Biomaterials Science

An Introduction to Materials in Medicine

Third Edition

Edited by

Buddy D. Ratner, Ph.D.
Professor, Bioengineering and Chemical Engineering,
Director of University of Washington Engineered Biomaterials (UWEB),
University of Washington, Seattle, WA, USA

Allan S. Hoffman, Sc.D.
Professor of Bioengineering and Chemical Engineering,
UWEB Investigator, University of Washington, Seattle, WA, USA

Frederick J. Schoen, M.D., Ph.D.
Professor of Pathology and Health Sciences and Technology (HST),
Harvard Medical School; Executive Vice Chairman,
Department of Pathology, Brigham and Women's Hospital;
Boston, MA, USA

Jack E. Lemons, Ph.D.
University Professor, Schools of Dentistry, Medicine and Engineering,
University of Alabama at Birmingham, Birmingham, AL, USA

Notices
Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

CONTENTS

PART ONE
Materials Science and Engineering

PART TWO
Biology and Medicine

SECTION II.6   Applications of Biomaterials in Functional Tissue Engineering

PART THREE
Practical Aspects of Biomaterials

SECTION III.1   Implants, Devices, and Biomaterials: Special Considerations

SECTION III.2   Voluntary Standards, Regulatory Compliance, and Non-Technical Issues

Appendices

Sascha Abramson
Department of Chemistry, Rutgers, The State University of New Jersey, New Brunswick, NJ, USA

D. Michael Ackermann, Jr.
Biodesign, Stanford University, Stanford, CA, USA

Robert Akins
Tissue Engineering and Regenerative Medicine Laboratory, Alfred I. duPont Hospital for Children/ Nemours Foundation, Wilmington, DE, USA

Richard Anders
Senior Lecturer, Massachusetts Institute of Technology, Cambridge, MA, USA

Phillip J. Andersen
Andersen Metallurgical, LLC

James M. Anderson
Department of Pathology, Case Western Reserve University, Cleveland, OH, USA

James A. Ankrum
Harvard-MIT Division of Health Sciences & Technology, USA; Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, USA

Kristi S. Anseth
Department of Chemical and Biological Engineering, Howard Hughes Medical Institute and University of Colorado, Boulder, CO, USA

Joe Antonucci
National Institute of Standards and Technology, Gaithersburg, MD, USA

Sarah Atzet
Glycosan BioSystems, Inc., Salt Lake City, Utah, USA

Stephen F. Badylak
McGowan Institute for Regenerative Medicine, University of Pittsburgh, Pittsburgh, PA, USA

Gail D. Baura
Keck Graduate Institute of Applied Life Sciences, Claremont, CA, USA

Ravi V. Bellamkonda
Department of Biomedical Engineering, Georgia Institute of Technology, Atlanta, GA, USA

Serena M. Best
University of Cambridge, Cambridge, UK

Sarindr Bhumiratana
Department of Biomedical Engineering, Columbia University, New York, USA

Richard W. Bianco
Department of Surgery, University of Minnesota, Minneapolis, MN, USA

Jack C. Bokros
On-X Life Technologies, Inc, Austin, TX, USA

Harvey S. Borovetz
University of Pittsburgh, Departments of Surgery and Departments of Bioengineering, & Chemical Engineering, Pittsburgh, PA, USA

Adele L. Boskey
Starr Chair in Mineralized Tissue Research, Hospital for Special Surgery and Professor, Weill Medical College of Cornell University; BME Faculty, Sibley School of Mechanical Engineering, Cornell, Ithaca

Justin L. Brown
Department of Bioengineering, The Pennsylvania State University, PA, USA

Bryan N. Brown
McGowan Institute for Regenerative Medicine, University of Pittsburgh, Pittsburgh, PA, USA

Stanley A. Brown
(retired)
17704 Stoneridge Dr., Gaithersburg MD, USA

John B. Brunski
Division of Plastic & Reconstructive Surgery, Department of Surgery, School of Medicine, Standford University, Standford, CA, USA

Fred Cahn
BioMedical Strategies, La Jolla, CA, USA

Alastair Campbell Ritchie
Department of Mechanical, Materials and Manufacturing Engineering, University of Nottingham, Nottingham, UK

Arnold I. Caplan
Professor of Biology, Director Skeletal Research Center, Case Western Reserve University, Cleveland, USA

Richard L. Carpenedo
The Wallace H. Coulter Department of Biomedical Engineering, Georgia Institute of Technology, Atlanta, Georgia, USA

Ashutosh Chilkoti
Center for Biologically Inspired Materials and Material Systems and Department of Biomedical Engineering, Duke University, Durham, NC, USA

Sangwon Chung
Fiber and Polymer Science, Department of Textile Engineering, Chemistry & Science, North Carolina State University, Raleigh, NC, USA; Biomedical Engineering, Joint Department of Biomedical Engineering, North Carolina State University and University of North Carolina at Chapel Hill, NC, USA

Elisa Cimetta
Department of Biomedical Engineering, Columbia University, New York, USA

Gary Cleary
Corium Inc. Menlo Park, CA, USA

Isaac P. Clements

Biomaterials Science: An introduction to Materials in Medicine was launched as an educational project to provide a nascent biomaterials community with an authoritative tool for training and education. Conceptual background material and a broad overview of applications were both envisioned as being integral to the textbook. In the late 1980s, biomaterials was in transition from an emerging field to a respected discipline embracing convergence (i.e., the merging of expertise from different "silos," such as provided by engineers, biomedical scientists and physicians) – the biomaterials community was in need of an integrated, comprehensive, and definitive educational resource. This rationale for launching the textbook has been validated by the success of earlier editions of *Biomaterials Science*: *An introduction to Materials in Medicine* – well over 25,000 copies have contributed to the biomaterials education of students and researchers around the world. The second edition has been widely adopted for classroom use, and is a reference resource for thousands of biomaterials professionals.

Biomaterials Science: *An Introduction to Materials in Medicine* strives for a balanced view of the biomaterials field. When this project was first launched, monographs available at that time did articulately address biomaterials, but they tended to strongly emphasize the authors' areas of expertise, while only superficially addressing other important subjects outside of their intellectual sphere. Balanced presentation means appropriate representation of:

- hard and soft biomaterials;
- orthopedic, cardiovascular, ophthalmologic, dental, and emerging applications;
- a balance of fundamental biological and materials science concepts, contemporary medical/clinical concerns, and government/commercial/societal issues that reflect the complex environment in which biomaterials are developed and used;
- coverage of the past, present, and future of biomaterials, their applications, and key challenges that lie ahead.

In this way, the reader can embrace the broad field, absorb the unifying principles common to all materials in contact with biological systems, and gain a solid appreciation for the special significance of the word *biomaterial*.

Biomaterials Science: *An Introduction to Materials in Medicine*, third edition, strives for curricular cohesion. Articles from the technical literature are commonly used in the classroom setting, but their scope and quality are inconsistent, and they are difficult to weave into a cohesive curriculum. Handout materials from professors are often graphically unsophisticated, and again, slanted to the specific interests of the individual. In *Biomaterials Science*: *An Introduction to Materials in Medicine*, by integrating the experience of many of leaders in the biomaterials field, we endeavor to present a balanced yet comprehensive perspective on an exciting and rapidly evolving discipline – and present this information in a graphically attractive, readable format, intended to be useful as an educational resource to a broad array of students, teachers, and practicing professionals.

Over 100 biomaterials experts from academia, industry, and government have contributed to this work. Certainly, such a distinguished group of authors can provide the needed balance, scope, and perspective. However, a sufficiently diverse group of authors also introduces unique complexities in a project of this type. Do the various writing styles clash? Does the presentation of material, particularly controversial material, result in one chapter contradicting another? Even with so many authors, can all subjects relevant to biomaterials be addressed? What subjects should be included, and which left out? How should such a project be refereed to ensure scientific quality, pedagogical effectiveness, and the balance we strive for? These are some of the issues the editors grappled with in the period from the conception of a revised, updated edition (shortly after the publication of the second edition), to the third edition publication in 2012. From this complex editorial process, a unique volume has evolved that the editors hope can make an ongoing contribution to the development of the biomaterials field. An educational tool has been synthesized here leading those new to biomaterials, and those with substantial experience in biomaterials (be they engineers, physicians, materials scientists, biological scientists, entrepreneurs, regulatory professionals or corporate leaders) to an appreciation of the scope, complexity, and significance of this enterprise.

What's new in this, the third, edition of *Biomaterials Science*: *An Introduction to Materials in Medicine*? All chapters have been updated, "colorized," and substantially rewritten. Many new chapters on important subjects have been added. The curricular organization for teaching fundamental materials science, cell and molecular biology, physiology, and pathology, key subjects that support the modern biomaterials research endeavor, has been restructured. The section on tissue engineering has been much expanded. The total content and size of the book have been significantly increased. A living website has been coupled to the book, offering supplemental material, homework problems, and other resources. The graphic design has been upgraded. This book addresses biomaterials for the 21st century.

Also, there is a new emphasis on regulatory and translational themes – how can we facilitate the progression of "smart ideas" from the biomaterials science lab bench to medical devices that save lives, improve the quality of life, generate jobs, and decrease overall healthcare costs through more effective therapies?

Acknowledgments and thanks are in order. First, the Society For Biomaterials, sponsor and inspiration for this book, is a model of "multidisciplinary cultural diversity." Composed of engineers, physicians, scientists, veterinarians, industrialists, inventors, regulators, attorneys, educators, ethicists, and others, the SFB provides the nidus for the intellectually exciting, humanitarian, and economically important biomaterials field. As was the case for the first and second editions, the editors recognize the importance of the Society For Biomaterials by donating all royalties from sales of this volume to the Society, to directly support education and career development related to biomaterials. For information on the Society For Biomaterials, visit the SFB website at http://www.biomaterials.org/.

We offer a special thanks to those who have generously invested time, energy, experience, and intelligence to author the chapters of this textbook. The many scientists, physicians, engineers, and industry leaders who contributed their expertise and perspectives are clearly the backbone of this work, and they deserve high praise – their efforts will strongly impact the education of the next generation of biomaterials scientists. We also pay respect and homage to biomaterials pioneers who have contributed to this work, but have since passed on – Jorge Heller, Michael Lysaght, Shalaby Shalaby, and Steven Slack; their contributions and collegiality are remembered and will be missed.

The organizational skills, experience, and encouragement of the staff at Elsevier Publishers, have led this third edition from a vague vision to a valuable volume – a tangible resource for the community. Thank you, Elsevier, for this contribution to the field of biomaterials.

The biomaterials field, since its inception in the 1950s, has been ripe with opportunity, intellectual stimulation, compassion, creativity, and rich collaboration. As a field we look to the horizons where the new ideas from science, technology, and medicine arise. Importantly, we strive to improve the survival and quality of life for millions through biomaterials-based medical devices and tissue engineering. We editors hope the biomaterials textbook you now hold will stimulate you as much as it has us.

January, 2012

Biomaterials Science: *An introduction to Materials in Medicine* was conceived as a learning tool to "compatibilize" through common language and fundamental principles a number of independent communities (basic sciences, engineering, medicine, dentistry, industry, regulatory, legal, etc.). Although the book has approximately 170 chapters, there is a logic of organization and curriculum that should make *Biomaterials Science*: *An introduction to Materials in Medicine*, third edition, straightforward to use in an academic course or as a reference work.

A guiding principle in assembling this multi-author, multidisciplinary textbook is that fundamental and translational progress in the field of biomaterials necessitates integration of concepts and tools from the full spectrum of the physical sciences, engineering, clinical medicine, biology, and the life sciences. Indeed, the discipline of biomaterials utilizes a *convergence* of multidisciplinary elements to enable the development of specific diagnostic or therapeutic devices – i.e., using biomaterials science and technology to create and implement real medical devices and other products that solve clinical problems and improve patient outcomes. Nevertheless, the editors believe (and the book has been assembled so) that a physician should be able to pick up the textbook and glean a baseline knowledge of the science, engineering, and commercialization aspects of biomaterials. A chemist could use this book to appreciate the biology behind biomaterials, the physiology associated with medical devices, and the applications in medicine. An engineer hired by a medical device company might learn the basic science underlying the technological development and details on medical applications. Similarly, for other disciplines that interface with biomaterials, this book can guide the reader through diverse but related topics that are generally not found in one volume.

The textbook has well over 100 authors. The field of biomaterials is so diverse in subject matter that a guiding principle has been that no one author can write it all – let us use the experience and wisdom of acknowledged masters of each subject to communicate the best information to the reader. But, to prevent this book from appearing to be simply a collection of review papers, considerable editorial effort has gone into ensuring logical curricular organization, continuity of ideas, and extensive cross-referencing between chapters.

Biomaterials Science: *An introduction to Materials in Medicine*, third edition, is divided into four parts (Materials Science and Engineering; Biology and Medicine; Practical Aspects of Biomaterials; Perspectives and Possibilities in Biomaterials Science), sections that subdivide each of the four parts (for example, under the part called "Materials Science and Engineering" there are sections on properties of materials and classes of materials used in medicine), and finally chapters, for example, chapters on each of the types of materials that are used in medicine (hydrogels, polyurethanes, titanium, etc.). Each section begins with an introduction by one of the editors that will guide the reader through the chapters, giving cohesion to the sections and highlighting key issues that are worthy of attention. Finally, there are appendices that tabulate use data and information.

Wherever possible, problems at the end of chapters are provided for classroom use and for self-testing. To permit updating problems and adding new ones, problems, and other resource materials including a full artwork catalog and downloadable images from the text, are provided on the companion website at http://www.elsevierdirect.com/companions/9780123746269.

We hope that the textbook organization, the extensive editorial effort, and the expertly authored chapters will serve their intended purpose – to guide a reader into and through this complex field of biomaterials science. The editors always appreciate feedback and commentary – contact information is provided for them.

And now, it is time to delve into the rich world of biomaterials science.

Biomaterials Science: An Evolving, Multidisciplinary Endeavor

Buddy D. Ratner, Allan S. Hoffman,
Frederick J. Schoen, and Jack E. Lemons

BIOMATERIALS AND BIOMATERIALS SCIENCE

Biomaterials Science: *An Introduction to Materials in Medicine*, third edition addresses the design, fabrication, testing, applications, and performance of synthetic and natural materials that are used in a wide variety of implants, devices, and process equipment that contact biological systems. These materials are referred to as biomaterials.

> The compelling, human side to biomaterials is that millions of lives are saved, and the quality of life is improved for millions more.

The field of biomaterials is some 60–70 years old (or young) at the time of publication of this third edition. It significantly impacts human health, the economy, and many scientific fields. Biomaterials and the medical devices comprised of them are now commonly used as *prostheses* in cardiovascular, orthopedic, dental, ophthalmological, and reconstructive surgery, and in other interventions such as surgical sutures, bioadhesives, and controlled drug release devices. The compelling, human side to biomaterials is that millions of lives have been saved, and the quality of life improved for millions more, based on devices fabricated from biomaterials. The biomaterials field has seen accelerating growth since the first medical devices that were based on accepted medical and scientific principles made their way into human usage in the late 1940s and early 1950s. And the growth of the field is ensured, with the aging population, the increasing standard of living in developing countries, and the growing ability to address previously untreatable medical conditions.

Biomaterials science addresses both therapeutics and diagnostics. It encompasses basic sciences (biology, chemistry, physics), and engineering and medicine. The translation of biomaterials science to clinically important medical devices is dependent on: (1) sound engineering design; (2) testing *in vitro*, in animals and in humans; (3) clinical realities; and (4) the involvement of industry permitting product development and commercialization. Figure 1 schematically illustrates the path from scientific development to the clinic.

Biomaterials science, in its modern incarnation, is an example of an important new research model – called *convergence* – an emerging paradigm that pushes multidisciplinary collaboration among experts and multidisciplinary integration of concepts and practice (Sharp and Langer, 2011). Not only biomaterials, but also bioinfomatics, synthetic biology, computational biology, nanobiology, systems biology, and other forefront fields, depend on convergence for their continued progress. This textbook aims to introduce these diverse multidisciplinary elements, particularly focusing on interrelationships rather than disciplinary boundaries, to systematize the biomaterials subject into a cohesive curriculum – a true convergence.

The title of this textbook, *Biomaterials Science*: *An Introduction to Materials in Medicine*, is accurate and descriptive. The intent of this work is: (1) to focus on the scientific and engineering fundamentals behind biomaterials and their applications; (2) to provide sufficient background material to guide the reader to a clear understanding and appreciation of the applications of biomaterials; and (3) to highlight the opportunities and challenges in the field. Every chapter in this textbook can serve as a portal to an extensive contemporary literature that expands on the basic ideas presented here. The magnitude of the biomaterials endeavor, its broadly integrated multidisciplinary scope, and examples of biomaterials applications will be revealed in this introductory chapter and throughout the book.

> The common thread in biomaterials is the physical and chemical interactions between complex biological systems and synthetic or modified natural materials.
FIGURE 1   The path from the basic science of biomaterials, to a medical device, to clinical application.

Although biomaterials are primarily used for medical applications (the focus of this text), they are also used to grow cells in culture, to assay for blood proteins in the clinical laboratory, in processing equipment for biotechnological applications, for implants to regulate fertility in cattle, in diagnostic gene arrays, in the aquaculture of oysters, and for investigational cell–silicon "neuronal computers." How do we reconcile these diverse uses of materials into one field? The common thread is the physical and chemical interactions between complex biological systems and synthetic materials or modified natural materials.

In medical applications, biomaterials are rarely used as isolated materials, but are more commonly integrated into devices or implants. Chemically pure titanium can be called a biomaterial, but shaped (machined) titanium in conjunction with ultrahigh molecular weight polyethylene becomes the device, a hip prosthesis. Although this is a text on biomaterials, it will quickly become apparent that the subject cannot be explored without also considering biomedical devices and the biological response to them. Indeed, both the material and the device impact the recipient (patient) and, as we will see, the patient's host tissue impacts the device. These interactions can lead to device success or, where there is inappropriate choice of biomaterials or poor device design, device failure.

Furthermore, a biomaterial must always be considered in the context of its final fabricated, sterilized form. For example, when a polyurethane elastomer is cast from a solvent onto a mold to form the pump bladder of a heart assist device, it can elicit different blood reactions than when injection molding is used to form the same device. A hemodialysis system serving as an artificial kidney requires materials that must function in contact with a patient's blood, and also exhibit appropriate membrane permeability and mass transport characteristics. Much fabrication technology is applied to convert the biomaterials of the hemodialysis system (polysulfone, silicone rubber, polyethylene) into the complex apparatus that is used for blood purification.

Due to space limitations and the materials focus of this work, many aspects of medical device design are not addressed in this book. Consider the example of the hemodialysis system. This textbook will overview membrane materials and their biocompatibility; there will be little coverage of mass transport through membranes, the burst strength of membranes, dialysate water purification, pumps, flow systems, and monitoring electronics. Other books and articles cover these topics in detail, and chapter authors provide references useful to learn more about topics not explicitly covered.

KEY DEFINITIONS

The words "biomaterial" and "biocompatibility" have already been used in this introduction without formal definition. A few definitions and descriptions are in order, and will be expanded upon in this and subsequent chapters.

A definition of "biomaterial" endorsed by a consensus of experts in the field is:

A biomaterial is a nonviable material used in a medical device, intended to interact with biological systems.

Williams, 1987

A biomaterial is a nonviable material used in a medical device, intended to interact with biological systems.

Although biomaterials are most often applied to meet a therapeutic or diagnostic medical need, if the word "medical" is removed, this definition becomes broader and can encompass the wide range of applications suggested above. If the word "nonviable" is removed, the definition becomes even more general, and can address many new tissue engineering and hybrid artificial organ applications where living cells are used.

"Biomaterials science" is the study (from the physical and/or biological perspective) of materials with special reference to their interaction with the biological environment. Traditionally, emphasis in the biomaterials field has been on synthesis, characterization, and the host–material interactions biology. Yet, most biomaterials (that meet the special criteria of biocompatibility – see Chapters II.3.2 and II.3.4) induce a non-specific biological reaction that we refer to as the foreign-body reaction (Chapter II.2.2). This leads us to consider a widely-used definition of biocompatibility.

"Biocompatibility" is the ability of a material to perform with an appropriate host response in a specific application.

Williams, 1987

"Biocompatibility" is the ability of a material to perform with an appropriate host response in a specific application.

Examples of "appropriate host responses" include resistance to blood clotting, resistance to bacterial colonization, and normal, uncomplicated healing. Examples of "specific applications" include a hemodialysis membrane, a urinary catheter or a hip joint replacement prosthesis. Note that the hemodialysis membrane might be in contact with the patient's blood for five hours, the catheter may be inserted for a week, and the hip joint may be in place for the life of the patient. This general concept of biocompatibility has been extended to tissue engineering,

in which *in vitro* and *in vivo* processes are harnessed by careful selection of cells, materials, and metabolic and biomechanical conditions to regenerate functional tissues. Ideas central to biocompatibility are elaborated upon in Ratner (2011), and Chapter II.3.2.

In the discussion of these definitions, we are introduced to considerations that set biomaterials apart from most materials explored in materials science. Table 1 lists a few applications for synthetic materials in the body. It includes many classes of materials used as biomaterials. Note that metals, ceramics, polymers, glasses, carbons, and composite materials (combinations of different classes of materials) are listed. Such materials are used as molded or machined parts, coatings, fibers, films, membranes, foams, fabrics, and nanoparticles. Table 1 also gives estimates of the numbers of medical devices containing biomaterials that are implanted in humans each year. The human impact, and the size of the commercial market for biomaterials and medical devices, is impressive (Table 1; Table 2).

TABLE 1	Key Applications of Synthetic Materials and Modified Natural Materials in Medicine*	
Application	**Biomaterials Used**	**Number/Year – World (or World Market in US$)**
Skeletal system		
Joint replacements (hip, knee, shoulder)	Titanium, stainless steel, polyethylene	2,500,000
Bone fixation plates and screws	Metals, poly(lactic acid) (PLA)	1,500,000
Spine disks and fusion hardware		800,000
Bone cement	Poly(methyl methacrylate)	($600M)
Bone defect repair	Calcium phosphates	–
Artificial tendon or ligament	Polyester fibers	–
Dental implant-tooth fixation	Titanium	($4B)
Cardiovascular system		
Blood vessel prosthesis	Dacron, expanded Teflon	200,000
Heart valve	Dacron, carbon, metal, treated natural tissue	400,000
Pacemaker	Titanium, polyurethane	600,000
Implantable defibrillator	Titanium, polyurethane	300,000
Stent	Stainless steel, other metals, PLA	1,500,000
Catheter	Teflon, silicone, polyurethane	1B ($20B)
Organs		
Heart assist device	Polyurethane, titanium, stainless steel	4000
Hemodialysis	Polysulfone, silicone	1,800,000 patients ($70B)
Blood oxygenator	silicone	1,000,000
Skin substitute	Collagen, cadaver skin, nylon, silicone	($1B)
Ophthalmologic		
Contact lens	Acrylate/methacrylate/silicone polymers	150,000,000
Intraocular lens	Acrylate/methacrylate polymers	7,000,000
Corneal bandage lens	hydrogel	–
Glaucoma drain	Silicone, polypropylene	($200M)
Other		
Cochlear prosthesis	Platinum, platinum-iridium, silicone	250,000 total users
Breast implant	Silicone	700,000
Hernia mesh	Silicone, polypropylene, Teflon	200,000 ($4B)
Sutures	PLA, polydioxanone, polypropylene, stainless steel	($2B)
Blood bags	Poly(vinyl chloride)	–
Ear tubes (Tympanostomy)	Silicone, Teflon	1,500,000
Intrauterine device (IUD)	Silicone, copper	1,000,000

*Data compiled from many sources – these numbers should be considered rough estimates that are changing with growing markets and new technologies. Where only US numbers are available, world usage is estimated at approximately 2.5× of US usage.
NOTE: M = millions, B = billions.

TABLE 2	The Biomaterials and Healthcare Market: Facts and Figures (Per Year)
Total US healthcare expenditures (1990)	$714 billion
Total US healthcare expenditures (2009)	$2.5 trillion
Total US health research and development expenditure (2009)	$139 billion
Number of medical device companies in the US	12,000
Jobs in the US medical device industry (2008)	425,000
Sales by US medical device industry (2008)	$136 billion
World medical device market forecast for 2013*	$286 billion

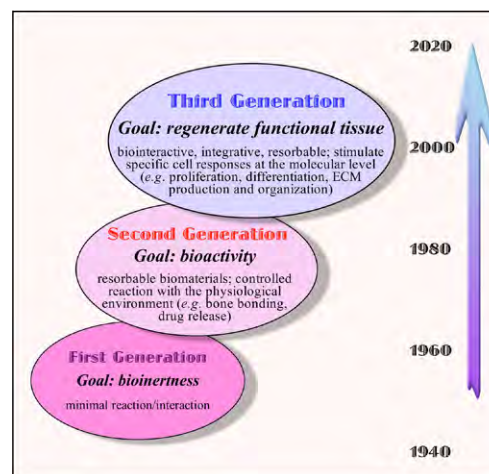
FIGURE 2 Evolution of biomaterials science and technology. (Based upon Rabkin, E. & Schoen, F. J. (2002). Cardiovascular tissue engineering. Cardiovasc Pathol, 11: 305.)

THE EVOLUTION OF THE BIOMATERIALS FIELD

Biomaterials research and development have been stimulated and guided by advances in cell and molecular biology, chemistry, materials science, and engineering. The biomaterials community has been the major contributor to the understanding of the interactions of materials with the physiological environment (often referred to as the biointerface). The development of biomaterials for medical and dental applications has evolved through three generations, each somewhat temporally overlapping, yet each with a distinct objective (Figure 2).

The goal of early biomaterials (first generation) was to achieve a suitable combination of functional properties to adequately match those of the replaced tissue without deleterious response by the host. First generation biomaterials (beginning in the 1950s and 1960s) were comprised largely of off-the-shelf, widely available industrial materials that were not developed specifically for medical use. They were selected because of the desirable combination of physical properties specific to the intended clinical use, and because they were *bioinert* (i.e., they elicited minimal response from the host tissues), and therefore they were considered *biocompatible* (see Chapter II.3.2). The widely used elastomeric polymer, silicone rubber, is prototypical. Pyrolytic carbon, originally developed in the 1960s as a coating material for nuclear fuel particles, and now widely used in modified compositions to coat components of mechanical heart valves, exemplifies one of the early biomaterials whose formulation and properties were studied, controlled according to engineering principles, and tuned specifically for medical application (Chapter I.2.8).

Second generation biomaterials evolved from those early biomaterials, and were intended to elicit a controlled reaction with the tissues into which they were implanted in order to induce a desired therapeutic effect. In the 1980s, these *bioactive* materials were in clinical use in orthopedic and dental surgeries as various compositions of bioactive glasses and ceramics (Hench and Pollak, 2002; Chapter I.2.4.A), in controlled localized drug release applications such as the Norplant


hormone-loaded contraceptive formulation (Meckstroth and Darney, 2001), and in devices such as the Heart-Mate® left ventricular assist device for patients with congestive heart failure (Chapter II.5.3.D). This cardiac assist device has an integrally-textured polyurethane surface that fosters a controlled surface thrombotic (clotting) reaction to minimize the risk of de-adhering fragments of clotted blood into the bloodstream (Rose et al., 2001). Still another example of second generation biomaterials used in medical devices are the drug-eluting endovascular stents that have been shown to markedly limit restenosis (blood vessel closure) following balloon angioplasty (Daemen et al., 2007a and 2007b; Chapter II.5.3.B).

The second generation of biomaterials also included the development of resorbable biomaterials, with rates of degradation that could be tailored to the requirements of a desired application (Chapters I.2.6 and II.4.3). Thus, the discrete interface between the implant site and the host tissue could be eliminated in the long-term, because the foreign material would ultimately be degraded to soluble, non-toxic products by the host. A biodegradable suture composed of polyglycolic (PGA) acid has been in clinical use since the 1960s (see "History of Biomaterials"). Many groups continue to search for biodegradable polymers with needed properties such as strength, flexibility, a chemical composition conducive to tissue development, and a degradation rate consistent with the specific application. Polymeric materials with other novel properties such as shape-memory and programmable and interactive surfaces that control the cellular microenvironment are also under investigation (Langer and Tirrell, 2004; Khademhosseini et al., 2006; Lutolf et al., 2009; Chapter I.2.11).

The need for maximally effective pharmacologic dosing regimens and minimization of systemic toxicities has stimulated development of new implantable polymers and innovative systems for controlled drug delivery and gene therapy (Chapter II.5.16 and subchapters under
FIGURE 3 The tissue engineering paradigm – various cell types are seeded on porous scaffolds, possibly proliferated in a bioreactor, and finally implanted in various tissue sites to restore or regenerate damaged or missing tissue. (nature.com.)

this section). Also, new protein and nucleic acid-based drugs (which cannot be taken in classical pill form) created the need for new technologies to deliver these valuable pharmacologic agents. Biomaterials systems can permit delivery of drugs, active proteins, and other macromolecules localized to the site where the drug is needed. The biomaterials-intensive field of controlled drug delivery is now capable of targeting a wide range of drugs to tumors, to diseased blood vessels, to the pulmonary alveoli, etc., on a one-time or sustained basis with highly-regulated dosage (Lawson et al., 2007). Biomaterial-based slow release mechanisms have been developed for delivery of growth factors to induce vascularization and other biological responses (Kong and Mooney, 2007). Moreover, nanoparticle delivery systems (Chapters II.5.16.A and I.2.19) and the development of microelectromechanical systems (MEMS) have opened new possibilities for fine control of dosage, perhaps regulated endogenously (Sengupta et al., 2005; Goldberg et al., 2007). Other formulations can regulate cell and tissue responses through delivery of growth factors, genes or small interfering RNAs (siRNA) (Whitehead et al., 2009).

The third generation of biomaterials, the logical extension of the rapidly progressing state-of-the-art, has the goal of supporting and stimulating the regeneration of functional tissue. Through all of human history, the ability of the physician or healer to actually regenerate tissues and organs lost due to disease or trauma was essentially nonexistent; the physician's role was palliative – ease the symptoms without curing. Now, with advances in tissue engineering and regenerative medicine, it seems that true replacement with living tissue will be possible. Biomaterials play a key role in the rapidly developing field

of tissue engineering and regenerative therapeutics (Section II.6). Tissue engineering is a broad term describing a set of tools at the interface of the biomedical and engineering sciences that use living cells (or attract endogenous cells) to aid tissue formation or regeneration, and thereby produce therapeutic or diagnostic benefit (Freed, 2006; Hunziker et al., 2006; Ingber, 2010; Mikos et al., 2006). In the most frequently applied paradigm, cells are seeded on a scaffold composed of synthetic polymer or natural material (collagen or chemically-treated tissue), a tissue is matured *in vitro*, and the construct is implanted in the appropriate anatomical location as a prosthesis (Figure 3). A typical scaffold is a bioresorbable polymer in a porous configuration in the desired geometry for the engineered tissue, often modified to be adhesive for cells, in some cases selective for a specific cell population; either application-specific and differentiated or undifferentiated (stem) cells are used (Stocum, 2005; Chapter II.1.7). Tissue engineering has led to the replacement in humans of damaged bladders, trachea, skin, corneal epithelium, and cartilage. Future directions in biomaterials, tissue engineering, and regenerative therapeutics are indeed exciting and priorities are under active discussion (Hacker et al., 2006; Goldberg et al., 2007; Hellman et al., 2007; Johnson, 2007; Daley et al., 2008; Kohane et al., 2008).

EXAMPLES OF TODAY'S BIOMATERIALS APPLICATIONS

Five examples of biomaterials applications now follow to illustrate important ideas. The specific devices discussed were chosen because they are widely used in humans with good success. However, key limitations with these
FIGURE 4   Prosthetic heart valves. Left: A bileaflet tilting disk mechanical heart valve. (St. Jude Medical Inc., St. Paul, MN.) Right: A bioprosthetic (xenograft) tissue heart valve (Hancock® valve, Medtronic Inc., MN.)

biomaterial devices are also highlighted. Each of these examples is also discussed in detail in later chapters in this textbook.

Heart Valve Prostheses

Diseases and degeneration of the heart valves often make surgical repair or replacement necessary. The natural heart valve opens and closes over 40 million times per year, and can require replacement due to disease or wear. Approximately 250,000 replacement valves are implanted each year worldwide, because of acquired damage to the natural valve and congenital heart anomalies. There are many types of heart valve prostheses, and they are fabricated from carbons, metals, elastomers, plastics, fabrics, and animal or human tissues chemically pretreated to reduce their immunologic reactivity, and to enhance durability. Figure 4 shows a bileaflet tilting disk mechanical heart valve and a bioprosthetic (xenograft) tissue heart valve, two of the most widely used designs. Generally, as soon as the valve is implanted, cardiac function is restored to near normal levels, and the patient shows rapid improvement. In spite of the overall success seen with replacement heart valves, there are problems, many of them specific to a specific type of valve; they include induction of blood clots (sometimes shed into the bloodstream as emboli), degeneration of valve tissue leaflets, mechanical failure (e.g., at weld joints), and infection. Heart valve substitutes are discussed in Chapter II.5.3.A.

Total Hip Replacement Prostheses

The human hip joint is subjected to high levels of mechanical stress, and receives considerable abuse in the course of normal and extraordinary activity. It is not surprising that after 50 or more years of cyclic mechanical stress or because of degenerative or rheumatoid disease,

FIGURE 5   A hip prosthesis. Microplasty® titanium alloy femoral stem, Biolox® alumina-zirconia ceramic femoral head, ultra-high molecular weight polyethylene acetabular cup infused with vitamin E antioxidant. (Image courtesy of Biomet, Inc.)

the natural joint wears out, leading to loss of mobility and sometimes confinement to a wheelchair. Hip joint prostheses are fabricated from a variety of materials, including titanium, stainless steel, special high-strength alloys, ceramics, composites, and ultrahigh molecular weight polyethylene (UHMWPE). Replacement hip joints (Figure 5) are implanted in more than 200,000 humans each year in the United States alone. With some types of replacement hip joints and surgical procedures which use a polymeric cement, ambulatory function is restored within days after surgery. For other types, a healing-in period is required for integration between bone and the implant before the joint can bear the full weight of the body. In most cases, good function is restored. Even athletic activities are possible, although those activities that subject the repaired joint to high stress are generally not advisable. After 10–15 years, many of these implants fail by loosening, which usually necessitates another operation (a revision procedure). Metal-on-metal implants also experience problems of corrosion and adverse responses to released metal ions. Artificial hip joint prostheses are discussed in Chapter II.5.6.
FIGURE 6   Schematic images of early dental root form implants and a photograph of several designs used in clinical practice.

Dental Implants

The development of root form designs of titanium implants (Figure 6) by Per-Ingvar Brånemark revolutionized dental implantology (Carlsson et al., 1986). These devices form an implanted artificial tooth anchor upon which a crown is affixed, and are implanted in 2,000,000 people each year in the US alone, according to the American Dental Association. A special requirement of a material in this application is the ability to form a tight seal against bacterial invasion where the implant traverses the gingiva (gum). Other issues are associated with the rapidly growing junctional epithelium inhibiting regrowth of the slower growing bone. Also, in normal physiology, the tooth is connected to the jaw by the periodontal ligament, and is not directly attached to the jawbone. One of the primary advantages originally cited for the titanium implant was its osseous integration with the bone of the jaw. In recent years, however, this attachment has been more accurately described as a tight apposition or mechanical fit, and not true bonding. Loss of tissue support leading to loosening remains an occasional problem, along with infection and issues associated with the mechanical properties of unalloyed titanium that is subjected to long-term cyclic loading. Dental implants are discussed in Chapter II.5.7.

Intraocular Lenses

Implants to replace lenses in the eye that have clouded due to cataracts are called intraocular lenses (IOLs). They have been fabricated from a variety of transparent materials including poly(methyl methacrylate), silicone elastomer, soft acrylic polymers, and hydrogels (Figure 7). By the age of 75, more than 50% of the population suffers from cataracts severe enough to warrant IOL implantation. This translates to more than three million implantations in the US alone each year, and more than double that number worldwide. Good vision is generally restored
FIGURE 7   Two styles of multipiece intraocular lenses.

almost immediately after the lens is inserted, and the success rate with this device is high. IOL surgical procedures are well-developed, and implantation is most often performed on an outpatient basis. Observations of implanted lenses through the cornea using a microscope to directly study the implants show that inflammatory cells such as macrophages migrate to the surface of the lenses after implantation. Thus, the conventional healing pathway is seen with these devices, similar to that observed with materials implanted in other sites in the body. Outgrowth of cells onto the IOL from the posterior lens capsule, stimulated by the presence of the IOL, can cloud vision, and this is a significant complication. IOLs are discussed in Chapter II.5.9.B.

