKT had a significantly shorter waiting time to transplantation compared to those receiving SKT (440 ± 38 days vs. 664 ± 51 days; $P = 0.002$), had similar length of stay, no differences in immediate postoperative complications such as myocardial infarction, infection or reoperation, nor in the proportion of those developing DGF or the need for the treatment of early rejection. The 5-year graft survival for DKT versus SKT was 79.5% versus 67%, and the 8-year survival was 69.7% and 59.4%, respectively (P = NS). In further subanalysis, recipients of DKT from donors having an estimated CrCl of <75 mL/min demonstrated an 8-year graft survival of 64.3%. Rejection, both acute and chronic, was the predominant cause of death-censored graft loss. Five-year patient survival for DKT versus SKT was 82.1% versus 80% and 8-year survival was 82.1% and 74.1%, respectively. The most prominent causes of death in both cohorts were cardiovascular and infectious complications. Importantly, the median 1- and 5-year serum creatinine for DKT versus SKT was 1.45 versus 1.7 mg/dL and 1.8 and 1.4 mg/dL, respectively (P = NS).

In another similar prospective case–control study, Remuzzi et al. analyzed graft survival of SKT or DKT for ECD allocated on the basis of clinical or preimplantation histologic evaluation [66]. Kidneys were considered eligible for DKT only if at macroscopic evaluation, major vascular abnormalities were excluded. Those organs with evidence of focal scarring were also excluded, due to a concern for non-homogeneous distribution of damage that could affect the microscopic view of the biopsy. A minimum of 25 glomeruli were required in order for the biopsy to be considered "complete." A biopsy-based scoring system was developed and kidneys were allocated to DKT, SKT, or discard. Twenty-four cases and 48 controls received a DKT and SKT, respectively. DKT donors and recipients were significantly older than SKT recipients. Donor CrCl was significantly lower in the DKT versus SKT recipients (54.5 ± 16.0 mL/min vs 78.1 ± 48.0 mL/min; $P = 0.03$) and no donor had clinical proteinuria. Otherwise, recipient characteristics were similar between the groups, including CIT. The incidence of DGF was identical (20.8%) in both groups and resolution of dialysis needs was rapid. Mean serum creatinine levels were comparable between the groups at all time points, with 6-month values of 1.48 ± 0.54 mg/dL versus 1.77 ± 0.93 mg/dL in DKT versus SKT recipients. At last follow-up, DKT recipients had a mean CrCl virtually identical to that for their corresponding donors, whereas those

receiving a SKT had a significantly lower CrCl than that for their donors. With reanalysis of halved donor CrCl (representing split function in a single transplanted kidney), SKT recipients had a significantly higher CrCl compared to the calculated "half" donor creatinine clearance (53.6 ± 16.2 mL/min vs. 41.0 ± 22.8 mL/min), suggesting a 30% hyperfiltration in recipients of single kidneys. These results strongly suggest a combination of both clinical characteristics and histologic criteria should be utilized concomitantly in the choice of SKT and DKT from an ECD.

Resource utilization

The preponderance of data has confirmed that ECD (and DCD) kidney recipients have a significantly higher incidence of DGF, a longer time to reach a serum creatinine below 3 mg/dL, a longer length of stay (LOS), and an increased number of readmissions for complications following the transplant procedure [23,43,45,73,74]. Therefore, it is incomplete to eliminate from discussion the financial and economic aspects often associated with ECD transplantation. In the US, the Medicare ESRD program pays >$1.2 billion/year for transplantation and is the responsible payer for approximately 70% of all kidney transplants [75].

In a retrospective analysis conducted by Saidi et al. at the Massachusetts General Hospital, investigators compared resource utilization and outcomes in adult recipients of ECD and DCD with SCD kidney recipients [76]; 271 deceased donor transplants (160 SCD, 44 ECD, 53 DCD, and 11 ECD/DCD) were analyzed. PP was routinely utilized in all ECD and DCD kidneys. The incidence of DGF was significantly higher in the ECD, DCD, and ECD/DCD groups compared to the SCD group (35.6%, 33.3%, 38.2%, and 15.1%; $P < 0.001$). The time to reach the plateau serum creatinine was significantly longer in all non-SCD groups as well. Initial LOS in the non-SCD versus SCD groups was 9.8–11 days versus 6.1 days ($P < 0.05$), respectively. The 90-day readmission rate was higher in the non-SCD groups as well. Along with an increasing incidence of DGF and longer hospital stays, non-SCD kidneys were associated with higher initial hospitalization charges. The charges for ECD, ECD/DCD, DCD, and SCD kidney recipients were $70 030, $72 438, $72 789, and $47 462 ($P < 0.001$), respectively. These differences became more significant as more readmissions were required in the care of the non-SCD recipient.

Whiting et al. merged UNOS registry data with Medicare claims data for almost 35 000 kidney transplant recipients, beginning in the pretransplant, dialysis period and projecting these same costs forward in an effort to determine a financial "break even" point for renal transplantation using ECD and high-risk recipients (HRRs) (defined as over the age of 60 years in this analysis) [77]. Utilizing this definition, there were 25 600 non-HRRs, of whom 5718 (22%) received an ECD, and 8934 HRR transplants, of whom 2200 (25%) received an ECD. When considering donor source only, recipients of ECDs had a significantly greater cumulative cost at 5 years compared to recipients of non-ECDs ($144 274 vs. $129 163 respectively; $P < 0.0001$). Similarly, when recipient risk only was evaluated, HRRs had significantly greater cumulative costs at 5 years compared to non-HRRs ($145 453 vs. $124 553, respectively; $P < 0.0001$). In analyses combining both donor–recipient groups, the payments for non-ECD–non-HRR versus ECD–HRR pairings were $121 698 versus $165 716 ($P < 0.0001$). By then plotting each transplant cost curve over time and intersecting the prospective ongoing costs of dialysis into the post-transplant period, the authors demonstrated the financial "break even" point occurs earliest with non-ECD–non-HRR pairings at 4.4 years, whereas hemodialysis does not become more costly until 13 years post-transplant for the more costly ECD/HRR donor–recipient pairs (Figure 53.4).

Although many transplant centers may fully support the utilization of ECD, it is certain that the "costs" of performing transplantation with ECD are far greater than those for SCD, making these types of organs prohibitive for low-volume centers that may not be able to invest in the infrastructure of additional staff to manage patients with DGF on an outpatient basis; as a result, the prolonged hospital admission may make use of ECD kidneys impractical. Many centers have established outpatient-driven protocols whereby recipients of ECD transplants experiencing DGF are discharged

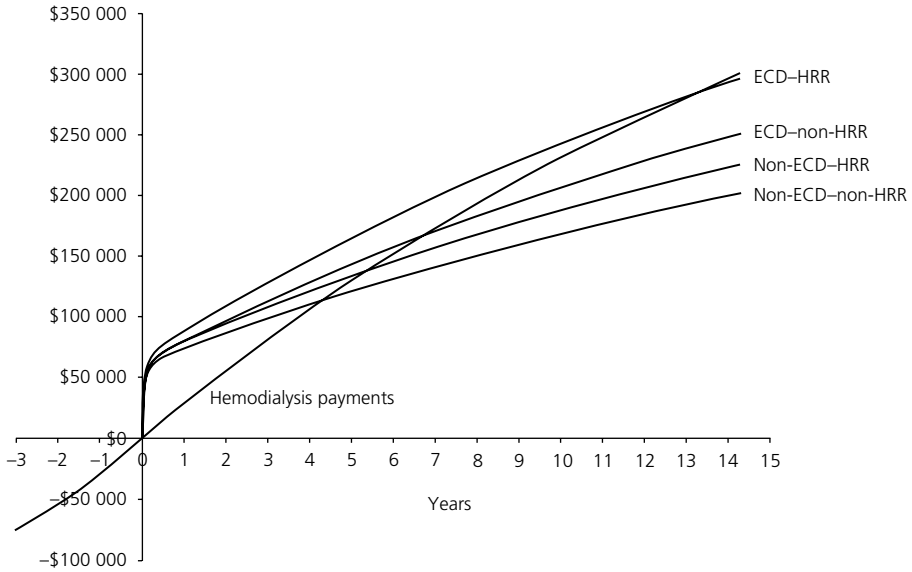

Figure 53.4. Medicare payment projections and "break even" point. This point is shown as the time point when each donor–recipient pairing crosses the projected hemodialysis payment line. Extended criteria donation (ECD) organs compound with high-risk recipient (HRR) status to substantially increase cost. (Reproduced from Whiting et al. [78], with permission from Wolters Kluwer Health.)

following cessation of their inpatient needs. Options include discharge to their pretransplant dialysis unit or to an outpatient site affiliated with the transplant institution. These strategies offset the initial costs while still providing the necessary vigilance in the early post-transplant period. The financial impact is, most certainly, another variable in some instances of organ evaluation for transplantation, and survival outcomes are critically assessed both within the institution and externally.