Left Ventricular Assist Devices

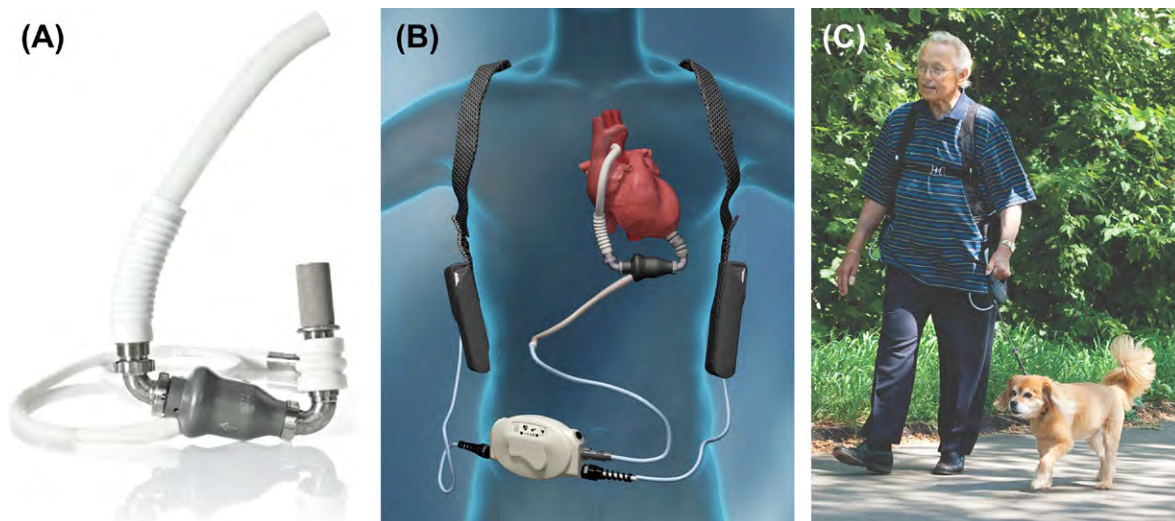
Nearly 5,000,0000 Americans are living with seriously failing hearts (congestive heart failure), and 300,000 individuals will die each year from this disease. According to the American Heart Association, 50,000–100,000 of these individuals might benefit from cardiac transplantation or mechanical assist. Since the available pool


FIGURE 8   Left ventricular assist device (LVAD). (A) Continuous flow pump with associated inflow/outflow grafts and electrical drive line (Heartmate II® device). (B) Schematic of LVAD implanted as a left ventricular assist device with associated external power source. (C) Patient (human) implanted with this LVAD device illustrating freedom of activity. (Reprinted with the permission of Thoratec Corporation, Pleasantville, CA.)

of donor hearts for transplantation is only 2000–3000 per year, effective and safe mechanical cardiac assist or replacement seems like a desirable option. Left ventricular assist devices (LVADs) have evolved from a daring experimental concept, the mechanical total heart, to a life-prolonging tool. A number of devices have received FDA approval. They are now used to maintain a patient with a failing heart while the patient awaits the availability of a transplant heart, and some patients receive these LVADs as a permanent ("destination") therapy. An LVAD is illustrated in Figure 8. LVAD recipients can have considerable mobility and freedom while cardiac support is provided by the device. Patients have lived on LVAD support for more than four years. However, a patient with an LVAD is always at risk for infection and blood clots initiated within the device. These could break off (embolize) and possibly obstruct blood flow to a vital organ. Furthermore, LVADs are well over $100,000 in price, not including associated surgical, drug, and hospital expenses. Can so expensive an innovation be made available to the wide patient base that could benefit from them? LVADs are discussed in detail in Chapter II.5.3.D.

These five cases, only a small fraction of the important medical devices that could have been used as examples, spotlight central ideas and themes relevant to most medical devices interfacing with the human biology. A few generalizations are:

- Implantation in hundreds of thousands of patients with good success is noted.
- A broad range of synthetic materials of varying properties are used.
- Most anatomical sites can be interfaced with a device.
- The normal response by which the body responds to foreign bodies is observed.

- Problems, concerns, unexplained observations or unintended consequences may be noted for each device.
- Most device complications are related to biomaterials–tissue interactions.
- Companies are manufacturing devices and bringing value to shareholders (and patients).
- Regulatory agencies are carefully assessing device performance, and making policy decisions to monitor the device industry, ensure quality, and protect the patient.
- Ethical and societal issues are associated with each device.

These ideas are relevant to nearly all medical devices. As you work through this textbook, consider how these ideas impact the specific topic you are studying.

CHARACTERISTICS OF BIOMATERIALS SCIENCE

Now that we've defined key terms and reviewed specific examples highlighting successes and also complications, we can examine core characteristics of the field of biomaterials.

Multidisciplinary

More than any other field of contemporary technology, biomaterials science brings together teams of researchers from diverse academic and industrial backgrounds, who must clearly communicate and integrate complex concepts and data. Figure 9 lists some of the disciplines and key steps that are encountered in the progression from identifying the need for a biomaterial or device to its testing, regulation, manufacture, sale, and implantation.

Necessary Steps   Facilitator

Identify a need
- Treat a condition
- Replace an organ
- Cosmetic

- Physician/Dentist
- Researcher
- Inventor
- Entrepreneur

Device Design

- Physician (consults)
- Engineer (implements)

Materials Synthesis

- Ceramicist
- Metallurgist
- Polymer Chemist

Materials testing
- Mechanical properties
- Toxicology
- Bioreaction to the material
  protein interactions
  cell activation
  tissue reaction
- Biostability
  mechanical
  chemical

- Bioengineer
- Mechanical Engineer
- Biochemist
- Cell biologist
- Veterinary surgeon

Fabrication

- Engineer
- Machinist

Sterilization and Packaging

- Bioengineer
- Industrial Designer

Device Testing
Toxicology
In Vitro Biointeraction
Animal Testing

- Bioengineer
- Veterinary surgeon
- Physician/Dentist

Regulatory
pre-market approval
limited clinical study
clinical trials
long-term follow-up

- Regulatory Specialist
- Regulatory Agency
- Legislators

Clinical Use

- Physician
- Dentist
- Optometrist

Explant Analysis
explant registry
pathological examination
testing to understand failure

- Pathologist
- Bioengineer

Diverse Materials are Used

The biomaterials scientist must have an appreciation of materials science including polymers, metals, ceramics, glasses, composites, and biological materials. This may range from an impressive command of the theory and practice of the field demonstrated by the professional materials scientist to a general understanding of the properties of materials that should be possessed by the physician or biologist investigator involved in biomaterials-related research.

A wide range of materials is routinely used in medical devices (Table 1), and no one researcher will be comfortable synthesizing, characterizing, designing, and fabricating with all these materials. Thus, specialization is common and appropriate. However, a broad appreciation of the properties and applications of these materials, the palette from which the biomaterials scientist "creates" medical devices, is a hallmark of professionals in the field.

There is a tendency to group biomaterials and researchers into the "hard tissue replacement" camp, typically represented by those involved in orthopedic and dental materials, and the "soft tissue replacement" camp, frequently associated with cardiovascular implants and

general plastic surgery materials. Hard tissue biomaterials researchers are thought to focus on metals and ceramics, while soft tissue biomaterials researchers are considered polymer experts. In practice, this division is artificial: a heart valve may be fabricated from polymers, metals, and carbons. A hip joint will also be composed of metals and polymers (and sometimes ceramics), and will be interfaced to the body via a polymeric bone cement. There is a need for a general understanding of all classes of materials and the common conceptual theme of their interaction with the biological milieu. This book provides a background to the important classes of materials, hard and soft, and their interactions with the biological environment.

Biomaterials to Devices to Materials to Markets and Medicine

Thomas Edison once said that he would only invent things that people would buy. In an interesting way, this idea is central to biomaterials device development. The process of biomaterial/medical device innovation is driven by clinical need: a patient or a physician defines a need and then initiates an invention. However, someone must test and manufacture the device, and shepherd it though the complex, expensive regulatory process. This "someone" is a company, and a company exists (by law) to return value to its shareholders. Figure 9 illustrates multidisciplinary interactions in biomaterials, and shows the progression in the development of a biomaterial or device. It provides a perspective on how different disciplines work together, starting from the identification of a need for a biomaterial through development, manufacture, implantation, and (possibly) removal from the patient. Note that the development process for medical devices is very different from that for drugs. There are insightful reference works available to help understand this specialized device commercialization process (Zenios et al., 2010).

Magnitude of the Field

The magnitude of the medical device field expresses both the magnitude of the need and a sizeable commercial market (Table 2). Consider four commonly used biomaterial devices: a contact lens; a hip joint; a hydrocephalous drainage shunt; and a heart valve. Let's examine these devices in the contexts of human needs and commercial markets. The contact lens offers improved vision and, some will argue, a cosmetic enhancement. The hip joint offers mobility to the patient who would otherwise need a cane or crutch or be confined to a bed or wheelchair. The hydrocephalus shunt will allow an infant to survive without brain damage. The heart valve offers a longer life with improved quality of life. The contact lens may sell for $100, and the hip joint, hydrocephalus shunt, and heart valve may sell for $1000–$4000 each. Each

year there will be millions of contact lenses purchased worldwide, 400,000 heart valves, 160,000 hydrocephalus shunts, and 500,000 total artificial hip prostheses. Here are the issues for consideration: (1) the large number of devices (an expression of both human needs and commercial markets); (2) medical significance (cosmetic to life saving); and (3) commercial potential (who will manufacture it and why – for example, what is the market for the hydrocephalus shunt?). Always, human needs and economic issues color this field we call "biomaterials science." Medical practice, market forces, and bioethics come into play almost every day.

Lysaght and O'Laughlin (2000) have estimated that the magnitude and economic scope of the contemporary organ replacement enterprise are much larger than is generally recognized. In the year 2000, the lives of over 20 million patients were sustained, supported, or significantly improved by functional organ replacement. The impacted population grows at over 10% per year. Worldwide, first year and follow-up costs of organ replacement and prostheses exceed $300 billion US dollars per year, and represents between 7% and 8% of total worldwide healthcare spending. In the United States, the costs of therapies enabled by organ replacement technology exceed 1% of the gross national product. The costs are also impressive when reduced to the needs of the individual patient. For example, the cost of an implanted heart valve is roughly $5000–$7000. The surgery to implant the device entails a hospital bill and first year follow-up costs upwards of $40,000. Reoperation for replacing a failed valve will have these same costs. Reoperations for failed valves now exceed 10% of all valve replacements. Overall costs of healthcare and medical devices are summarized in Table 2.

Success and Failure. Most biomaterials and medical devices perform satisfactorily, improving the quality of life for the recipient or saving lives. However, no man-made construct is perfect. All manufactured devices have a failure rate. Also, all humans are different, with differing ethnicities, ages, genetics, gender, body chemistries, living environments, and degrees of physical activity. Furthermore, physicians implant or use these devices with varying degrees of skill. The other side to the medical device success story is that there are problems, compromises, complications, and unintended consequences that often occur with medical devices. Central issues for the biomaterials scientist, manufacturer, patient, physician, and attorney are: (1) is the design competent and optimal; (2) who should be responsible when devices perform "with an inappropriate host response"; and (3) what are the cost:risk or cost:benefit ratios for the implant or therapy?

Some examples may clarify these issues. Clearly, heart valve disease is a serious medical problem. Patients with diseased aortic heart valves have a 50% chance of dying within three years. Surgical replacement of the diseased valve leads to an expected survival of 10 years in 70%

of the cases. However, of these patients whose longevity and quality of life have clearly been enhanced, approximately 60% will suffer a serious valve-related complication within 10 years after the operation. Another example involves LVADs. A clinical trial called Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH) led to the following important statistics (Rose et al., 2001). Patients with an implanted Heartmate® LVAD (Thoratec Laboratories) had a 52% chance of surviving for one year, compared with a 25% survival rate for patients who took medication. Survival for two years in patients with the Heartmate® was 23% versus 8% in the medication group. Also, the LVAD enhanced the quality of life for the patients – they felt better, were less depressed, and were mobile. Importantly, patients participating in the REMATCH trial were not eligible for a heart transplant. In the cases of the heart valve and the LVAD, clinical complications possibly associated with less than stellar biomaterials performance do not preclude widespread clinical acceptance.

Biomaterials science:
- multidisciplinary;
- multi-biomaterial;
- clinical need-driven;
- substantial world market;
- risk–benefit issues.

Thus, these five characteristics of biomaterials science:

- multidisciplinary;
- multi-material;
- clinical need-driven;
- substantial market; and
- risk–benefit issues.

color all aspects of the field.

In addition, there are certain unique subjects that are particularly prominent in our field and help delineate the biomaterials endeavor as a unique field of science and engineering. Let us review a few of these.

SUBJECTS INTEGRAL TO BIOMATERIALS SCIENCE

Toxicology. A biomaterial should not be toxic, unless it is specifically engineered for such requirements (e.g., a "smart" drug delivery system that targets cancer cells with a toxic drug and destroys them). Since the nontoxic requirement is the norm, toxicology for biomaterials has evolved into a sophisticated science. It deals with the substances that migrate out of biomaterials. For example, for polymers, many low molecular weight "leachables" exhibit some level of physiologic activity and cell toxicity. It is reasonable to say that a biomaterial should not give off anything from its mass unless it is specifically

designed to do so. Toxicology also deals with methods to evaluate how well this design criterion is met when a new biomaterial is under development. Chapter II.3.3 provides an overview of methods in biomaterials toxicology. Implications of toxicity are addressed in Chapters II.2.5, II.3.2, and II.3.4.

Biocompatibility. The understanding and measurement of biocompatibility is unique to biomaterials science. Unfortunately, we do not have precise definitions or accurate measurements of biocompatibility. More often than not, biocompatibility is defined in terms of performance or success at a specific task. Thus, for a patient who is doing well with an implanted large diameter Dacron fabric vascular prosthesis, few would argue that this prosthesis is not "biocompatible." However, the prosthesis probably did not recellularize (although it was designed to do so), and is also embolic, although the emboli in this case usually have little clinical consequence. This operational definition of biocompatible ("the patient is alive so it must be biocompatible") offers us little insight in designing new or improved vascular prostheses. It is probable that biocompatibility may have to be specifically defined for applications in soft tissue, hard tissue, and the cardiovascular system (blood compatibility, Chapters II.2.6 and II.3.5). In fact, biocompatibility may have to be uniquely defined for each application. The problems and meanings of biocompatibility will be explored and expanded upon throughout this textbook; in particular see Chapters II.2.2, II.3.2 and II.3.4.

Inflammation and Healing. Specialized biological mechanisms are triggered when a material or device interfaces with the body. Injury to tissue will stimulate the well-defined inflammatory reaction sequence that ultimately leads to healing. Healing can be normal (physiological) or abnormal (pathological). Where a foreign body (e.g., an implant) is present in the wound site (the surgical incision), the reaction sequence is referred to as the "foreign-body reaction" (Chapters II.2.2 and II.3.4). The normal response of the body will be modulated because of the solid implant. Furthermore, this reaction will differ in intensity and duration, depending upon the anatomical site involved. An understanding of how a foreign object shifts the normal inflammatory reaction sequence is an important concern for the biomaterials scientist.

Functional Tissue Structure and Pathobiology. Biomaterials-based medical devices are implanted into almost all tissues and organs. Tissues and organs vary widely in cell composition, morphological organization, vascularization, and innervation. Implantation of a biomaterial into bone, liver, or heart will have special physiological consequences. Therefore, key principles governing the structure of normal (and abnormal) cells, tissues, and organs are important to biomaterials researchers. Also, techniques by which the structure and function of normal and abnormal tissue are studied must be mastered. In addition, fundamental mechanisms

leading to abnormal cell, tissue, and organ structures (i.e., diseases and other pathologies) are critical considerations to biomaterials researchers (see Chapter II.1.5).

Dependence on Specific Anatomical Sites of Implantation. Consideration of the anatomical site of an implant is essential. An intraocular lens may be implanted into the lens capsule or the anterior chamber of the eye. A hip joint will be implanted in bone across an articulating joint space. A prosthetic heart valve will be sutured into cardiac muscle, and will contact both soft tissue and blood. A catheter may be placed in an artery, a vein or the urinary tract. Each of these sites challenges the biomedical device designer with special requirements for anatomy, physiology, geometry, size, mechanical properties, and bioresponses.

Mechanical Requirements and Physical Performance Requirements. Each biomaterial and device has mechanical and performance requirements originating from the need to perform a physiological function. These requirements can be divided into three categories: mechanical performance, mechanical durability, and physical properties.

First, consider mechanical performance. A hip prosthesis must be strong and rigid. A tendon material must be strong and flexible. A tissue heart valve leaflet must be flexible and tough. A dialysis membrane must be strong and flexible, but not elastomeric. An articular cartilage substitute must be soft and elastomeric. One significant example of a controlled micro-mechanical interface is the contact zone between a synthetic biomaterial (titanium, tantalum, alumina, zirconia, and hydroxyapatites) and oral bones. Microstrain magnitudes have been controlled through macro/micro/nano surface/topographies and construct designs to be within the microstrain limits of bone. The result has been decades of chemical stability, now called osseous integration.

Then, we must address mechanical durability. A catheter may only have to perform for three days. A bone plate may fulfill its function in six months or longer. A leaflet in a heart valve must flex 60 times per minute without tearing for the lifetime of the patient (realistically, at least for 10 or more years). A hip joint must not fail under heavy loads for 20 years or more.

Finally, the bulk physical properties impact other aspects of performance. The dialysis membrane has a specified permeability, the acetabular cup of the hip joint must have high lubricity, and the intraocular lens has transparency and refraction requirements. To meet these requirements, design principles are borrowed from physics, chemistry, mechanical engineering, chemical engineering, and materials science.

Industrial Involvement. A significant basic research effort is now under way, primarily at universities, to understand how biomaterials function and how to optimize them. At the same time, companies are producing implants for use in humans and, appropriate to the mission of a company, earning profits on the sale of medical devices. Thus, although we are now only learning about the fundamentals of biointeraction, we manufacture millions of devices for implantation in humans. How is this dichotomy explained? Basically, as a result of 50 or more years of experience we now have a set of materials that perform satisfactorily in the body. The medical practitioner can use them with reasonable confidence, and the performance in the patient is largely acceptable (generally considerably better than other alternatives). Though the devices and materials are far from perfect, the complications associated with the devices are fewer than the complications of the original diseases.

Risk–Benefit and Corporate Realities. A risk–benefit analysis must be considered in developing new devices and improving existing devices. Central to biomaterials science is the desire to alleviate suffering and death, and also the desire to improve the quality of life for patients. These considerations are convoluted with the excitement of new scientific ideas, the corporate imperative to turn a profit, and the mandate of the regulatory agencies to protect the public. For example, the acceptable risk varies with different types of medical devices. The acceptable risk of devices that sustain life (e.g., heart valve, defibrillator, cardiac assist device, hemodialysis device/access graft, hydrocephalus shunt) is greater than that of devices that alleviate pain/disability or enhance function (e.g., hip joint, artificial skin, drug delivery device, intraocular lens, intrauterine contraceptive device). Then consider the acceptable risk for devices that have only cosmetic application (e.g., collagen injections, breast implants). Obviously, ethical concerns enter into the risk–benefit picture. Remember that companies have large investments in the development, manufacture, quality control, clinical testing, regulatory clearance, and distribution of medical devices. How much of an advantage (for the company and the patient) will be realized in introducing an improved device? The improved device may indeed work better for the patient. However, the company will incur a large expense (development and regulatory costs) that will be perceived by the stockholders as reduced profits. The development of a new or improved device, as well as offering benefits, entails risks that months or years after introduction some unforeseen complication will compromise the device. Product liability issues are a major concern to manufacturers. Consider questions about the ethics of withholding improved devices from people who could benefit from them because of development costs and regulatory hurdles, the market share advantages of having a better product, and the gargantuan costs (possibly nonrecoverable) of introducing a new product into the medical marketplace. If companies did not have the profit incentive, would there be any medical devices, let alone improved ones, available for clinical application?

From the biomaterials industry, we see specialized, essential contributions to our field. Industry deals well with technologies such as packaging, sterilization, storage, distribution, quality control, and analysis. These

subjects are grounded in specialized technologies, often ignored in academic communities, but having the potential to generate stimulating research questions. Also, many companies support in-house basic research laboratories, and contribute in important ways to the fundamental study of biomaterials science.

Ethics. A wide range of ethical considerations impact biomaterials science. Some key ethical questions in biomaterials science are summarized in Table 3. Typical of ethical questions, an absolute answer may be difficult to come by. Some articles have addressed ethical questions in biomaterials and debated the important points (Saha and Saha, 1987; Schiedermayer and Shapiro, 1989; Merryman, 2008). Chapter III.2.7 introduces ethics and ethical issues related to biomaterials and medical devices.

Regulation. The consumer (the patient) and the physician demand safe medical devices. To prevent inadequately tested devices and materials from coming on the market, and to screen out those clearly unqualified to produce biomaterials, the United States government has evolved a complex regulatory system administered by the US Food and Drug Administration (FDA). Most nations of the world have similar medical device regulatory bodies. The International Standards Organization (ISO) has introduced international standards for the world community. Obviously, a substantial base of biomaterials knowledge went into establishing these standards. The costs to comply with the standards and to implement materials, biological, and clinical testing are enormous. Introducing a new biomedical device to the market requires a regulatory investment of tens of millions of dollars. Are the regulations and standards truly addressing the safety issues? Is the cost of regulation inflating the cost of healthcare and preventing improved devices from reaching those who need them? Under this regulation topic, we see the intersection of all the players in the biomaterials community: government, industry, scientists, physicians, and patients. The answers are not simple, but the problems must be addressed every day. Chapters III.2.2 and III.2.3 expand on standards and regulatory concerns.

BIOMATERIALS LITERATURE

Over the past 50 years, the field of biomaterials has evolved from individual physicians innovating to save the lives of their patients to the science-grounded multidisciplinary endeavor we see today. In 1950, there were no biomaterials or medical device journals, and few books. Concurrent with the evolution of the discipline, a literature has also developed addressing basic science, applied science, engineering, medicine, and commercial issues. A bibliography is provided in Appendix D to highlight key reference works and technical journals in the biomaterials field. As might be expected, these journals stem from many disciplines and technical societies.

BIOMATERIALS SOCIETIES

The biomaterials field evolved from individual researchers and clinicians who intellectually associated their efforts with established disciplines such as medicine, chemistry, chemical engineering, or mechanical engineering, to a modern field called "biomaterials." This evolution is paralleled by the growing sense of professionalism and the formation of biomaterials societies as homes for the profession to develop in. Probably the first biomaterials-related society was the American Society for Artificial Internal Organs (ASAIO). Founded in 1954, this group of visionaries established a platform to consider the development of devices such as the artificial kidney and the artificial heart. A Division of Interdisciplinary Studies, the administrative home of a nascent biomaterials effort, was established at Clemson University, Clemson, South Carolina in 1969. Clemson began organizing annual International Biomaterials Symposia in 1969. The first of these symposia was titled "Use of Ceramics in Surgical Implants." About 100 scientists and physicians attended, and 17 papers were presented. The cover of the 1975 International Biomaterials Symposium program is shown in Figure 10.

In 1974–1975, these symposia evolved into the Society for Biomaterials, the world's first biomaterials

TABLE 3	Ethical Concerns Relevant to Biomaterials Science

Animals
Is the animal model relevant to human physiology? Specifically, is the experiment well-designed and outcome sufficiently important so that the data obtained will justify the suffering and sacrifice of the life of a living creature?

Human Subjects
How should human subject research be conducted to minimize negative outcomes to the patient and offer a reasonable risk-to-benefit ratio? How can we best ensure informed consent?

Industrial Involvement
Companies fund much biomaterials research and also own proprietary biomaterials. How can the needs of the patient be best balanced with the financial goals of a company? Consider that someone must manufacture devices – these would not be available if a company did not choose to manufacture them.

Researchers
Since researchers often stand to benefit financially from a successful biomedical device, and sometimes even have devices named after them, how can investigator bias be minimized in biomaterials research?

Patients
For life-sustaining devices, what is the trade-off between sustaining life and the quality of life with the device for the patient? Should the patient be permitted to "pull the plug" if the quality of life is not satisfactory?

Regulatory Agencies
With so many unanswered questions about the basic science of biomaterials, do government regulatory agencies have sufficient information to define adequate tests for materials and devices and to properly regulate biomaterials?
FIGURE 10   The cover of the program book for the 1975 International Biomaterials Symposium, Clemson, South Carolina.

society. Founding members, about 40, plus those who joined in 1975 and 1976, numbered less than 100, and included clinicians, engineers, chemists, and biologists. Their common interest, biomaterials, was the engaging focus for the multidisciplinary participants. The European Society for Biomaterials was founded in 1975. Shortly after that, the Canadian Biomaterials Society and the Japanese Society for Biomaterials were formed. The Controlled Release Society, a group strongly rooted in biomaterials for drug delivery, was founded in 1978. At this time there are many national biomaterials societies and specialty societies. For example, the Tissue Engineering and Regenerative Medicine International Society (TERMIS) now has about 3000 members. The development of biomaterials professionalism and a sense of identity for the field called biomaterials can be attributed to these societies and the researchers who organized and led them.

SUMMARY

This chapter provides a broad overview of the biomaterials field. It offers a vantage point from which the reader can gain a perspective to see how the sub-themes fit into the larger whole.

Biomaterials science may be the most multidisciplinary of all the sciences. Consequently, biomaterials scientists must master certain key material from many fields of science, technology, engineering, and medicine in order to be competent and conversant in this profession. The reward for mastering this volume of material is immersion in an intellectually stimulating endeavor that advances a new basic science of biointeraction and contributes to reducing human suffering.

A HISTORY OF BIOMATERIALS

Buddy D. Ratner

"History consists of a series of accumulated imaginative inventions"

Voltaire

A decade into the twenty-first century, biomaterials are widely used throughout medicine, dentistry, and biotechnology. Just 60 years ago biomaterials as we think of them today did not exist. The word "biomaterial" was not used. There were no medical device manufacturers (except for external prosthetics such as limbs, fracture fixation devices, glass eyes, and dental fillings and devices), no formalized regulatory approval processes, no understanding of biocompatibility, and certainly no academic courses on biomaterials. Yet, crude biomaterials have been used, generally with poor to mixed results, throughout history. This chapter will broadly trace the history of biomaterials from the earliest days of human civilization to the dawn of the twenty-first century. It is convenient to organize the history of biomaterials into four eras: prehistory; the era of the surgeon hero; designed biomaterials/engineered devices; and the contemporary era taking us into the new millennium. The emphasis of this chapter will be on the experiments and studies that set the foundation for the field we call biomaterials, largely between 1920 and 1980.

BIOMATERIALS BEFORE WORLD WAR II

Before Civilization

The introduction of non-biological materials into the human body took place throughout history. The remains of a human found near Kennewick, Washington, USA (often referred to as the "Kennewick Man") were dated (with some controversy) to be 9000 years old. This individual, described by archeologists as a tall, healthy, active person, wandered through the region now know as southern Washington with a spear point embedded in his hip. It had apparently healed in, and did not significantly impede his activity. This unintended implant illustrates the body's capacity to deal with implanted foreign materials. The spear point has little resemblance to modern biomaterials, but it was a "tolerated" foreign material implant, just the same. Another example of the introduction of foreign material into the skin, dated to over 5000 years ago, is the tattoo. The carbon particles and other substances probably elicited a classic foreign-body reaction.

Dental Implants in Early Civilizations

Unlike the spear point described above, dental implants were devised as implants and used early in history. The Mayan people fashioned nacre teeth from sea shells in roughly 600 AD, and apparently achieved what we now refer to as osseointegration (see Chapter II.5.7), basically a seamless integration into the bone (Bobbio, 1972). Similarly, in France, a wrought iron dental implant in a corpse was dated to 200 AD (Crubezy et al., 1998). This implant, too, was described as properly osseointegrated. There was no materials science, biological understanding, or medicine behind these procedures. Still, their success (and longevity) is impressive and highlights two points: the forgiving nature of the human body and the pressing drive, even in prehistoric times, to address the loss of physiologic/anatomic function with an implant.

Sutures Dating Back Thousands of Years

There is loose evidence that sutures may have been used even in the Neolithic period. Large wounds were closed early in history primarily by one of two methods – cautery or sutures. Linen sutures were used by the early Egyptians. Catgut was used in the middle ages in Europe. In South Africa and India, the heads of large, biting ants clamped wound edges together.

Metallic sutures are first mentioned in early Greek literature. Galen of Pergamon (circa 130–200 AD) described ligatures of gold wire. In 1816, Philip Physick, University of Pennsylvania Professor of Surgery, suggested the use of lead wire sutures, noting little reaction. J. Marion Sims of Alabama had a jeweler fabricate sutures of silver wire, and in 1849 performed many successful operations with this metal.

Consider the problems that must have been experienced with sutures in eras with no knowledge of sterilization, toxicology, immunological reaction to extraneous biological materials, inflammation, and biodegradation. Yet sutures were a relatively common fabricated or manufactured biomaterial for thousands of years.

Artificial Hearts and Organ Perfusion

In the fourth century BC, Aristotle called the heart the most important organ in the body. Galen proposed that veins connected the liver to the heart to circulate "vital spirits throughout the body via the arteries." English physician William Harvey, in 1628 espoused a relatively modern view of heart function when he wrote: "the heart's one role is the transmission of the blood and its propulsion, by means of the arteries, to the extremities everywhere." With the appreciation of the heart as a pump, it was a logical idea to think of replacing the heart with an artificial pump. In 1812, the French physiologist Le Gallois expressed his idea that organs could be kept alive by pumping blood through them. A number of experiments on organ perfusion with pumps were performed from 1828 to 1868. In 1881, Étienne-Jules Marey, a brilliant scientist and thinker who published and invented in photographic technology, motion studies, and physiology, described an artificial heart device (Figure 1), primarily oriented to studying the beating of the heart.

In 1938, aviator (and engineer) Charles Lindbergh and surgeon (and Nobel Prize Winner) Alexis Carrel wrote a visionary book, *The Culture of Organs*. They addressed issues of pump design (referred to as the Lindbergh
FIGURE 1   An artificial heart by Étienne-Jules Marey, Paris, 1881.

pump), sterility, blood damage, the nutritional needs of perfused organs, and mechanics. This book is a seminal document in the history of artificial organs. In the mid-1950s, Dr. Paul Winchell, better known as a ventriloquist, patented an artificial heart. In 1957, Dr. Willem Kolff and a team of scientists tested the artificial heart in animals. More modern conceptions of the artificial heart (and left ventricular assist device) will be presented below and in Chapter II.5.3.D).

Contact Lenses

Leonardo DaVinci, in the year 1508, developed the concept of contact lenses. Rene Descartes is credited with the idea of the corneal contact lens (1632) and Sir John F. W. Herschel (1827) suggested that a glass lens could protect the eye. Adolf Gaston Eugen Fick (nephew of Adolf Eugen Fick of Fick's Law of Diffusion fame) was an optometrist by profession. One of his inventions (roughly 1860) was a glass contact lens, possibly the first contact lens offering real success. He experimented on both animals and humans with contact lenses. In the period from 1936 to 1948, plastic contact lenses were developed, primarily of poly(methyl methacrylate).

Basic Concepts of Biocompatibility

Most implants prior to 1950 had a low probability of success, because of a poor understanding of biocompatibility and sterilization. As will be elaborated upon throughout the textbook, factors that contribute to biocompatibility include the chemistry of the implant, leachables, shape, mechanics, and design. Early studies, especially with metals, focused primarily on ideas from chemistry to explain the observed bioreaction.

Possibly the first study assessing the *in vivo* bioreactivity of implant materials was performed by H. S. Levert (1829). Gold, silver, lead, and platinum specimens were studied in dogs, and platinum, in particular, was found to be well-tolerated. In 1886, bone fixation plates of nickel-plated sheet steel with nickel-plated screws were studied. In 1924, A. Zierold published a study on tissue reaction to various materials in dogs. Iron and steel were found to corrode rapidly, leading to resorption of adjacent bone. Copper, magnesium, aluminum alloy, zinc, and nickel discolored the surrounding tissue. Gold, silver, lead, and aluminum were tolerated, but inadequate mechanically. Stellite, a Co–Cr–Mo alloy, was well tolerated and strong. In 1926, M. Large noted inertness displayed by 18-8 stainless steel containing molybdenum. By 1929 Vitallium alloy (65% Co–30% Cr–5%Mo) was developed and used with success in dentistry. In 1947, J. Cotton of the UK discussed the possible use of titanium and alloys for medical implants.

The history of plastics as implantation materials does not extend as far back as metals, simply because there were few plastics prior to the 1940s. What is possibly

the first paper on the implantation of a modern synthetic polymer, nylon, as a suture appeared in 1941. Papers on the implantation of cellophane, a polymer made from plant sources, were published as early as 1939, it being used as a wrapping for blood vessels. The response to this implant was described as a "marked fibrotic reaction." In the early 1940s papers appeared discussing the reaction to implanted poly(methyl methacrylate) (PMMA) and nylon. The first paper on polyethylene as a synthetic implant material was published in 1947 (Ingraham et al.). The paper pointed out that polyethylene production using a new high pressure polymerization technique began in 1936. This process enabled the production of polyethylene free of initiator fragments and other additives. Ingraham et al. demonstrated good results on implantation (i.e., a mild foreign-body reaction), and attributed these results to the high purity of the polymer they used. A 1949 paper commented on the fact that additives to many plastics had a tendency to "sweat out," and this might be responsible for the strong biological reaction to those plastics (LeVeen and Barberio, 1949). They found a vigorous foreign-body reaction to cellophane, Lucite®, and nylon, but an extremely mild reaction to "a new plastic," Teflon®. The authors incisively concluded: "Whether the tissue reaction is due to the dissolution of traces of the unpolymerized chemical used in plastics manufacture or actually to the solution of an infinitesimal amount of the plastic itself cannot be determined." The possibility that cellulose might trigger the severe reaction by activating the complement system could not have been imagined, because the complement system had not yet been discovered.

WORLD WAR II TO THE MODERN ERA: THE SURGEON/PHYSICIAN HERO

During World War I, and particularly at the end of the war, newly developed high-performance metal, ceramic, and especially polymeric materials, transitioned from wartime restriction to peacetime availability. The possibilities for using these durable, inert materials immediately intrigued surgeons with needs to replace diseased or damaged body parts. Materials, originally manufactured for airplanes, automobiles, clocks, and radios were taken "off-the-shelf" by surgeons and applied to medical problems. These early biomaterials included silicones, polyurethanes, Teflon®, nylon, methacrylates, titanium, and stainless steel.

A historical context helps us appreciate the contribution made primarily by medical and dental practitioners. Just after World War II, there was little precedent for surgeons to collaborate with scientists and engineers. Medical and dental practitioners of this era felt it was appropriate to invent (improvise) where the life or functionality of their patient was at stake. Also, there was minimal government regulatory activity, and human subject protections as we know them today were

non-existent (see Chapters III.2.4 and III.2.7). The physician was implicitly entrusted with the life and health of the patient and had much more freedom than is seen today to take heroic action when other options were exhausted.[1] These medical practitioners had read about the post-World War II marvels of materials science. Looking at a patient open on the operating table, they could imagine replacements, bridges, conduits, and even organ systems based on such materials. Many materials were tried on the spur of the moment. Some fortuitously succeeded. These were high risk trials, but usually they took place where other options were not available. The term "surgeon hero" seems justified, since the surgeon often had a life (or a quality of life) at stake and was willing to take a huge technological and professional leap to repair the individual. This *laissez faire* biomaterials era quickly led to a new order characterized by scientific/engineering input, government quality controls, and a sharing of decisions prior to attempting high-risk, novel procedures. Still, a foundation of ideas and materials for the biomaterials field was built by courageous, fiercely committed, creative individuals, and it is important to look at this foundation to understand many of the attitudes, trends, and materials common today.

Intraocular Lenses

Sir Harold Ridley, MD (1906–2001) (Figure 2), inventor of the plastic intraocular lens (IOL), made early, accurate observations of biological reaction to implants consistent with currently accepted ideas of biocompatibility. After World War II, he had the opportunity to examine aviators who were unintentionally implanted in their eyes with shards of plastic from shattered canopies in Spitfire and Hurricane fighter planes (Figure 2). Most of these flyers had plastic fragments years after the war. The conventional wisdom at that time was that the human body would not tolerate implanted foreign objects, especially in the eye – the body's reaction to a splinter or a bullet was cited as examples of the difficulty of implanting materials in the body. The eye is an interesting implant site, because you can look in through a transparent window to observe the reaction. When Ridley did so, he noted that the shards had healed in place with no further reaction. They were, by his standard, tolerated

---

[1]The regulatory climate in the US in the 1950s was strikingly different from today. This can be appreciated in this recollection from Willem Kolff about a pump oxygenator he made and brought with him from Holland to the Cleveland Clinic (Kolff, W. J., 1998): "Before allowing Dr. Effler and Dr. Groves to apply the pump oxygenator clinically to human babies, I insisted they do 10 consecutive, successful operations in baby dogs. The chests were opened, the dogs were connected to a heart-lung machine to maintain the circulation, the right ventricles were opened, a cut was made in the interventricular septa, the septa holes were closed, the right ventricles were closed, the tubes were removed and the chests were closed. (I have a beautiful movie that shows these 10 puppies trying to crawl out of a basket).

FIGURE 2   Left: Sir Harold Ridley, inventor of the intraocular lens, knighted by Queen Elizabeth II for his achievement. by the eye. Today, we would describe this stable healing without significant ongoing inflammation or irritation as "biocompatible." This is an early observation of "biocompatibility" in humans, perhaps the first, using criteria similar to those accepted today. Based on this observation, Ridley traced down the source of the plastic domes, ICI Perspex® poly(methyl methacrylate). He used this material to fabricate implant lenses (intraocular lenses) that were found, after some experimentation, to function reasonably in humans as replacements for surgically removed natural lenses that had been clouded by cataracts. The first implantation in a human was on November 29, 1949. For many years, Ridley was the center of fierce controversy because he challenged the dogma that spoke against implanting foreign materials in eyes – it is hard to believe that the implantation of a biomaterial would provoke such an outcry. Because of this controversy, this industry did not instantly arise – it was the early 1980s before IOLs became a major force in the biomedical device market. Ridley's insightful observation, creativity, persistence, and surgical talent in the late 1940s evolved into an industry that presently puts more than 7,000,000 of these lenses annually in humans. Through all of human history, cataracts meant blindness or a surgical procedure that left the recipient needing thick, unaesthetic spectacle lenses that poorly corrected the vision. Ridley's concept, using a plastic material found to be "biocompatible," changed the course of history and substantially improved the quality of life for millions of individuals with cataracts. Harold Ridley's story is elaborated upon in an obituary (Apple and Trivedi, 2002).

Hip and Knee Prostheses

The first hip replacement was probably performed in 1891 by a German surgeon, Theodore Gluck, using a cemented ivory ball. This procedure was not successful. Numerous attempts were made between 1920 and 1950 to develop a hip replacement prosthesis. Surgeon M. N. Smith-Petersen, in 1925, explored the use of a glass hemisphere to fit over the ball of the hip joint. This failed

due to poor durability. Chrome–cobalt alloys and stainless steel offered improvements in mechanical properties, and many variants of these were explored. In 1938, the Judet brothers of Paris, Robert and Jean, explored an acrylic surface for hip procedures, but it had a tendency to loosen. The idea of using fast setting dental acrylics to glue prosthetics to bone was developed by Dr. Edward J. Haboush in 1953. In 1956, McKee and Watson-Farrar developed a "total" hip with an acetabular cup of metal that was cemented in place. Metal-on-metal wear products probably led to high complication rates. It was John Charnley (1911–1982) (Figure 3), working at an isolated tuberculosis sanatorium in Wrightington, Manchester, England, who invented the first really successful hip joint prosthesis. The femoral stem, ball head, and plastic acetabular cup proved to be a reasonable solution to the problem of damaged joint replacement. In 1958, Dr. Charnley used a Teflon acetabular cup with poor outcomes due to wear debris. By 1961 he was using a high molecular weight polyethylene cup, and was achieving much higher success rates. Interestingly, Charnley learned of high molecular weight polyethylene from a salesman selling novel plastic gears to one of his technicians. Dr. Dennis Smith contributed in an important way to the development of the hip prosthesis by introducing Dr. Charnley to poly(methyl methacrylate) cements, developed in the dental community, and optimizing those cements for hip replacement use. Total knee replacements borrowed elements of the hip prosthesis technology, and successful results were obtained in the period 1968–1972 with surgeons Frank Gunston and John Insall leading the way.

Dental Implants

Some "prehistory" of dental implants has been described above. In 1809, Maggiolo implanted a gold post anchor into fresh extraction sockets. After allowing this to heal, he affixed to it a tooth. This has remarkable similarity to modern dental implant procedures. In 1887, this procedure was used with a platinum post. Gold and platinum gave poor long-term results, and so this procedure
FIGURE 3   Left: Sir John Charnley. Right: The original Charnley hip prosthesis. (Hip prosthesis photo courtesy of the South Australian Medical Heritage Society, Inc.)

was never widely adopted. In 1937, Venable used surgical Vitallium and Co–Cr–Mo alloy for such implants. Also around 1937, Strock at Harvard used a screw-type implant of Vitallium, and this may be the first successful dental implant. A number of developments in surgical procedure and implant design (for example, the endosteal blade implant) then took place. In 1952, a fortuitous discovery was made. Per Ingvar Brånemark, an orthopedic surgeon at the University of Lund, Sweden, was implanting an experimental cage device in rabbit bone for observing healing reactions. The cage was a titanium cylinder that screwed into the bone. After completing the experiment that lasted several months, he tried to remove the titanium device and found it tightly integrated in the bone (Brånemark et al., 1964). Dr. Brånemark named the phenomenon "osseointegration," and explored the application of titanium implants to surgical and dental procedures. He also developed low-impact surgical protocols for tooth implantation that reduced tissue necrosis and enhanced the probability of good outcomes. Most dental implants and many other orthopedic implants are now made of titanium and its alloys.

The Artificial Kidney

Kidney failure, through most of history, was a sentence to an unpleasant death lasting over a period of about a month. In 1910, at Johns Hopkins University, the first attempts to remove toxins from blood were made by John Jacob Abel. The experiments were with rabbit blood, and it was not possible to perform this procedure on humans. In 1943, in Nazi-occupied Holland, Willem Kolff (Figure 4), a physician just beginning his career at that time, built a drum dialyzer system from a 100 liter tank, wood slats, and 130 feet of cellulose sausage casing tubing as the dialysis membrane. Some successes were seen in saving lives where prior to this there was only one unpleasant outcome to kidney failure. Kolff took his ideas to the United States and in 1960, at the Cleveland Clinic, developed a "washing machine artificial kidney" (Figure 5).

Major advances in kidney dialysis were made by Dr. Belding Scribner at the University of Washington (Figure 6). Scribner devised a method to routinely access the bloodstream for dialysis treatments. Prior to this, after just a few treatments, access sites to the blood were used up and further dialysis was not possible. After seeing the potential of dialysis to help patients, but only acutely, Scribner tells the story of waking up in the middle of the night with an idea to gain easy access to the blood – a shunt implanted between an artery and vein that emerged through the skin as a "U." Through the exposed portion of the shunt, blood access could be readily achieved. When Dr. Scribner heard about the new plastic, Teflon®, he envisioned how to get the blood out of and into the blood vessels. His device, built with the assistance of Wayne Quinton (Figure 6), used Teflon tubes to access the vessels, a Dacron® sewing cuff through the skin, and a silicone rubber tube for blood flow. The Quinton–Scribner shunt made chronic dialysis possible, and is said to be responsible for more than a million patients being alive today. Interestingly, Dr. Scribner refused to patent

his invention because of its importance to medical care. Additional important contributions to the artificial kidney were made by Chemical Engineering Professor Les Babb (University of Washington) who, working with Scribner, improved dialysis performance and invented a proportioning mixer for the dialysate fluid. The first dialysis center was opened in Seattle making use of these important technological advances (Figure 6). The early experience with dialyzing patients where there were not enough dialyzers to meet the demand also made important contributions to bioethics associated with medical devices (Blagg, 1998).

The Artificial Heart

Willem Kolff was also a pioneer in the development of the artificial heart. He implanted the first artificial heart in the Western hemisphere in a dog in 1957 (a Russian artificial heart was implanted in a dog in the late 1930s). The Kolff artificial heart was made of a thermosetting poly(vinyl chloride) cast inside hollow molds to prevent seams. In 1953, the heart-lung machine was invented by John Gibbon, but this was useful only for acute treatment, such as during open heart surgery. In 1964, the National Heart and Lung Institute of the NIH set a goal of a total artificial heart by 1970. Dr. Michael DeBakey implanted a left ventricular assist device in a human in 1966, and Dr. Denton Cooley and Dr. William Hall implanted a polyurethane total artificial heart in 1969. In the period 1982–1985, Dr. William DeVries implanted a number of Jarvik hearts based upon designs originated by Drs. Clifford Kwan-Gett and Donald Lyman – patients lived up to 620 days on the Jarvik 7® device.

Breast Implants

The breast implant evolved to address the poor results achieved with direct injection of substances into the breast for augmentation. In fact, in the 1960s, California and Utah classified use of silicone injections as a criminal offense. In the 1950s, poly(vinyl alcohol) sponges were implanted as breast prostheses, but results with these were also poor. University of Texas plastic surgeons Thomas Cronin and Frank Gerow invented the first silicone breast implant in the early 1960s, a silicone shell filled with silicone gel. Many variations of this device have been tried over the years, including cladding the device with polyurethane foam (the Natural Y implant). This variant of the breast implant was fraught with problems. However, the basic silicone rubber–silicone gel breast implant was generally acceptable in performance (Bondurant et al., 1999).

Vascular Grafts

Surgeons have long needed methods and materials to repair damaged and diseased blood vessels. Early in the century, Dr. Alexis Carrel developed methods to anastomose (suture) blood vessels, an achievement for which he won the Nobel Prize in medicine in 1912. In 1942 Blackmore used Vitallium metal tubes to bridge arterial defects in war wounded soldiers. Columbia University surgical intern Arthur Voorhees (1922–1992), in 1947, noticed during a post-mortem that tissue had grown around a silk suture left inside a lab animal. This observation stimulated the idea that a cloth tube might also heal by being populated by the tissues of the body. Perhaps such a healing reaction in a tube could be used to replace an artery? His first experimental vascular grafts were sewn from a silk handkerchief and then parachute fabric (Vinyon N), using his wife's sewing machine. The first human implant of a prosthetic vascular graft was in 1952. The patient lived many years after this procedure, inspiring many surgeons to copy the procedure. By 1954, another paper was published establishing the clear benefit of a porous (fabric) tube over a solid polyethylene tube (Egdahl et al., 1954). In 1958, the following technique was described in a textbook on vascular surgery (Rob, 1958): "The Terylene, Orlon or nylon cloth is bought from a draper's shop and cut with pinking shears to the required shape. It is then sewn with thread of similar material into a tube and sterilized by autoclaving before use."

Stents

Partially occluded coronary arteries lead to angina, diminished heart functionality and eventually, when the artery occludes (i.e., myocardial infarction), death of a localized portion of the heart muscle. Bypass operations take a section of vein from another part of the body and replace the occluded coronary artery with a clean conduit – this is major surgery, hard on the patient, and expensive. Synthetic vascular grafts in the 3 mm diameter size that is appropriate to the human coronary artery anatomy will thrombose, and thus cannot be used. Another option is percutaneous transluminal coronary angioplasty (PTCA). In this procedure, a balloon is threaded on a catheter into the coronary artery and then inflated to open the lumen of the occluding vessel. However, in many cases the coronary artery can spasm and close from the trauma of the procedure. The invention of the coronary artery stent, an expandable mesh structure that holds the lumen open after PTCA, was revolutionary in the treatment of coronary occlusive disease. In his own words, Dr. Julio Palmaz (Figure 7) describes the origins and history of the cardiovascular stent.

> I was at a meeting of the Society of Cardiovascular and Interventional Radiology in February 1978 when a visiting lecturer, Doctor Andreas Gruntzig from Switzerland, was presenting his preliminary experience with coronary balloon angioplasty. As you know, in 1978 the mainstay therapy of coronary heart disease was surgical bypass. Doctor Gruntzig showed his promising new technique to open up coronary atherosclerotic blockages without the need for open chest surgery, using his own plastic balloon catheters. During his presentation, he made it clear that in a third of the cases, the treated vessel closed back after initial opening with the angioplasty balloon because of elastic recoil or delamination of the vessel wall layers. This required standby surgery facilities and personnel, in case acute closure after balloon angioplasty prompted emergency coronary bypass. Gruntzig's description of the problem of vessel reclosure elicited in my mind the idea of using some sort of support, such as used in mine tunnels or in oil well drilling. Since

FIGURE 7 Dr. Julio Palmaz, inventor of the coronary artery stent. (Photograph by B. Ratner.)

the coronary balloon goes in small (folded like an umbrella) and is inflated to about 3–4 times its initial diameter, my idealistic support device needed to go in small and expand at the site of blockage with the balloon. I thought one way to solve this was a malleable, tubular, criss-cross mesh. I went back home in the Bay Area and started making crude prototypes with copper wire and lead solder, which I first tested in rubber tubes mimicking arteries. I called the device a BEIS or balloon-expandable intravascular graft. However, the reviewers of my first submitted paper wanted to call it a stent. When I looked the word up, I found out that it derives from Charles Stent, a British dentist who died at the turn of the century. Stent invented a wax material to make dental molds for dentures. This material was later used by plastic surgeons to keep tissues in place, while healing after surgery. The word "stent" was then generically used for any device intended to keep tissues in place while healing.

I made the early experimental device of stainless steel wire soldered with silver. These were materials I thought would be appropriate for initial laboratory animal testing. To carry on with my project I moved to the University of Texas Health Science Center in San Antonio (UTHSCSA). From 1983–1986 I performed mainly bench and animal testing that showed the promise of the technique and the potential applications it had in many areas of vascular surgery and cardiology. With a UTHSCSA pathologist, Doctor Fermin Tio, we observed our first microscopic specimen of implanted stents in awe. After weeks to months after implantation by catheterization under X-ray guidance, the stent had remained open, carrying blood flow. The metal mesh was covered with translucent, glistening tissue similar to the lining of a normal vessel. The question remained whether the same would happen in atherosclerotic vessels. We tested this question in the atherosclerotic rabbit model and to our surprise, the new tissue free of atherosclerotic plaque encapsulated the stent wires, despite the fact that the animals were still on a high cholesterol diet. Eventually, a large sponsor (Johnson & Johnson) adopted the project and clinical trials were instituted under the scrutiny of the Food and Drug Administration.

Coronary artery stenting is now performed in well over 1.5 million procedures per year.

Pacemakers

In London in 1788, Charles Kite wrote "An Essay Upon the Recovery of the Apparently Dead," where he discussed electrical discharges to the chest for heart resuscitation. In the period 1820–1880 it was already known that electric shocks could modulate the heartbeat (and,

of course, consider the *Frankenstein* story from that era). The invention of the portable pacemaker, hardly portable by modern standards, may have taken place almost simultaneously in two groups in 1930–1931 – Dr. Albert S. Hyman (USA) (Figure 8), and Dr. Mark C. Lidwill (working in Australia with physicist Major Edgar Booth).

Canadian electrical engineer, John Hopps, while conducting research on hypothermia in 1949, invented an early cardiac pacemaker. Hopps' discovery was if a cooled heart stopped beating, it could be electrically restarted. This led to Hopps' invention of a vacuum tube cardiac pacemaker in 1950. Paul M. Zoll developed a pacemaker in conjunction with the Electrodyne Company in 1952. The device was about the size of a small microwave oven, was powered with external current, and stimulated the heart using electrodes placed on the chest – this therapy caused pain and burns, although it could pace the heart.

In the period 1957–1958, Earl E. Bakken, founder of Medtronics, Inc. developed the first wearable transistorized (external) pacemaker at the request of heart surgeon Dr. C. Walton Lillehei. Bakken quickly produced a prototype that Lillehei used on children with post-surgery heart block. Medtronic commercially produced this wearable, transistorized unit as the 5800 pacemaker.

In 1959 the first fully-implantable pacemaker was developed by engineer Wilson Greatbatch and cardiologist W.M. Chardack. He used two Texas Instruments transistors, a technical innovation that permitted small size and low power drain. The pacemaker was encased in epoxy to inhibit body fluids from inactivating it.

Heart Valves

The development of the prosthetic heart valve paralleled developments in cardiac surgery. Until the heart could be stopped and blood flow diverted, the replacement of a valve would be challenging. Charles Hufnagel, in 1952, implanted a valve consisting of a poly(methyl methacrylate) tube and nylon ball in a beating heart (Figure 9). This was a heroic operation and basically unsuccessful, but an operation that inspired cardiac surgeons to consider that valve prostheses might be possible. The 1953 development of the heart-lung machine by Gibbon allowed the next stage in the evolution of the prosthetic heart valve to take place. In 1960, a mitral valve replacement was performed in a human by surgeon Albert Starr, using a valve design consisting of a silicone ball and poly(methyl methacrylate) cage (later replaced by a stainless steel cage). The valve was invented by engineer Lowell Edwards. The heart valve was based on a design for a bottle stopper invented in 1858. Starr was quoted as saying: "Let's make a valve that works and not worry about its looks," referring to its design that was radically different from the leaflet valve that nature evolved in mammals. Prior to the Starr–Edwards valve, no human had lived with a prosthetic heart valve longer than three months. The Starr–Edwards valve was found to permit good patient survival. The major issues in valve development in that era were thrombosis and durability. In 1969, Warren Hancock started the development of the first leaflet tissue heart valve based upon

FIGURE 9   The Hufnagel heart valve consisting of a poly(methyl methacrylate) tube and nylon ball. (United States Federal Government image in the public domain.)

glutaraldehyde-treated pig valves, and his company and valve were acquired by Johnson & Johnson in 1979.

Drug Delivery and Controlled Release

Through most of history drugs were administered orally or by hypodermic syringe. In general, there was no effort to modulate the rate of uptake of the drug into the body. In 1949, Dale Wurster invented what is now known as the Wurster process that permitted pills and tablets to be encapsulated and therefore slow their release rate. However, modern ideas of controlled release can be traced to a medical doctor, Judah Folkman. Dr. Folkman noted that dyes penetrated deeply into silicone rubber, and he surmised from this that drugs might do the same. He sealed isoproterenol (a drug used to treat heart block) into silicone tubes, and implanted these into the hearts of dogs (Folkman and Long, 1964). He noted the delayed release and later applied this same idea to delivering a birth control steroid. He donated this development, patent-free, to the World Population Council. An entrepreneur and chemist, Alejandro Zaffaroni, heard of the Folkman work, and launched a company in 1970, Alza (originally called Pharmetrics), to develop these ideas for the pharmaceutical industry. The company developed families of new polymers for controlled release, and also novel delivery strategies. Alza was a leader in launching this new field that is so important today; further details on the field of controlled release are provided in an excellent historical overview (Hoffman, 2008).

DESIGNED BIOMATERIALS

In contrast to the biomaterials of the surgeon-hero era, when largely off-the-shelf materials were used to fabricate medical devices, the 1960s on saw the development of materials designed specifically for biomaterials applications. Here are some key classes of materials and their evolution from commodity materials to engineered/synthesized biomaterials.

Silicones

Although the class of polymers known as silicones has been explored for many years, it was not until the early 1940s that Eugene Rochow of GE pioneered the scale-up and manufacture of commercial silicones via the reaction of methyl chloride with silicon in the presence of catalysts. In Rochow's 1946 book, *The Chemistry of Silicones* (John Wiley & Sons, Publishers), he comments anecdotally on the low toxicity of silicones, but did not propose medical applications. Possibly the first report of silicones for implantation was by Lahey (1946) (see also Chapter II.5.18). The potential for medical uses of these materials was realized shortly after this. In a 1954 book on silicones, McGregor has a whole chapter titled "Physiological Response to Silicones." Toxicological studies were cited

suggesting to McGregor that the quantities of silicones that humans might take into their bodies should be "entirely harmless." He mentions, without citation, the application of silicone rubber in artificial kidneys. Silicone-coated rubber grids were also used to support a dialysis membrane (Skeggs and Leonards, 1948). Many other early applications of silicones in medicine are cited in Chapter II.5.18.

Polyurethanes

Polyurethane was invented by Otto Bayer and colleagues in Germany in 1937. The chemistry of polyurethanes intrinsically offered a wide range of synthetic options leading to hard plastics, flexible films, or elastomers (Chapter I.2.2.A). Interestingly, this was the first class of polymers to exhibit rubber elasticity without covalent cross-linking. As early as 1959, polyurethanes were explored for biomedical applications, specifically heart valves (Akutsu et al., 1959). In the mid-1960s a class of segmented polyurethanes was developed that showed both good biocompatibility and outstanding flex life in biological solutions at 37°C (Boretos and Pierce, 1967). Sold under the name Biomer® by Ethicon and based upon DuPont Lycra®, these segmented polyurethanes comprised the pump diaphragms of the Jarvik 7® hearts that were implanted in seven humans.

Teflon®

DuPont chemist Roy Plunkett discovered a remarkably inert polymer, Teflon® (polytetrafluoroethylene) (PTFE), in 1938. William L. Gore and his wife, Vieve started a company in 1958 to apply Teflon® for wire insulation. In 1969, their son Bob found that Teflon®, if heated and stretched, forms a porous membrane with attractive physical and chemical properties. Bill Gore tells the story that, on a chairlift at a ski resort, he pulled from his parka pocket a piece of porous Teflon® tubing to show to his fellow ski lift passenger. The skier was a physician and asked for a specimen to try as a vascular prosthesis. Now, Goretex® porous Teflon® and similar expanded PTFEs are the leading synthetic vascular grafts, and are also used in numerous other applications in surgery and biotechnology (Chapters I.2.2.C and II.5.3.B).

Hydrogels

Hydrogels have been found in nature since life on earth evolved. Bacterial biofilms, hydrated extracellular matrix components, and plant structures are ubiquitous, water-swollen motifs in nature. Gelatin and agar were also known and used for various applictions early in human history. But the modern history of hydrogels as a class of materials designed for medical applications can be accurately traced.

In 1936, DuPont scientists published a paper on recently synthesized methacrylic polymers. In this paper, poly(2-hydroxyethyl methacrylate) (polyHEMA) was mentioned. It was briefly described as a hard, brittle, glassy polymer, and clearly was not considered of importance. After that paper, polyHEMA was essentially forgotten until 1960. Wichterle and Lim published a paper in *Nature* describing the polymerization of HEMA monomer and a cross-linking agent in the presence of water and other solvents (Wichterle and Lim, 1960). Instead of a brittle polymer, they obtained a soft, water-swollen, elastic, clear gel. Wichterle went on to develop an apparatus (built originally from a children's construction set; Figure 10) for centrifugally casting the hydrogel into contact lenses of the appropriate refractive power.
FIGURE 10   Left: Otto Wichterle (1913–1998). (Wikipedia.) Right: The centrifugal casting apparatus Wichterle used to create the first soft, hydrogel contact lenses. (Photograph by Jan Suchy, Wikipedia public domain.)

This innovation led to the soft contact lens industry, and to the modern field of biomedical hydrogels as we know them today.

Interest and applications for hydrogels have steadily grown over the years, and these are described in detail in Chapter I.2.5. Important early applications included acrylamide gels for electrophoresis, poly(vinyl alcohol) porous sponges (Ivalon) as implants, many hydrogel formulations as soft contact lenses, and alginate gels for cell encapsulation.

Poly(Ethylene Glycol)

Poly(ethylene glycol) (PEG), also called poly(ethylene oxide) (PEO) in its high molecular weight form, can be categorized as a hydrogel, especially when the chains are cross-linked. However, PEG has many other applications and implementations. It is so widely used today that its history is best discussed in its own section.

The low reactivity of PEG with living organisms has been known since at least 1944, when it was examined as a possible vehicle for intravenously administering fat-soluble hormones (Friedman, 1944). In the mid-1970s, Frank Davis and colleagues (Abuchowski et al., 1977) discovered that if PEG chains were attached to enzymes and proteins, they would a have a much longer functional residence time *in vivo* than biomolecules that were not PEGylated. Professor Edward Merrill of MIT, based upon what he called "various bits of evidence" from the literature, concluded that surface-immobilized PEG would resist protein and cell pickup. The experimental results from his research group in the early 1980s bore out this conclusion (Merrill, 1992). The application of PEGs to wide range of biomedical problems was significantly accelerated by the synthetic chemistry developments of Dr. Milton Harris while at the University of Alabama, Huntsville.

Poly(Lactic-Glycolic Acid)

Although originally discovered in 1833, the anionic polymerization from the cyclic lactide monomer in the early 1960s made creating materials with mechanical properties comparable to Dacron possible. The first publication on the application of poly(lactic acid) in medicine may be by Kulkarni et al. (1966). This group demonstrated that the polymer degraded slowly after implantation in guinea pigs or rats, and was well-tolerated by the organisms. Cutright et al. (1971) were the first to apply this polymer for orthopedic fixation. Poly(glycolic acid) and copolymers of lactic and glycolic acid were subsequently developed. Early clinical applications of polymers in this family were for sutures, based upon the work of Joe Frazza and Ed Schmitt at David & Geck, Inc. (Frazza and Schmitt, 1971). The glycolic acid/lactic acid polymers have also been widely applied for controlled release of drugs and proteins. Professor Robert Langer's group at MIT was the leader in developing these polymers in the

form of porous scaffolds for tissue engineering (Langer and Vacanti, 1993).

Hydroxyapatite

Hydroxyapatite is one of the most widely studied materials for healing in bone. It is a naturally occurring mineral, a component of bone, and a synthesized material with wide application in medicine. Hydroxyapatite can be easily made as a powder. One of the first papers to describe biomedical applications of this material was by Levitt et al. (1969), in which they hot-pressed the hydroxyapatite power into useful shapes for biological experimentation. From this early appreciation of the materials science aspect of a natural biomineral, a literature of thousands of papers has evolved. In fact, the nacre implant described in the prehistory section may owe its effectiveness to hydroxyapatite – it has been shown that the calcium carbonate of nacre can transform in phosphate solutions to hydroxapatite (Ni and Ratner, 2003).

Titanium

In 1791, William Gregor, a Cornish amateur chemist, used a magnet to extract the ore that we now know as ilmenite from a local river. He then extracted the iron from this black powder with hydrochloric acid, and was left with a residue that was the impure oxide of titanium. After 1932, a process developed by William Kroll permitted the commercial extraction of titanium from mineral sources. At the end of World War II, titanium metallurgy methods and titanium materials made their way from military application to peacetime uses. By 1940, satisfactory results had already been achieved with titanium implants (Bothe et al., 1940). The major breakthrough in the use of titanium for bony tissue implants was the Brånemark discovery of osseointegration, described above in the section on dental implants.

Bioglass

Bioglass is important to biomaterials as one of the first completely synthetic materials that seamlessly bonds to bone. It was developed by Professor Larry Hench and colleagues. In 1967 Hench was Assistant Professor at the University of Florida. At that time his work focused on glass materials and their interaction with nuclear radiation. In August of that year, he shared a bus ride to an Army Materials Conference in Sagamore, New York with a US Army Colonel who had just returned from Vietnam where he was in charge of supplies to 15 MASH units. This colonel was not particularly interested in the radiation resistance of glass. Rather, he challenged Hench with the following: hundreds of limbs a week in Vietnam were being amputated because the body was found to reject the metals and polymer materials used to repair the body. "If you can make a material that will

resist gamma rays why not make a material the body won't resist?"

Hench returned from the conference and wrote a proposal to the US Army Medical R and D Command. In October 1969 the project was funded to test the hypothesis that silicate-based glasses and glass-ceramics containing critical amounts of Ca and P ions would not be rejected by bone. In November 1969 Hench made small rectangles of what he called 45S5 glass (44.5 weight % SiO_2), and Ted Greenlee, Assistant Professor of Orthopaedic Surgery at the University of Florida, implanted them in rat femurs at the VA Hospital in Gainesville. Six weeks later Greenlee called: "Larry, what are those samples you gave me? They will not come out of the bone. I have pulled on them, I have pushed on them, I have cracked the bone and they are still bonded in place." Bioglass was born, and with the first composition studied! Later studies by Hench using surface analysis equipment showed that the surface of the bioglass, in biological fluids, transformed from a silicate rich composition to a phosphate rich structure, possibly hydroxyapatite (Clark et al., 1976).

THE CONTEMPORARY ERA (MODERN BIOLOGY AND MODERN MATERIALS)

It is probable that the modern era in the history of biomaterials, biomaterials engineered to control specific biological reactions, was ushered in by rapid developments in modern biology (second and third generation biomaterials; see Figure 2 in "Biomaterials Science: An Evolving, Multidisciplinary Endeavor"). In the 1960s, when the field of biomaterials was laying down its foundation principles and ideas, concepts such as cell-surface receptors, growth factors, nuclear control of protein expression and phenotype, cell attachment proteins, stem cells, and gene delivery were either controversial observations or not yet discovered. Thus, pioneers in the field could not have designed materials with these ideas in mind. It is to the credit of the biomaterials community that it has been quick to embrace and exploit new ideas from biology. Similarly, new ideas from materials science such as phase separation, anodization, self-assembly, surface modification, and surface analysis were quickly assimilated into the biomaterial scientists' toolbox and vocabulary. A few of the important ideas in biomaterials literature that set the stage for the biomaterials science we see today are useful to list:

- Protein adsorption
- Biospecific biomaterials
- Non-fouling materials
- Healing and the foreign-body reaction
- Controlled release
- Tissue engineering
- Regenerative medicine
- Nanotechnology.

Since these topics are addressed later in some detail in *Biomaterials Science*: *An Introduction to Materials in Medicine*, third edition, they will not be expanded upon in this history section. Still, it is important to appreciate the intellectual leadership of many researchers that promoted these ideas that comprise modern biomaterials – this is part of a recent history of biomaterials that will someday be completed. We practice biomaterials today immersed within an evolving history.

CONCLUSIONS

Biomaterials have progressed from surgeon-heroes, sometimes working with engineers, to a field dominated by engineers, chemists, and physicists, to our modern era with biologists and bioengineers as the key players. As *Biomaterials Science*: *An Introduction to Materials in Medicine*, third edition, is being published, many individuals who were biomaterials pioneers in the formative days of the field are well into their eighth or ninth decades of life. A number of leaders of biomaterials, pioneers who spearheaded the field with vision, creativity, and integrity, have passed away. Biomaterials is a field so new that the first-hand accounts of its roots are available. I encourage readers of the textbook to document their conversations with pioneers of the field (many of whom still attend biomaterials conferences), so that the exciting stories that led to the successful and intellectually stimulating field we see today are not lost.

Properties of Materials

CHAPTER I.1.1 INTRODUCTION: PROPERTIES OF MATERIALS: THE PALETTE OF THE BIOMATERIALS ENGINEER

Jack E. Lemons
University Professor, Schools of Dentistry, Medicine and
Engineering, University of Alabama at Birmingham,
Birmingham, AL, USA

The platform, or palette, upon which the biomaterials engineer arranges information into parts for subsequent blending, let us say an art of biomaterials science, has expanded and evolved significantly in content over past decades. The depth and breadth of what is now included on this palette goes well beyond expectations expressed by founding members of the Society for Biomaterials in the late 1960s and early 1970s.

The science in biomaterials science has included fundamental aspects of physical, mechanical, chemical, electrical, and biological (compatibility) properties of the synthetic and natural origin biomaterials *per se*. Also, the methods for measuring and analyzing properties are equally applicable to the structures of the biological host. Following the recognition of the need by founders of the discipline in the 1960s, one focus has been the fundamental structure versus property relationships leading to *in vivo* biocompatibility. These relationships, and the supporting scientific information, have changed with time and experience, especially as the biological and clinical disciplines have also evolved. For example, considerations for biocompatibility are very different for biomaterials listed within biotolerant (called inert), surface bioactive (intended), and biodegradable categories. This shift of emphasis is reflected in the progression of content of the first three editions of this book. For example, initial considerations focused on materials were based primarily on substances of the metallics, ceramics, and polymerics available within various industrial applications. Thus, the emphasis in the first edition was on materials of synthetic origin and the science leading

to biomaterials. The second and third editions represent the transitions from combination products to the new areas of bioactives and biodegradables. Thus, as an integrated, comprehensive, and authoritative text, this third edition reflects a broad range of biomaterials, and therefore basic properties of new generation biomaterials for regenerative medicine.

Considering relationships between biomaterial and biological systems (the interface) and the dynamics of change from nanoseconds to years, we now better understand many mechanisms of interaction at the dimensions and concentrations used to describe interactions of atoms. It is also realized that all biomaterial and host environment interactions play a role in the broader aspects of biocompatibility, especially the functionality and longevity of implant devices. In this regard, Part I on "Materials Science and Engineering" emphasizes the more basic information on the bulk and surface properties of synthetic and natural origin biomaterials. Critical aspects of constitution (chemistry) and structure (nano-, micro-, and macrodimension) relationships are presented as related to properties of implant systems. These basic considerations from the nature (I.1.2), bulk (I.1.3), and surface (I.1.5) properties are also interrelated to biomechanics (I.1.4).

In this edition, the concepts of property versus structure relationships have been expanded in terms of the role of water in biomaterials (I.1.6). The science of interactions of synthetic and natural substances with water is recognized as one of the key aspects of surgical implant biocompatibilities. This is especially important for the evolution of the discipline to include new generation biomaterials needed for future implant applications.

In summary, the content of this Part I is broadly applicable to all parts of the third edition. Therefore, students are advised to always consider the basic principles as provided in this section. This has been recognized as critical to the education of a specialist in biomaterials science leading to the selection of biomaterials for medical treatments utilizing all types of implant devices.

CHAPTER I.1.2 THE NATURE OF MATTER AND MATERIALS

Buddy D. Ratner

Professor, Bioengineering and Chemical Engineering, Director of University of Washington Engineered Biomaterials (UWEB), Seattle, WA, USA

INTRODUCTION

> Biomaterials are *materials.*

Biomaterials are *materials*. What are materials and how are they structured? This is the subject of this chapter, a lead into subsequent chapters with discussions of the bulk properties of materials, mechanics of materials, surface properties, a discussion of water (since all biomaterials function in an aqueous environment, and that environment can alter both the nature of the material and the interaction that occurs with the material), and finally discussions of specific classes of materials relevant to biomaterials (polymers, metals, ceramics, etc.).

ATOMS AND MOLECULES

> The key to understanding matter is to understand attractive and interactive forces between atoms.

This "Nature of Matter" section aims to communicate an understanding of the basic structure of materials that will drive their properties – both the mechanical properties important for specific applications (strong, elastic, ductile, permeable, etc.), and the surface properties that will mediate reactions with the external biological environment.

The key to understanding matter is to understand attractive and interactive forces between atoms. Argon is a gas at room temperature – it must be cooled to extremely low temperatures to transition it into liquid form. An argon atom interacts (attracts) very, very weakly with another argon atom – so at room temperature, thermal fluctuations that randomly propel the atoms exceed attractive forces that might result in the coalescence to a solid material. A titanium atom strongly interacts with another titanium atom. Extremely high temperatures are required to vaporize titanium and liberate those atoms from each other. The understanding of matter is an appreciation of interactive forces between atoms.

What holds those atoms and molecules together to make a strong nylon fiber or a cell membrane, or a hard, brittle hydroxyapatite ceramic, or a sheet of gold, or a drop of water? Even in the early 18th century, Isaac Newton was pondering this issue: "There are therefore Agents in Nature able to make the Particles of Bodies stick together by very strong Attractions."

Entropy consideration would say these molecules and atoms should "fly apart" to increase randomness. However, there is an energy term contributing to the stability of the ensemble leading to a negative Gibbs free energy, which, according to the second law of thermodynamics, should make such solids energetically favorable (of course, we intuitively know this). Thus, we must examine this energy term. We know of just four attractive forces in this universe:

- Gravitational
- Weak nuclear
- Strong nuclear
- Electromagnetic.

Gravity holds us to the surface of the planet Earth (a massive body), but the gravitational potential energy of two argon atoms is only about 10^{-52} J, 30 orders of magnitude weaker than is observed for intermolecular forces. The weak nuclear force and the strong nuclear force are only significant over 10^{-4} nm – but molecular dimensions are 5×10^{-1} nm. So these forces do not explain what holds atoms together. This leaves, by default, electromagnetic forces (positive charge attracts negative charge). Electromagnetic forces have appropriate magnitudes and distance dependencies to justify why atoms interact. Interactions can be weak, leading to liquids, or stronger, leading to solids.

Electromagnetic forces manifest themselves in a number of ways. The types of interactions usually observed between atoms (all explained by electrostatics) are summarized in Table I.1.2.1. We consider here van der Waals forces (also called induction or dispersion forces), ionic forces, hydrogen bonding, metallic forces, and covalent interactions.

Van der Waals or dispersion forces rationalize the interaction of two atoms or molecules, each without a dipole (no plus or minus faces to the molecules). For example, argon atoms can be liquefied at low temperature. Why should this happen? Why should argon atoms want to interact with each other enough to form a liquid? Figure I.1.2.1 explains the origin of dispersive forces. Such forces are important, as they dictate the properties of many materials (for example, some polymers such as polyethylene which has no obvious dipole), but also they explain why the lipids in cell membranes assemble into the bilayer structure described later in this textbook. A typical van der Waals interactive force (for example, $CH_4 \ldots CH_4$) is about 9 kJ/mol. The Ar ... Ar interactive force is approximately 1 kJ/mol.