Expanded criteria liver donation

Similar restraints in organ availability have led transplant teams to concurrently prioritize liver allocation based upon severity of illness, along with the use of organs that were previously thought to be associated with an unacceptably high risk of primary nonfunction (PNF) or initial poor function [78]. Several donor characteristics, including age, race, height, cause of death, degree of steatosis, split versus whole grafts, and CIT have been identified to have an independent relationship with liver allograft outcomes [79].

Mullhaupt et al. in a review of the literature reported a clear association between donor age and recipient outcome, particularly for donors over the age of 60 years. African–American race was found to have a relative risk of 1.19 compared to Caucasian race. Donor height, but not weight, was also independently associated with outcomes. Cause of donor death other than trauma was associated with a 16% (CVA) and 20% (other causes) increased risk of graft failure. Further, DCD donation was associated with a 51% increased risk compared to DBD [79,80].

The gross visual assessment of the liver allograft, although fairly reliable in determining the presence of severe steatosis, has been regularly reported to be generally unreliable to detect moderate and mild degrees [75]. In addition, various tissue processing and staining techniques can affect histopathologic assessments of fatty infiltration [76]. There is, however, current agreement that even moderately steatotic grafts qualify as expanded criteria due to the increased rates of PNF (13% vs. 3% for SCD) [77,78]. Finally, >14 h of CIT has been consistently linked with preservation damage associated with prolonged postoperative course, biliary strictures, and decreased graft survival [81,82].

In an effort to counter-balance these identified donor risk factors, liver surgeons have sought to transplant these grafts with increased risk into older candidates (>50 years of age) with moderate disease severity [i.e. lower Model for End-stage Liver Disease (MELD) scores] and without hepatitis C [78,80,83,84].

Organ-specific donor risk indices

The ECD designation alone does not effectively determine donor quality as organ survival cannot be predicted solely from a dichotomous variable (SCD vs. ECD). A more graded organ evaluation with organ-specific donor risk indices has been developed to predict graft survival with various combinations of donor and recipient characteristics [81–83]. The kidney donor risk index (KDRI) developed by Rao et al. provides a continuous risk score developed with SRTR data from 1995 to 2005. The final KDRI includes 14 donor and recipient factors, each found to independently impact graft outcomes: age, African–American race, serum creatinine, donor hypertension and diabetes, cause of death, height, weight, DCD, HCV, HLA mismatches, CIT, en-bloc transplantation, and dual transplantation. The KDRI provides a continuous score which, when compared to a reference donor score of 1.00, provides the evaluator with a relative risk of allograft failure or patient death associated with the use of the organ in question. The OPTN/UNOS has developed a similar model for organ evaluation and potential allocation. The kidney donor profile index (KDPI) is a similar score based only on donor characteristics. Kidneys with the lowest KDPI represent those with the longest predicted survival time. Potential allocation of these organs to those with the longest expected post-transplant survival to maximize life-years gained has been offered as a necessary evolution in the preservation of this valuable resource [85].

The liver donor risk index (LDRI), first described by Feng et al., identified seven donor characteristics that were significantly associated with liver allograft failure: age, African–American race, height, non-traumatic cause of death, DCD, and partial/split liver. Additionally, variables of CIT and regional/national sharing were included in the final model. Allograft survival rates correlated with increasing LDRI. The authors went on to report that allografts with higher LDRIs were best suited for recipients with low MELD scores [85]. Further application of the LDRI by Maluf et al. examined the outcome of ECD livers (i.e. LDRI ≥ 1.7) and demonstrated a significant increase in relative risk of organ failure for increasing MELD score [86].

Summary

The opportunities via transplantation have supported the increased use of deceased donor organs from ECD donors. While overall graft survival outcomes are decreased compared to SCD donors, the data clearly support a benefit to transplantation versus remaining on the waitlist. As we continue to learn more about the most appropriate recipient demographics, i.e. which recipients can be expected to do well with these organs, as well as continue to develop specific follow-up protocols and immunosuppressive regimens to best care for the patient and the organ, the results may continue to improve. The use of pulsatile perfusion, discrete pathologic criteria, and dual organ transplantation has allowed for greater utilization of ECD kidneys with ongoing efforts to decrease CIT and organ discard. Similar results have been demonstrated in the use of ECD liver donors, with a more directed use in recipients of low MELD scores. As the costs for an institution performing ECD transplants are clearly increased, cost has become yet another variable in kidney allocation, program development, and resource allocation. The development and ongoing refinement of organ-specific donor risk indices has provided the transplant community with improved discriminatory tools to better assess the suitability and viability of organs from expanded criteria donors as we seek to ensure that organ utilization is balanced by ethical decision-making.

CHAPTER 54

Organ Assessment and Acceptance for Donation after Circulatory Death Donors

Silke Niederhaus[1] and Anthony M. D'Alessandro[2]

[1] University of Maryland Medical System, Transplant Program Office, Baltimore, MD, USA
[2] University of Wisconsin School of Medicine and Public Health, Madison, WI, USA

Introduction

In the US, 18 people die every day while waiting for a life-saving organ. Those who are fortunate to receive a transplant mostly receive organs from brain dead donors. With the increasing success of transplantation as life-saving therapy, the waitlist is growing rapidly and the demand for transplantable organs continues to grow accordingly. To overcome this disparity, alternate organ donors are increasingly sought. These include living donor lung transplants, marginal or extended criteria donation (ECD), and donation after circulatory death (DCD), sometimes referred to as donation after cardiac death or non-heart beating donation. DCD was reintroduced in the mid 1990s by several programs and has since contributed to a steady increase in organs available for transplantation. Kidneys, livers, pancreata, and lungs have been successfully transplanted from DCD donors, with some centers even accepting DCD organs for combined transplants [1,2] and reporting reasonable outcomes.

However, the use of organs from DCD donors has trade-offs, which manifest in higher numbers of complications that vary by the type of transplant. Since 1995, DCD donors have been classified according to the Maastricht categories [3] (Table 54.1). With few exceptions, DCD across the US are Maastricht category 3 donors, meaning that the cardiopulmonary arrest and subsequent organ procurement is in a controlled in-hospital setting. These donors are stable and expected to expire after planned withdrawal of life support, most often in the operating room, but on occasion in the intensive care unit (ICU). As a result, the ischemic insult is known and typically limited. In Europe, however, a much broader mixture of DCD donors from all Maastricht categories is being used for transplantation. These donors have less anticipatable ischemic insults and are thought to push the limit of acceptability in some circumstances. In general, the risks associated with acceptance of DCD organs are offset by a compensatory benefit to the patient in terms of more rapid organ transplantation and a reduced risk of the consequences of end-organ failure in properly selected settings. Their use thus requires that the clinician has a heightened understanding of the likely consequences of the uncontrolled arrest and procurement, and a clear insight into the risks that are assumed by the recipient of these organs. In this chapter, we will review acceptance criteria for DCD organs. We will discuss the risks and benefits of DCD transplantation as they pertain to each organ. Lastly, we will delineate the function as well as short- and long-term outcomes after DCD transplantation. Specific discussion of standard criteria donors and extended criteria donors can be found in Chapter 53. Technical details regarding the procurement of organs in a DCD scenario are found in Chapter 22.