Ionic forces are probably the easiest of the intermolecular forces to understand. Figure I.1.2.2 illustrates a unit cell of a sodium chloride crystal. The + and – charges are arrayed to achieve the closest interaction of opposite charges, and the furthest separation of similar charges. This unit cell can be repeated over and over in space, and the forces that hold it together are the electrostatic interaction of a permanent + charge and a permanent – charge. Typical ionic bond strengths (for example, NaCl) are about 770 kJ/mol.

Hydrogen bonding interactions are also straightforward to appreciate as electrostatic interactions. An electronegative element such as oxygen (it demands electrons) can distort the binding electron cloud from the

TABLE I.1.2.1	Forces that Hold Atoms Together		
Interatomic Force	**Explanation**	**Relative Strength**	**Examples**
Van der Waals interactions	Transient fluctuations in the spatial localization of electron clouds surrounding atoms lead to transient positive and negative charges, and consequent interactive forces in molecules would seem to have no permanent polarity	Weak	Argon at cryogenic temperatures. Polyethylene (the forces that hold the chains together to make a solid)
Ionic	Atoms with a permanent positive (+) charge attract atoms with a permanent negative (–) charge	Very strong	NaCl $CaCl_2$
Hydrogen (H) bonding	The interaction of a covalently bound hydrogen with an electronegative atom, such as oxygen or fluorine	Medium	Water ice Nylon (the forces that hold the chains together to make a strong, high-melting point solid)
Metallic	The attractive force between a "sea" of positively charged atoms and delocalized electrons	Medium-strong	Gold Titanium metal
Covalent	A sharing of electrons between two atoms	Strong	The carbon–carbon bond Cross-links in a polyacrylamide hydrogel
FIGURE I.1.2.1 (A) Consider the electron clouds (charge density in space) of two atoms or molecules, both without permanent dipole moments. (B) Electron clouds are continuously in motion and can shift to one side of the atom or molecule; therefore, at any moment, the atoms or molecules can create a "fluctuating instantaneous dipole." (C) The "fluctuating instantaneous dipole" in one molecule electrostatically induces such an "instantaneous dipole" in the next molecule.
FIGURE I.1.2.3 A hydrogen bond between two water molecules.
FIGURE I.1.2.2 The unit cell of a sodium chloride crystal illustrating the plus–minus electrostatic interactions.

hydrogen nucleus leaving the hydrogen (just a proton and electron), with less electron and thus more plus-charged proton. This somewhat positive charge will, in turn, then interact with an electronegative oxygen (Figure I.1.2.3). Typical hydrogen bond strengths (for example, O–H…H) are about 20 kJ/mol.

Metallic bonding is explained by a delocalized "sea" of electrons with positively charged nuclear cores

dispersed within it (Figure I.1.2.4). A single metallic bond is rarely discussed. The total interactive strength is realized through the multiplicity of the plus–minus interactions. The strength of this interaction can be expressed by heats of sublimation. For example, at 25°C, aluminum will have a heat of sublimation of 325 kJ/mol, while titanium will be about 475 kJ/mol.

Covalent bonds are relatively strong bonds associated with sharing of pairs of electrons between atoms (Figure I.1.2.5). Typical covalent bond strengths (for example, C–C) are about 350 kJ/mol.

MOLECULAR ASSEMBLIES

Atoms can combine in defined ratios to form molecules (usually they combine with covalent bonds), or they can form cohesive assemblies of atoms (think of gold and metallic interactive forces, for example). Thus, materials can be made of atoms or of molecules (i.e., covalently joined atoms). The difference between the dense, lubricious plastics used in orthopedics, the soft, elastic materials of catheters, and the hard, strong metals of a hip
FIGURE I.1.2.4 Metallic bonding in magnesium. The 12 electrons from each Mg atom are shared among positively charged nuclear cores (the single + charge on each magnesium atom in the figure is simply intended to indicate there is some degree of positive charge on each magnesium nuclear core).
FIGURE I.1.2.5 Covalent bonding along a section of polyethylene chain. Carbons share pairs of electrons with each other, and each hydrogen shares an electron pair with carbon.

joint is associated with how those atoms and molecules are organized (due to attractive and interactive forces) in materials. Metals used in biomaterials applications can be strong, rigid and brittle, or flexible and ductile. Again, the difference is largely how the atoms making up the metal are organized, and how strongly their atoms interact.

Molecules also organize or assemble. The widely varying properties of polymers are due to molecular organization. The assembly of lipid molecules to make a cell membrane is another example of this organization.

A key concept in appreciating the properties of materials is hierarchical structures. The smallest size scale that we need consider here in materials is atoms, typically about 0.2 nm in diameter. Atoms combine to form molecules with dimensions ranging from 1 nm to 100 nm (some large macromolecules). Molecules may assemble or order to form supramolecular structures with dimensions up to 1000 nm or more. These supramolecular structures may themselves organize in bundles, fibers or larger assemblies with dimensions reaching into the range visible to the human eye. This concept of hierarchical structure is illustrated in Figure I.1.2.6, using collagen protein as the example.

The single α-chains comprising the collagen triple helix would break under tension with an application of nanograms of force. On the other hand, the collagen

(C) Collagen molecules (triple helices)

(B) Collagen fibrils

(A) Collagen fibers

(D) α-chains

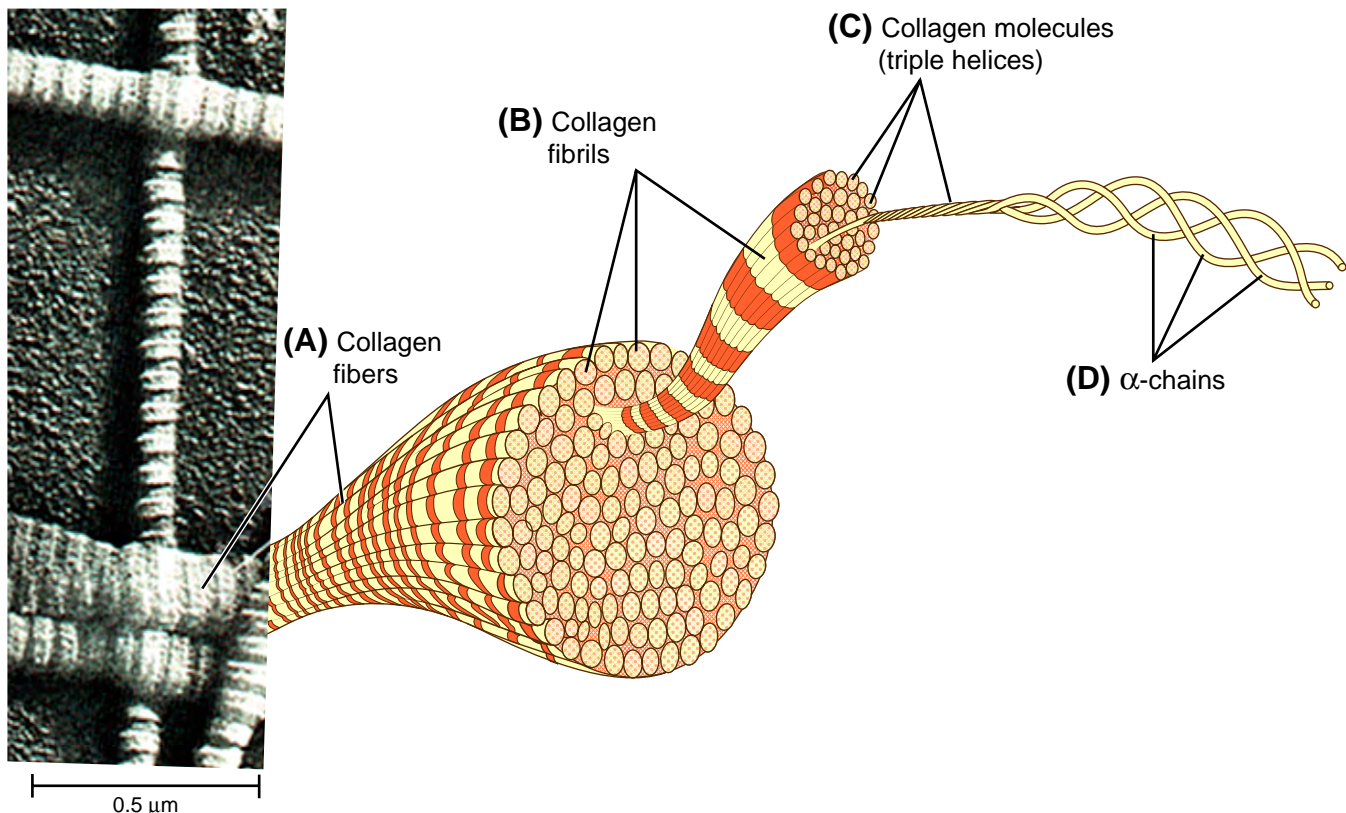
0.5 μm


FIGURE I.1.2.6 Collagen fibers make up many structures in the body (tendons, for example). Such anatomical structures as tendons are comprised of collagen fibrils, formed of aligned bundles of collagen triple helices that are themselves made up of single collagen protein chains (α-chains). The α-chains are constructed of joined amino acid units, and the amino acids are molecules of carbon, oxygen, nitrogen, and hydrogen atoms in defined ratios and orders. (Illustration from Becker, W. (2002). *The World of the Cell.* Reprinted with permission of Pearson Education, Inc.)

fibers in a hierarchical structure such as a tendon can support many kilograms of force. Such hierarchical structures are noted frequently in both materials science and in biology.

SURFACES

As assemblies of atoms and/or molecules form, within the bulk of the material, each unit is uniformly "bathed" in a field of attractive forces of the types described in Table I.1.2.1. However, those structural units that are at the surface are pulled upon asymmetrically by just the units beneath them. This asymmetric attraction distorts the electron distributions of the surface atoms or molecules, and gives rise to the phenomenon of surface energy, an excess energy associated with this imbalance. For this reason surfaces always have unique reactivities and properties. This idea will be expanded upon in Chapter I.1.5.

CONCLUSION

In this section we have reviewed the transition from chemistry to matter. Interacting assemblies of atoms and molecules comprise matter. Without matter, we cannot have biomaterials. Matter exists because of electrostatic forces – positive and negative charges, in all cases, hold atoms together. The strength of those interactions, associated with the magnitude of the charge on each atom, and the environment the atoms are in (water, air, etc.) ultimately dictates the properties of matter (a soft gel, a hard metal, etc.). Now that we have a general idea what "matter" is, we can take these concepts from physics and chemistry and bring them to a consideration of the mechanical properties of materials, the surface properties of materials, and then into the specifics of polymers, metals, ceramics, and other types of materials.

CHAPTER I.1.3 BULK PROPERTIES OF MATERIALS

Christopher Viney
School of Engineering, University of California at Merced, Merced, CA, USA

INTRODUCTION

Bulk Versus Surface

The success or failure of many biomaterials depends on the physical and chemical characteristics of their surface. It is the surface properties that dictate interactions between a material and its environment, and thus whether a permanently implanted material will be tolerated or rejected. In cases where the implanted material is required to degrade at a controlled rate (e.g., when the implant is a temporary support, such as a dissolving suture or a scaffolding for cells that regenerate tissue), then the bulk material must be capable of sustaining those properties continuously as it becomes the new surface.

Regardless of their particular surface properties, biomaterials are usually also required to exhibit certain *bulk* characteristics, especially including those attributes (mechanical properties) that relate to the ability to carry loads dependably without undue deflection or premature failure. Mechanical properties will be addressed in detail in this chapter, followed by a brief consideration of selected other bulk properties (thermal, optical) that are often significant in the context of biomaterials.

The concepts addressed in this chapter are fundamental. They can be found scattered through standard materials science or mechanical engineering textbooks, and undergraduate materials science or mechanical engineering courses. The aim in this chapter is to achieve consistency of presentation, connectivity of knowledge, and appreciation of relevance.

Microstructure and Properties

The bulk properties of a material depend not only on what types of atoms and molecules it contains (composition), but also on how those atoms and molecules are arranged (microstructure). For example, if the material is a polymer, do the individual molecules follow a random trajectory (and so occupy an approximately spherical region of space), or are they extended (so that they occupy a region of space approximated by a rectangular prism or a cylinder)? Are the molecules locally packed in a regular array? Do the molecules locally all point in the same direction? And how are these various spatial attributes controlled by processing – assuming that they can be controlled? A strong culinary analogy can be made: in addition to specifying a list of ingredients, recipes also contain instructions on how to process the ingredients to obtain the desired dish. Processing is what makes baked potatoes, mashed potatoes, fries, and shepherd's pie crust so different.

The microstructure of a material is a specification of the structural features at length scales that cannot be discerned with the naked eye. Most materials exhibit microstructural

detail at several different length scales, down to the nanoscale. Therefore, the term "microstructure" encompasses structures in the size range 10^{-4} m to 10^{-9} m.

Some bulk properties, such as the stiffness of a metal, depend principally on the type (composition) of metal being characterized, and not on the microstructure. Such properties are referred to as *intrinsic properties*, and they include density and heat capacity. (Note that the stiffness of a *polymer* is not an intrinsic property, because the stiffness measured by attempting to stretch the polymer in a particular direction depends on whether or not the molecules are preferentially aligned in that direction.)

Other bulk properties, such as the yield strength of a metal, depend on attributes such as the average grain (crystal) size, as well as the number and distribution of defects in the crystal structure. Yield strength is an example of an *extrinsic property* – as is the stiffness of polymers. (Both stiffness and yield strength will be defined and discussed in detail in the section "Bulk Mechanical Properties Determined from Stress–Strain Plots.")

It is because some properties are intrinsic while others are extrinsic, and because different extrinsic properties are sensitive to changes in different microstructural attributes at different length scales, that it is possible to control and therefore optimize several bulk properties simultaneously. For example, a metal with a fine grain size will have higher yield strength than a coarser-grained metal, but both can have the same stiffness.

LOAD, NOMINAL STRESS, EXTENSION, AND NOMINAL STRAIN

When a load (force) is applied to an object, the possible consequences include translation, rotation, and deformation of the object. We are concerned here with deformation. To properly quantify the deformation caused by a load, we need to take into account the dimensions of the object to which the load is being applied. For example, we are often told that spider silk (especially the dragline) is "strong," although it is our experience that a strand of spider silk can be broken more easily than a strand of dental floss. The difference is that the dental floss is much thicker than the spider dragline; a bundle of spider dragline having a total thickness equal to that of the dental floss would be significantly more resistant to breaking than the floss. Consider a sample of material represented by the rectangular prism shown in Figure I.1.3.1.

Let a force F be applied normal to a pair of opposite faces (in this case the top and bottom faces) of the sample, which initially each have area A_1. The actual shape of the sample is not important for the analysis that follows; all that is necessary is that the cross-section perpendicular to the applied force should be uniform. A cylinder (e.g., representing a fiber) would serve just as well. The ratio:

$$\sigma_n = \frac{F}{A_1}$$
FIGURE I.1.3.1 Examples of a tensile (normal) stress, a shear stress, and a mixed stress with both normal and shear components, illustrating the relationship between load direction and surface orientation in each case. For the example of shear stress, the originally rectangular front face of the sample distorts to a parallelogram as shown, and the corresponding shear strain is defined as tan θ.

defines the *nominal stress* being applied to the sample. It is a nominal stress because the actual value of the area (cross-section) to which the load is applied will change as the sample deforms in response to the load; electing to calculate stress with reference to the initial cross-sectional area is a contrived choice. Nominal stress is often synonymously referred to as *engineering stress*. The stress is *tensile* if it is a "pull," elongating the sample, and it is *compressive* if it is a "push," shortening the sample. The SI units of stress are newtons per square meter ($N.m^{-2}$) or pascals (Pa).

The elongation of a sample in response to a tensile load will depend on the length of sample that there is to elongate. To visualize this, think of a line of atoms in the direction of the load, with the bonds between atoms being represented by springs. A tensile load causes each bond to stretch; consequently, the more bonds there are in the line, the longer the line will become in response to a given load. For purposes of comparing the responses of different types of material, it is therefore useful to quantify the effect of loads (and their related stresses) by considering the resultant *length change per unit length*, more commonly known as *strain*. If the initial length of the sample is l_1, and the applied stress causes a change to length l_2, then the *nominal* (or *engineering*) *strain* is given by:

$$\varepsilon_n = \frac{l_2 - l_1}{l_1} = \frac{\Delta l}{l_1} = \lambda_{1 \to 2} - 1$$

where λ denotes the *extension ratio*, i.e., the ratio of final length to initial length.

It is a nominal strain because electing to calculate strain with reference to the initial length is again a

contrived choice. The strain is *tensile* or *compressive* in accordance with whether it is caused by a tensile stress or a compressive stress. Strain, like extension ratio, is dimensionless.

The relationship between stress and resultant strain is commonly summarized in a *stress–strain plot*, where by convention the stress is plotted vertically and the strain is plotted horizontally, with data being collected while the sample is deformed at a constant strain rate.

TRUE STRESS AND TRUE STRAIN

A more realistic sense of stress imposed on a material during a stress–strain test is obtained if the applied force is scaled with reference to the *actual* cross-sectional area of the sample, A. In that case, we refer to the sample being subjected to a *true stress* defined by:

$$\sigma_t = \frac{F}{A}$$

Unfortunately, because A changes continuously during the course of a stress–strain test, it can be difficult to measure in practice. This is why the contrived, but more expedient, nominal stress is so often used instead of true stress.

The inadequacy of nominal strain as a measure of sample deformation becomes apparent when we consider the cumulative effect of successive strains. Let a sample of initial length l_1 be stretched to a length l_2, and thence to length l_3. Calculated separately, the corresponding nominal strains are:

$$\varepsilon_{n(1 \to 2)} = \frac{l_2 - l_1}{l_1} \quad \text{and} \quad \varepsilon_{n(2 \to 3)} = \frac{l_3 - l_2}{l_2}$$

The nominal strain for the deformation directly from length l_1 to length l_3 would be calculated as:

$$\varepsilon_{n(1 \to 3)} = \frac{l_3 - l_1}{l_1} \text{ which is not equal to } \varepsilon_{n(1 \to 2)} + \varepsilon_{n(2 \to 3)}$$

To address this limitation, we consider a revised definition of strain, in which the length change of the sample is measured in very small increments dl, with each increment being scaled relative to the length l of the sample immediately prior to that increment. Thus, a small increment in *true strain* is defined as:

$$d\varepsilon_t = \frac{dl}{l}$$

The true strain corresponding to deformation from length l_1 to l_2 can then be found by integrating the above expression between limits l_1 and l_2:

$$\varepsilon_{t(1 \to 2)} = \int_{l_1}^{l_2} \frac{dl}{l} = \ln \frac{l_2}{l_1}$$

If this new interpretation of strain is applied to the case of a sample of initial length l_1 being stretched to a length l_2, and thence to length l_3, the separate nominal strains are now:

$$\varepsilon_{t(1 \to 2)} = \ln \frac{l_2}{l_1} \quad \text{and} \quad \varepsilon_{t(2 \to 3)} = \ln \frac{l_3}{l_2}$$

The sum of these true strains is:

$$\ln \frac{l_2}{l_1} + \ln \frac{l_3}{l_2} = \ln \frac{l_3}{l_1} = \varepsilon_{t(1 \to 3)}$$

In other words, true strains behave properly when we try to add them.

Stresses and strains are almost always presented without formal identification as nominal or true, in which case it can (usually) be assumed that they are nominal. True stresses and strains are (usually) identified explicitly as such. However, it is good practice to avoid any possible ambiguity by being explicit and specific when talking about stresses and strains.

It is possible to interconvert nominal and true stresses, and nominal and true strains, if we make the assumption that the sample volume does not change during deformation. The circumstances under which this assumption is valid will be addressed in the section "Condition for Incompressibility (Zero Volume Change)" below.

If volume is conserved during deformation from condition 1 (characterized by sample length l_1 and cross-sectional area A_1) to condition 2 (characterized by length l_2 and cross-section A_2), then:

$$l_2 A_2 = l_1 A_1$$

At that stage in the deformation, the true stress is:

$$\sigma_t = \frac{F}{A_2} = F \frac{l_2}{A_1 l_1} = \sigma_n \frac{l_2}{l_1} = \sigma_n(\varepsilon_n + 1)$$

The interconversion between nominal and true strains is even easier to obtain:

$$\varepsilon_{t(1 \to 2)} = \ln \frac{l_2}{l_1} = \ln(\varepsilon_n + 1)$$

SHEAR STRESS AND SHEAR STRAIN

Referring again to the rectangular prism of material shown in Figure I.1.3.1, consider now the effect of applying the force F *parallel* to a pair of opposite faces (in this case again the top and bottom faces), which initially each have area A_1. For this configuration of applied load, the ratio:

$$\tau = \frac{F}{A_1}$$

defines the *shear stress* being applied to the sample.

Seen from the front of the sample, the outline becomes distorted from a rectangle to a more general parallelogram. This shape change can be used to describe the *shear strain* γ caused by the shear stress:

$$\gamma = \tan \theta$$

The use of σ to denote tensile or compressive stress, ε to denote tensile or compressive strain, τ to denote shear

stress, and γ to denote shear strain is a widely adopted convention.

If a force is applied obliquely (neither perpendicular nor parallel; see Figure I.1.3.1) to a pair of opposite faces of the sample, the ensuing stress can be resolved into normal and shear components, as can the resulting strain.

BULK MECHANICAL PROPERTIES DETERMINED FROM STRESS–STRAIN PLOTS

Simple stress–strain plots can be used to define and quantify several mechanical properties of a material. Figure I.1.3.2 displays representative plots for a ductile metal (titanium), a ceramic (alumina, Al_2O_3), and a crystalline polymer (high density polyethylene, HDPE) subjected to a tensile stress.

Figure I.1.3.3 repeats the stress–strain plot for titanium schematically, emphasizing features that relate to specific mechanical properties.
FIGURE I.1.3.2 Representative nominal stress versus nominal strain plots for three different classes of implantable material: ductile metal (titanium alloy; 6 wt% Al, 4 wt% V); ceramic (alumina); and crystalline polymer (high density polyethylene).
FIGURE I.1.3.3 Schematic nominal stress versus nominal strain plot for a ductile metal, emphasizing the features that relate to specific mechanical properties.

Elastic Deformation

Elastic Constants. The relationship between stress and strain is initially linear as the stress is increased from zero. This behavior is equivalent to the load-extension response of a simple spring, as first stated quantitatively by Robert Hooke and embodied in Hooke's Law. In the case of bulk material, the constant of proportionality between *tensile* (or *compressive*) stress and strain is known as the *Young's modulus*, E:

$$\sigma = E\,\varepsilon$$

The equivalent constant of proportionality in the case of a *shear* stress being applied is known as the *shear modulus*, G:

$$\tau = G\,\gamma$$

Similarly, we can define a *bulk modulus*, K, as the constant of proportionality relating pressure to the volume change caused by that pressure:

$$P = -K\,\frac{V_2 - V_1}{V_1} = -K\,\frac{\Delta V}{V_1}$$

where a pressure P causes a reduction in volume from an initial volume V_1 to a final volume V_2. The negative sign is used to obtain a convention in which the values of K are positive.

In all three cases above, the definitions of the different types of elastic modulus assume that the cause of deformation (tensile stress, shear stress or pressure) is sufficiently small to ensure that the response (tensile strain, shear strain or volume change) is *proportional* to the cause. This condition also ensures that the response is *reversible*; when the stress or pressure is removed, the material returns to its original dimensions.

There is one additional constant that is commonly encountered in the context of the elastic deformation of materials: *Poisson's ratio*, v (Figure I.1.3.4).

For most materials subjected to a tensile stress, the resulting longitudinal strain (parallel to the direction of the applied load) is accompanied by a transverse strain (perpendicular to the direction of the applied load). In other words, when we pull on a piece of material, it usually becomes thinner as well as longer. Poisson's ratio is defined as:

$$v = -\frac{\varepsilon_{transverse}}{\varepsilon_{longitudinal}}$$

The negative sign is used to obtain a convention in which the values of v are positive for most materials.
FIGURE I.1.3.4 Longitudinal elastic strain (in this case elongation) parallel to the direction of the applied load is accompanied by a transverse elastic strain (in this case contraction) perpendicular to the direction of the applied load. The negative of the ratio of transverse elastic strain to longitudinal elastic strain defines Poisson's ratio.

A relatively small number of materials – known as auxetic materials – have a negative Poisson's ratio. Typically, these are low-density, cellular materials, with cell walls that are able to hinge or buckle when loads are applied. Pulling on a piece of auxetic material causes it to become *wider* as well as longer, while attempting to squash it will cause it to become thinner as well as shorter.

For isotropic materials, i.e., those in which structure and therefore properties do not vary with direction, it can be shown that only two of the four elastic constants are independent. The relationship between the elastic constants is captured in the following two equations:

$$G = \frac{E}{2(1+\nu)} \quad \text{and} \quad K = \frac{E}{3(1-2\nu)}$$

Given any two of the constants E, G, K, and ν, these equations suffice to find the remaining two. E, G, and K all have the same units as stress, while ν is dimensionless.

In the case of many biological materials, especially those with a fibrous microstructure, E, G, and ν are *anisotropic* – in other words, the values obtained when these constants are measured depend on the direction along which load is applied to the sample. (The bulk modulus, K, relates to uniform compression of a material, and so, while its value is dependent on whether and to what extent the sample is microstructurally anisotropic, it does not depend on the orientation of the sample during tests.)

The transverse Young's modulus of fibers can be difficult to measure accurately, because of the practical challenges inherent in obtaining dependable stress versus strain data from fiber samples loaded parallel to a diameter. There are relatively few options for obtaining such data. We can attempt to use atomic force microscopy, applying and measuring force parallel to the fiber diameter on a suitably small target area of sample, and measuring the very small deflections that characterize strain in a thin (equivalent to short) sample. Alternatively, we can attempt to produce and test a significantly thicker sample of the same material while preserving the molecular alignment typical of the fiber. Better yet, we might be able to *calculate* the transverse Young's modulus from first principles, building on the methods that will be introduced in the sections "Quantitative Prediction of Elastic Behavior in an Atomic Solid" and "Quantitative Prediction of Elastic Behavior in a Molecular Solid." However, each of these methods has limitations, so that it is not at all unusual for fibers to be subjected to the simplifying – and itself incorrect – assumption that they are elastically isotropic.

Materials that are used as loadbearing implants need to have elastic properties that appropriately match the properties of the tissue that they replace. For example, if a dental filling has a Young's modulus significantly different from that of the tooth, the compressive stresses that accompany chewing will cause the filling and adjacent natural material to respond with different longitudinal strains, which in turn may cause the interface between the filling and the tooth to fail. Also, the filling and the tooth must have compatible values of Poisson's ratio. If the transverse strain induced in the filling is smaller than that which would have been induced in the material replaced by the filling, then the remaining tooth will tend to pull away from the filling.

Condition for Incompressibility (Zero Volume Change). Consider a rectangular block of material, initially having length l_1, width b_1, and thickness t_1. A force applied parallel to the length of the block stretches the sample to a new length l_1; correspondingly, the width decreases to b_1 and the thickness decreases to t_2. Initially, the volume of the block is:

$$V_1 = l_1\, b_1\, t_1$$

After stretching, the volume of the block is:

$$V_2 = l_2\, b_2\, t_2 = (l_1 + l_1\, \varepsilon_{longitudinal})\,(b_1 + b_1\, \varepsilon_{transverse})\,(t_1 + t_1\, \varepsilon_{transverse}),$$

from the definition of strain;

$$= (l_1 + l_1\, \varepsilon_{longitudinal})\,(b_1 - b_1\, \nu\varepsilon_{longitudinal})\,(t_1 - t_1\, \nu\varepsilon_{longitudinal}),$$

from the definition of ν

$$= l_1\, b_1\, t_1 + l_1\, \varepsilon_{longitudinal}\, b_1\, t_1 - l_1\, b_1\, \nu\varepsilon_{longitudinal}\, t_1 - l_1\, b_1\, t_1\, \nu\varepsilon_{longitudinal}$$

plus higher order terms in $\varepsilon_{longitudinal}$.

Because we are dealing with small strains, the higher order terms in $\varepsilon_{longitudinal}$ can be approximated as zero, so that:

$$V_2 \approx l_1\, b_1\, t_1 + l_1\, \varepsilon_{longitudinal}\, b_1\, t_1 - l_1\, b_1\, \nu\varepsilon_{longitudinal}\, t_1 - l_1\, b_1\, t_1\, \nu\varepsilon_{longitudinal}$$

Zero volume change in response to elastic deformation requires:

$$V_2 = l_1\, b_1\, t_1 + l_1\, \varepsilon_{longitudinal}\, b_1 t_1 - l_1\, b_1\, \nu\varepsilon_{longitudinal}\, t_1 - l_1\, b_1\, t_1\, \nu\varepsilon_{longitudinal} = V_1 = l_1\, b_1\, t_1$$

$$\therefore\ l_1\, \varepsilon_{longitudinal}\, b_1\, t_1 - l_1\, b_1\, \nu\varepsilon_{longitudinal}\, t_1 - l_1\, b_1\, t_1\, \nu\varepsilon_{longitudinal} = 0$$

$$\therefore\ 1 - 2\nu = 0$$

$$\therefore\ \nu = 0.5$$

This condition pertains in mammalian arteries. The walls have to "give" in response to each pulse of blood delivered by the heart, but the volume of arterial lumen occupied by fluid is necessarily constant. Therefore, the artery itself has to be incompressible.

There is a second consideration involving Poisson's ratio that is important in the context of arteries. An artery can be approximated as a (variably) pressurized cylinder. Simple elasticity theory shows that a pressurized cylinder made from incompressible material will become wider and shorter, rather than longer and thinner. Joints made to secure an arterial graft must be able to withstand the longitudinal tensile stress that develops during each pressurization cycle.

Quantitative Prediction of Elastic Behavior in an Atomic Solid. Some quite simple models can be used to predict the load versus extension, and hence stress versus strain relationship for the elastic deformation of materials, allowing us to obtain values of elastic modulus from first principles.

The *Morse potential* is often used to describe the energy of interaction, $U(r)$, which exists between two atoms, in terms of their separation, r:

$$U = U_0 \left\{ \exp\left[-2a\,(r - r_0) \right] - 2 \exp\left[-a\,(r - r_0) \right] \right\}$$

where U_0, a, and r_0 are constants.

The positive and negative terms respectively represent the short-range repulsion and long-range attraction between the two atoms.

Given $U(r)$, it is possible to calculate the force $F(r)$ between the atoms, and thence the stiffness $E(r)$ of the bond between them.

Energy and force are related by the definition:

$$F = \frac{dU}{dr}$$

$$= U_0 \left\{ (-2a)\, \exp\left[-2a\,(r - r_0) \right] - 2\,(-a)\, \exp\left[-a\,(r - r_0) \right] \right\}$$

$$= 2aU_0 \left\{ -\exp\left[-2a\,(r - r_0) \right] + \exp\left[-a\,(r - r_0) \right] \right\}$$

Force and stiffness are related by the differential form of Hooke's Law:

$$E = \frac{dF}{dr} = \frac{d^2U}{dr^2}$$

$$= 2aU_0 \left\{ -(-2a)\, \exp\left[-2a\,(r - r_0) \right] + (-a)\, \exp\left[-a\,(r - r_0) \right] \right\}$$

$$= 2a^2 U_0 \left\{ 2 \exp\left[-2a\,(r - r_0) \right] - \exp\left[-a\,(r - r_0) \right] \right\}$$

The initial stiffness that would be exhibited in a stress–strain test can now be predicted by setting $r = r_0$:

$$E_{initial} = 2a^2 U_0 \left\{ 2 \exp[0] - \exp[0] \right\} = 2a^2 U_0 \left\{ 2 - 1 \right\} = 2a^2 U_0$$

This type of analysis lies at the heart of many materials modeling programs.

Quantitative Prediction of Elastic Behavior in a Molecular Solid. Here we consider materials in which the basic unit of structure is a flexible chain of covalently bonded atoms. Flexibility is afforded by the backbone bonds being able to rotate, as illustrated in Figure I.1.3.5.

Such rotations allow the chains to adopt many different conformations (shapes), and are therefore associated with increased entropy. By quantifying how stretching the material restricts the number of conformations accessible to the chains, it is possible to calculate the accompanying entropy change, and hence the change in free energy. It is then simple to proceed from the relationship between energy and strain to a relationship between force (or stress) and strain, as we saw in the previous example.

We start by fixing one end of a chain at the origin (0,0,0) of a (Cartesian) coordinate system. Let the other end be at position (x,y,z). The probability of this
FIGURE I.1.3.5 Schematic illustration of a linear polymer chain, where vertices denote the location of backbone atoms. The black and blue lines together represent an extended (rod-like) conformation (shape) of the molecule. Rotation around backbone bonds can produce many other conformations, conferring flexibility on the molecule. For example, rotation around bond AB can move the segment denoted in blue to the position denoted in red, leading to a more compact conformation.

happening depends on the number of possible chain conformations between the ends thus positioned.

We make some assumptions that will simplify the subsequent mathematics without diminishing the lessons that are learned from this example. The assumptions are: (1) the chains are freely-jointed, which means that we do not impose specific valence angles on the covalently bonded atoms; (2) each chain follows a random walk between its ends, which is only strictly true while the material remains unstretched; (3) the chains have length but no width, so that self-intersection is allowed; and (4) the chains are infinitely long.

A Gaussian (statistical) analysis of random walks can be used to show that the number of conformations between the ends of a chain with ends at (0,0,0) and (x,y,z) is proportional to:

$$P(x, y, z) = \left(\frac{3}{2\pi\, nl^2} \right)^{\frac{3}{2}} \exp\left[-\left(\frac{3}{2\, nl^2} \right) \left(x^2 + y^2 + z^2 \right) \right]$$

Here n is the number of links in the flexible chain, and l is the length of each link. The quantity nl^2 represents the mean square end-to-end distance of the chains $\langle r^2 \rangle$, i.e., the root mean square end-to-end distance $\sqrt{\langle r^2 \rangle}$ is equal to $\sqrt{n}\, l$, consistent with the properties of a random walk. The entropy of the chain is therefore:

$$S = k \ln W$$

where W is the number of ways in which the chain can be rearranged between its fixed end points, and k is Boltzmann's constant:

$$= k \ln \left[C \cdot P(x, y, z) \right]$$

where C is a constant:

$$= k \left[\text{constant} - \left(\frac{3}{2\, nl^2} \right) \left(x^2 + y^2 + z^2 \right) \right]$$

Now consider stretching the chain to extension ratios λ_x, λ_y, λ_z, along axes x, y, and z respectively. After stretching:

$$S_{new} = k \left[\text{constant} - \left(\frac{3}{2\, nl^2} \right) \left(\lambda_x^2 x^2 + \lambda_y^2 y^2 + \lambda_z^2 z^2 \right) \right]$$

Therefore, as a result of stretching:

$$\Delta S = S_{new} - S$$
$$= -k\frac{3}{2\,nl^2}\left[(\lambda_x^2 - 1)\,x^2 + (\lambda_y^2 - 1)\,y^2 + (\lambda_z^2 - 1)\,z^2\right]$$

This change in entropy reflects the decreased number of conformations available to the chain when stretched – in other words, the stretched state is less probable than the relaxed state. Now consider all the chains in a unit volume of the material:

$$\Delta S = -k\frac{3}{2\,nl^2}$$
$$\left[(\lambda_x^2 - 1)\sum x^2 + (\lambda_y^2 - 1)\sum y^2 + (\lambda_z^2 - 1)\sum z^2\right]$$

But $x^2 + y^2 + z^2 = r^2$, where r is the straight line distance between the ends of each chain. So, because the distribution of chains is spherically symmetrical in the undeformed state:

$$\sum x^2 = \sum y^2 = \sum z^2 = \frac{1}{3}\sum r^2$$

$$= \frac{1}{3}N\langle r^2\rangle \text{ if } N \text{ is the number of chains per unit volume}$$

$$= \frac{1}{3}N\,nl^2 \text{ because freely-jointed chains are assumed.}$$

$$\therefore \Delta S = -k\frac{3}{2\,nl^2}\left[(\lambda_x^2 - 1)\frac{1}{3}Nnl^2 + (\lambda_y^2 - 1)\frac{1}{3}Nnl^2\right.$$
$$\left. + (\lambda_z^2 - 1\frac{1}{3}Nnl^2]\right.$$

$$= -\frac{1}{2}Nk\left[\lambda_x^2 + \lambda_y^2 + \lambda_z^2 - 3\right] \text{ per unit volume.}$$

If we assume that the work done (energy needed) to stretch the chains is only used to decrease entropy, i.e., the chain conformations change, but the bonds are not stretched, then:

$$\Delta U = -T\,\Delta S = +\frac{1}{2}NkT\left[\lambda_x^2 + \lambda_y^2 + \lambda_z^2 - 3\right]$$

per unit volume,
where T denotes absolute temperature.

This result is similar in structure to the formula for stored energy per unit volume during the elastic deformation of a metal, ceramic or glass (see the section on "Resilience" below):

$$\Delta U = \frac{1}{2}(\text{Young's modulus}) \cdot (\text{strain})^2$$

We therefore refer to:
NkT as the *statistical modulus* or *rubber modulus*, and
ΔU as the *stored energy function* (SEF).
Now consider the bulk deformation of rubber.

On stretching: $l_1 \rightarrow l_1\,\lambda_x = l_2$

$$b_1 \rightarrow b_1\,\lambda_y = b_2$$

$$t_1 \rightarrow t_1\,\lambda_z = t_2$$

Conservation of volume requires that:

$$l_1\,\lambda_x \cdot b_1\,\lambda_y \cdot t_1\,\lambda_z = l_1 \cdot b_1 \cdot t_1$$

$$\therefore \lambda_x \cdot \lambda_y \cdot \lambda_z = 1$$

Assuming that the force is applied uniaxially along x, and that the transverse response is uniform ($\lambda_y = \lambda_z$) leads to:

$$\lambda_x = \frac{1}{\lambda_y^2} \equiv \frac{1}{\lambda_z^2}$$

$$\therefore \lambda_y^2 \equiv \lambda_z^2 = \frac{1}{\lambda_x}$$

Substituting this result into the SEF gives:

$$\Delta U = \frac{1}{2}NkT\left[\lambda_x^2 + \lambda_y^2 + \lambda_z^2 - 3\right] = \frac{1}{2}NkT\left[\lambda_x^2 + \frac{1}{\lambda_x} + \frac{1}{\lambda_x} - 3\right]$$

$$= \frac{1}{2}NkT\left[\lambda_x^2 + \frac{2}{\lambda_x} - 3\right]$$

The total work done in deforming the entire volume of the sample is therefore:

$$\Delta U_t = \frac{1}{2}NkT\left[\lambda_x^2 + \frac{2}{\lambda_x} - 3\right] \cdot l_1 \cdot b_1 \cdot t_1$$

This work is related to the necessary force by:

$$F = \frac{d(\Delta U_t)}{dl} = \frac{d(\Delta U_t)}{d\lambda_x}\frac{d\lambda_x}{dl} = \frac{d(\Delta U_t)}{d\lambda_x}\frac{1}{l_1}$$

$$\therefore F \cdot l_1 = \frac{d(\Delta U_t)}{d\lambda_x} = \frac{1}{2}NkT\left[2\lambda_x - \frac{2}{\lambda_x^2}\right] \cdot l_1 \cdot b_1 \cdot t_1$$

$$\therefore F = NkT\left[\lambda_x - \frac{1}{\lambda_x^2}\right] \cdot b_1 \cdot t_1$$

$$\therefore \sigma_n = \frac{F}{b_0 \cdot t_0} = NkT\left[\lambda_x - \frac{1}{\lambda_x^2}\right]$$

$$= NkT\left[(\varepsilon_n + 1) - \frac{1}{(\varepsilon_n + 1)^2}\right] \text{ because } \varepsilon_n = \frac{l_2 - l_1}{l_1} = \lambda_x - 1$$

We now have a result that predicts the relationship between nominal stress and nominal strain for a molecular solid that consists of flexible chains of covalently bonded atoms. Such a material is known as an *elastomer*. The correspondence between theory and experiment is good (perhaps surprisingly, given the number of assumptions in this relatively simple model), up to an extension ratio of about six. At higher extension ratios, the chains are far from the assumed condition of a random trajectory, and the effects of finite chain length become significant. Also, at that stage of sample deformation the molecules are so well-ordered that crystallization can occur, and so the material no longer has the flexibility that is characteristic of an elastomer.

Examples of elastomers include both natural and synthetic rubber, as well as the tissue that comprises arterial walls. The relationship derived above shows that the stress required to maintain a given strain is an increasing function of temperature. We therefore see that arteries are more resistant to dilation a higher temperatures, requiring a corresponding increase in the effort expended by the heart to maintain blood circulation. This can be a contributing factor to heat stroke.

Plastic Deformation

Yield Strength and Ductility. We return now to consider additional mechanical properties that can be gleaned from nominal stress versus nominal strain curves such as those shown in Figures I.1.3.2 and I.1.3.3. As the stress on a material increases, a point may be reached where the response is no longer linear. There is a permanent (irreversible) deformation, i.e., deformation that is not recovered on removing the stress. This means that some rearrangement of the atoms or molecules must have been triggered. Irreversible deformation is known as *plastic* deformation. It occurs commonly in metals and polymers, and rarely in ceramics.

The amount of plastic deformation associated with a given stress is found by drawing a line from the point of interest on the stress–strain curve, parallel to the initial linear segment of the curve, and marking the point where this constructed line intersects the horizontal (strain) axis. The horizontal distance from the origin to the point of intersection is a measure of the plastic strain. The value of plastic strain required to break the material defines the *ductility* (Figure I.1.3.3). The stress at which departure from a linear stress–strain relationship occurs is known as the *proportional limit* (Figure I.1.3.3).

It is not always easy to ascertain the proportional limit accurately, and so a more practical determination of the condition for plastic deformation is provided by the *yield strength* (Figure I.1.3.3), which is the stress at which *noticeable* plastic strain occurs. In this context, "noticeable" is often taken to be a value of 0.002 (0.2%) for metals – although it may be chosen to be much higher in polymers, where elastic behavior persists to strains that may be ten or even a hundred times higher, and where the transition from elastic to plastic behavior may be difficult to pinpoint.

A marked *yield drop* is often displayed in the stress versus strain plot when the yield stress of a polymer is exceeded (Figure I.1.3.2). The yield drop occurs because the polymer chains become partially aligned during initial deformation, allowing easier relative motion of chains and reducing the stress needed to further deform the material. The chains then straighten and extend as deformation continues, requiring little increase in stress. Eventually, the opportunities for relative motion of chains are exhausted, along with the capacity for additional chain extension, and the stress versus strain plot then rises sharply.

Strength and Failure. Failure of a loadbearing material occurs when the material ceases to perform its loadbearing function. Different interpretations of "failure" are in common use, and so it is important to be clear about the intended meaning when we speak of materials failure.

For materials that must not undergo in situ permanent deformation, failure is synonymous with the yield stress being exceeded, and so the yield stress represents an estimate of the strength of the material in those cases.

For materials in which permanent deformation (and the attendant shape change) is acceptable, failure may be deemed to occur when a noticeable "neck" (constriction) develops in the material. The effect of the neck is to concentrate the load on a smaller area; therefore, the load that can be supported by the sample is decreased. On a nominal stress versus nominal strain plot, where stresses are referred to the *original* loadbearing areas of the sample, the stress required for additional deformation decreases. Therefore, the onset of necking corresponds to a maximum in the nominal stress versus nominal strain plot, defining the *ultimate tensile strength* (UTS) or simply the *tensile strength* of the material (Figure I.1.3.3). There is no corresponding maximum on a true stress versus true strain plot, because the stress continues to rise past the onset of necking as values of stress are obtained by dividing the applied load by the actual (small) cross-section of the neck.

On both nominal stress versus nominal strain and true stress versus true strain plots, a *breaking strength* can be defined at the point where the material actually breaks. However, to reach this point practically, at least in the case of most metals, the tensile strength of the material must first be reached, and it is tensile strength that represents the practically measurable maximum stress that a metal can survive. Ceramics, on the other hand, usually reach their breaking stress before they yield.

Thus, the perceived strength of a material depends in part on the definition of failure that is used (onset of plastic deformation, onset of necking, or actual occurrence of breaking). It also depends on the conditions that are used for testing. The *strain rate* used in a tensile test can affect the maximum stress that is reached, depending on the ability of the microstructure to undergo rearrangement to accommodate the imposed deformation.

Over long periods of time, even stresses that are below the conventionally measured yield strength of a material may be sufficient to cause gradual elongation and eventual failure via *creep*. Therefore, creep tests, in which a fixed load is applied while the strain is monitored until the sample breaks, are important for materials that are required to have a long projected service life – as is the case with many implants.

Similarly, materials that will be subjected to cyclic loading patterns during service may undergo *fatigue* failure at loads that are smaller than those needed to trigger failure in a conventional stress versus strain test. Testing to determine the relationship between average load,
FIGURE I.1.3.6 True stress and sample geometry in the vicinity of a neck.

FIGURE I.1.3.7 Considère's construction for determining the stability of a neck. At all points between A and B on the true stress versus nominal strain plot shown, the local slope $d\sigma_t / d\varepsilon_n$ of the plot is less than the local value of $\sigma_t / (\varepsilon_n + 1)$.

maximum and minimum load, and the number of loading cycles that lead to failure is required in such cases. Finally, the catastrophic failure of a material can be triggered by pre-existing flaws that locally concentrate the effect of an applied stress. We will explore this phenomenon in the section "Statistical Aspects of Failure."

Stability of Necks. A neck will be stable if its formation is accompanied by sufficient *work hardening*, i.e., by microstructural changes that increase the resistance of the material to further deformation and thus increase the load that can be carried by the necked region. Referring to Figure I.1.3.6 we see that this condition requires:

$$(\sigma_t + d\sigma_t)(A - dA) \geq \sigma_t A$$

$$\therefore \sigma_t A - \sigma_t dA + A d\sigma_t - dA d\sigma_t \geq \sigma_t A$$

$\therefore -\sigma_t dA + A d\sigma_t \geq 0$ if we neglect the product of infinitesimals.

$$\therefore \frac{d\sigma_t}{\sigma_t} \geq \frac{dA}{A}$$

We need to convert the change in area into a change in length, in order to write this condition in terms of stress and *strain*. Because the deformation is *plastic* at the stage where necking occurs, we can assume constant volume:

$$(A - dA)(l + dl) = Al$$

$$\therefore Al + A dl - l dA - dA dl = Al$$

$\therefore A dl - l dA = 0$ if we again neglect the product of infinitesimals.

$$\therefore \frac{dA}{A} = \frac{dl}{l}$$

$$\therefore \frac{d\sigma_t}{\sigma_t} \geq \frac{dl}{l}$$

$\therefore \dfrac{d\sigma_t}{\sigma_t} \geq d\varepsilon_t$ from the definition of ε_t.

But previously (see section "True Stress and True Strain") we saw that $\varepsilon_t = \ln(\varepsilon_n + 1)$. Therefore:

$$\frac{d\varepsilon_t}{d\varepsilon_n} = \frac{1}{\varepsilon_n + 1}$$

$$\therefore d\varepsilon_t = \frac{d\varepsilon_n}{\varepsilon_n + 1}$$

$$\therefore \frac{d\sigma_t}{\sigma_t} \geq \frac{d\varepsilon_n}{\varepsilon_n + 1}$$

$$\therefore \frac{d\sigma_t}{d\varepsilon_n} \geq \frac{\sigma_t}{\varepsilon_n + 1} \text{ for stability}$$

This is Considère's criterion. Applied graphically (Figure I.1.3.7) it is known as Considère's construction.

Hardness

The hardness of a material is measured by applying a known load to a small indenter of known geometry (typically pyramidal or spherical) in contact with the surface of the material, for a known period of time. The dimensions of the resulting indentation are measured, and this information, together with the experimental conditions, is used to rate the hardness of the material on a relative scale.

Indents made in a soft material under a given set of conditions are larger than those made in a hard material. Therefore, hardness provides a measure of how successfully a material resists plastic deformation, which in turn is characterized by both yield strength and tensile strength. It is therefore possible to empirically develop calibration charts that can be used to convert hardness measurements into both yield strength and tensile strength values.

Hardness testing is popular for estimating the yield strength and tensile strength of materials because the equipment is relatively simple and inexpensive, and the tests are nondestructive.

Resilience

Resilience is a measure of the *elastic energy* that can be stored in a unit volume of stressed material. It corresponds to the area underneath a stress versus strain plot, extending from zero strain up to the strain at which the sample yields:

$$U_r = \int_0^{\varepsilon_y} \sigma d\varepsilon$$

If the stress versus strain relationship is linear up to the yield strain (typical for ceramics, and approximate for many metals and polymers), the corresponding area under the stress versus strain plot is triangular, and the integral in the previous equation simplifies to:

$$U_r \cong \frac{1}{2}\sigma_y\varepsilon_y = \frac{\sigma_y^2}{2E}$$

Resilience is an important consideration for materials that need to be "springy," i.e., that absorb and return significant amounts of energy. Examples include natural and replacement tendons and ligaments, and materials used in foot arch reconstruction or support.

Toughness and Fracture Toughness

Although these two terms sound superficially similar, they refer to quite different properties.

Toughness is a measure of the energy required to deform a unit volume of material to its breaking point. Therefore, the definition is similar to that used for resilience, except that we now take into account the entire area under the stress versus strain plot, extending from zero strain up to the strain at which the sample breaks:

$$U_{break} = \int_0^{\varepsilon_{break}} \sigma d\varepsilon$$

Fracture toughness is a measure of how successfully a material resists the propagation of cracks. Consider a sample of material containing either an internal crack of length 2*a* or a surface crack of length *a*, and subjected to a stress σ, as shown in Figure I.1.3.8. We will explore the former case in detail; the results are identical in the second case.
FIGURE I.1.3.8 Sample geometry used in defining the fracture toughness of a material. Examples of both a surface crack and an internal crack are shown. The cracks are assumed to be cylindrical (blue circles) for ease of mathematical description; a flattened profile (red ellipses) would be more realistic.

When the crack grows, elastic energy stored in the material is used to break bonds and create new surface. The energy released in forming a cylindrical crack is:

$$U_{volume} = \left(\frac{1}{2}\sigma\varepsilon\right) (\text{volume})$$

$$= \left(\frac{1}{2}\sigma\frac{\sigma}{E}\right)(\pi a^2 t) \text{ where } t \text{ represents sample thickness}$$

$$= \frac{\pi \sigma^2 a^2 t}{2E}$$

Exact calculation gives $\dfrac{\pi \sigma^2 a^2 t}{E}$ if we perform a rigorous analysis on a flattened (more realistic) crack rather than the cylindrical one. The energy required to make the surface of the crack (the new interface between the material and its environment) is:

$$U_{surface} = 2 \times 2\,at \times \Gamma_s = 4\,at\,\Gamma_s$$

taking account of the fact that *two* surfaces are created by interrupting bulk material, and using Γ_s to denote energy per unit area of surface.

Propagation (growth) of the crack requires the accompanying energy release to exceed the accompanying energy consumption:

$$\frac{\partial U_{volume}}{\partial a} > \frac{\partial U_{surface}}{\partial a}$$

$$\therefore \frac{\partial}{\partial a}\left(\frac{\pi \sigma^2 a^2 t}{E}\right) > \frac{\partial}{\partial a}(4\,at\,\Gamma_s)$$

$$\therefore \frac{\pi \sigma^2 t}{E}2a > 4t\,\Gamma_s$$

$$\therefore \sigma > \sqrt{\frac{2E\,\Gamma_s}{\pi\,a}}$$

or we can identify a critical stress σ_c for crack propagation:

$$\sigma_c = \sqrt{\frac{2E\,\Gamma_s}{\pi\,a}}$$

For a material in which plastic deformation occurs while cracks propagate, the factor Γ_s is increased accordingly. The previous equation can be rearranged to give:

$$2^{-1/2}\sigma_c\sqrt{\pi\,a} = \sqrt{E\,\Gamma_s}$$

or, more generally:

$$Y\sigma_c\sqrt{\pi\,a} = \sqrt{E\,\Gamma_s}$$

where *Y* is a constant that depends on sample and loading geometry. Since the quantities on the right-hand side of this equation are material-specific properties, it follows that the expression on the left-hand side is also a material-specific property. It is known as the *fracture toughness* of the material. It quantifies the maximum

size of flaw (crack) that can be tolerated if the material is to support a particular stress. Its units are unusual: $MPa.m^{1/2}$.

The presence of the factor Γ_s in the equation for fracture toughness emphasizes that the ability of a material to resist fracture *depends on the environment* in which it is tested. In particular for biomaterials, where long in-service lifetimes are required and expected, it is important for mechanical testing to be performed under environmental conditions that are properly representative of the conditions that will be encountered by the material when in service.

Statistical Aspects of Failure

Microstructural variability between samples, especially the distribution of pre-existing flaws of different sizes, leads to variable results in tests of mechanical properties. From an engineering design point of view, materials selection should be guided by the low values of whatever property is (or properties are) relevant to the product being able to perform properly. Even if a property such as ultimate tensile strength is high on average, it is the probability of encountering a sample with a low value of tensile strength that must be used to inform the choice of safe design limits. Thus, statistical measures of spread in measured data – and hence of a material's reliability – are needed.

Consider a batch of samples, each of which is tested to determine the ultimate tensile strength. Let $\mathfrak{F}$ denote the fraction of those samples that have failed at a stress σ. $\mathfrak{F}$ therefore represents a cumulative failure probability, and it is an increasing function of σ. It can be shown that, if all the samples have the same size and shape:

$$\mathfrak{F} = 1 - \exp\left(-\frac{\sigma}{\sigma_0}\right)^m$$

where the parameters m and σ_0 are characteristic of the material, and m is known as the *Weibull modulus*. Therefore:

$$1 - \mathfrak{F} = \exp\left(-\frac{\sigma}{\sigma_0}\right)^m$$

$$\therefore \frac{1}{1-\mathfrak{F}} = \exp\left(\frac{\sigma}{\sigma_0}\right)^m$$

$$\therefore \ln\left(\frac{1}{1-\mathfrak{F}}\right) = \left(\frac{\sigma}{\sigma_0}\right)^m$$

$$\therefore \ln\left[\ln\left(\frac{1}{1-\mathfrak{F}}\right)\right] = m \ln\sigma - m \ln\sigma_0$$

So a plot of $\ln\left[\ln\left(\frac{1}{1-\mathfrak{F}}\right)\right]$ versus $\ln\sigma$ will yield a straight line with slope equal to the Weibull modulus of the material. The term "modulus" is sometimes incorrectly interpreted here as referring to a type of stiffness, because of its frequent association with elastic constants. However, in *all* the senses that it is used in this chapter, "modulus" simply means "number," in keeping with its origin in the Latin word *modulus*, a (small) measure.

Engineering materials that are required to exhibit great in-service reliability, for example the metal alloys used in critical aircraft components, exhibit Weibull moduli well over 100. In contrast, ordinary glass has a Weibull modulus of around 5, and common ceramics typically have Weibull moduli in the range $5 \leq m \leq 25$. Perhaps surprisingly, the Weibull modulus of natural materials can be quite low. Despite their reputation for high *average* breaking strength, stiffness, and toughness in conventional tensile tests, natural silk fibers exhibit low Weibull moduli (5.8 for silkworm silk, and 3.4 for spider dragline). The poor *reproducibility* of breaking strength constrains our ability to incorporate these materials in reliable design, and suggests that their best use might be in composites where applied loads are distributed across multiple fibers.

OTHER BULK PROPERTIES

The bulk properties of a material are of course not limited to performance in mechanical tests. Other types of bulk properties that may have to be taken into account during the selection of a biomaterial include: thermal properties; optical properties; electrical properties; and magnetic properties. Even cost – financial and environmental – can be considered to be a bulk property, given the dependence of cost on: (1) the type and volume of material that is used; and (2) the complexity of microstructural rearrangement during processing.

Thermal Properties

Thermal conductivity becomes a significant consideration if an implanted material contributes to an unnatural flow of heat through the surrounding tissue. For example, metal rods selected for their combination of stiffness, strength, fracture toughness, and biocompatibility can promote heat loss and cause the patient to feel colder than normal. Heat conduction through a metal dental filling can also be a source of discomfort, and may therefore play a role in the choice between a metal or non-metal filling.

Thermal expansion is a (nominal) strain that occurs when the temperature of a material is changed:

$$\varepsilon_{thermal} = \alpha \left(T_{final} - T_{initial}\right)$$

where α is the thermal expansion coefficient; its units are $(degrees)^{-1}$, with "degrees" measured on whatever standard scale is used to measure temperature T.

Attempts to match the properties of a dental filling to those of the surrounding tissue must therefore extend

beyond achieving compatible elastic constants (see section "Elastic Constants") to include consideration of thermal expansion, to avoid premature failure of the interface.

Optical Properties

In the context of biomaterials, the most significant bulk optical properties are color, refractive index, and transparency; all three are important in the selection of materials for intraocular lenses or fluids.

The color of a transparent material is controlled by composition, and therefore demands a high degree of quality control to avoid impurities that could adversely affect color. Long-term stability of material composition is also important: components should not selectively diffuse into the surrounding tissue, and no chemical changes should occur – either by reactions between the components or in response to light.

Refractive index n of a material is defined as:

$$n = \frac{c_{vacuum}}{c_{material}}$$

where c denotes the speed of light in the subscripted medium.

When light crosses the interface between two media (materials), it is deviated from its original path by an angle that is an increasing function of the difference between the refractive indices of the media. Therefore, the effectiveness of a material as a lens is directly related to its refractive index. Refractive index increases along with the content of electron-rich atoms, which is why lead "crystal" is so useful in both lenses and decorative glassware.

Transparency is a qualitative term that describes the ability of a material to transmit light without attenuating (absorbing or scattering) it. To minimize absorption, the primary bonds in the material must be strongly covalent or ionic (and definitely not metallic). Scattering is minimized if the material is free of internal interfaces (which could reflect light) and compositional differences (which would be associated with refractive index differences that could deviate light from an uninterrupted path through the material). Thus, an optimally transparent material will either be a homogenous single crystal or it will be completely and homogeneously amorphous.

There is no commonly accepted quantitative definition of transparency. Instead, it is usual to consider the complementary property, *opacity*. This is itself a colloquial term, but it lends itself to a more formal description by way of the *mass attenuation coefficient*. If light of a given frequency (color) and initial intensity I_0 travels a distance x through a material, then the intensity is decreased to:

$$I(x) = I_0 \exp(-\mu \rho x)$$

where μ is the mass attenuation coefficient of the material, and ρ is the density.

Weibull Modulus and Non-Brittle Materials

The Weibull distribution of fracture probability for materials provides a statistical measure of brittleness, via the specification of a Weibull modulus m (Derby et al., 1992). The value of m can in theory range from zero (totally random fracture behavior, where the failure probability is the same at all stresses, equivalent to an ideally brittle material) to infinity (representing a precisely unique, reproducible fracture stress, equivalent to an ideally non-brittle material).

This quantitative approach to defining non-brittleness is more robust than qualitative description, since there is no single antonym of "brittle." Both "tough" and "ductile" are in particular senses the opposite of "brittle," but we have seen that "tough" and "ductile" are not interchangeable, and their corresponding nouns are associated with very different features on a stress–strain curve (Figure I.1.3.3).

Weibull statistics were initially adopted to quantify failure in classically brittle materials (Kelly and Macmillan, 1986) where tensile strength is dominated by the size distribution of pre-existing flaws, and the use of this method is rarely extended to materials that are regarded as non-brittle. However, there is no *a priori* reason to restrict Weibull statistics to the analysis of failure in classically brittle materials. For example, although natural silks exhibit large extensions to failure, and many of them behave like an elastomer at least during the initial stages of deformation, Weibull analysis has proved to be useful for characterizing and contextualizing the failure strength variability of these materials (Pérez-Rigueiro et al., 1998, 2001).

Why *is* a Weibull analysis appropriate for non-brittle materials? A justification can be formulated simply on phenomenological grounds: after significant deformation, silk *develops* the statistical failure *characteristics* of a brittle material, even though it initially deserves classification as an elastomer. While the existence of strength-limiting defects can be inferred from this description, their nature has yet to be confirmed; it is not clear whether they are present in as-spun material, or whether they begin to develop during the earlier stages of deformation.

The appropriateness of Weibull analysis for a non-brittle material can also be justified fundamentally (Viney, 2002), given the equation that is used as the basis for measuring m (section "Statistical Aspects of Failure"):

$$1 - \mathfrak{F} = \exp\left(-\frac{\sigma}{\sigma_0}\right)^m$$

If F is to be independent of σ, which is the hallmark of an ideally brittle material, this equation requires m to be equal to zero. However, practical Weibull analysis necessarily admits to non-zero values of m, so it is implicit that ductile contributions to failure can also be accommodated.

WORKED EXAMPLE

QUESTION:

A stainless steel rod with a circular cross-section has a length of 100 mm and a diameter of 2.0 mm. It is deformed elastically in compression by a force of 500 N applied parallel to its length. The material has a Young's modulus of 200 GPa, a shear modulus of 77 GPa, and a yield strength of 0.3 GPa. Calculate: (1) the amount by which the rod will decrease in length; and (2) the amount by which the rod will increase in diameter.

SOLUTION:

(1) Deformation is elastic, so we can use Hooke's Law:

$$\sigma = E\varepsilon$$

$$\therefore \varepsilon = \frac{\sigma}{E} = \frac{F/A_1}{E} = \frac{F}{EA_1} = \frac{F}{E\,\pi\left(d_1/2\right)^2} = \frac{4F}{E\,\pi\,d_1^2}$$

where the symbols are used consistently with their meaning elsewhere in this chapter; d_1 is the initial diameter of the rod. But:

$$\varepsilon = \frac{l_2 - l_1}{l_1} = \frac{\text{elongation}}{l_1}$$

$$\therefore\ \text{elongation} = l_1\,\varepsilon = \frac{4Fl_1}{E\,\pi\,d_1^2} = \frac{(4)(-500\ \text{N})(0.1\ \text{m})}{\left(200\times10^9\,\frac{\text{N}}{\text{m}^2}\right)\pi(0.002\ \text{m})^2}$$

$$= -7.96\times10^{-5}\ m\ \text{or}\ -0.0796\ \text{mm}$$

The negative value of force is used because the rod is loaded in compression.

(2) We need a value of Poisson's ratio, which can be obtained from the two elastic constants provided if we use the following equation from the section "Elastic Constants":

$$G = \frac{E}{2(1+\nu)}$$

Rearrangement and substitution gives:

$$\nu = \frac{E}{2G} - 1 = \frac{200\times10^9\,\frac{\text{N}}{\text{m}^2}}{2\times77\times10^9\,\frac{\text{N}}{\text{m}^2}} - 1 = 0.299$$

Now we can use the definition of Poisson's ratio, ν:

$$\nu = -\frac{\varepsilon_{transverse}}{\varepsilon_{longitudinal}} = -\frac{\dfrac{d_2-d_1}{d_1}}{\dfrac{l_2-l_1}{l_1}} = -\left(\frac{d_2-d_1}{d_1}\right)\left(\frac{l_1}{l_2-l_1}\right)$$

$$\therefore\ d_2 - d_1 = -\nu d_1\left(\frac{l_2-l_1}{l_1}\right)$$

$$= -(0.299)(0.002\ \text{m})\left(\frac{-7.96\times10^{-5}\ \text{m}}{0.1\ \text{m}}\right)$$

$$= 4.76\times10^{-7}\ \text{m or}\ 4.76\times10^{-4}\ \text{mm}$$

The value of the yield strength that was provided in the question is apparently superfluous. However, it is useful for checking whether the given load does indeed cause only elastic deformation as claimed. The stress on the rod is:

$$\sigma_n = \frac{F}{A_1} = \frac{-500\ \text{N}}{\pi\,(0.001\ \text{m})^2} = \frac{-3,000\ \text{N}}{\pi\,(0.001\ \text{m})^2} = 0.159\ \text{GPa}$$

This result is well below the quoted yield strength of 0.3 GPa, and so is consistent with the deformation being elastic.

CHAPTER I.1.4 FINITE ELEMENT ANALYSIS IN BIOMECHANICS

Michael Sacks[1], Antonio D'Amore[2], and Christopher Hobson[2]
[1]Department of Biomedical Engineering, The University Texas at Austin, Austin, TX, USA
[2]University of Pittsburgh, Pittsburgh, PA, USA

INTRODUCTION

In many biomedical engineering design problems, accurate prediction of the biomaterial mechanical response is essential in the development of many prostheses and medical devices. In this process, structural analysis is a critical step in the prediction of fatigue limits and potential failure modalities. Practically, simulation methods are essential since experimental methods often require the creation of expensive, time-intensive prototypes and evaluations. Further, many experimental parameters cannot be directly measured, but can only be computed (e.g., shear stress). Moreover, analytical approaches can only provide a complete solution for simple geometries and loading conditions. In contrast, all biological and biologically derived or inspired materials exhibit pronounced mechanical anisotropy, highly nonlinear stress–strain relationships, large deformations, viscoelasticity, and strong material coupling. Taken as a whole, most biomaterials defy simple material models. Therefore, numerical approaches such as the Finite Element Method (FEM) or the Boundary Element Method (BEM) are more suitable for biomechanical problems. FEM, also known as Finite Element Analysis (FEA), represents the most popular numerical technique to perform stress and strain analysis. Although

the approach was originally formulated to perform structural analyses, it has become increasingly adopted in biomechanics and biomaterial sciences to solve complex multi-physics problems. In the following, we present a brief introduction of the mathematical formulation of FEM for the biomaterials audience. We utilize the infinitesimal strain linear elasticity which, while not realistic for most biological materials, allows the basic theory to be presented with maximum clarity.

OVERVIEW OF THE FINITE ELEMENT METHOD

In FEM, a real structure is replaced by a discrete model obtained by subdivision into a number of finite elements (Figure I.1.4.1). The discretized model is composed of appropriately shaped elements defined by a series of interconnected points known as nodes. The continuum problem with infinite degrees of freedom can thus be reduced to a discrete problem with finite degrees of freedom, and solved computationally with a series of simultaneous algebraic equations. In the ordinary formulation, the displacement field within each finite element is strictly related to nodal displacement by shape functions that can be derived from the interpolation of nodal displacements. Under this assumption, the initial problem can be reduced to a discrete problem where the unknowns are the Cartesian components of the nodal displacements, in effect reducing the initial three-dimensional problem to one with only three degrees of freedom per node (Tottenham and Brebbia, 1970; Zienkiewicz, 1971; Middleton et al., 1996).
FIGURE I.1.4.1 An arbitrary area discretized with tetrahedral elements.

Problem

Consider first the simple case of a triangular plane element defined by three nodes (Figure I.1.4.2a) (Tottenham and Brebbia, 1970; Zienkiewicz, 1971). Two displacement components $u(x,y)$ and $v(x,y)$ of an arbitrary point $P(x,y)$ within the element can be expressed by the relationship (Eq. 1):

$$u(x, y) = a_1 + a_2x + a_3y$$
$$v(x, y) = a_4 + a_5x + a_6y \tag{1}$$
FIGURE I.1.4.2 (a) A triangular element defined by three nodes with an arbitrary point P within the element at position (x,y). (b) Two triangular elements, A and B, defined by four nodes sharing a common edge.

which can be expressed in matrix form as (Eq. 2):

$$\begin{bmatrix} u_i \\ v_i \end{bmatrix} = \begin{bmatrix} 1 & x_i & y_i & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & x_i & y_i \end{bmatrix} \cdot \begin{bmatrix} a_1 \\ a_2 \\ a_3 \\ a_4 \\ a_5 \\ a_6 \end{bmatrix} \tag{2}$$

Assembling the equations for the three nodes ($i = 1,2,3$) we can derive $\vec{d}$, the nodal displacement vector, and $[C]$ the nodal coordinates matrix:

$$\vec{d} = [C] \cdot \vec{a} \tag{3}$$

These relationships enable the displacement of an arbitrary point P within the element to be expressed as a function of the nodal displacements. Solving Eq. 3 for $\vec{a}$ and substituting into Eq. 2.

$$\begin{bmatrix} u_i \\ v_i \end{bmatrix} = \begin{bmatrix} 1 & x_i & y_i & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & x_i & y_i \end{bmatrix} \cdot [C]^{-1} \cdot \vec{d} = [N] \cdot \vec{d} \tag{4}$$

where $[N]$ is the shape function matrix that can be written as (Eq. 4):

$$[N] = \begin{bmatrix} N_{11} & N_{12} & N_{13} & 0 & 0 & 0 \\ 0 & 0 & 0 & N_{24} & N_{25} & N_{26} \end{bmatrix} \tag{5}$$

with:

$$N_{11} = 1 - \frac{1}{2} \left[\frac{(x - x_1)(y_3 - y_2) - (x_3 - x_2)(y - y_1)}{element\ area} \right] \tag{6}$$

The other shape functions can be similarly obtained from Eq. 6. For a two-dimensional triangular element with three degrees of freedom (DoF) nodes (6), the shape functions must be linear. Given the nodal displacements from the derivative of Eq. 4, the relationship between deformation and nodal displacement can be obtained (Eq. 6).

$$\begin{bmatrix} \varepsilon_{xi} \\ \varepsilon_{yi} \\ \gamma_{xyi} \end{bmatrix} = [D] \cdot \begin{bmatrix} u_i \\ v_i \end{bmatrix} \text{ where } [D] = \begin{bmatrix} \dfrac{\partial}{\partial x} & 0 \\ 0 & \dfrac{\partial}{\partial y} \\ \dfrac{\partial}{\partial y} & \dfrac{\partial}{\partial x} \end{bmatrix} \quad (7)$$

$$\vec{\varepsilon} = [D] \cdot [N] \cdot \vec{d} = [B] \cdot \vec{d} \quad (8)$$

$[D]$ is a differential operator. Since the shape functions are linear, the matrix $[B]$ is defined purely by the geometry and orientation of the finite element considered. Under the hypothesis of planar tension, Hooke's law can be written as (Eq. 9):

$$\begin{bmatrix} \sigma_{xi} \\ \sigma_{yi} \\ \tau_{xyi} \end{bmatrix} = \dfrac{E}{(1+v)(1-2v)} \begin{bmatrix} 1-v & v & 0 \\ v & v & 0 \\ 0 & 0 & \dfrac{(1-2v)}{2} \end{bmatrix} \begin{bmatrix} \in_{xi} \\ \in_{yi} \\ \gamma_{xyi} \end{bmatrix}$$

$$(9)$$

$$\vec{\sigma} = [E] \cdot \vec{\varepsilon} \quad (10)$$

Nonlinear Analysis

Modern FEA packages incorporate a Newton–Raphson computational approach to solve nonlinear problems. In this approach, the load is subdivided into a series of load increments. The load increments are then applied over a series of load steps. The program performs a linear solution and checks for convergence. If convergence criteria are not met, the stiffness matrix is updated and a new solution is obtained. This iterative procedure continues until the problem converges. If convergence is not achieved, then the program attempts to solve with a smaller load increment (Bicanic and Johnson, 1979).

Substituting Eq. 8 into Eq. 10 the link between the stress field and nodal displacements (Eq. 11):

$$\vec{\sigma} = [E] \cdot [B] \cdot \vec{d} \quad (11)$$

The displacements, deformations and stress were expressed as a function of the nodal displacements. The nodal displacements can be evaluated with equilibrium equations derived using the virtual work principle, which states that for an arbitrary congruent deformation, the work (virtual) produced by external forces for the related nodal displacements will be equal to the work done by the internal stress throughout the deformation. In matrix form (Eq. 12):

$$\overrightarrow{\delta d}^T \cdot \vec{F} = \int_V \overrightarrow{\delta e}^T \cdot \vec{\sigma} \, dV = \int_V [B]^T \cdot [E] \cdot [B] \, dV \quad (12)$$

Where V is the element volume and $\overrightarrow{\delta d}$ and $\overrightarrow{\delta e}$ are the virtual nodal displacements and the virtual deformations vectors respectively; finally $\vec{F}$ is the nodal force vector (Eq. 13):

$$\vec{F}^T = \begin{bmatrix} F_{1x} & F_{1y} & F_{2x} & F_{2y} & F_{3x} & F_{3y} \end{bmatrix} \quad (13)$$

Fij ($i = 1,2,3$ and $j = x,y$) is the arbitrary force applied to the node i in the direction j. From Eq. 12, defining $[K]$ as the stiffness matrix (6×6) of the element given by Eq. 14 the fundamental FEM equation can be obtained representing the relationship between the forces and nodal displacements (Eq. 16).

$$[K] = \int_V [B]^T \bullet [E] \bullet [B] \, dv = \begin{bmatrix} k_{1x,1x} & k_{1x,1y} & k_{1x,2x} & k_{1x,2y} & k_{1x,3x} & k_{1x,3y} \\ k_{1y,1x} & \cdot & \cdot & \cdot & \cdot & \cdot \\ k_{2x,1x} & \cdot & \cdot & \cdot & \cdot & \cdot \\ k_{2y,1x} & \cdot & \cdot & \cdot & \cdot & \cdot \\ k_{3x,1x} & \cdot & \cdot & \cdot & \cdot & \cdot \\ k_{3y,1x} & \cdot & \cdot & \cdot & \cdot & \cdot \end{bmatrix} \quad (14)$$

$$\vec{F} = [K] \cdot \vec{d} \quad (15)$$

Equation 15 shows that the stiffness matrix term k_{ij} represents the force applied to the node i along the direction x that produces a unitary displacement of the node j along the direction y, assuming all of the other displacements are equal to zero. As a consequence of the Betti Theorem, the stiffness matrix must be symmetric. The

stiffness matrix depends on the element geometry, orientation, and mechanical characteristic of the material described by the matrix $[E]$.