DCD lung transplantation

Criteria for acceptance

Hardy and others described the first successful human lung transplant in 1963 using what would now be considered a DCD lung donor [4]. Shortly thereafter, brain death was defined and soon became accepted as the legal definition of death [5]. As a result, due to concerns over deleterious effects of warm ischemia time on donor organs, most organs for donation were subsequently recovered from brain dead donors [6] until DCD transplantation resurfaced in the mid 1990s due to pressures imposed by ever-increasing waitlists [7]. Since 1988, the number of lung donors has increased significantly from 33 to 1770 in 2010. As with other organs, the waitlist has continued to increase faster than the rise in donor numbers. For DCD lung donors, most programs endorse the International Society for Heart & Lung Transplantation (ISHLT) criteria for lung donor selection [8]. However, due to the additional risk that warm ischemia time poses, many centers apply the ISHLT criteria more strictly to DCD donors than to their donation after brain death (DBD) counterparts. Some centers have even more stringent criteria for acceptance of DCD lung donors. Table 54.2 lists the ISHLT criteria as well as additional criteria used by various lung transplant centers around the world for consideration of potential DCD lung donors. Puri et al. [9] have also used organs from extended criteria donors (listed in parentheses in Table 54.2).

Risks and benefits

The benefit of a DCD lung transplantation is increased availability of organs for the lung recipient population, and thus shorter waiting time for individual patients, reducing the risk of waitlist death [10]. In order to optimize outcomes after DCD lung transplantation, selection of appropriate recipient candidates is crucial. Recipients with pulmonary hypertension, idiopathic pulmonary fibrosis, or prior pleurodesis are not considered candidates for DCD lung

Textbook of Organ Transplantation, First Edition. Edited by Allan D. Kirk, Stuart J. Knechtle, Christian P. Larsen, Joren C. Madsen, Thomas C. Pearson, and Steven A. Webber.

transplantation at some centers [9], either due to predictable difficulties during the recipient pneumonectomy, or for fear of further reperfusion injury to the pulmonary allograft. However, some institutions, including ours, will consider all recipients as potential recipients for DCD lung transplantation. Overall, considering the altered selection criteria utilized for DCD lungs, the outcomes of DCD lung transplantation are similar to those for DBD lung transplantation, with some important exceptions, which are discussed below.

The incidence of primary graft dysfunction after DCD lung transplantation is roughly the same as that after DBD lung transplantation at about 10–18% [9,11,12]. The need for extracorporeal membrane oxygenation (ECMO) due to primary graft dysfunction post transplant is similar if not slightly less [13]. Other metrics such as time to extubation, discharge from the ICU or hospital discharge are also similar [13]. Grade 1 acute rejection may occur more frequently in DCD lung transplant recipients (53.7%) than in DBD recipients (27.8%) [12], but in other reports the incidence of rejection is similar in DCD and DBD lung transplantation [13]. Others report rejection rates after DCD lung transplantation of 20% [11]. The rates of grade 2 or higher acute rejection are the same [12].

Airway complications after DCD lung transplantation include bronchial stenosis, bronchial dehiscence, excessive growth of granulation tissue at the bronchial anastomosis, and bronchial fistulas. Indeed, the occurrence of airway complications has been reported to be numerically doubled after DCD transplantation at 27.8% when compared to 12.8% for DBD transplantation, although this does not reach statistical significance in the small studies reported to date [12]. Nevertheless, these complications, likely the result of

small vessel ischemic or thrombotic biology occurring during the circulatory arrest period, are similar to those realized in liver transplantation (discussed below) and likely reflect a real consequence of the DCD process.

Infections are also reported postoperatively, but not at higher rates than after DBD transplantation. Other reported complications include pneumonia, atrial fibrillation (41%), pericardial effusion, confusion (23%), acute kidney injury (12%), hematologic abnormalities (18%), ileus (12%), and ischemia (6%) [14], all of which likely relate more to the recipient physiology than the donor source.

As with DBD lung transplantation, primary graft dysfunction and longer cold ischemia times correlate with earlier death after DCD donation [9]. Mortality over the first 3 months after DCD lung transplantation has been reported at 18% [14].

Function of DCD and DBD lung transplants

Only two groups have described functional outcomes after DCD lung transplantation. DeOliveira et al. systematically examined the percent predicted forced expiratory volume in 1 s (FEV_1) at 1, 6, 12, 24, 36, 48, and 60 months post transplant. Lung function was the same between DCD and DBD lung recipients. Percent predicted FEV_1 was between 50% and 60% at 1 month post transplant, peaked at 6–12 months post transplant at 60–70% for both DCD and DBD lung recipients, and then remained stable for up to 48 months post transplant, after which there was a decline in the DCD group at 60 months to 40% predicted, while the DBD group stayed at approximately 60% predicted [12]. DeVleeschauwer et al. evaluated the best FEV_1 after transplant and compared DCD and DBD groups. The FEV_1 in this study also was similar; the best FEV_1 in the DCD group was 94% (range 78–106%), and in the DBD group 93% (75–112%) [13]. There was also a continuing improvement in FEV_1 after postoperative day 30 in both groups. By day 30, FEV_1 was increased by 1.58 L in DCD and by 0.84 L in DBD lung transplant recipients. Further improvements in FEV_1 were seen of up to 2.77 L on postoperative day 180 in DCD recipients and 2.31 L on postoperative day 185 in DBD recipients [14].

Chronic allograft injury in lung transplantation manifests as bronchiolitis obliterans. After DCD lung transplantation, bronchiolitis obliterans occurs in 7–20% of patients, and at 3 years in 20–50% of patients [1,12,14]. This compares to rates of 6% in DBD recipients at 1 year and 25% at 3 years. DeOliveira et al. found that the rates of bronchiolitis obliterans after DCD and DBD lung transplantation were nearly identical if DCD lung donors and recipients were carefully selected. Similar rates of bronchiolitis obliterans have been reported in Belgium by DeVleeschauwer et al., with bronchiolitis obliterans occurring in approximately 14% of DCD patients with a median onset at 328 days and in 10% of DBD patients with a median onset at 480 days, numbers that are statistically similar [13]. In a recent review, Wigfield and Love collected and summarized bronchiolitis obliterans cases from different centers after DCD lung transplantation. When added together, bronchiolitis obliterans was found in 21 of 191 (11%) patients at 3 years [15].

Long-term outcome

Data on long-term outcomes after DCD lung transplantation are rare [16], as DCD lung transplantation is a recently growing field and few programs have even small numbers of long-term survivors.

In terms of graft survival (Figure 54.1), DCD and DBD lung transplantation fare equally well, with the caveat that DCD donors are more stringently selected. Graft survival after DCD lung transplantation ranges from 69% to 83% at 1 year, from 61% to 77% at 3 years, and is 77% in the one study that reports up to 5-year graft