Assembly

An equation similar to Eq. 15 can be written for each of the elements within the model. These equations can be

assembled into a unique system representing the entire model (Eq. 16) where the bar indicates that the vectors and the matrices refer to the global system:

$$\bar{F} = \left[\bar{K} \right] \cdot \bar{d} \qquad (16)$$

In Eq. 16 $\bar{F}$ and $\bar{d}$ represent the organized force and nodal displacement vectors, whereas $\left[\bar{K} \right]$ is the system global stiffness matrix. The latter is a square symmetric matrix having size equal to the number of DoF for the entire model, which is equal to the total number of nodes multiplied by the DoF for a single node. $\left[\bar{K} \right]$ is obtained from the element stiffness matrices where $\bar{k}_{ix,jy}$ represents the force applied to the node i over the direction

x producing the unitary displacement of the node j over the direction y. This force is the sum of the single forces applied to the same node that produces the same effect considering the elements that share nodes i and j separately. The arbitrary element $\bar{k}_{ix,jy}$ is, therefore, the sum of the homologous elements of the matrixes of m elements sharing the nodes i and j (Eq. 17):

$$\bar{k}_{ix,jy} = \sum_{r=1}^{m} k_{ix,jy}^{(r)} \qquad (17)$$

where the index (r) indicates the element. Considering the simple case of two elements A and B sharing the nodes 1 and 3 (Figure I.1.4.2b), the global stiffness matrix is then given by Eq. 18.

$$\begin{bmatrix}
k_{1x,1x}^{a}+k_{1x,1x}^{b} & k_{1x,1y}^{a}+k_{1x,1y}^{b} & k_{1x,2x}^{a} & k_{1y,2y}^{a} & k_{1x,3x}^{a}+k_{1x,3x}^{b} & k_{1x,3y}^{a}+k_{1x,3y}^{b} & k_{1x,4x}^{b} & k_{1x,4y}^{b} \\
k_{1y,1x}^{a}+k_{1y,1x}^{b} & k_{1y,1y}^{a}+k_{1y,1y}^{b} & k_{1y,2x}^{a} & k_{1y,2y}^{a} & k_{1y,3x}^{a}+k_{1y,3x}^{b} & k_{1y,3y}^{a}+k_{1y,3y}^{b} & k_{1y,4x}^{b} & k_{1y,4y}^{b} \\
k_{2x,1x}^{a} & k_{2x,1y}^{a} & k_{2x,2x}^{a} & k_{2x,2y}^{a} & k_{2x,3x}^{a} & k_{2x,3x}^{a} & 0 & 0 \\
k_{2y,1x}^{a} & k_{2y,1y}^{a} & k_{2y,2x}^{a} & k_{2y,2y}^{a} & k_{2y,3x}^{a} & k_{2y,3y}^{a} & 0 & 0 \\
k_{3x,1x}^{a}+k_{3x,1x}^{b} & k_{1x,1y}^{a}+k_{1x,1y}^{b} & k_{3x,2x}^{a} & k_{3x,2y}^{a} & k_{3x,3x}^{a}+k_{3x,3x}^{b} & k_{3x,3y}^{a}+k_{3x,3y}^{b} & k_{3x,4x}^{b} & k_{3x,4y}^{b} \\
k_{3y,1x}^{a}+k_{3y,1x}^{b} & k_{3y,1y}^{a}+k_{3y,1y}^{b} & k_{3y,2x}^{a} & k_{3y,2y}^{a} & k_{3y,3x}^{a}+k_{3y,3x}^{b} & k_{3y,3y}^{a}+k_{3y,3y}^{b} & k_{3y,4x}^{b} & k_{3y,4y}^{b} \\
k_{4x,1x}^{b} & k_{4x,1y}^{b} & 0 & 0 & k_{4x,3x}^{b} & k_{4x,3y}^{b} & k_{4x,4x}^{b} & k_{4x,4y}^{b} \\
k_{4y,1x}^{b} & k_{4y,1y}^{b} & 0 & 0 & k_{4y,3x}^{b} & k_{4y,3y}^{b} & k_{4y,4x}^{b} & k_{4y,4y}^{b}
\end{bmatrix} \qquad (18)$$

Global stiffness matrix terms referring to nodes not shared by elements are equal to zero. Due to the large number of elements composing a finite element model, this condition is frequent. Thus, the global stiffness matrix is a sparse matrix (many elements are equal to zero). Non-zero terms can be grouped along the principal diagonal by appropriately sorting nodes. The result is a band matrix which corresponds to a linear system of equations. Considering the arrangement in Figure I.1.4.3, the resulting matrix (Eq. 19) is a band matrix with a width of 5.

$$\begin{bmatrix}
k_{11} & k_{12} & k_{13} & 0 & 0 & 0 & 0 \\
k_{21} & k_{22} & k_{23} & k_{33} & 0 & 0 & 0 \\
k_{31} & k_{32} & k_{33} & k_{33} & k_{33} & 0 & 0 \\
0 & k_{42} & k_{43} & k_{44} & k_{54} & k_{46} & 0 \\
0 & 0 & * & * & * & * & * \\
0 & 0 & 0 & * & * & * & * \\
0 & 0 & 0 & 0 & * & * & *
\end{bmatrix} \qquad (19)$$

The adoption of band matrices significantly reduces the computational cost to solve a system of linear equations. For this reason industrial finite element (FE) codes

include advanced algorithms to optimize the global stiffness matrix. The ability to reduce the sparse global stiffness matrix to a band matrix represents one of the strengths of FEA over other numerical methods.

Isoparametric Elements

Isoparametric elements can have either straight or curvilinear boundaries, making them useful for the discretization of complex geometries with a limited number of elements. Isoparametric elements are unique in that they utilize the same shape functions to interpolate nodal coordinates and displacements. Unfortunately, switching to an isoparametric element significantly increases computational requirements (Zienkiewicz and Irons, 1969).

Problem Solution

Equation 16 represents a linear system of equations with nodal displacements and nodal forces as unknowns. At free nodes under load, nodal displacements are unknown whilst the forces are known. At constrained nodes, the forces are unknown whilst the displacements are known. It is therefore possible to partition the stiffness matrix by dividing the equation containing the unknown displacements by the equation with unknown nodal forces.
FIGURE I.1.4.3 Approximation of the deformation with higher order displacement functions. (A) Linear; (B) Quadratic; (C) Cubic.

Indicating with d_k and d_u the known and unknown nodal displacements vectors respectively, and with F_k and F_u the known and unknown nodal forces, Eq. 16 can then be rewritten as Eq. 20:

$$\begin{bmatrix} \bar{K}_{11} & \bar{K}_{12} \\ \bar{K}_{21} & \bar{K}_{22} \end{bmatrix} \cdot \begin{matrix} \overrightarrow{\bar{d}_u} \\ \overrightarrow{\bar{d}_k} \end{matrix} = \begin{matrix} \overrightarrow{\bar{F}_k} \\ \overrightarrow{\bar{F}_u} \end{matrix} \tag{20}$$

From which:

$$\bar{K}_{11} \cdot \bar{d}_u + \bar{K}_{12} \cdot \bar{d}_k = \tilde{F}_k \tag{21}$$

$$\bar{d}_u = \bar{K}_{11}^{-1} \left(\tilde{F}_k - \bar{K}_{12} \cdot \bar{d}_k \right) \tag{22}$$

and

$$\tilde{F}_u = \bar{K}_{21} \cdot \bar{d}_u + \bar{K}_{22} \cdot \bar{d}_k \tag{23}$$

Once the nodal displacements are known (Eq. 23), the global solution can be obtained by evaluating the displacement field, the deformations, and tensions on every element (Eqs. 4, 8, and 10) within the entire model.

Solution Accuracy and Convergence

The final result from FEA consists simply of nodal displacements, whereas deformations and tensions can be obtained by numerical derivation of the deformation field. Therefore, the deformations and tensions are inherently less precise than the displacements. Due to the reduction in DoFs, the solution to the elastic problem given by FEA is approximate. The number of DoFs for each finite element is a result of the reduced number of allowed deformations, which in turn are strongly related to the choice of shape function. For the triangular element example, the selection of a linear shape function produces a constant deformation and tension (Eq. 7). As a consequence the deformations and stress field within the model are approximates by step functions (Figure I.1.4.3a). The adoption of higher degree displacement functions (therefore with finite elements of higher complexity) enables for a given element size, a better approximation of the exact solution (Figure I.1.4.3b,c).

Another approach to increase the solution accuracy is to implement a finer mesh within the model, especially where high stress gradients are expected (stress concentrations, concentrated loads, etc.). However, as the number of elements is increased the size of the global stiffness matrix is also increased. The optimal number of elements within the mesh must be verified by performing a convergence test, comparing solutions from meshes of increasing density.

Model Preparation and Element Selection

Mesh generation is a fundamental step that deeply influences the quality of the result. Although general criteria cannot be provided, the following suggestion should be taken into consideration (George, 1991):

- Avoid using irregularly shaped elements. Highly deformed elements can lead to a poorly conditioned simulation, which can increase sensitivity to approximation errors;
- Appropriately refine the mesh at stress concentrations;
- Avoid the adoption of different elements types within the same model;
- Utilize both geometrical and load symmetries, when appropriate, to reduce the problem to a portion of the whole structure;
- In general, the overall precision of the results increases with the increase in the number of DoF per element.

BIOMECHANICS EXAMPLES

A Finite Element Analysis of Glenoid Replacement Prostheses in Normal and Rheumatoid Arthritic Bone

Among glenoid replacement post-operative complications, glenoid component loosening is the most reoccurring problem (Lacroix et al., 2000).

Glenoid prosthesis design can be grouped into two categories: "keeled" or "pegged". The first design is characterized by a tapered "fin" of a rectangular cross-section. The pegged design includes several circular pegs of various lengths inserted into the glenoid volume. A three-dimensional FE model including the entire scapula, cement fixation, and polyethylene keeled glenoid prostheses, was generated to investigate the hypothesis according to which keeled prostheses are performing better than pegged designs in patients affected by rheumatoid arthritis. Quantitative computed tomography (qCT) and experimental driven muscle loading

were adopted to recapitulate bone geometry, material property, and a realistic mechanical loading scenario. Three-dimensional brick and wedge elements were used to generate the bone, the cement, the pegged (8148 elements) and keeled (8411 elements) prostheses meshes (Figure I.1.4.4).

Results showed that the stresses in the polyethylene components for both designs were not high enough (~2 MPa) to cause failure. In contrast, twisting of the components was shown to occur, and was more prominent in the pegged prosthesis. More importantly, the analysis demonstrated a clear distinction in the

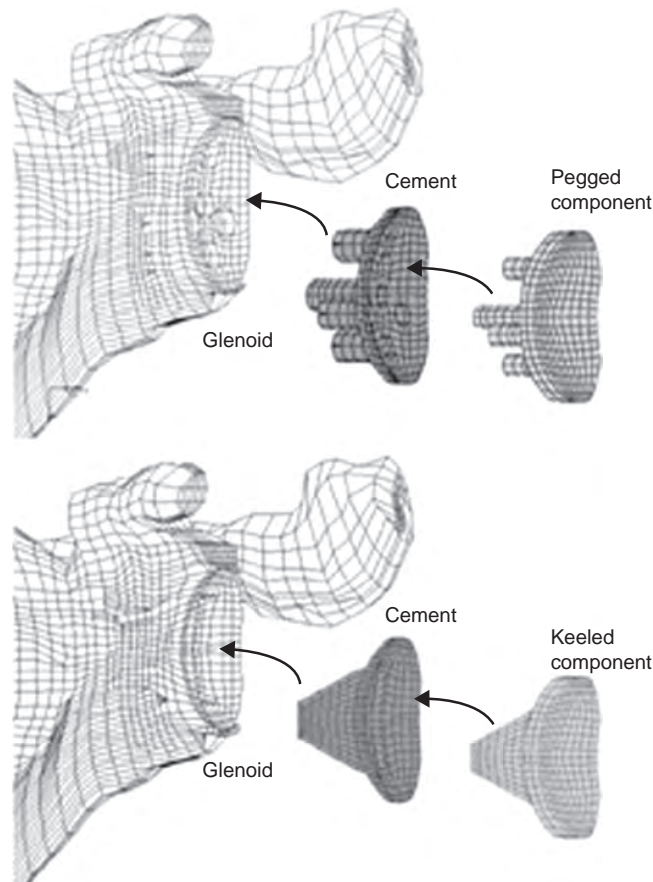
prostheses' performance depending on the patient's bone quality. The starting hypothesis derived from the clinical experience was confirmed: in normal bone keeled design (94% and 68% probability to survive for the pegged and keeled prostheses, respectively) has a larger volume of highly stressed cement, compared to the pegged design (Figure I.1.4.5A). In simulated rheumatoid arthritic bone the situation reverses. A limited fraction of cement around the keeled design (86% and 99% probability to survive for the pegged and keeled prostheses respectively) is highly stressed because the large majority of the load is carried by the cortical shell, whereas the pegged


FIGURE I.1.4.4 Exploded view of the insertion of pegged and keeled prostheses.
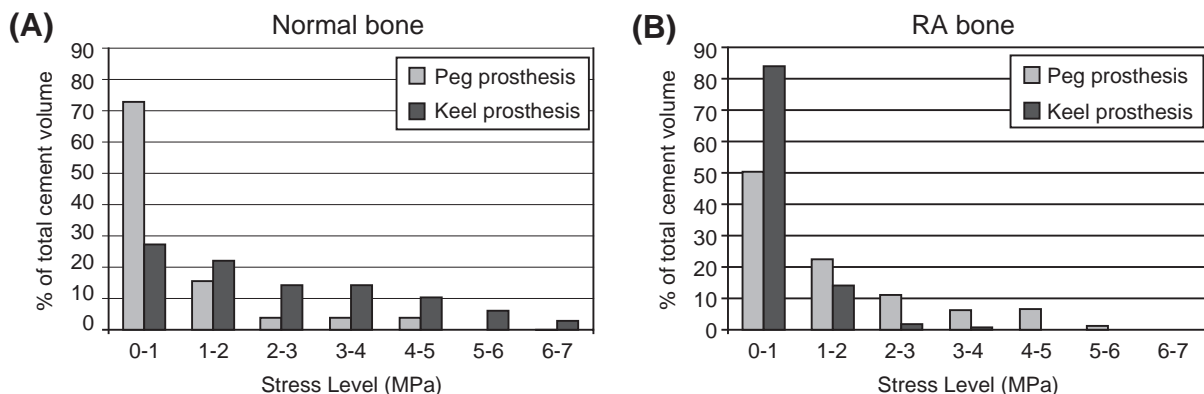

FIGURE I.1.4.5 Maximal principle stress distribution for the pegged and keeled prostheses in: (A) normal bone; and (B) rheumatoid bone.

prosthesis has a greater volume of highly stressed cement (Figure I.1.4.5B). This study demonstrates the importance of a holistic approach to the design of orthopedic prostheses in diverse patient populations.

Finite Element Analysis of a Glass Fiber Reinforced Composite Endodontic Post

In this work the mechanical behavior of a new polymeric composite endodontic post reinforced with glass fibers was analyzed through experimental and FE analysis (Pegoretti et al., 2002). Implant (Model D; Figure I.1.4.6) performance was compared with commercially available carbon fiber reinforced (Model C; Figure I.1.4.6) and gold alloy cast posts (Model B; Figure I.1.4.6). A natural tooth model (Model A; Figure I.1.4.6) restored with ideal materials, whose stiffness is equal to those of enamel and dentine, will be considered as a reference.

The main design target was to minimize the rigidity difference between the dentine and the post. The composite post consisted of unidirectional continuous E-glass fibers (Hybon® 2001 by PPG Industries) up to a volume fraction of 60% embedded in a matrix of acrylic resin, whose main component is 2,2-bis[4-(2-hydroxy-3-methacryloyloxypropoxy)-phenyl]-propane. Two-dimensional models of the vertical section of an upper central incisor were developed under the hypothesis of plane strain fields. Models were composed of 3500–4500 nodes and 3700–4400 quadrilateral and triangular elements. Elastic constants were empirically derived or selected from the literature. Von Mises equivalent stress and shear stress were identified as critical parameters for evaluation of the FE simulation results. Von Mises equivalent stress was chosen as an indicator of the average stress level. High stress values are associated with zones of higher probability of damage. Similarly, high shear stress can lead to failure of the tooth–post interface and to post detachment. Von Mises and shear stress maps were obtained for the four models under three different load configurations: a vertical load (100 N, see Figure I.1.4.7); an oblique load (50 N); and a horizontal load (10 N). FE results showed that the gold alloy cast post and core produced the greatest stress concentration at the post-dentine interface, whereas the carbon fiber-reinforced composite posts were characterized by high stresses in the cervical region due to increased flexibility and less stiff core material. Finally, the glass fiber composite, having a stiffness much closer to dentine, exhibited the lowest peak stresses within the root. The glass fiber composite post induced a stress field quite similar to that of the natural tooth. The FE analysis was crucial to identify the glass fiber composite post as the best design strategy, and to elucidate how its mechanics recapitulate the one of the natural tooth model.

A Finite Element Multiscale Approach Methodology for Predicting Mechanical Behavior of Collagen Fibers

Most biological tissues serving a predominately mechanical function are based on collagen fiber networks (Stylianopoulos and Barocas, 2007). While the tissue characteristic functional length is of the order of centimeters, the underlying fiber network is on the micrometer scale. In a structural deterministic approach the material microstructure is described in a representative way and coupled to the macroscopic equations through a multi-scale technique. A volume averaging approach replaces the material unit cell by a representative volume element (RVE). The RVE is most easily described as a heterogeneous medium where global continuum fields are locally applied and the macroscopic quantities are then derived from the volume average of the corresponding microscopic quantities. In this work a volume averaged structural model is adopted to study the inherently multiscale mechanical behavior of collagen networks. The model was formulated in two scales: the macroscopic scale that represents the functional level; and the microscopic scale that duplicates the structural level of collagen networks. The macroscopic scale was modeled by a Galerkin FE model with 720 nodes and 2160 degrees of freedom. The microscopic scale, composing the RVE, was represented by an ideal collagen network consisting of struts and nodes. Each of the 3872 RVEs contained roughly 330 cross-links, totaling almost four million degrees of

freedom. Within each RVE, fibers were assumed to obey an exponential stress–strain law neglecting bending stiffness, but presumed to stretch, compress, and rotate at cross-links. The solution algorithm can be summarized in five steps. (1) The macroscopic problem is posed via suitable boundary conditions; (2) the deformation of the RVE boundary of each RVE is determined by the macroscopic deformation field (down-scaling); (3) the force balance at each RVE is solved; (4) the averaged Cauchy stress tensor is calculated (up-scaling) by volume-averaging theory; and (5) the macroscopic force balance is solved. The algorithm iterates until convergence is reached. The macroscopic problem consisted of a rectangular slab of collagen under uniaxial extension. Two different scenarios were studied: (1) a homogeneous slab and a heterogeneous slab composed of two networks of similar density but different orientation; (2) a network with a preferred alignment along the direction of extension and a nearly isotropic network (Figure I.1.4.8A).

The accuracy of the modeling approach was addressed by comparison to experimental data. The simulation was able to quantitatively assess the Poisson ratios (Figures I.1.4.8B and I.1.4.9) and engineering stress–strain curves; both were in good agreement with the experimental data.

The model was also able to predict microscale deformations. Orientation parameters equal to 1/3 for isotropic network and 1 for perfectly aligned network changed according to the local deformation field (isotropic network
FIGURE I.1.4.8 (A) Heterogeneous collagen slab composed of two different microstructures. The central region has a preferred fiber align-ment, while the surrounding region has nearly isotropic orientation. from 0.35338 to 0.38189, aligned network from 0.54856 to 0.5830) indicating that the fibers realign along the direction of extension (Figure I.1.4.10). This work shows the great potential of a multiscale FE approach to both predict and link mechanical responses across different length scales.

A Three-Dimensional Numerical Simulation of Flow Through Mechanical Heart Valves

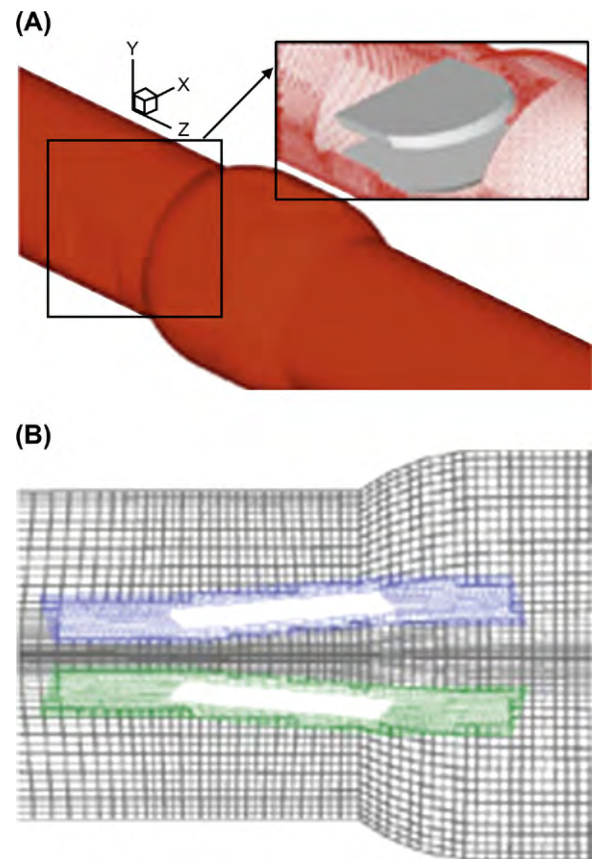
Mechanical heart valves have traditionally represented the gold standard for valvular replacement therapies (Schoen, 2005). Unfortunately, due to the possibility of thromboembolic complications, recipients require lifelong anticoagulation medication. This susceptibility is typically attributed to altered hemodynamics, specifically increased blood shear stress and turbulence. Therefore, developing an understanding of the complex and time varying mechanical forces is key to the development of a successful heart valve replacement therapy (Ge et al., 2003; Govindarajan et al., 2010). In the work presented, a three-dimensional numeric method is utilized to study a fixed bileaflet valve closely resembling the St. Jude Standard Mechanical. The model assumes a time-dependent Navier–Stokes formulation of an incompressible Newtonian fluid. The rigid aorta and leaflets are separately meshed with increasing resolution and superimposed without requiring one to one node correspondence (Figure I.1.4.11). Total node number was increased from 4×10^5 to 1.6×10^6. Steady inflow with sub-physiologic Reynolds numbers increasing from 500 to 1200 was applied.


FIGURE I.1.4.11 Geometry and coordinate definitions for the finite element mesh showing: (A) the symmetric aorta, with inset of the bileaflet valve; and (B) Y–Z cross-section showing the overlaid leaflet meshes.
FIGURE I.1.4.12 Time course of the transverse velocity vectors at a section downstream of the valve showing the break in symmetry with impulsive acceleration from Re 1000 to Re 1200. (A) t = 0.5; (B) t = 8.4; (C) t = 8.6; (D) t = 9.2; (E) t = 9.6; and (F) t = 29.

Results demonstrated two pairs of counter-rotating vortices originating on either side of the valve orifice on the leading edge of the leaflets. These vortices increased with Reynolds number, and even at a Reynolds number of 1200 complex interactions between the vortices led to the onset of unsteady flow and a break in both planes of symmetry (Figure I.1.4.12). While it is not possible to draw any specific conclusions regarding asymmetric flow fields in a pulsatile flow regime, these results strongly suggest the importance of fully three-dimensional simulations, especially when considering higher, physiologic Reynolds numbers. During a mesh refinement study, inadequate mesh resolution was demonstrated to result in unsteady, physically unrealistic flow fields. However, the recent dramatic increase in computational power will likely enable the analysis of systems with suitably high resolution. While the techniques developed in this paper have been applied exclusively to mechanical prostheses, many of the computational developments designed to handle unsteady flows and complex geometric configurations in mechanical valves are also directly relevant to increasingly prevalent bioprosthetic valves. Essentially, a computational fluid dynamics approach can provide insight into the *in vivo* performance of prosthetic heart valves in general; however, as with any computational model of a complex system, the results must be carefully reviewed and validated.

Simulated Bioprosthetic Heart Valve Biomaterials under Quasi-Static Loading

Bioprosthetic heart valves (BHV) typically fail structurally, due to poor tissue durability and calcification (Sacks and Schoen, 2002). Clearly, an in-depth understanding of the biomechanical behavior of the BHV at both the tissue and functional prosthesis levels is essential to improving BHV design and reducing failure rates. Evaluation and simulation of the multiaxial mechanical behavior of BHV tissues is becoming more prevalent, yet testing methods have not been standardized and methodologies vary widely. As it is not possible to experimentally evaluate the effects of different biaxial test boundary conditions on test specimen internal stress distributions, numerical simulations were conducted to explore these effects (Sun et al., 2005). A nonlinear Fung-elastic constitutive model (Sun and Sacks, 2005), which fully incorporated the effects of in-plane shear, was used to simulate soft tissue mechanical behavior. Effects of boundary conditions, including varying the number of suture attachments, different gripping methods, specimen shapes, and material axes orientations were examined. Results demonstrated strong boundary effects with the clamped methods, while suture attachment methods demonstrated minimal boundary effects (Figure I.1.4.13). Suture-based methods appeared to be best suited for biaxial mechanical tests of biological materials. Moreover, the simulations demonstrated that St. Venant's effects depended significantly on the material axes orientation. While not exhaustive, these comprehensive simulations provide experimentalists with additional insight into the stress–strain fields associated with different biaxial testing boundary conditions, and may be used as a rational basis for the design of testing.

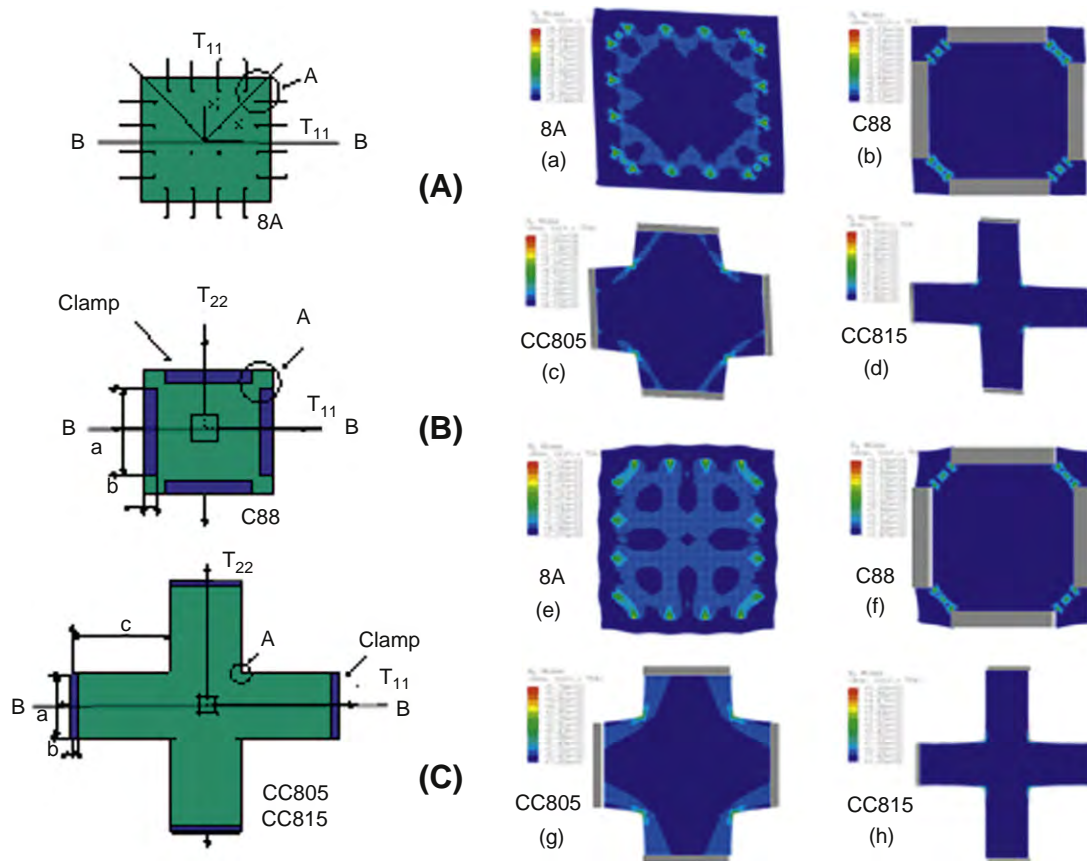
Next, these findings were applied to an actual pericardial BHV under quasi-static loading under 40, 80, and 120 mmHg pressures. Rigorous experimental validation of predicted leaflet strain field was used to validate the model


FIGURE I.1.4.13 (A) A schematic of the biaxial testing setup with four suture attachments, indicating the material axes X1–X2; (B) biaxial testing setup with gripping method as using clamp on each side of a square sample; and (C) biaxial testing setup with clamps on each side of a cruciform sample. results. The overall leaflet shape when loaded agreed well with experimental observations (Figure I.1.4.14). The predicted major principal strain field results demonstrated a generally smooth spatial distribution, increasing with transvalvular pressure (Figures I.1.4.14c,d).

Over most of the leaflet surface, the major principal strain values at 40 mmHg were ~8%, with focal regions of high values of ~12% located in the right and left sides just below the commissure regions. At 120 mmHg transvalvular pressure, the corresponding major principal strains increased to 12%–14%, with the focal regions' major principal strain values increasing to ~17%. Parametric studies utilizing the material parameter from one leaflet for all three pressures resulted in substantial variations in leaflet stress and strain distributions (Figure I.1.4.15) using a degree of anisotropy DA = E_{11}/E_{22}, where E_{11} and E_{22} are the peak strains under 1 MPa equi-biaxial stress. Note the high stresses were also observed in the belly region at all three DA values, appearing in similar locations for the aortic side. For the ventricular side of the leaflet surface, the peak stresses were slightly higher than that of the aortic side when DAs were 0.83 and 2.12; all occurring in the commissure region (Figure I.1.4.15). When DA was 1.14, a large region of high stress was concentrated in the belly region. The free edge experienced the lowest amounts of stress on the ventricular side

surface, consistent with the stress levels determined at the free edge on the aortic side. This is most likely due to the contact of the leaflets that lead to the compression stress at the free edge. This result suggests that utilization of actual leaflet material properties is essential for accurate BHV FE simulations, and underscores the need for rigorous experimentation and accurate constitutive models in simulating BHV function and design.

CONCLUSION

The FE methods briefly illustrated in this chapter are applicable to a large variety of contemporary biomedical problems. As with all modeling efforts, the most important part is often focused on model development and its ability to reproduce the salient physical characteristics of interest. While established, there are many new developments in the ability of FE models to simulate increasingly complex biomedical problems, and these will increasingly be used as problems with prosthetic design and biomaterials development become increasingly sophisticated. Perhaps the most exciting aspect is the ability to reduce the often empirical nature of biomaterials development and allow novel biomaterials to be developed in a rational manner for targeted use in novel biomedical therapies.

CHAPTER I.1.5   SURFACE PROPERTIES AND SURFACE CHARACTERIZATION OF BIOMATERIALS

Buddy D. Ratner

Professor, Bioengineering and Chemical Engineering, Director of University of Washington Engineered Biomaterials (UWEB), Seattle, WA, USA

INTRODUCTION

> *Nothing is rich but the inexhaustible wealth of nature. She shows us only surfaces, but she is a million fathoms deep.*
> **Ralph Waldo Emerson**

Biomaterials "show" to the world (and the biological environment) only surfaces. Atoms and molecules make up the outermost surface of a biomaterial (the interface between the material and the world). As we shall discuss in this section, these atoms and molecules that reside at the surface have a special organization and reactivity. They require special methods to characterize them, novel methods to tailor them, and they drive many of the biological reactions that occur in response to the biomaterial (protein adsorption, cell adhesion, cell growth, blood compatibility, etc.). The importance of surfaces for biomaterials science has been appreciated since the 1960s. Almost every biomaterials meeting will have sessions addressing surfaces and interfaces. In this chapter we focus on the special properties of surfaces, definitions of terms, methods to characterize surfaces, and some implications of surfaces as the drivers of bioreaction to biomaterials.

> Atoms and molecules that reside at the surface of a biomaterial have special reactivity and direct biological response.

During the development of biomedical implant devices and materials, we are concerned with physical properties, durability, and biocompatibility. The understanding of physical properties (e.g., mechanical strength, permeability, elasticity) has evolved over hundreds of years and is relatively well-understood – the standard tools of engineers and materials scientists are appropriate to characterize and study physical properties (see Chapters I.1.2, I.1.3). Durability, particularly in the biological environment, is less well-understood. Still, the tests we need to evaluate durability are clear (see Chapters I.1.2, II.4.3, II.4.4). Biocompatibility represents a frontier of knowledge in this field, and its study is often assigned to the biochemist, biologist, and physician (see Chapters II.3.2, II.3.3, II.3.4). However, an important question in biocompatibility is how the device or material "transduces" its structural make-up to direct or influence the response of proteins, cells, and the organism to it. For devices and materials that do not leach undesirable substances (i.e., that have passed routine toxicological evaluation; see Chapter II.3.3), this transduction occurs through the surface structure. The body "reads" the surface structure and responds to the particular chemistry and organization. For this reason we must understand the surface structure of biomaterials, and thus there is an important role for the physical scientist in understanding surface-driven biointeractions. Chapter III.1.4 elaborates on the biological implications of this idea.

General Surface Considerations and Definitions

This is the appropriate point to highlight general ideas about surfaces, especially solid surfaces. First, the surface
FIGURE I.1.5.1 (a) A two-dimensional representation of a crystal lattice suggesting bonding orbitals (red or pink ovals). For atoms in the center (bulk) of the crystal (pink ovals), all binding sites have associations with those of other atoms (sharing electrons). At planar exterior surfaces, one of the bonding sites is unfulfilled (red oval). At corners, two bonding sites are unfulfilled. The single atom on top of the crystal (an adatom) has three unfulfilled valencies. Energy is minimized where more of these unfulfilled valencies can interact. Where interactions do not satisfy all binding orbitals, there is an asymmetric electrical field driving a surface dipole. (b) In a "real-world" material (a block of metal from an orthopedic device, for example), if we cleave the block (under ultrahigh vacuum to prevent recontamination), we should find hydrocarbon on the outermost layer (perhaps 3 nm, surface energy ~22 ergs/cm^2), polar organic molecules (>1 nm, surface energy ~45 ergs/cm^2), adsorbed water (<1 nm, surface energy ~72 ergs/cm^2), metal oxide (approximately 5 nm, surface energy ~200 ergs/cm^2), and finally, the uniform bulk interior (surface energy ~1000 ergs/cm^2). The interface between air and material has the lowest interfacial energy (~22 ergs/cm^2). The layers are not drawn to scale.

region of a material is known to be of unique reactivity (Figure I.1.5.1a). Catalysis (for example, as used in petrochemical processing) and microelectronics both capitalize on special *surface* organization and reactivity – biology also exploits this enhanced surface reactivity to do its work. Second, the surface of a material is inevitably different from the bulk. The traditional techniques used to analyze the bulk structure of materials are not suitable for surface determination, because they typically do not have the sensitivity to observe the small amount of material comprising the unique surface chemistry/structure. Third, there is not much total mass of material at a surface. An example may help us to appreciate this – on a 1 cm^3 cube of titanium, the 100 Å oxide surrounding the cube is in the same proportion as a 5 meter-wide beach on each coast of the United States is to the roughly 5,000,000 meters distance from coast to coast. Fourth, surfaces readily contaminate with components from the vapor phase (some common examples are hydrocarbons, silicones, sulfur compounds, iodine). Under ultrahigh vacuum conditions (pressures <10^{-7} Pa) we can retard this contamination. However, in view of the atmospheric pressure conditions under which all biomedical devices are used, we must learn to live with some contamination. The key questions here are whether we can make devices with controlled and acceptable levels of contamination and also avoid undesirable contaminants. This is critical so that a laboratory experiment on a biomaterial generates the same results when repeated after 1 day, 1 week

or 1 year, and so that the biomedical device is dependable and has a reasonable shelf-life. Finally, the surface structure of a material is often mobile. A modern view of what might be seen at the surface of a real-world material is illustrated in Figure I.1.5.1b.