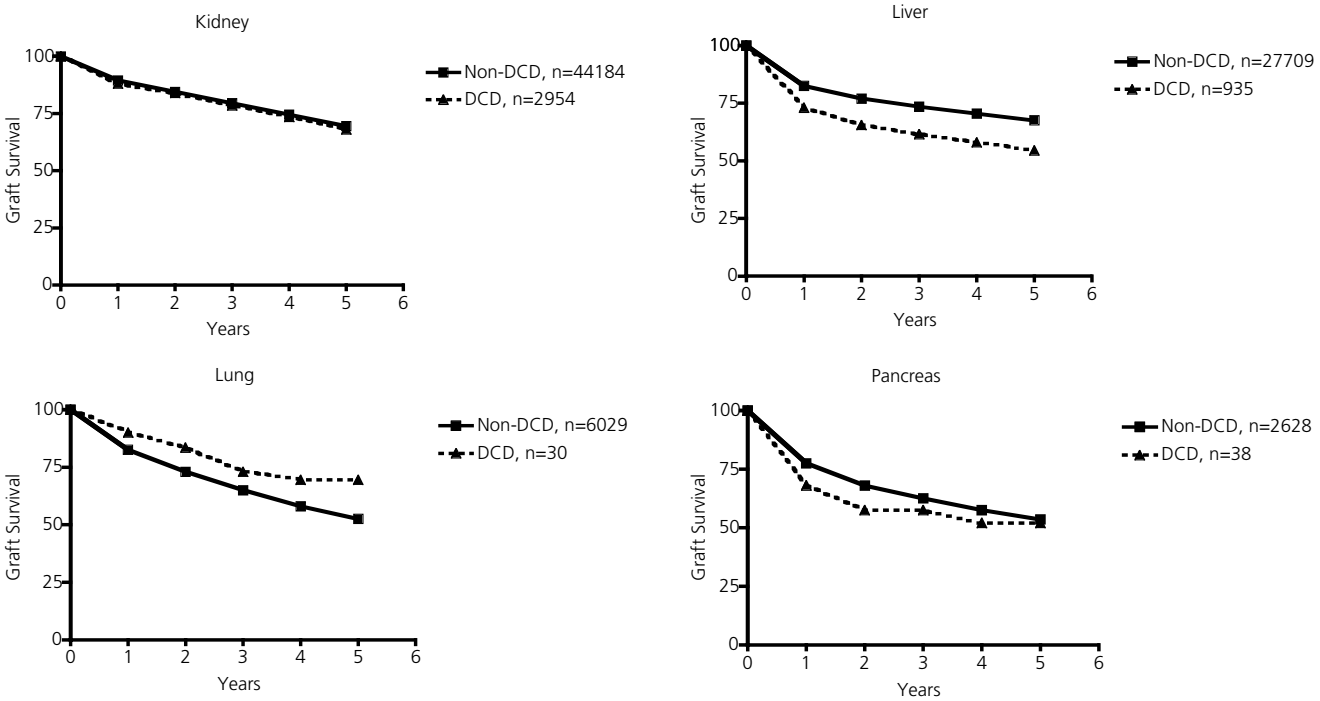

Figure 54.1. Graft survival of deceased donor organs for kidney, liver, lung, and pancreas transplant. There is no significant difference in outcomes after kidney, pancreas, and lung transplantation. Liver transplantation from donation after circulatory death (DCD) donors has statistically significant worse graft survival. (Based on OPTN data from 2002 to 2006.)

survival. This compares favorably to DBD lung transplantation, where 1-year graft survival ranges from 82% to 85%, 3-year graft survival ranges from 68% to 70%, and 5-year graft survival is reported at 60% [1,9,12–14,17].

Patient survival after DCD lung transplantation ranges from 80% to 95% at 1 year, from 69–95% at 3 years, and from 71% to 82% at 5 years. After DBD lung transplantation, the 1-year patient survival is between 78% and 96%, the 3-year patient survival is 72–91%, and the 5-year patient survival is 63–75%. Again, there are no major differences in patient survival between DCD and DBD lung transplant recipients [1,9,12–14,17].

DCD liver transplantation

Criteria for acceptance

Liver DCD donors are somewhat more common, and has been practiced and refined to a greater degree, than lung DCD donation. As such, the selection criteria have been more generally established (Table 54.3). Selection criteria for DCD liver donors vary between centers, but in general are more stringent than selection criteria for DBD livers. Most centers require a heparinized flush at cross-clamp or, preferably, systemic heparinization with high doses of intravenous heparin prior to withdrawal of life support, depending on variations in the law in each donor service area or country. A 30-min warm ischemia time is generally considered the upper limit. The most common definition of warm ischemia time is from withdrawal of all life support to cold flush or cross-clamp, but in some centers, it is defined alternatively as systolic blood pressure of <50 mmHg to flush, and then the maximum allowable warm ischemia time can be up to 60 min [18]. The conservative maximum donor age for DCD donation varies between 40 and 50 years in most centers; however, there are reports of programs successfully transplanting livers from DCD donors up to 65 years old [18–20].

The prior hospital course of DCD liver donors should preferentially be hemodynamically stable and reveal normal, or near normal, liver function tests [21]. DCD liver donors are ideally lean, with different center cut-offs being a body mass index (BMI) of <28–30 kg/m^2 or a body weight of <100 kg. Some programs prefer a history of a short hospital stay prior to donation [21–23]. Gross inspection and biopsy for hepatocyte viability and to rule out macrosteatosis or fibrosis are routinely required in some [1,18], but not all, institutions [20,21]. One study from the UK [24] recently reported a very aggressive use of DCD livers by accepting donor livers from extended criteria DCD donors. These were defined as having one or more of the following criteria: warm ischemia time

Table 54.3. Donation after circulatory death (DCD) liver selection criteria.

	Netherlands [68]	United Kingdom [18]	Spain [19]	Pittsburg [20]	Los Angeles [21]	United Kingdom [23]	University of Wisconsin [63]	Spain [69]	Boston [70]
Systemic heparinization or heparinized flush	Heparin in flush	Heparin in flush			Heparin prewithdrawal		Heparin prewithdrawal	Heparin 3 g/kg, 1.5 mg/kg every 90 min

MAP, mean arterial blood pressure; SBP, systolic blood pressure; BMI, body mass index; CPR, cardiopulmonary resuscitation; NECMO, normothermic extracorporeal membrane oxygenation.

of >30 min (but under 60 min from systolic blood pressure of <50 mmHg to flush, or from oxygen saturation of <80% to flush), donor age of over 60 years, donor BMI of >30 kg/m^2, or cold ischemia time of >8 h. With careful selection of these donors, acceptable outcomes were achieved with graft survivals at 1 year similar to those for non-extended criteria DCD donors.

Risk factors for post-transplant graft loss, primary non-function, biliary complications, and recipient death include donor age over 40–50 years, donor weight exceeding 100 kg, donor warm ischemia time of >35 min (vs. <15 min), or prolonged donor hypotension [20,22,25]. Prolonged cold ischemia time also adversely affects outcomes [25], with each hour of cold ischemia time increasing the chance of allograft loss by 6% [20,22]. Recipient mortality is increased by increased donor weight and cold ischemia time [22]. Anticipated cold ischemia time of <8 h is required by some centers [20,21]. Organ sharing, requiring additional time for hepatic division into two usable lobes, is another potential for increased cold ischemia time and has been shown to correlate with worse outcomes after DCD transplantation. Recipient age over 60 years, renal dysfunction at transplant, and donor hepatitis C positivity also worsen outcomes after DCD transplantation [25].

Recipient selection for DCD donor livers is key to optimizing outcomes. Recipients older than 55 years have 26% higher rates of graft failure than younger adult recipients. Male recipients and African–American recipients also fare worse with DCD livers than their female and non-African–American counterparts. Retransplant recipients have a 45% higher rate of graft failure than primary DCD liver transplant recipients. Patients with metabolic liver disease also have a higher graft failure risk. Recipients with Model for End-stage Liver Disease (MELD) scores >35 have a 47% higher rate of graft failure than recipients with MELD scores between 15 and 25. Thus, liver transplant candidates older than 55 years, or who are waiting for a repeat transplant, or who have a high MELD score need to carefully consider the risk of waiting for a DBD liver versus accepting the increased risk of graft loss after DCD transplantation [22].

There are very few data in the literature to support DCD liver transplantation in children. However, Gozzini et al. have transplanted two full size and two reduced size (segment II–III) DCD liver grafts successfully into children [23].

In Spain, DCD livers have been used for transplant since 2002, and most of the DCD organs used have come from uncontrolled donors, and have been preserved with normothermic ECMO. Flow parameters on cardiopulmonary bypass have been used to determine graft viability, with good flow considered to be >1.7 L/min. Exclusion criteria have included a history of cancer, drug abuse, or other biologic risks. Donors with a criminal history or violent death have been excluded from consideration. Negative human immunodeficiency virus (HIV), hepatitis B and C virus (HBV and HCV) testing is required, as is normal abdominal and femoral vasculature. Organs with gross macroscopic steatosis have been excluded. Other criteria have included unsupported cardiac arrest for under 15 min, ventilator support, and cardiopulmonary resuscitation or compressor time of <130 min in total [19], and normothermic ECMO for <4 h in total. Donor age of under 55 years has been preferable; although in select cases, donors up to the age of 65 years have been used.