> **Five Points About Surfaces**
> 1. Surfaces have unique reactivity
> 2. The surface is inevitably different from the bulk
> 3. The mass of material that makes up the surface zone is very small
> 4. Surfaces readily contaminate
> 5. Surface molecules can exhibit considerable mobility.

The movement of atoms and molecules near the surface in response to the outside environment is often highly significant. In response to a hydrophobic environment (e.g., air), more hydrophobic (lower energy) components may migrate to the surface of a material – a process that reduces interfacial energy (Figure I.1.5.1b). Responding to an aqueous environment, the surface may reverse its structure and point polar (hydrophilic) groups outward to interact with the polar water molecules. Again, energy minimization drives this process. An example of this is schematically illustrated in Figure I.1.5.2. For metal alloys, one metal tends to dominate the surface, for example, silver in a silver–gold alloy or chromium in stainless steel.
FIGURE I.1.5.2 Many materials can undergo a reversal of surface structure when transferred from air into a water environment. In this schematic illustration, a hydroxylated polymer (for example a pHEMA contact lens) exhibits a surface rich in methyl groups (from the polymer chain backbone) in air, and a surface rich in hydroxyl groups under water. This has been observed experimentally, see Ratner et al. (1978). *J Appl Polym Sci*, 22, 643; Chen et al. (1999). *J Am Chem Soc*, 121(2); 446.

The nature of surfaces is complex and is the subject of much independent investigation. The reader is referred to one of many excellent monographs on this important subject for a complete and rigorous introduction (see Somorjai, 1981; Andrade, 1985; Adamson and Gast, 1997; Garbassi et al., 1998; Somorjai and Li, 2010). Biosurfaces, with particular relevance for biomaterials, are reviewed in articles and books (Ratner, 1988; Castner and Ratner, 2002; Kasemo, 2002; Tirrell et al., 2002).

When we say "surface," a question that immediately comes to mind is: "how deep into the material does it extend?" Although formal definitions are available, for all practical purposes, the surface is the zone where the structure and composition, influenced by the interface, differs from the average (bulk) composition and structure. This value often scales with the size of the molecules making up the surface. For an "atomic" material, for example gold, after penetration of about 5 atomic layers (0.5–1 nm), the composition becomes uniform from layer to layer (i.e., you are seeing the bulk structure). At the outermost atomic layer, the organization of the gold atoms at the surface (and their reactivity) can be substantially different from the organization in the averaged bulk. The gold, in air, will always have a contaminant overlayer, largely hydrocarbon, which may be roughly 2 nm thick. There is also a difference in composition between bulk and surface, but it is not the atomic/molecular rearrangements we are discussing here. For a polymer, the unique surface zone may extend from 10 nm to 100 nm (depending on the polymeric system and the chain molecular weight). Figure I.1.5.1b addresses some of these issues about surface definitions. Two more definitions must be considered. An interface is the transition between two phases, in principle an infinitely thin separation plane. An interphase is the unique compositional zone between two phases. For the example, for gold, we might say that the interphase between gold and air is 3 nm thick (the structurally rearranged gold atoms plus the contaminant layer).

What Surface Properties are we Interested in?

A surface is fully described by many parameters (Figure I.1.5.3). The more of these parameters we measure, the more we can piece together a complete description of the surface. A complete characterization requires a cadre of techniques to examine the many facets that contribute to the surface properties. Unfortunately, we cannot yet specify which parameters are most important for understanding specific biological responses to surfaces. Studies have been published on the importance of roughness, patterns, wettability, surface mobility, chemical composition, electrical charge, crystallinity, modulus and heterogeneity to biological reaction. Since we cannot be certain which surface factors are predominant in each situation, the controlling variable or variables must be independently measured and correlated. We use surface analysis techniques to measure these surface properties.

SURFACE ANALYSIS TECHNIQUES: PRINCIPLES AND METHODS

Sample Preparation

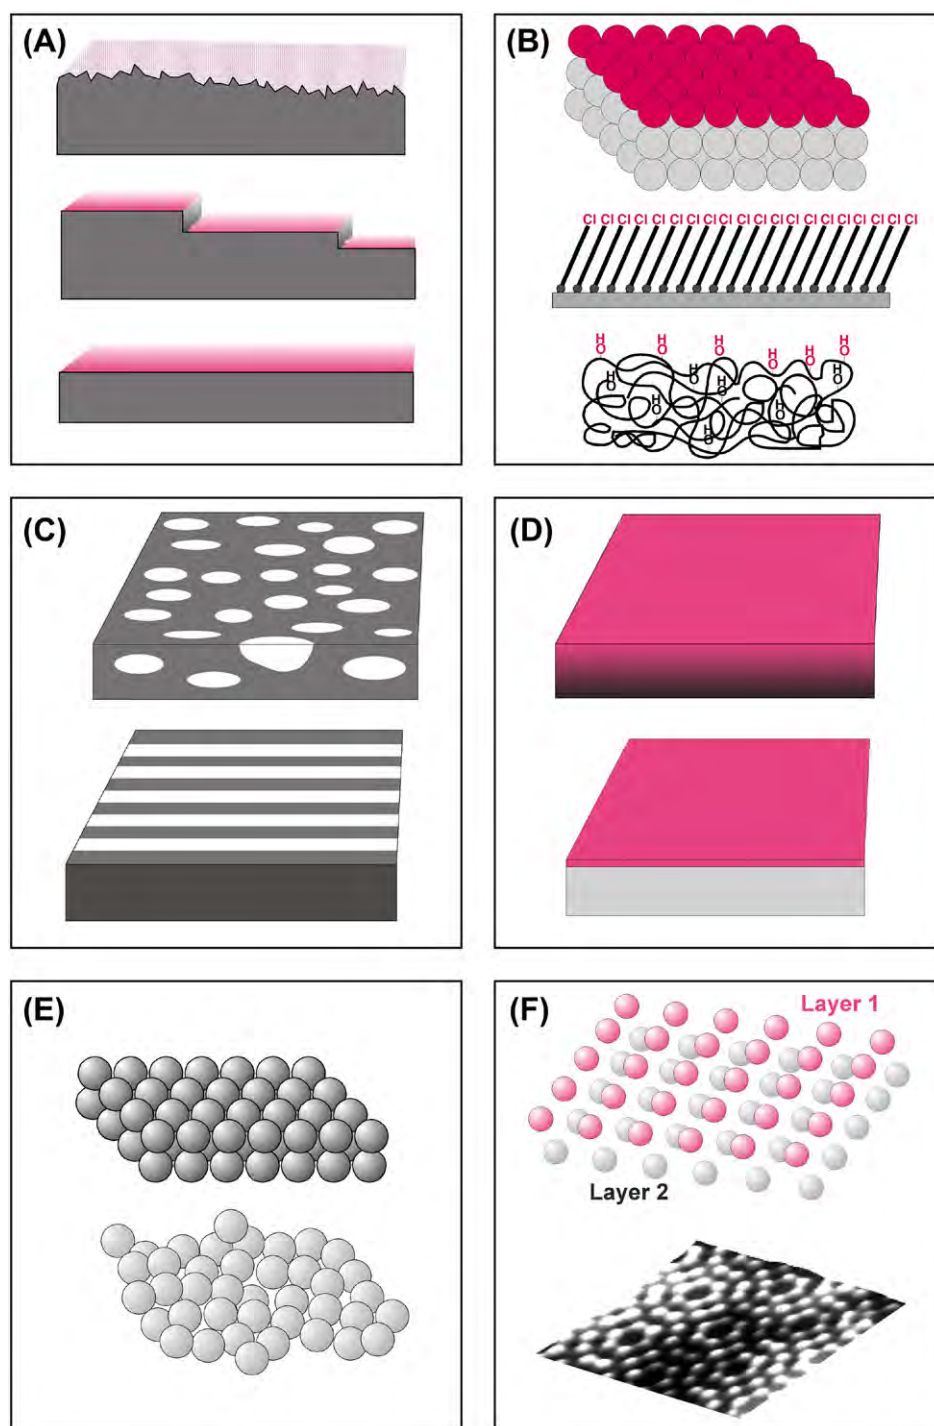
A guiding principle of surface analysis sample preparation is that the sample should resemble, as closely as possible, the material or device in the form that it is used for biological testing or implantation. Needless to say, fingerprints on the surface of the sample will obscure surface properties of interest. If the sample is placed in a package for shipping or storage prior to surface analysis, it is critical to know whether the packaging material may deliver surface contamination. Plain paper in contact with most specimens will transfer contaminants (often metal ions) to the surface of the material. Many plastics are processed with silicone oils or other additives that can migrate to the specimen. The packaging material used should be examined by surface analysis methods


FIGURE I.1.5.3 What might be measured to define surface structure? (A) Surfaces can be rough, stepped or smooth. (B) Surfaces can be comprised of different chemistries (atomic, supramolecular, macromolecular). (C) Surfaces may be structurally or compositionally inhomogeneous in the plane of the surface such as phase-separated domains or micro-contact printed lanes. (D) Surfaces may be inhomogeneous with depth into the specimen or simply overlayered with a thin film. (E) Surfaces may be highly crystalline or disordered. (F) Crystalline surfaces are found with many organizations such as a silicon (100) unreconstructed surface or a silicon (111) (7 × 7) reconstructed surface.

to ascertain its purity. Samples can be surface analyzed prior to and after storage in containers to ensure that the surface composition measured is not due to the container. As a general rule, the polyethylene press-close bags used in electron microscopy and cell culture plasticware are clean storage containers. However, abrasive contact must be avoided, and each brand must be evaluated so that a meticulously prepared specimen is not ruined by contamination. Many brands of aluminum foil are useful for packing specimens, but some are treated with a surface layer of stearic acid that can surface-contaminate biomaterials, implants or medical devices. Aluminum

TABLE I.1.5.1	Common Methods to Characterize Biomaterial Surfaces					
Method	**Principle**	**Depth Analyzed**	**Spatial Resolution**	**Analytical Sensitivity**	**Cost**	
Contact Angles	Liquid wetting of surfaces is used to estimate the energy of surfaces	3–20 Å	1 mm	Low or high depending on the chemistry	$	
ESCA (XPS)	X-rays induce the emission of electrons of characteristic energy	10–250 Å	10–150 μm	0.1 atom %	$$$	
Auger Electron Spectroscopy*	A focused electron beam stimulates the emission of Auger electrons	50–100 Å	100 Å	0.1 atom %	$$$	
SIMS	Ion bombardment sputters secondary ions from the surface	10 Å–1 μm**	100 Å	Very high	$$$	
FTIR-ATR	IR radiation is adsorbed and excites molecular vibrations	1–5 μm	10 μm	1 mole %	$$	
STM	Measurement of the quantum tunneling current between a metal tip and a conductive surface	5 Å	1 Å	single atoms	$$	
SEM	Secondary electron emission induced by a focused electron beam is spatially imaged	5 Å	40 Å typically	High, but not quantitative	$$	

*Auger electron spectroscopy is damaging to organic materials, and best used for inorganics.
**Static SIMS ≈ 10 Å, dynamic SIMS to 1 μm.
$: up to $5000
$$: $5000–$100,000
$$$: >$100,000

foil should be checked for surface contamination layers by surface analysis methods prior to wrapping important specimens.

Surface Analysis: General Comments

Two general principles guide sample analysis. First, all methods used to analyze surfaces also have the potential to alter the surface. The analyst must be aware of the damage potential of the method used. Second, because of the potential for artifacts and the need for corroborative information to construct a complete picture of the surface (Figure I.1.5.3), more than one method should be used whenever possible. The data derived from two or more methods should be internally consistent. When data are contradictory, be suspicious and question why. A third or fourth method may then be necessary to draw confident conclusions about the nature of a surface. These general principles are applicable to all materials.

There are properties (only a few of which will be presented here) that are specific to specific classes of materials. Compared to metals, ceramics and glasses, organic, and polymeric materials are more easily damaged by surface analysis methods. Polymeric systems also exhibit greater surface molecular mobility than inorganic systems. The surfaces of inorganic materials are contaminated more rapidly than polymeric materials because of their higher surface energy. Electrically conductive metals and carbons will often be easier to characterize than insulators using electron, X-ray, and ion interaction methods. Insulators accumulate a surface electrical charge that requires special methods (e.g., a low energy electron beam) to neutralize. To learn about other concerns in surface analysis that are specific to specific classes of materials, published papers become a valuable resource for understanding the pitfalls that can lead to artifact or inaccuracy.

Table I.1.5.1 summarizes the characteristics of many common surface analysis methods, including their depth of analysis under standard conditions and their spatial resolution (spot size analyzed). A few of the more frequently applied techniques are described in the next section. However, space limitations prevent an intensive discussion of these methods. The reader is referred to many comprehensive books on the general subject of surface analysis (Briggs and Seah, 1983; Andrade, 1985; Feldman and Mayer, 1986; Vickerman and Gilmore, 2009). References describing specific surface analysis methods will be presented in sections on each of the key methods.

Contact Angle Methods

A drop of liquid sitting on a solid surface represents a simple, but potentially powerful, method to probe surface properties. Experience tells us that a drop of water on a highly polished automobile body surface will stand up (bead up), while on an old, weathered car, the liquid will flow evenly over the surface. This observation, for those knowledgeable about contact angles, tells us that the highly polished car probably has silicones or hydrocarbons at its surface, while the unpolished car surface is oxidized material. Quantitative contact angle measurement has, in fact, been used to predict the performance of vascular grafts, and the adhesion of cells to surfaces.

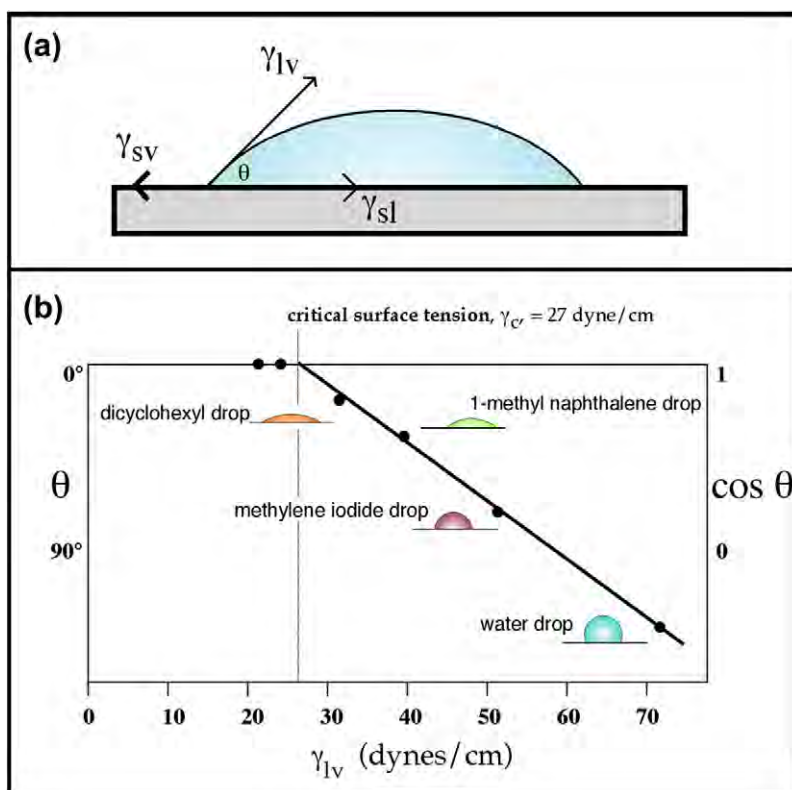
The phenomenon of the contact angle can be explained as a balance between the force with which the molecules of the drop liquid are being attracted to each other (a


FIGURE I.1.5.4 (a) An equilibrium is established between surface tension forces contracting a liquid drop to a spherical shape and forces interacting the drop with the surface. The force balance between the liquid–vapor surface tension (γ_{lv}) of a liquid drop and the interfacial tension between a solid and the drop (γ_{sl}), manifested through the contact angle (θ) of the drop can be used to quantitatively characterize the surface–vapor interfacial tension (γ_{sv}). (b) The Zisman method permits a critical surface tension value, an approximation to the solid surface tension, to be measured. Drops of liquids of different surface tensions are placed on the solid, and the contact angles of the drops are measured. The plot of liquid surface tension versus angle is extrapolated to zero contact angle to give the critical surface tension value.

cohesive force) and the attraction of the liquid molecules for the surface (an adhesive force). An equilibrium is established between these forces. The force balance between the liquid–vapor surface tension (γ_{lv}) of a liquid drop and the interfacial tension between a solid and the drop (γ_{sl}), manifested through the contact angle (θ) of the drop with the surface, can be used to quantitatively characterize the energy of the surface (γ_{sv}) (Figure I.1.5.4a). The basic relationship describing this force balance is:

$$\gamma_{sv} = \gamma_{sl} + \gamma_{lv}\ \cos\theta$$

The surface energy, closely related to wettability, is a useful parameter that has often been correlated with biological interaction. Unfortunately, γ_{sv} cannot be directly obtained since this equation contains two unknowns, γ_{sl} and γ_{sv}. Therefore, the γ_{sv} is sometimes approximated by the Zisman method for obtaining the critical surface tension (Figure I.1.5.4b) or calculated by solving simultaneous equations with data from liquids of different surface tensions. Some critical surface tensions for common materials are listed in Table I.1.5.2.

Experimentally, there are a number of ways to measure the contact angle. Some of these are illustrated in Figure I.1.5.5. Contact angle methods can be inexpensive and, with

some practice, easy to perform. A contact angle goniometer (a telescope to observe the drop that is equipped with a protractor eyepiece) is the least expensive method for contact angle measurement. A number of companies now offer video systems that compute the contact angle and other surface energy parameters from digitial image analysis of the liquid drop profile. Accessories to control humidity and temperature and deposit drops of liquid are available.

> Contact angles directly measure surface wettability, and indirectly probe surface energy, roughness, heterogeneity, contamination, and molecular mobility.

Contact angle measurements provide a "first line" characterization of materials and can be performed in any laboratory. Contact angle measurements provide unique insight into how the surface will interact with the external world. However, in performing such measurements, a number of concerns must be addressed to obtain meaningful data (Table I.1.5.3). Review articles are available on contact angle measurement for surface characterization (Zisman, 1964; Andrade, 1985; Ratner, 1988; Good, 1993).

TABLE I.1.5.2	Critical Surface Tension Values for Common Polymeric Materials Calculated from Contact Angle Measurements
Material	**Critical Surface Tension (dynes/cm)**
Polytetrafluoroethylene	19
Poly(dimethyl siloxane)	24
Poly(vinylidine fluoride)	25
Poly(vinyl fluoride)	28
Polyethylene	31
Polystyrene	33

Polyacrylonitrile	50

TABLE I.1.5.3	Concerns in Contact Angle Measurement

- The measurement is operator dependent (for manual, goniometer instruments)
- Surface roughness influences the results
- Surface heterogeneity influences the results
- The liquids used are easily contaminated (typically reducing their γ_{lv})
- Liquid evaporation and temperature changes can impact measurement
- The liquids used can reorient the surface structure
- The liquids used can absorb into the surface, leading to swelling
- The liquids used can dissolve the surface
- Few sample geometries are appropriate for contact angle measurement
- Information on surface structure must be inferred from the data obtained
FIGURE I.1.5.5 Four possibilities for contact angle measurement: (a) sessile drop; (b) captive air bubble method; (c) capillary rise method; (d) Wilhelmy plate method.

Electron Spectroscopy for Chemical Analysis

Electron spectroscopy for chemical analysis (ESCA) provides a comprehensive qualitative and quantitative overview of a surface that would be challenging to obtain by other means (Dilks, 1981; Andrade, 1985; Ratner and McElroy, 1986; Ratner, 1988; Watts and Wolstenholme, 2003; Ratner and Castner, 2009). In contrast to the contact angle technique, ESCA requires complex, expensive apparatus (Figure I.1.5.6a) and demands considerable training to perform the measurements. However, since ESCA is available from commercial laboratories, university analytical facilities, national centers (for example, NESAC/BIO at the University of Washington), and specialized research laboratories, most biomaterials scientists can access instrumentation for sample analysis. ESCA has contributed significantly to the development of biomaterials and medical devices, and to understanding the fundamentals of biointeraction.

The ESCA method (also called X-ray photoelectron spectroscopy, XPS) is based upon the photoelectric effect, properly described by Einstein in 1905. X-rays are focused upon a specimen. The interaction of the X-rays with the atoms in the specimen causes the emission of core level (inner shell) electrons. The energy of these electrons is measured and their values provide information about the nature and environment of the atom or atoms from which they came. The basic energy balance describing this process is given by the relationship:

$$BE = h\nu - KE$$

where BE is the energy binding the electron to an atom (the value desired), KE is the kinetic energy of the emitted electron (the value measured in the ESCA spectrometer), and hν is the energy of the X-rays, a known value. A schematic diagram illustrating an ESCA instrument is shown in Figure I.1.5.6b. Table I.1.5.4 lists the types of information about the nature of a surface that can be obtained by using ESCA. The origin of the surface sensitivity of ESCA is described in Figure I.1.5.7.

ESCA has many advantages, and a few disadvantages, for studying biomaterials. The advantages include high information content, surface localization of the measurement (outermost 8–10 nm), speed of analysis, low damage potential, and the ability to analyze most samples with no special specimen preparation. The latter advantage is particularly important since biomedical devices (or parts of devices) can often be inserted, as fabricated and sterilized, directly in the analysis chamber for study. The disadvantages include the need for vacuum compatibility (i.e., no outgassing of volatile components), the vacuum environment and its impact on the specimen (particularly for hydrated specimens), the possibility of sample damage by X-rays if long analysis times are used, the need for experienced operators, and the cost associated with this complex instrumentation.

The vacuum limitations can be sidestepped by using an ESCA system with a cryogenic sample stage. At liquid nitrogen temperatures, samples with volatile components, or even wet, hydrated samples, can be analyzed.

> ESCA analyzes to approximately 10 nm and gives information on elements present, their concentrations and their bonding environments.

The use of ESCA is best illustrated with a brief example. A poly(methyl methacrylate) (PMMA) ophthalmologic device is to be examined. Taking care not to touch or damage the surface of interest, the device is inserted into the ESCA instrument introduction chamber. The introduction chamber is then pumped down to 10^{-6} torr (1.33×10^{-4} Pa) pressure. A gate valve between the introduction chamber and the analytical chamber is opened and the specimen is moved into the analysis chamber. In the analysis chamber, at 10^{-9} torr (1.33×10^{-7} Pa) pressure, the specimen is positioned using a microscope or TV camera and the X-ray source is turned on. The ranges of electron energies to be observed are computer-controlled with the retardation lens on the spectrometer. First, a wide scan is made in which the energies of all emitted electrons over a 1000 eV range are detected (Figure I.1.5.8). Then, narrow scans are made in which each of the elements detected in the wide scan is examined in higher resolution (Figure I.1.5.9).

From the wide scan, we learn that the specimen contains carbon, oxygen, nitrogen, and sulfur. The presence of sulfur and nitrogen is unexpected for PMMA. We can calculate atomic percentage composition from the wide scan spectral data. The sample surface contains 58.2% carbon, 27.7% oxygen, 9.5% nitrogen, and 4.5% sulfur. The narrow scan for the carbon region (C1s spectrum) suggests four classes of compounds: hydrocarbons; carbons singly bonded to oxygen (the predominant species); carbons in amide-like molecular environments; and carbons in carboxylic acid or ester environments. This is quite different from the spectrum expected for pure PMMA. An examination of the peak position in the narrow scan of the sulfur region (S2p spectrum) suggests sulfonate-type groups. The shape of the C1s spectrum, the position of the sulfur peak, and the presence of nitrogen all suggest that heparin was immobilized to the surface of the PMMA device. Since the stoichiometry of the lens surface does not match that for pure heparin, this suggests that we are seeing either some of the PMMA substrate through a <100 Å layer of heparin or we are seeing some of the bonding links used to immobilize the heparin to the lens surface. Further ESCA analysis will permit the extraction of more detail about this surface-modified device, including an estimate of surface modification thickness, further confirmation that the coating is indeed heparin, and additional information about the nature of the immobilization chemistry.

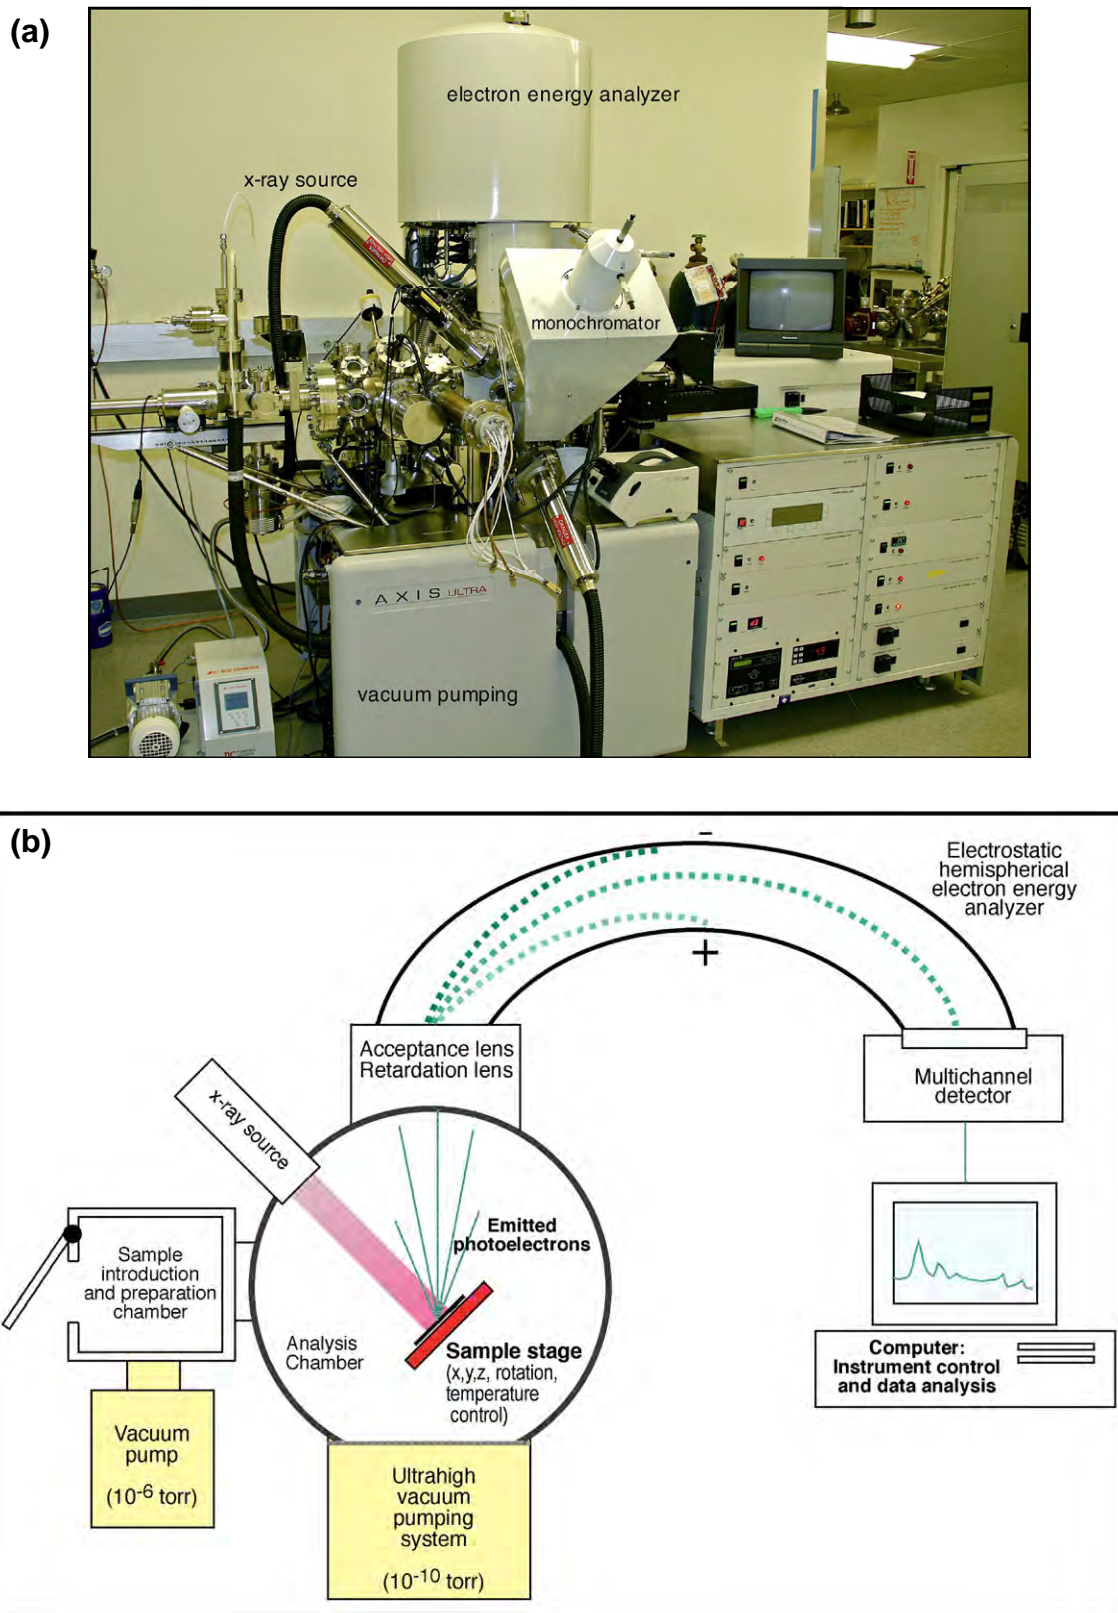
(b)


FIGURE I.1.5.6 (a) Photograph of a contemporary ESCA instrument (photo by Kratos Analytical Corp.). (b) Schematic diagram of a monochromatized ESCA instrument.

TABLE I.1.5.4	Information Derived From an ESCA Experiment

In the outermost 100 Å of a surface, ESCA can provide:

- Identification of all elements (except H and He) present at concentrations >0.1 atomic %
- Semiquantitative determination of the approximate elemental surface composition (±10%)
- Information about the molecular environment (oxidation state, bonding atoms, etc.)
- Information about aromatic or unsaturated structures from shake-up $\pi^* \leftarrow \pi$) transitions
- Identification of organic groups using derivatization reactions
- Nondestructive elemental depth profiles 100 Å into the sample and surface heterogeneity assessment using angular-dependent ESCA studies and photoelectrons with differing escape depths
- Destructive elemental depth profiles several thousand angstroms into the sample using argon etching (for inorganics)
- Lateral variations in surface composition (spatial resolution 8–150 μm, depending upon the instrument)
- "Fingerprinting" of materials using valence band spectra and identification of bonding orbitals
- Studies on hydrated (frozen) surfaces
FIGURE I.1.5.7 ESCA is a surface-sensitive method. Although the X-ray beam can penetrate deeply into a specimen, electrons emitted deep in the specimen (D, E, F, G) will lose their energy in inelastic collisions and never emerge from the surface. Only those electrons emitted near the surface that lose no energy (A, B) will contribute to the ESCA signal used analytically. Electrons that lose some energy, but still have sufficient energy to emerge from the surface (C) contribute to the background signal.

Secondary Ion Mass Spectrometry

Secondary ion mass spectrometry (SIMS) is an information-rich tool that the surface analyst can bring to bear on a biomedical problem. SIMS produces a mass spectrum of the outermost 1–2 nm of a surface. Like ESCA, it requires complex instrumentation and an ultrahigh vacuum chamber for the analysis. However, it provides unique information that is complementary to ESCA, and greatly aids in understanding surface composition. Some of the analytical capabilities of SIMS are summarized in Table I.1.5.5. Review articles on SIMS are available (Benninghoven, 1983; Scheutzle et al., 1984; Ratner,
FIGURE I.1.5.8 ESCA wide scan of a surface-modified poly(methyl methacrylate) ophthalmologic device.
FIGURE I.1.5.9 The carbon 1s narrow scan ESCA spectrum of a surface-modified poly(methyl methacrylate) ophthalmologic device. Narrow scan spectra can be generated for each element seen in low energy resolution mode in Figure I.1.5.8.

TABLE I.1.5.5	Analytical Capabilities of SIMS	
	Static SIMS	**Dynamic SIMS**
Identify hydrogen and deuterium	✓	✓
Identify other elements (often must be inferred from the data)	✓	✓
Suggest molecular structures (inferred from the data)	✓	—
Observe extremely high mass fragments (proteins, polymers)	✓	—
Detection of extremely low concentrations	✓	✓
Depth profile to 1 μm into the sample	*	✓
Observe the outermost 1–2 atomic layers	✓	—
High spatial resolution (features as small as approximately 400 Å)	✓	✓
Semiquantitative analysis (for limited sets of specimens)	✓	—
Useful for polymers	✓	—
Useful for inorganics (metals, ceramics, etc.)	✓	✓
Useful for powders, films, fibers, etc.	✓	✓

*Cluster ion sources allow depth profiling with static-SIMS-like information content.

1988; Briggs, 1986; Vickerman et al., 1989; Davies and Lynn, 1990; Van Vaeck et al., 1999; Belu et al., 2003; Michel and Castner, 2006).

In SIMS analysis, a surface is bombarded with a beam of accelerated ions. The collision of these ions with the atoms and molecules in the surface zone can transfer enough energy that they sputter from the surface into the vacuum phase. The process is analogous to racked pool balls that are ejected from the ball cluster by the impact of the cue ball; the harder the cue ball hits the rack of balls, the more balls are emitted from the rack. In SIMS, the "cue balls" are positive ions (cesium, gallium, bismuth, C60-buckyballs, and cluster ions are commonly used) that are accelerated at the surface to be analyzed with energies of 5000–20,000 eV. The particles ejected from the surface are positive and negative ions (secondary ions), radicals, excited states, and neutrals. Only the secondary ions are measured in SIMS. In ESCA, the energy of emitted particles (electrons) is measured. SIMS measures the mass of emitted ions (more rigorously, the ratio of mass to charge, m/z) using a time-of-flight (TOF) mass analyzer, magnetic sector analyzer or, in older instruments, a quadrupole mass analyzer.

There are two modes for SIMS analysis, dynamic and static. Dynamic SIMS uses high ion doses over a given analysis time. The primary ion beam sputters sufficient material from the surface that the surface erodes away at an appreciable rate. We can capitalize on this to depth-profile into a specimen, and this works particularly well for metallic, semiconductor, and ceramic materials. The intensity of the m/z peak of a species of interest (e.g., sodium ion, m/z = 23) might be followed as a function of time. If the ion beam is well-controlled and the sputtering rate is constant, the sodium ion signal intensity measured at any time will be directly related to its concentration at the erosion depth of the ion beam into the specimen. A concentration depth profile (sodium concentration versus depth) can be constructed from the outermost atoms to a micron or more into the specimen. Depending on the primary ion used, for example, cesium or gallium, and its energy, the high-flux ion beam can destroy organic samples and relevant organic fragments, and predominantly atomic fragments (e.g., C^-, CH^-, O^-, OH^-, Na^+, etc.) will be detected. Also, as the beam erodes deeper into the specimen, more artifacts are introduced in the data by "knock-in" and scrambling of atoms.

Static SIMS, in contrast, induces minimal surface destruction. The ion dose is adjusted so that during the period of the analysis less than 10% of one monolayer of surface atoms is sputtered. Since there are typically 10^{13}–10^{15} atoms in 1 cm^2 of surface, a total ion dose of less than 10^{13} ions/cm^2 during the analysis period is appropriate. Under these conditions, extensive degradation and rearrangement of the chemistry at the surface does not take place, and large, relatively intact molecular fragments can be ejected into the vacuum for measurement. Examples of molecular fragments are shown in

Figure I.1.5.10. This figure also introduces some of the ideas behind SIMS spectral interpretation. A more complete introduction to the concepts behind static SIMS spectral interpretation can be found in Van Vaeck et al. (1999) or in standard texts on mass spectrometry.

> Static SIMS provides qualitative information on the atomic and molecular composition in the outermost 1–2 nm of surface with high analytical sensitivity and excellent *x,y* spatial resolution.

Magnetically or electrostatically focusing the primary ion beam permits the SIMS technique to have high spatial resolution in the *x,y* plane. In fact, SIMS analysis can be performed in surface regions of 10 nm diameter on optimal specimens. For static SIMS analysis, only 1–10% of the atoms in any area are sampled. Thus, as the spot size gets smaller, the challenge to achieve high analytical sensitivity increases sharply. Still, static SIMS measurements have been performed in areas as small as 40 nm. Newly-developed cluster ion sources (for example, using gold molecular clusters, Au_3, C_{60} or argon clusters as the impacting primary particles) show high secondary ion yields, and relatively low surface damage. These improve spatial resolution and also permit depth profiling of organic surfaces by sputtering down into a surface, while monitoring secondary ion emission as a function of time (Ninomiya et al., 2009).