In the Netherlands, mostly Maastricht category 3 donors are used. Donor selection criteria include a donor warm ischemia time of <30 min, donor age of 1–55 years, BMI of <28 kg/m^2, and mean arterial pressure of <50 mmHg for <15 min.

Risks and benefits

The single benefit of using DCD livers for transplantation is that it ameliorates the growing waitlist and allows patients faster access to transplantation. Thus, by adding livers from the DCD donor pool, waitlist deaths are reduced. Although this indirectly provides a benefit to all patients waiting for transplantation, the benefits to the individual patient are less clearly defined. This is particularly relevant given that, compared to DCD transplantation of other organs, the risks of DCD liver transplantation are significantly increased over its DBD counterpart. Primary non-function, biliary complications, especially ischemic-type biliary strictures, hepatic artery thrombosis, and shortened graft survival remain barriers to achieving similar outcomes after DCD and DBD liver transplantation. This holds true for DCD donors from all Maastricht categories.

DCD liver donation from uncontrolled donors has been practiced most commonly in Europe; specifically in Spain. One Spanish group transplanted 10 DCD livers after maintenance of uncontrolled donors by cardiopulmonary resuscitation or compressor and normothermic ECMO. At a mean of 23 months of follow-up, five (50%) of those livers were functioning. The others had failed due to primary non-function or hepatic artery thrombosis, or were lost to death with function secondary to other complications or recurrent hepatitis C [26]. Another Spanish report described the outcomes of 16 category 2 donor livers used for transplantation [19]. There were significantly higher rates of biliary complications occurring in DCD recipients of uncontrolled livers (42%) than in DBD recipients (17%). There also were more non-anastomotic biliary strictures after DCD transplantation (25%) than after DBD transplantation (2%). These complications were ultimately associated with a three-fold higher relative risk of graft loss. A large survey of European countries practicing DCD donation has shown similar 1-year patient and graft survival after controlled and uncontrolled DCD liver transplantation [27].

Controlled DCD livers have been transplanted by several groups in both the US and Europe in efforts to decrease waitlist deaths. The costs for DCD liver transplantation exceed those of DBD liver transplantation by about 25%. This is due to higher numbers of retransplants (21% vs. 7%) and higher rates of biliary complications (58% vs. 21%). Even when retransplant costs are excluded, DCD transplants remain 20% more expensive than DBD transplants [28].

Larger database studies have reviewed outcomes after DCD liver transplantation in the US. Specifically, Scientific Registry of Transplant Recipients (SRTR) data from 1996 to 2007 showed worse patient survival in the DCD group, which did not improve with increasing experience in DCD transplantation [25]. Retransplantation is twice as common for DCD recipients (14.7% vs. 6.8%); and patient survival after retransplantation is less than survival after primary liver transplantation. Mortality after DCD transplantation is higher than after DBD transplantation, which confirms death as a risk of DCD liver transplantation.

Risk factors for poor outcomes after DCD liver transplantation include long donor warm ischemia time (>20–30 min), long cold ischemia time (>8–10 h), and older donor age (>40–60 years) [29,30]. Specific complications and risks of controlled DCD liver transplantation are delineated below.

Primary non-function

Primary non-function after liver transplantation is defined as severe hepatocyte injury [as evidenced by an aspartate transaminase (AST) of ≥3000 U/L] and the failure to synthesize clotting factors (manifest by an INR of >2.5) or clear lactate (a serum lactate

≥4 mmol/L). Primary non-function occurs 3.6 times more frequently after liver transplantation from DCD donors than after liver transplantation from DBD donors [31]. The incidence of primary non-function in recent studies lies between 0% and 12% of patients after DCD transplantation from controlled (Maastricht category 3) donors [20] compared to 1.4–3% after DBD transplantation [20,32]. A survey of Europe has shown similarly different rates of primary non-function between controlled and uncontrolled DCD donors [27]. Larger studies have shown somewhat lower rates of primary non-function (around 2.5–3%) [29,32,33]. Risk factors for primary non-function have included transplanting a male liver into a female recipient, older recipient age (>60 years), and higher recipient BMI (>30 kg/m^2) [20].

Hepatic artery thrombosis

Hepatic artery thrombosis is uncommon but quite problematic after liver transplantation. Its incidence ranges from 0% to 33% after DCD liver transplantation, with larger studies reporting lower rates (0–6%) [20,29,32,33]. A large SRTR database review showed that the incidence of hepatic artery thrombosis is similar after DCD and DBD liver transplantation [31], as expected based on previous reports [20,33,34]. One study, however, reported hepatic artery stenosis to be more common after DCD liver transplantation. Hepatic artery stenosis in recipients of DCD livers more frequently led to biliary strictures than hepatic artery stenosis after DBD liver transplantation [34]. Treatment for hepatic artery thrombosis after DCD liver transplantation frequently includes retransplantation [18,35].

Biliary complications

Biliary complications are more common after DCD liver transplantation than after DBD transplantation [30], and comprise one of the more significant issues when considering acceptance of a DCD organ. This is likely related to the adverse effects of warm ischemia time on the microvasculature of the biliary tree during the donation process. These may be similar to the issues seen in the bronchial tree in lung transplantation from DCD donors, discussed above. Thus, minimizing ischemia time may be beneficial in preventing biliary complications. Others have attempted to minimize biliary ischemia by infusing tissue plasminogen activator (tPA) in the hepatic artery during implantation, with acceptable results [36].

The incidence of biliary complications after DCD liver transplantation is between 15% and 58% [18,20,21,28,29,31–33,37]. This compares to much lower rates of biliary complications (6–21%) in DBD liver recipients [18,20,21,28,29,31–35,37]. In a multinational meta-analysis, the odds of biliary complications were 2.4 times higher after DCD than after DBD liver transplantation. Donor age over 40 years is a risk factor for biliary complications [30]. Interestingly, higher donor BMI or donor weight may increase the risk of anastomotic biliary strictures [30].

Biliary complications include a variety of problems, such as anastomotic and non-anastomotic biliary strictures, bile leaks, bile casts, biliary sludge, bilomas, biliary abscesses, and ischemic cholangiopathy, among others. Some biliary complications can be managed endoscopically, while others require repeat operations, which include a subset of retransplants [29,32]. Because more biliary complications occur in DCD liver transplant recipients, more of these patients require subsequent diagnostic and corrective procedures, which negatively impacts quality of life [32].

Ischemic cholangiopathy deserves specific consideration. It is difficult to treat, often associated with intrahepatic bilomas or biliary sepsis, and not infrequently leads to repeat transplantation. Like all biliary complications, it is significantly more common after DCD than after DBD liver transplantation; the incidence has been reported to be anywhere between 0% and 44% [28,32,33,37] after DCD transplantation, compared to around 3% after DBD transplantation [31–33]. Ischemic cholangiopathy manifests itself as non-anastomotic biliary strictures, either in isolation or diffusely. Most ischemic cholangiopathy manifests within the first 4 months post transplant [30]. Some cases can be managed percutaneously with dilations via endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiography (PTC), but up to 50% eventually require retransplantation [30,33,37]. Ischemic cholangiopathy can lead to graft failure [21]. Predictors of ischemic cholangiopathy include a longer time from asystole to cross-clamp and having an African–American recipient [33]. For every minute increase in asystole to cross-clamp time, the risk of ischemic cholangiopathy increases 16% [33]. Further risk factors for ischemic cholangiopathy include cold ischemia time of >8 h and donor age over 40 years [30].

Other risks

Ischemia–reperfusion injury is exacerbated after DCD liver transplantation, and is initially manifest as aberrant laboratory parameters such as a higher peak AST [29] or a higher INR 1 week post transplant [20]. One study addressed the occurrence of a post-reperfusion syndrome during the DCD liver transplant operation, with the finding that all patients required transient vasopressor support beginning at or before reperfusion [18], and lasting through to the end of the operation in six of 32 patients.

Recovery after DCD liver transplantation is similar to that following DBD liver transplantation. Overall length of hospital stay post transplant is similar to that for DBD transplantation [20,32], although ICU length of stay was longer in DCD recipients in one study [20]. Rejection occurs with similar frequency by 90 days and 1 year post transplant [32,34].

Short-term graft survival after DCD liver transplantation is similar to that after DBD liver transplantation in some studies [32,33], but not others [30]. Two-fold higher graft failure rates after DCD liver transplantation at 1 and 3 years were seen in a meta-analysis of DCD and DBD liver transplantation [31]. Retransplantation occurs more than twice as often in DCD recipients than DBD recipients (15–18% vs. 7%), and is mostly seen in older DCD donor–older recipient pairs [20]. Worse outcomes after DCD transplantation are seen, especially when donors are older than 40 years, cold ischemia time is >12 h, and livers are shared. Similarly, recipient age over 60 years, renal insufficiency at transplant, and donor HCV status have been reported to exacerbate the risk for poor outcome after DCD transplantation. Risk factors for graft loss after DCD transplantation include non-Caucasian recipient ethnicity and retransplantation, but interestingly not necessarily older donor age [33]. Causes of graft loss have been variable, and include recurrent hepatitis C, primary non-function, hepatic artery thrombosis, and infections [21]. Recurrent hepatitis C has been seen with the same or higher frequency after DCD liver transplantation compared to after DBD liver transplantation [20].

Patient survival after DCD liver transplantation equals that after DBD liver transplantation in some studies [32,33]. Others, however, have seen an increase in 1-year patient mortality after DCD transplantation, but at 3 years, mortality was the same [31]. Patient survival is worse following DCD transplantation according to another large study, at 82% and 71% at 1 and 3 years, compared to

86% and 77% at 1 and 3 years after DBD liver transplantation, respectively. Mortality for retransplant recipients of DCD livers is even worse, with survival at 1 and 3 years of 71% and 59%, respectively. These rates are very similar to the 68% and 60% at 1 and 3 years after DBD retransplantation, respectively [25]. Causes of death are variable, including recurrent hepatocellular carcinoma, complications of retransplantation, intraoperative cardiac death, and multisystem organ failure [32,33]. Of note, splitting of DCD livers has been described and performed with some success in terms of reasonable patient and graft survival at 1 year [18].

Long-term outcome

Graft survival and retransplantation

Long-term graft survival after DCD liver transplantation is inferior to that for DBD liver transplantation (Figure 54.1). At 5 years, DCD liver graft survival is 43–53% compared to 51–68% DBD liver graft survival [19–21,30]. Only one report has described similar graft survival at 5 years (around 69% in both the DCD and DBD groups) [33]. In the very long term, over 10–20 years postoperatively, graft survival is ultimately similar at 37.5% at 10 years in both groups and 29% and 25% at 20 years in DCD and DBD groups, respectively [35]. As graft survival is worse after DCD liver transplantation, retransplantation is more common after DCD liver transplantation, with rates around 19% for DCD liver transplantation compared to only 5–7% for DBD transplantation [30,34]. Causes for retransplantation include ischemic cholangiopathy in 81%, primary nonfunction in 13%, and vascular complications in 6% [30].

Patient survival

Patient survival after DCD transplantation is similar or slightly less than after DBD transplantation, depending on the study. At 5 years, patient survival after DCD and DBD liver transplantation ranges between 68% and 77%, and 62% and 81%, respectively [19,20,30,33]. At 10 years, patient survival after DCD transplantation lies between 43% and 57% [20,30,35], at 15 years around 54%, and at 20 years around 38%. This compares to 10- and 15-year survival after DBD liver transplantation of 64–67% and 58%, respectively [20,30].

Rejection and other complications

No differences exist in long-term immunologic complications, including acute or chronic rejection [30]. One study suggests that hepatitis C recurrence is more severe after DCD than after DBD liver transplantation [38].

DCD pancreas transplantation

Criteria for acceptance

DCD pancreas transplantation for the treatment of severe type 1 diabetes with or without simultaneous kidney transplantation remains relatively uncommon worldwide. In the US, only select centers choose to transplant pancreata recovered from DCD donors [39]. In Europe, currently only the UK, Belgium, and the Netherlands perform DCD pancreas transplants [27]. There is also a case report of a DCD pancreas transplant in Australia [40]. Selection criteria for DCD pancreata are qualitatively similar to those for DBD pancreata; however, they are more stringent with regard to the quantitative aspects of selection.

Donor age ranges from 3 to 60 years [1,41], but the trend is toward more moderate ages rather than the extremes of this range, and some programs will only accept organs from adult DCD donors [39]. There can be no history of diabetes or pancreatitis. Intra-abdominal sepsis, prior pancreatic surgery, or pancreatic trauma are likewise exclusion criteria. Donors must be HIV negative and have no history of recent malignancy [42]. The presence of hyperglycemia or mild hyperamylasemia at the time of organ donation is acceptable [41]. Young donors with a low BMI who are hemodynamically stable are generally preferred if DCD pancreas transplantation is planned. Other considerations in deciding whether to proceed with recovery and transplantation of a DCD pancreas include whether the donor operation is performed in the local donor service area, whether the anticipated cold ischemia time is short, whether the same team is available for recovery, whether the quality of the flush and gross visualization of the organ is good, and whether there is a possibility of pumping an accompanying kidney in the case of simultaneous pancreas–kidney transplant [39]. The cut-off for warm ischemia time varies between centers from 20 to 45 min and depends somewhat on the course after withdrawal of support [39,41]. Warm ischemia time is variably defined as time from withdrawal of support to cold perfusion, or alternatively beginning at hypotension (systolic blood pressure <50 mmHg) or hypoxia (oxygen saturation $<70\%$) [39,41].

Risks and benefits

Overall, complication rates after DCD and DBD pancreas transplantation are similar. Rejection rates are 14% at 1 year and 19% at 5 years for DCD transplantation, which compares well to rates of 13% at 1 year and 15% at 5 years for DBD pancreas transplantation. Graft thrombosis is uncommon, typically occurring in 2–6% or recipients [1,41]. Enteric conversion is necessary slightly more often if DCD pancreas transplantation is performed initially via bladder drainage (17% at 1 year and 28% at 5 years vs. 8% at 1 year and 15% at 5 years in DBD transplantation). Enzyme leaks occur in 4% of patients in the first year post transplant and this percentage does not increase further over the following 5 years. In DBD transplantation, enzyme leaks are more common at 9% in the first year and 10% over a 5-year period. The rates of pancreatitis at 1 and 5 years post transplant are similar after DCD (9% and 9%, respectively) and DBD transplantation (9% and 14%, respectively). Pancreatic pseudocysts and pancreatic necrosis occur infrequently ($<1\%$) in both groups. Peripancreatic abscesses develop in about 8–10% of patients in both the DCD and DBD groups up to 5 years post transplant.

Function of DCD and DBD pancreas transplants

Transplantation of the pancreas occurs either as whole organ or islet transplantation. Outcomes after whole organ transplantation are discussed, followed by brief mention of outcomes after transplantation of DCD islets.

Glucose control after whole organ pancreas transplantation is similar at discharge and long-term between DCD and DBD pancreata [1,41,43]. In the long term, fasting blood glucose and hemoglobin A1c (HbA1c) are reported as nearly identical. One year post transplant, HbA1c is $5.43 \pm 0.75\%$ after DBD and $5.63 \pm 0.57\%$ after DCD pancreas transplantation [1,41,43]. Patient and graft survival are comparable after solitary pancreas transplantation and after simultaneous pancreas–kidney transplantation from DCD donors. Patient and pancreas graft survival at 12 months is 100% each, when in-situ perfusion via extracorporeal support is used in uncontrolled donors [42]. After controlled DCD pancreas transplantation, patient survival is similar at 1, 3, and 10 years after DBD transplantation (97%, 94%, and 79%, respectively) and after DCD transplantation (94%, 93%, and 87%, respectively). Pancreas graft

survival is slightly lower after DBD (87%, 81%, and 61%) than after DCD transplantation (83%, 78%, and 63%) at 1, 3, and 10 years, respectively [1]. Most patients (93%) are free from hypoglycemia at 1 year, regardless of DCD or DBD donor type [1]. Nine percent of patients in each group develop post-transplant diabetes mellitus [1]. Hospital length of stay is the same for both groups [41,43]. Pancreas graft thrombosis occurs in 13% of DCD and 6% of DBD pancreata. Causes of pancreatic graft loss after DCD simultaneous kidney–pancreas transplantation include bleeding (18%), acute rejection (9%), and chronic rejection (9%), whereas causes of pancreatic graft loss after DBD simultaneous kidney–pancreas transplantation are mostly chronic rejection and infection.

Clinical islet transplantation from DCD donors has mostly been described in Japan. Seven of eight recovered organs were transplanted with good islet yields and reasonable purity [44]. Another Japanese group later reported 34 DCD islet transplants from 64 donors into 18 recipients. Islet quality was worse with longer prearrest hypotension and longer cold ischemia time, and better with the use of Kyoto solution during recovery [45]. Markmann et al. similarly reported a lower islet yield with longer warm ischemia time [46]. While in Japan 16 of 18 recipients had immediate islet function, half lost islet function within 1 year. Still, HbA1c was improved overall after islet transplantation, and all patients eventually achieved freedom from hypoglycemia [45].

Long-term outcomes

Little data exist on long-term outcomes after DCD pancreas transplantation. DCD pancreas graft survival is 83% and 72% at 1 and 5 years, respectively, and is similar to pancreas graft survival after DBD pancreas transplantation at 89% and 79%, respectively (Figure 54.1) [41,43]. Pancreas graft survival after simultaneous pancreas kidney transplantation is 85%, 80%, and 74% at 1, 3, and 5 years after DCD transplantation, respectively [39]. Patient survival after simultaneous pancreas–kidney transplantation is 98%, 93%, and 89% at 1, 3, and 5 years after DCD transplantation, respectively [39]. Patient survival after DCD pancreas transplantation is 92% at 1 and 5 years post transplant, which is similar to the 97% and 89% survival after DBD pancreas transplantation, respectively [41,43].

DCD kidney transplantation

Of all organs, kidneys are the most frequently transplanted from DCD donors. Thus, there is more experience with DCD kidneys than with any other DCD organs. Furthermore, DCD kidneys are also most often considered for multiorgan transplants, including simultaneous kidney–pancreas transplants and simultaneous liver–kidney transplants [2].

Criteria for acceptance

In addition to the usual kidney acceptance criteria, additional selection criteria apply to DCD kidneys that vary by center; some of these are delineated here. Uncontrolled DCD donors should be reasonably young (under 60–65 years), and have no history of renal impairment, cancer, sepsis, or advanced diabetes. Warm ischemia time limits are between 40 and 120 min. Most uncontrolled DCD donors are identified in the emergency room after unsuccessful resuscitation [46,47].

In Belgium, the maximum age for DCD kidney donation is 75 years, with a warm ischemia time up to 60 min and a cold ischemia time that often exceeds 24 h due to timing of HLA typing, crossmatching, and allocation. All DCD kidneys are routinely machine preserved [48].

Farney et al. have described their optimal DCD donor as a standard criteria donor (SCD), with a cold ischemia time of under 30 h, and a kidney that is transplanted into a recipient under 60 years of age. Contraindications to DCD donation include a glomerular filtration rate (GFR) of <70 mL/min on admission, a history of cancer, HIV positivity, cold ischemia time of >45 h, and warm ischemia time of >90 min for SCD donors and >60 min for ECD donors. Machine perfusion criteria are used, with flows of <60 mL/min or resistance of >0.4 mmHg/mL/min being contraindications to transplantation of adult DCD kidneys [49].

Our own criteria for DCD kidney donation are a warm ischemia time of <120 min. However, most patients in whom support is withdrawn go on to expire and meet the criterion for donation in 60 min or less. The mean time for the few cases who expire after >60 min is 75 min. Initially, our maximum DCD donor age was 65 years; however, more recently we avoid the DCD/ECD donor unless their creatinine, creatinine clearance, and medical history are all optimal. We biopsy all DCD kidneys for Remuzzi scoring and to check for fibrin thrombi. Kidneys with Remuzzi scores of >6 are discarded.

Risks and benefits

DCD kidneys, like DBD kidneys, provide life-saving organs to patients. Waitlist mortality is reduced by using DCD kidneys for transplantation [50]. Delayed graft function (DGF), often defined as the need for dialysis within 1 week after kidney transplantation, is more common after DCD kidney transplantation than after DBD transplantation. DGF rates of 28–57% after DCD kidney transplantation, even with relatively short cold ischemia times (13 ± 5 h), are significantly higher than rates of 19–21% after DBD kidney transplantation [1,42,43,51–55]. After DCD kidney transplantation from uncontrolled donors, DGF rates of 93% have been reported [46,56]; thus, DGF rates are definitely higher after transplantation of DCD kidneys from uncontrolled donors than from controlled DCD donors [27]. The average duration of DGF is 13 ± 8 days [51]. Risk factors for DGF are donor systolic blood pressure of <60 mmHg for >20 min and donor age over 50 years [51,52]. Cold ischemia times of >30 h may also increase the incidence of DGF [49]. DGF often results in a prolonged hospital stay and more procedures [41,54,57]. A multicenter Eurotransplant study of paired DCD kidneys determined that pulsatile perfusion preserved kidneys have a shorter period of DGF than cold stored DCD kidneys, although 1-year graft survival was the same at 94% versus 95%, respectively [57]. DGF may indeed be reduced by pulsatile perfusion preservation, though not all studies confirm this [57,58]. DGF does not have a negative effect on long-term outcomes, nor does the duration of DGF affect graft survival [49,54].

Primary non-function after DCD kidney transplantation is uncommon (1–5%) [43,46,47,49,51,52], as it is after DBD kidney transplantation [55]. Lower intraoperative blood pressure ($<110/80$ mmHg) and central venous pressure (<6 cmH_2O) are risk factors for primary non-function [59].

Rejection occurs at similar or slightly higher rates after DCD and DBD kidney transplantation [1,42,54,60]. Acute rejection is reported to occur in 19–24% of patients after DCD transplantation and in 10% after DBD transplantation [42,46]. When comparing the two, others have reported higher rates of rejection after DCD transplantation than after DBD transplantation (29% vs. 16%) [53].

Rates of other complications, including renal artery stenosis or thrombosis (<2%), ureteral complications (<5%), or lymphoceles (<10%), do not differ between DCD and DBD kidneys [1,41,43,55].

Function of DCD and DBD kidney transplants

Immediately postoperatively, DGF occurs more frequently after DCD than after DBD kidney transplantation, but primary nonfunction is rare. The discharge creatinine is higher after DCD kidney transplantation than after DBD kidney transplantation (1.9 vs. 1.7 mg/dL) [43,55]. Creatinine on day 7 is also reported as higher in DCD compared to SCD or ECD kidneys [42]. DCD kidneys have comparable creatinine clearance at 112 mL/min compared to 101 mL/min for SCD kidneys and 77 mL/min for ECD kidneys [42]. Serum creatinine is reported as similar up to 10 years after DCD and DBD kidney transplantation [47,61]. Data reported from the Netherlands have suggested that DCD kidneys have a higher rate of graft loss than DBD kidney (12% vs. 6%), although it is not clear if these data are globally generalizable.

Long-term outcomes

Long-term graft survival is similar for DCD and DBD kidneys (Figure 54.1) [43,53]. Even graft survival of kidneys from DCD donors who develop DGF after transplantation is rather good at 88% at 1 year, 84% at 3 years, and 84% at 6 years [45]. Actuarial graft survival after DCD kidney transplantation is 89% at 1 year, 76% at 3 years, and 76% at 5 years. Graft failure is mostly due to chronic allograft nephropathy and death with function. Actuarial death-censored graft survival after DCD kidney transplantation is 93% at 1 year, 84% at 3 years, and 84% at 5 years. Recipients over the age of 60 years have lower 1- and 3-year graft survival at 79% and 64%, respectively [49]. DCD kidney graft survival in one report was 88%, 77%, and 44% compared to 78%, 69%, and 42% after DBD kidney transplantation at 1, 3, and 10 years post transplant, respectively [62]; and in another report was was high at 79%, 70%, and 62% after DCD transplantation and 83%, 72%, and 62% after DBD transplantation, respectively [47]. Others have also found no difference in allograft survival at 5, 10, or 15 years post transplant [55].

Patient survival is identical for DCD and DBD kidney recipients, even up to 15 years post transplant [10,17,21]. Actuarial patient survival is 93% at 1 year, 91% at 3 years, and 89% at 5 years post transplant [49]. These rates are similar to reported rates of 1-, 3-, and 10-year patient survival of 92%, 85%, and 60% after DCD transplantation [1]. Sepsis, cardiovascular disease, cancer, and gastrointestinal hemorrhage are common causes of death. Older recipients of DCD organs have lower patient survival than their younger counterparts (81% vs. 98% at 1 year, 76% vs. 97% at 3 years, and 69% vs. 97% at 5 years) [49]. Patient survival is lower in DCD–ECD recipients than in DCD–SCD recipients [49].

DCD heart and intestine transplantation

Neither cardiac nor small bowel transplants from DCD donors currently play a clinical role. As we gain more experience from preclinical studies, however, these organs may be considered for transplantation in the future.

DCD process

In general, the initial DCD process is no different from that for DBD donors (Figure 54.2). All patients with a Glasgow coma score (GCS) of 5 are referred to the Organ Procurement Organization (OPO). Also, all patients for whom a decision has been made to withdraw life support are referred to the OPO. The OPO then determines medical suitability and makes an assessment of whether the patient is likely to expire in a 2-h time frame. A respiratory drive assessment is made utilizing the University of Wisconsin (UW) DCD tool, which has been previously validated and published [63]. If a patient is on maximum ventilation or on multiple vasopressors, the tool is not performed. Our data show that when we make a decision to proceed with a DCD donor based on the tool's criteria, we recover organs 80% of the time. Families are always informed that there is a possibility that the donation may not occur. Our experience is that they are thankful that we attempted to honor their loved one's wishes to be an organ donor.

One guideline for DCD recovery of kidneys is that from Thomas et al. in the UK [64]; ICU practice determines whether or not life support will be withdrawn. Once the decision to withdraw support has been reached, potential donors are referred to the OPO in discussion with the OPO coordinator. The family is approached after the decision to withdraw support has been made by a senior ICU team member and once candidacy has been established. At this point, escalation of treatment is no longer allowed. Support is withdrawn in the ICU in the usual way and is dictated by local practice. Up to 2 h of warm ischemia time, defined as time from withdrawal of support to organ recovery, are allowed. The ICU physicians declare death after a mandatory 5-min hands-off period. The family then gets an extra 5 min with the patient before he/she is taken to the operating room. If the family requires more time, then donation is aborted. Of 100 potential donors, 29 were realized, while 30% refused donation. This process again is resource intensive and commitment is particularly required by those involved in the donation process. This protocol has been expanded to liver and pancreas DCD donation.

In Leicester, UK, 73 DCD referrals took place in 3 years, 64 from the emergency room, and nine from the wards, resulting in 24 cases (33%) and 44 recovered kidneys. Thirty kidneys were transplanted locally, eight were shipped out, and six were discarded. These DCD kidneys made up 21% of the entire transplant activity at that center. Consistent with our experience, the authors concluded that the DCD process is labor intensive and requires highly committed staff [65].

The DCD process takes resources beyond those required for DBD donation, both on the part of the OPO and the donor hospital. For example, of 56 DCD lung referrals, nine did not progress within the 2-h cut-off, and 13 needed support to be evaluated on site of these 13 lungs, only nine were transplanted. Two hospital physicians needed to be present to declare death after a 5-min wait period, ICU staff were present for withdrawal of support in either the ICU or postanesthesia care unit (PACU), and the operating room staff were tied up and ready to go [11].

Hospital relations

Currently, all hospitals in the US that have potential for DCD are required to have policies and protocols in place by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO). Additionally, the guidelines of the United Network for Organ Sharing (UNOS) must be followed in DCD donor cases. Similar processes are in place in Europe, and it is likely that global adoption of DCD donation will require process adaptation to meet local practice requirements and customs. As already mentioned, DCD donor cases are more labor intensive and require more OPO

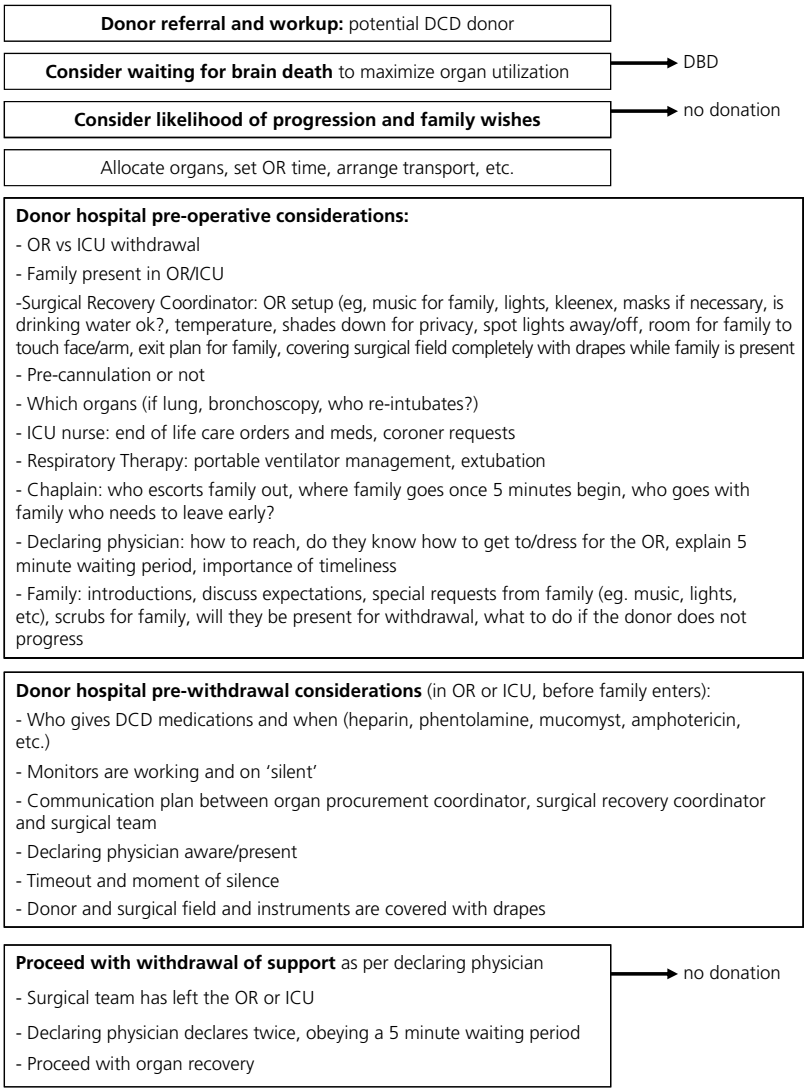

Figure 54.2. The donation after circulatory death (DCD) process.

resources due to processes that must be communicated and followed regarding roles and responsibilities to a patient who has not yet been declared dead. We always send two OPO coordinators to DCD cases to ensure all protocols are being followed, families' needs are being met, and all personnel in the OPO and donor hospital understand their roles and responsibilities. We believe that DCD donation belongs in the continuity of care for patients at the end of life and offers the patient and his/her family the opportunity to leave a lasting legacy through donation. By caring for the potential donor and his/her family and by providing a DCD donation opportunity, we also provide desperately ill potential recipients the chance of a renewed life that otherwise might not be possible.

Summary

It is now evident that organ demand will continuously outpace organ supply. As such, additional opportunities for donor organ acquisition will remain important to best provide organ replacement for those in need. DCD donor organs are acceptable alternatives to SCD organs in many settings, especially in kidney and increasingly in liver transplantation. However, their use requires attention to risk–benefit assessment and proper patient selection, as well as a dedication to perform the organ procurements with heightened attention to established protocol and mindful of the requirement for maintaining professional decorum throughout the process.