If the focused primary ion beam is rastered over the surface, and the *x,y* position of the beam correlated with the signal emitted from a given spot, the SIMS data can be converted into an elemental image. Patterning and spatial control of chemistry is becoming increasingly important in biomaterials surface design. For example, microcontact printing allows patterned chemistry to be transferred to surfaces at the micron level using a relatively simple rubber stamp. Imaging SIMS is well-suited to studying and monitoring such spatially defined chemistry (Dubey et al., 2009; Bolles et al., 2010). An example is presented in Figure I.1.5.11. Imaging SIMS is also valuable for observing defects in thin films (pinholes), analyzing the chemistry of fine particulates or assessing causes of implant failure.

Scanning Electron Microscopy

Scanning electron microscopy (SEM) images of surfaces have great resolution and depth of field, with a three-dimensional quality that offers a visual perspective familiar to most users. SEM images are widely used, and much has been written about the technique. The comments here are primarily oriented toward SEM as a surface analysis tool.

SEM functions by focusing and rastering a relatively high-energy electron beam (typically, 5–100 keV) on a specimen that is under vacuum. Low-energy secondary electrons (1–20 eV) are emitted from each spot where the
FIGURE I.1.5.10 Static positive and negative ion SIMS spectra of a poly(ethylene glycol)–poly(dimethyl siloxane) copolymer containing disulfide side groups on a gold surface. The primary peaks are identified. The low mass region of the negative ion spectrum offers little insight into the polymer structure, but the high mass region is rich in information. In this case, the low mass positive spectrum is rich in information. Further details on this class of polymers can be found in *Macromolecules*, 27, 3053 (1994). (Figure supplied by D. Castner.)

focused electron beam makes an impact. The intensity of the secondary electron emission is a function of the atomic composition of the sample and the geometry of the features under observation. The image of the surface is spatially reconstructed on a phosphor screen (or CCD detector) from the intensity of the secondary electron emission at each point. Because of the shallow penetration depth of low-energy electrons produced by the primary electron beam, only the secondary electrons generated near the surface can escape and be detected (this is analogous to the surface sensitivity described in Figure I.1.5.7). Consequently, SEM is a surface analysis method.

> SEM provides a high resolution image of the surface. On insulating materials, metallic coating is required and the image is actually of the coating surface, not the underlying material.

Nonconductive materials observed in the SEM are typically coated with a thin, electrically grounded layer
FIGURE I.1.5.11 Negative TOF-SIMS ion images exploring the N-hydroxysuccinimide (NHS) reaction used to immobilize biomolecules to surfaces. Yellow colors show regions rich in NHS groups based on peaks at m/z 42, 98, 107, and 114. The image shows a spatially defined sample with freshly prepared, hydrolyzed and regenerated photopatterned surfaces. Further details can be found in Dubey et al. (2009). (Used with permission of the publisher.)

of metal to minimize negative charge accumulation from the electron beam. However, this metal layer is always thick enough (>200 Å) so that the electrons emitted from the sample beneath cannot penetrate. Therefore, in SEM analysis of nonconductors, the surface of the metal coating is, in effect, what is being monitored. If the metal coat is truly conformal, a good representation of the surface geometry will be conveyed. However, the specimen surface chemistry no longer influences secondary electron emission. Also, at very high magnifications, the texture of the metal coat and not the surface may be under observation.

SEM, in spite of these limitations, is an important corroborative method to use in conjunction with other surface analysis methods. Surface roughness and texture can have a profound influence on data from ESCA, SIMS, and contact angle determinations. Therefore, SEM provides important information in the interpretation of data from these methods.

The development of low-voltage SEM does study the surface chemistry (and geometry) of nonconductors. With the electron accelerating voltage lowered to approximately 1 keV, charge accumulation is not as critical and metallization is not required. Low-voltage SEM has been used to study platelets and phase separation in polymers. Also, the environmental SEM (ESEM) permits wet, uncoated specimens to be studied.

The primary electron beam also stimulates the emission of X-rays. These X-rays are used to identify elements with the technique called energy-dispersive X-ray analysis (EDXA). However, the high-energy primary electron beam penetrates deeply into a specimen (a micron or more). The X-rays produced from the interaction of these electrons with atoms deep in the bulk of the specimen can penetrate through the material and be detected. Therefore, EDXA is not a surface analysis method.

The primary use of SEM is to image topography. SEM for this application is elaborated upon in the chapter on microscopy in biomaterials research (Chapter II.3.8).

Infrared Spectroscopy

Infrared spectroscopy provides information on the bond vibrations of molecular species. It is a widely used analytical method that can reveal information on specific chemistries and the orientation of structures. Fourier transform infrared (FTIR) spectrometry offers outstanding signal-to-noise ratio (S/N) and spectral accuracy. However, even with this high S/N, the small absorption signal associated with the minute mass of material in a surface region can challenge the sensitivity of the spectrometer. Also, the problem of separating the vastly larger bulk absorption signal from the surface signal must be addressed.

Surface FTIR methods couple the infrared radiation to the sample surface to increase the intensity of the surface signal and reduce the bulk signal (Allara, 1982; Leyden and Murthy, 1987; Urban, 1993; Dumas et al., 1999). Some of these sampling modes, and their characteristics, are illustrated in Figure I.1.5.12.

The attenuated total reflectance (ATR) mode of sampling has been used most often in biomaterials studies. The penetration depth into the sample is 1–5 μm. Therefore, ATR is not highly surface sensitive, but observes a broad region near the surface. However, it does offer the wealth of rich structural information common to infrared spectra. With extremely high S/N FTIR instruments, ATR studies of proteins and polymers under water have been performed. In these experiments, the water signal (which is typically 99% or more of the total signal) is subtracted from the spectrum to leave only the surface material (e.g., adsorbed protein) under observation. Micro-ATR, coupling a microscope, IR spectrometer, and micro-ATR crystal, permits ATR analysis with high spatial resolution (approximately 1 μm^2 pixel size).

> ATR-IR permits detailed molecular analysis of the outermost 1–5 microns of a sample.

Another infrared method that has proven immensely valuable for observing extremely thin films on reflective surfaces is infrared reflection absorption spectroscopy (IRAS) (Figure I.1.5.12). This method has been widely applied to self assembled monolayers (SAMs), but is applicable to many surface films that are less than 10 nm in thickness. The surface upon which the thin film resides must be highly reflective and metal surfaces work best, although a silicon wafer can be used. IRAS gives information about composition, crystallinity, and molecular orientation. Infrared spectroscopy is one member of a family of methods called vibrational spectroscopies. Two other vibrational spectroscopies, sum

frequency generation and Raman (in particular, surface enhanced), will be mentioned below in the section on newer methods.

Scanning Tunneling Microscopy (STM), Atomic Force Microscopy (AFM), and the Scanning Probe Microscopies (SPM). In the 16 years since the first edition of this book, scanning tunneling microscopy (STM) and atomic force microscopy (AFM) have devolved from novel research tools to key methods for biomaterials characterization. AFM is more widely used than STM because electrically conductive surfaces are not needed with AFM and quantitative force measurements can be

made. General review articles are available (Binnig and Rohrer, 1986; Albrecht et al., 1988; Avouris, 1990) and articles oriented toward biological studies with these methods (Hansma et al., 1988; Miles et al., 1990; Rugar and Hansma, 1990; Jandt, 2001; Dufrêne, 2004).

The STM was invented in 1981 and led to a Nobel Prize for G. Binnig and H. Rohrer in 1986. The STM capitalizes on quantum tunneling to generate an atom-scale, electron density image of a surface. A metal tip terminating in a single atom is brought within 5–10 Å of an electrically conducting surface. At these distances, the electron cloud of the atom at the "tip of the tip" will

significantly overlap the electron cloud of an atom on the surface. If a potential is applied between the tip and the surface, an electron tunneling current will be established whose magnitude, J, follows the proportionality:

$$J \alpha\ e^{(-Ak_0S)}$$

where A is a constant, k_0 is an average inverse decay length (related to the electron affinity of the metals), and S is the separation distance in angstrom units. For most metals, a 1 Å change in the distance of the tip to the surface results in an order of magnitude change in tunneling current. Even though this current is small, it can be measured with good accuracy.

To image a surface, this quantum tunneling current is used in one of two ways. In constant current mode, a piezoelectric driver scans a tip over a surface. When the tip approaches an atom protruding above the plane of the surface, the current rapidly increases, and a feedback circuit moves the tip up to keep the current constant. Then, a plot is made of the tip height required to maintain constant current versus distance along the plane. In constant height mode, the tip is moved over the surface and the change in current with distance traveled along the plane of the surface is directly recorded. A schematic diagram of a scanning tunneling microscope is presented in Figure I.1.5.13. Two STM scanning modes are illustrated in Figure I.1.5.14.

The STM measures electrical current, and therefore is well suited for conductive and semiconductor surfaces. However, biomolecules (even proteins) on conductive substrates appear amenable to imaging. STM does not "see" atoms, but rather monitors electron density. The conductive and imaging mechanism for proteins is not well-understood. Still, publications suggest that information-rich images of biomolecules on conductive surfaces can be obtained (Campbell et al., 2007).

The AFM uses a similar piezo drive mechanism. However, instead of recording tunneling current, the deflection of a tip mounted on a flexible cantilever arm due to van der Waals forces and electrostatic repulsion/attraction between an atom at the tip and an atom on the surface is measured. Atomic-dimension measurements of cantilever arm movements can be made by reflecting a laser beam off a mirror on the cantilever arm (an optical lever). A one-atom deflection of the cantilever arm can easily be measured by monitoring the position of the laser reflection on a spatially resolved photosensitive detector. Other principles are also used to measure the deflection of the tip. These include capacitance measurements and interferometry. A diagram of a typical AFM is presented in Figure I.1.5.15. Images of protein molecules recorded by AFM are shown in Figure I.1.5.16 to demonstrate the sub-nanometer resolution possible on biological specimens.

Tips are important in AFM, as the spatial resolution is significantly associated with tip terminal diameter and shape. Tips are made from microlithographically fabricated silicon or silicon nitride. Also carbon whiskers,
FIGURE I.1.5.13 Schematic diagram illustrating the principle of the scanning tunneling microscope – a tip terminating in a single atom permits localized quantum tunneling current from surface features (or atoms) to tip. This tunneling current can be spatially reconstructed to form an image.
FIGURE I.1.5.14 Scanning tunneling microscopy can be performed in two modes. In constant height mode, the tip is scanned a constant distance from the surface (typically 5–10 Å) and the change in tunneling current is recorded. In constant current mode, the tip height is adjusted so that the tunneling current is always constant, and the tip distance from the surface is recorded as a function of distance traveled in the plane of the surface.

nanotubes, and a variety of nanospherical particles have been mounted on AFM tips to increase their sharpness or improve the ability to precisely define tip geometry. Tips are also surface-modified to alter the strength and types of interactions with surfaces (static SIMS can be used to image these surface modifications). Finally, cantilevers are sold in a range of stiffnesses, so that the analysis modes can be tuned to needs of the sample and the type of data being acquired. The forces associated with the interaction of an AFM tip with a surface as it approaches

FIGURE I.1.5.16 An AFM image of porin proteins from the outer membrane of *E. coli* imaged with nanoscale resolution. Comparison of high-resolution AFM images of OmpF crystals (in brown-yellow) and the atomic model rendered at 3 Å (in blue). (From Müller, D. J. & Engel, A. (1999). Journal of Molecular Biology, **285**, 1347, used with permission of the authors and the publisher.)

tapping, force modulation, and phase imaging. In contact mode, the tip is in contact with the surface (or at least the electron clouds of tip and surface essentially overlap). The pressures resulting from the force of the cantilever delivered through the extremely small surface area of the tip can be damaging to soft specimens (proteins, polymers, etc.). However, for more rigid specimens, excellent topographical imaging can be achieved in contact mode. In tapping mode, the tip is oscillated at a frequency near the resonant frequency of the cantilever. The tip barely grazes the surface. The force interaction of tip and surface can affect the amplitude of oscillation and the oscillating frequency of the tip. In standard tapping mode, the amplitude change is translated into topographic spatial information. Many variants of tapping mode have been developed allowing imaging under different conditions, and using the phase shift between the applied oscillation to the tip and the actual tip oscillation in the force field of the surface to provide information about the mechanical properties of the surface (in essence, the viscoelasticity of the surface can be appreciated).

> AFM allows imaging of surfaces at sub-nanometer resolutions, and also provides detail on surface mechanics and molecular interactions.

The potential of the AFM to explore surface problems has been greatly expanded by ingenious variants of the technique. In fact, the term "atomic force microscopy" has been generalized to "scanning probe microscopy" (SPM). Table I.1.5.6 lists many of these creative applications of the AFM/STM idea.

Since the AFM measures force, it can be used with both conductive and nonconductive specimens. Force must be applied to bend a cantilever, so AFM is subject to artifacts caused by damage to fragile structures on the surface. Both AFM and STM can function well for specimens under water, in air or under vacuum. For exploring biomolecules or mobile organic surfaces, the "pushing around" of structures by the tip is a significant concern. This surface artifact can be capitalized upon to write and fabricate surface structures at the nanometer scale (Figure I.1.5.17) (Quate, 1997; Boland et al., 1998; Rosa and Liang, 2009).

Newer Methods

There are many other surface characterization methods that have the potential to become important in future years. Some of these are listed in Table I.1.5.7. A few of these evolving techniques which will be specifically mentioned here include sum frequency generation (SFG), Raman, and synchrotron methods.

SFG is a vibration spectroscopy method that looks at the outmost surface of materials in aqueous, air or vacuum. SFG uses two high intensity, pulsed laser beams, one in the visible range (frequency = $\omega_{visible}$), and one in

and is retracted are illustrated in Figure I.1.5.15. Since force is being measured and Hooke's Law applies to the deformation of an elastic cantilever, AFM can be used to quantify the forces between surface and tip. Quantitative AFM is now widely used to measure the strength of interaction between biomolecules (Chilkoti et al., 1995; Muller and Dufrêne, 2008) and the mechanical properties of proteins (Li and Cao, 2010).

AFM instruments are commonly applied to surface problems using many possible tip interaction modes. Some AFM modes are contact, lateral force, non-contact,

TABLE I.1.5.6	Scanning Probe Microscopy (SPM) Modes	
Name	**Acronym**	**Use**
Contact mode	CM-AFM	Topographic imaging of harder specimens
Tapping (intermittent force) mode	IF-AFM	Imaging softer specimens
Non-contact mode	NCM-AFM	Imaging soft structures
Force modulation (allows slope of force-distance curve to be measured	FM-AFM	Enhances image contrast based on surface mechanics
Scanning surface potential microscopy (Kelvin probe microscopy)	SSPM, KPM	Measures the spatial distribution of surface potential
Magnetic force microscopy	MFM	Maps the surface magnetic forces
Scanning thermal microcopy	SThM	Maps the thermal conductivity characteristics of a surface
Recognition force microscopy	RFM	Uses a biomolecule on a tip to probe for regions of specific biorecognition on a surface
Chemical force microscopy	CFM	A tip derivatized with a given chemistry is scanned on a surface to spatially measure differences of interaction strength
Lateral force microscopy	LFM	Maps frictional force on a surface
Electrochemical force microscopy	EFM	The tip is scanned under water and the electrochemical potential between tip and surface is spatially measured
Nearfield scanning optical microscopy	NSOM	A sharp optical fiber is scanned over a surface allowing optical microscopy or spectroscopy at 100 nm resolution
Electrostatic force microscopy	EFM	Surface electrostatic potential are mapped
Scanning capacitance microscopy	SCM	Surface capacitance is mapped
Conductive atomic force microscopy	CAFM	Surface conductivity is mapped with an AFM instrument
Nanolithographic AFM	NAFM	An AFM tip etches, oxidizes or reacts a space permitting pattern fabrication at 10 nm or better resolution
Dip-pen nanolithography	DPN	An AFM tip, inked with a thiol or other molecule, writes on a surface at the nanometer scale
FIGURE I.1.5.17 An AFM tip, using relatively high force, was used to scratch a rectangular feature into a thin (70 Å) plasma-deposited film. The AFM also characterized the feature created.

the infrared (frequency = ω_{ir}), to illuminate a specimen. The light emitted from the specimen by a non-linear optical process, $\omega_{sum} = \omega_{visible} + \omega_{ir}$, is detected and quantified (Figure I.1.5.18). The intensity of the light at ω_{sum} is proportional to the square of the sample's second-order non-linear susceptibility (χ_2). The term susceptibility refers to the effect of the light field strength in polarizing molecules (molecular polarizability). The ω_{sum} light intensity vanishes where a material has inversion symmetry, i.e., in the bulk of the material there is compositional homogeneity so on either side of an introduced plane, there is symmetry. At an interface, the inversion symmetry is broken and an SFG signal is generated. Thus, SFG is exquisitely sensitive to the plane of the interface. In practice, ω_{ir} is scanned over a vibrational frequency range.

This leads to vibrational absorptions that occur with only interface molecules. For this case, the SFG signal is resonantly enhanced and we see a vibrational spectrum. The advantages of SFG are the superb surface sensitivity, the cancellation of bulk spectral intensity (for example, this allows measurements at a water/solid interface), the richness of information from vibrational spectra, and the ability to study molecular orientation by the polarization of the laser light. SFG is not yet a routine method. The lasers and optical components are expensive and require precision alignment. However, the power of SFG for biomaterials studies has already been proven with studies on hydrated hydrogels, polyurethanes, surface active polymer additives, proteins, and non-fouling surfaces (Shen, 1989; Chen et al., 2002; Stein et al., 2009).

> SFG is among the most surface-sensitive of all surface methods. It provides vibrational spectroscopic detail on surface composition, orientation, and interactions.

In Raman spectroscopy a bright light is focused on a specimen; most of the light scatters back at the same frequency as the incident beam. However, a tiny fraction of this light excites vibrations in the specimen, and thereby loses or gains energy. The frequency shift of the light corresponds to vibrational bands indicative of the molecular structure of the specimen. The Raman spectroscopic technique has been severely limited for surface studies due to its low signal level. However, in recent years

TABLE I.1.5.7	Methods Applicable for the Surface Characterization of Biomaterials
Method	**Information Obtained**
Second-harmonic generation (SHG)	Detect submolayer amounts of adsorbate at any light-accessible interface (air–liquid, solid–liquid, solid–gas)
Surface-enhanced Raman spectroscopy (SERS)	High-sensitivity Raman at rough metal interfaces
Ion scattering spectroscopy (ISS)	Elastically reflected ions probe only the outermost atomic layer
Laser desorption mass spectrometry (LDMS)	Mass spectra of adsorbates at surfaces
Matrix assisted laser desorption ionization (MALDI)	Though generally a bulk mass spectrometry method, MALDI has been used to analyze large adsorbed proteins
IR photoacoustic spectroscopy (IR-PAS)	IR spectra of surfaces with no sample preparation based on wavelength-dependent thermal response
High-resolution electron energy loss spectroscopy (HREELS)	Vibrational spectroscopy of a highly surface-localized region, under ultrahigh vacuum
X-ray reflection	Structural information about order at surfaces and interfaces
Neutron reflection	Thickness and refractive index information about interfaces from scattered neutrons – where H and D are used, unique information on interface organization can be obtained
Extended X-ray absorption fine structure (EXAFS)	A synchrotron method giving atomic-level chemical and nearest-neighbor (morphological) information
Near edge X-ray absorption fine structure (NEXAFS)	A synchrotron method providing information about bonding environments and chain orientation
Scanning Auger microprobe (SAM)	Spatially defined Auger analysis at the nanometer scale
Surface plasmon resonance (SPR)	Study aqueous adsorption events in real time by monitoring changes in surface refractive index
Rutherford backscattering spectroscopy (RBS)	Depth profiling of complex, multiplayer interfacial systems
FIGURE I.1.5.18 Schematic diagram of a sum frequency generation (SFG) apparatus. (Based upon a diagram by Polymer Technology Group, Inc.)

great strides in detector sensitivity have allowed Raman to be applied for studying the minute mass of material at a surface. Also, surface enhanced Raman spectroscopy (SERS), Raman spectra taken from molecules on a roughened metal surface, can enhance Raman signal intensity by 10^6 or more. Raman spectra will be valuable for biomedical surface studies, because water, which absorbs radiation very strongly in the infrared range, has little effect on Raman spectra that are often acquired with visible light (Storey et al., 1995; Smith, 2008).

Synchrotron sources generate energetic radiation that can be used to probe matter. Such sources were originally confined to the physics community and devoted to fundamental studies. However, there are now many synchrotron sources offering access to researchers in all communities, with better instrumentation and improved data interpretation. Synchrotron sources are typically national facilities costing more than $100,000,000, and often occupying hundreds of acres (Figure I.1.5.19). By accelerating electrons to near the speed of light in a large, circular ring, energies covering a broad swathe of the electromagnetic spectrum (IR to energetic X-rays) are emitted. A synchrotron source (and ancillary equipment) permits a desired energy of the probe beam to be "dialed in" or scanned through a frequency range. Other advantages include high source intensity (bright light), and polarized light. Some of the experimental methods that can be performed with great success at synchrotron sources include crystallography, scattering, spectroscopy, microimaging, and nanofabrication. Specific surface spectroscopic methods include scanning photoemission microscopy (SPEM, 100 nm spatial resolution) (Leung et al., 2010), ultraESCA (100 μm spatial resolution, high energy resolution), and near edge X-ray absorption spectrometry (NEXAFS).

STUDIES WITH SURFACE METHODS

Hundreds of studies have appeared in the literature in which surface methods have been used to enhance the understanding of biomaterial systems. A few studies that demonstrate the power of surface analytical methods for biomaterials science are briefly described here.

Platelet Consumption and Surface Composition

Using a baboon arteriovenous shunt model of platelet interaction with surfaces, a first-order rate constant of

reaction of platelets with a series of polyurethanes was measured. This rate constant, the platelet consumption by the material, correlated in an inverse linear fashion with the fraction of hydrocarbon-type groups in the ESCA C1s spectra of the polyurethanes (Hanson et al., 1982). Thus, surface analysis revealed a chemical parameter about the surface that could be used to predict long-term biological reactivity of materials in a complex *ex vivo* environment.

Contact-Angle Correlations

The adhesion of a number of cell types, including bacteria, granulocytes, and erythrocytes, has been shown, under certain conditions, to correlate with solid–vapor surface tension as determined from contact-angle measurements. In addition, immunoglobulin G adsorption is related to γ_{sv} (Neumann et al., 1983).

Contamination of Intraocular Lenses

Commercial intraocular lenses were examined by ESCA. The presence of sulfur, sodium, and excess hydrocarbon at their surfaces suggested contamination by sodium dodecyl sulfate (SDS) during the manufacture of the lenses (Ratner, 1983). A cleaning protocol was developed using ESCA to monitor results that produced a lens surface of clean PMMA.

Titanium

The discoloration sometimes observed on titanium implants after autoclaving was examined by ESCA and SIMS (Lausmaa et al., 1985). The discoloration was found to be related to accelerated oxide growth, with oxide thicknesses to 650 Å. The oxide contained considerable fluorine, along with alkali metals, and silicon. The

source of the oxide was the cloth used to wrap the implant storage box during autoclaving. Since fluorine strongly affects oxide growth, and since the oxide layer has been associated with the biocompatibility of titanium implants, the authors advise avoiding fluorinated materials during sterilization of samples. Another paper by this group contains detailed surface characterization of titanium using a battery of surface methods, and addresses surface preparation, contamination, and cleaning (Lausmaa, 1996).

SIMS for Adsorbed Protein Identification and Quantification

All proteins are comprised of the same 20 amino acids and thus, on average, are compositionally similar. Surface analysis methods have shown the ability to detect and quantify surface-bound protein, but biological tools have, until recently, been needed to identify specific proteins. Modern static SIMS instrumentation, using a multivariate statistical analysis of the data, has demonstrated the ability to distinguish between more than 13 different proteins adsorbed on surfaces (Wagner and Castner, 2001). Also, the limits of detection for adsorbed proteins on various surfaces were compared by ESCA and SIMS (Wagner et al., 2002).

Poly(glycolic acid) Degradation Studied by SIMS

The degradation of an important polymer for tissue engineering, poly(glycolic acid), has been studied by static SIMS. As well as providing useful information on this degradation process, the study illustrates the power of SIMS for characterizing synthetic polymers and their molecular weight distributions (Chen et al., 2000).
Peptides on Polystyrene Studied by SFG and NMR. Although proteins at interfaces are critically important to biomaterials science, we have an incomplete picture of what proteins really look like and behave like on surfaces. Using the surface method, SFG, and a traditional bulk analysis method, solid-state NMR, an elegant picture of peptides on surfaces emerges. The study quantified, with site specificity and atomic resolution, the orientation and dynamics of side chains in labeled, synthetic model peptides adsorbed onto polystyrene (Weidner et al., 2010).

CONCLUSIONS

The instrumentation of surface analysis steadily advances, and newer instruments and techniques can provide invaluable information about biomaterials and medical devices. The information obtained can be used to monitor contamination, ensure surface reproducibility, and explore fundamental aspects of the interaction of biological systems with living systems. Considering that biomedical experiments, especially *in vivo* experiments, are typically expensive to perform, the costs for

surface analysis are modest to ensure that the surface is as expected, stable, and identical from experiment to experiment. Surface analysis can also contribute to the understanding of medical device failure (and success). Myriad applications for surface methods are found in device optimization, manufacture, and quality control. Predicting biological reaction based on measured surface structure is a frontier area for surface analysis.

CHAPTER I.1.6 ROLE OF WATER IN BIOMATERIALS

Buddy D. Ratner
Professor, Bioengineering and Chemical Engineering, Director of University of Washington Engineered Biomaterials (UWEB), Seattle, WA, USA

In the world there is nothing more submissive and weak than water. Yet for attacking that which is hard and strong nothing can surpass it.

Lao Tzu

Water! Omnipresent, inert, a simple diluent – these words come to mind and prompt the question: "why is there a section of this textbook devoted to water?" The special properties of water, this substance that is critical for life as we know it, significantly impact the "materials-centric" subject of biomaterials, and the biology closely associated with biomaterials. Water is a unique, remarkable substance – in this instance, the word "unique" can be used without hyperbole. Although its chemical composition was elucidated in the 1770s by Lavoisier and others, its liquid structure continues to be explored today using state-of-the-art physical characterization methods. The importance of water for life as we know it was appreciated as early as 1913 in an interesting historical volume, *The Fitness of the Environment* (Henderson, 1913; available in reprint).

This chapter will first introduce the physical and chemical properties of water. Then water's significance for biomaterials and biology will be expanded upon.

WATER: THE SPECIAL MOLECULE

The simple "H_2O" structure of the water molecule does not immediately communicate the ability of one water molecule to interact with many other water molecules, in particular to interact not too strongly, and not too weakly. This interaction, largely via the hydrogen bond, is associated with the dipole of the water molecule (slightly more negatively charged at the oxygen and positively charged at the hydrogen, i.e., partial negative and positive charges). This dipole, combined with the bent shape (bond angle of 104.6°) of the molecule and its small size contributes to the special properties of liquid

water. Figure I.1.6.1 illustrates schematically the geometry of the water molecule, and suggests some hydrogen bonding possibilities with neighboring water molecules (as well as the occasional H^+ or OH^-).

> The physical properties of water are profoundly unique compared to all other substances.

The unique physical and chemical properties of water, attributable to the 104.6° bond angle and the ability to form multiple hydrogen bonds, are discussed here. Note how special water is compared to other liquid and solid substances.

Melting Point and Boiling Point

The physical properties of H_2O that make it stand out from all other related molecules are best appreciated from the data in Table I.1.6.1.

As the molecular weight for compounds in this series of related molecules decreases, the boiling points also decrease, until you reach water, where the boiling point is (unexpectedly) up to 160°C higher. At common temperatures and pressures on earth, all the other compounds exist as gases, except water. A similar dramatic trend is seen in freezing point.
FIGURE I.1.6.1 Schematic illustration of five water molecules suggesting their geometry and dipole. A hydrogen bond is represented by a dotted line. Consider the many possibilities for these electrostatic (charge) interactions.

Density and Surface Tension

Water has a density of 0.997 g/ml at 25°C. As the temperature decreases, water, like most substances, increases in density, until 4°C where its density is 1.00 g/ml. Then, as temperature is decreased further, an unusual phenomenon is observed. The density decreases as the temperature is lowered. At 0°C, the density is 0.92 g/ml. Thus, ice floats on liquid water. There is special significance to this. If bodies of water froze from the bottom to the top (i.e., if ice were heavier than water), during cold periods in earth's geological history most aquatic life might have been destroyed.

Surface tension is a measure of the magnitude of cohesive forces holding molecules together. For substances at ambient temperature and pressure, water has the highest surface tension with one exception – mercury. The water surface tension is 72.8 dyne/cm. Compare this to, for example, ethanol at 22.3 dyne/cm (mN/m) and ethylene glycol at 47.7 dyne/cm. This surface tension permits a water strider insect (family Gerridae) to transport across lakes riding on the "surface skin" of water, a metal paper clip to float (Figure I.1.6.2), and assists with the transport of water from soil to the tops of tall trees.

TABLE I.1.6.1	Boiling Point and Freezing Point of Water Contrasted to Other H_2X Compounds		
H_2X Compound	**Molecular Weight**	**Boiling Point**	**Freezing Point**
H_2Te Hydrogen telluride	130	−2°C	−49°C
H_2Se Hydrogen selenide	81	−41°C	−66°C
H_2S Hydrogen sulfide	34	−60°C	−82°C
H_2O Water	18	100°C	0°C

FIGURE I.1.6.2 A metal paper clip floats on the water surface "skin," a manifestation of water's high surface tension. (Photograph by Buddy Ratner.)

Specific Heat and Latent Heats of Fusion and Evaporation

Water has a specific heat of 1.0 calorie/g°C, that is, the heat per unit mass required to raise the temperature of water 1°C. For comparison, copper has a specific heat of 0.1 cal/g°C, and ethyl alcohol has a specific heat of 0.6 cal/g°C. Water has a higher specific heat than any other common substance. Related to the specific heat is the latent heat of fusion or evaporation. The latent heat is the energy in calories per gram taken up or released by matter changing phase (liquid/solid or solid/liquid) with no change in temperature. Again, water has anomalously high values compared to other common substances.

Water as a Solvent

Water is a remarkably powerful and versatile solvent. It will dissolve proteins, ions, sugars, gases, many organic liquids, and even lipids (up to the critical micelle concentration). In fact, it is the most versatile solvent that we know.

WATER: STRUCTURE

Figure I.1.6.1 suggests that water can form extended hydrogen bonding structures. These structures grow in three dimensions. The molecular crystal structure of ice is shown in Figure I.1.6.3. At temperatures of 0°C and below, thermal fluctuations of molecules (referred to as kT vibrations) are low and a continuous, ordered three-dimensional network of water molecules can form. The hydrogen bonds in water are relatively low strength, approximately 5 kcal/mol (21 kJ/mol); in contrast, a C–H bond is approximately 100 kcal/mol. At room temperature, the thermal fluctuations of water molecules can disrupt this H-bond association – if it were not so, water
FIGURE I.1.6.3 The hexagonal ice structure. (Wikipedia public domain image.)

would coalesce into a solid at room temperature. An oft-cited model of water molecule organization suggests that disrupted groupings of water molecules rapidly form new clusters (dimers, trimers, tetramers, pentamers, hexamers, etc.) (Keutsch and Saykally, 2001). This is the "flickering cluster" model of water structure. More recently, it has been established that liquid water is closer to a hydrogen-bonded continuum with much bond angle distortion from the tetrahedral organization seen in the ice structure, and with bonds breaking and reforming so rapidly (in the order of 200 femtoseconds), that the cluster model is not an accurate description (Smith et al., 2005). The continuum model is now the most accepted model for water structure, through there is still much controversy about water structure, and new insights are frequently reported.

The water structure discussion, above, applies to bulk, pure water. The water continuum organization can be disrupted or reorganized by dissolved ions or solutes, by absorption into hydrophilic polymers (hydrogels when the polymer is cross-linked), and by solid surfaces. Each of these cases will be very briefly addressed.

Dissolved ions and solutes may have a profound impact on water organization (Marcus, 2009). Dissolved salts are dissociated to form an anion and a cation, with each ion having a shell of water of different structure from the bulk. This hydration shell perturbs the structure of water adjacent to it (Marcus, 2009). Much of the study of dissolved ions has centered around studies of the Hofmeister series of anions:

$$CO_3^{2-} > SO_4^{2-} > S_2O_3^{2-} > H_2PO_4^{-} > F^{-} >$$
$$Cl^{-} > Br^{-} < NO_3^{-} > I^{-} > ClO_4^{-} > SCN^{-}$$
Ions to the left of the series are referred to as kosmotropes – they generally precipitate proteins from solution and inhibit denaturation. Ions on the right side of the series are considered chaotropes, and these increase protein solubility and are more denaturing. Note that chloride is roughly at the center of the series, and thus might be expected to induce little change in proteins and water. Though earlier theories on the Hofmeister series suggested that ions to the left enhanced water structure while those to the right destructured or disordered water, this concept is not fully supported by recent experiments. The Hofmeister effect is impacted by the degree of hydration of ions in water, which cation is involved and specific interactions of ions with solutes. Review articles that discuss the complexities of the Hofmeister effect and consider contemporary experimental and theoretical work are available (Zhang and Cremer, 2010; Paschek and Ludwig, 2011).

The "swelling" water entrained in gels (hydrogels, see Chapter I.2.5) is thought to be in three possible forms. Different nomenclatures are used to describe these forms, but basically three states have been proposed: (1) free water (similar to bulk water); (2) tightly-bound water (more structured and with limited mobility); and (3) intermediate water (with characteristics of both free and bound water) (Jhon and Andrade, 1973; Akaike et al., 1979). Below, when the hydrophobic effect is discussed, other possibilities will be suggested. Evidence for different forms of water in gels continues to accumulate (Sekine and Ikeda-Fukazawa, 2009) and implications for biomaterials and biocompatibility have been discussed (Tsuruta, 2010). The nature of the water in the gel may also impact on the diffusion of molecules through it, blood interactions, and its performance as a cell-support in tissue engineering. The water that swells a hydrogel is impacted by the polymer chains at a nanoscale, because of its close proximity to the polymer that comprises the mesh of the hydrogel. When macroscopic pores are introduced into the hydrogel, the polymer will impact the water in a different fashion, i.e., the surface of the pores will interact with water in a manner similar to surface effects discussed in the next paragraph; in the interior of the pore (away from the pore wall), the water will have an organization more similar to bulk water.

When a solid surface or biomaterial disrupts the continuum structure of water, the water near the solid surface will have to adopt a new organization to achieve energy minimization for the total system. Since all our biomaterials will first see water before proteins or cells ever diffuse or transport to the surface, the nature of this surface water layer may be, from a biomaterials science standpoint, the most important event driving biointeractions at interfaces.

> The nature of water in proximity to surfaces may be the primary driver for interactions between biomaterials and biological systems.

There is ample evidence from many analytical techniques, and also from computational methods, that water organization is altered close to a surface compared to the bulk. Most experimental data suggests this difference persists over a length of 1 to 4 water molecules, before reverting to a structure indistinguishable from the bulk water. There is much research on the adsorption of the first layer of water on materials. Clearly, the organization of this first layer will dictate the structure of subsequent layers. On many close packed metal crystal surfaces (for example, Pt, Ni, Pd) results suggest that a water bilayer exists with a structure analogous to ice (Hodgson and Haq, 2009). This may have led to the somewhat misleading term for interfacial water, "ice-like water." Although the water structure is different from the bulk liquid at all surfaces, the specific ice-like organization is predominantly seen at these close packed metal crystal surfaces. Above the water bilayer directly in contact with the metal, water structure is altered for a few molecular layers until it becomes indistinguishable from bulk water. Other studies demonstrate differences between hydrophilic and hydrophobic surfaces as to their interactions with water (Howell et al., 2010). Hydrophilic surfaces largely have a substantial effect

on water organization, while at hydrophobic interfaces there appears to be a low water density zone, sometimes called a depletion zone, less than a nanometer from the surface. There are hundreds of recent studies on the water–solid interface, mostly in physical chemistry journals. A comprehensive review of this complex and still controversial subject would be impossible in this textbook. However, the take home message is relatively straightforward – the presence of an interface alters the water structure adjacent to it.

WATER: SIGNIFICANCE FOR BIOMATERIALS

When a protein or a cell approaches a biomaterial, it interacts with the surface water first. This final section will briefly review some implications of this surface water for biomaterials.

> When a protein or a cell approaches a biomaterial, it interacts with the surface water first.

Hydrophobic Effect, Liposomes, and Micelles

If we place a drop of oil under water it will round up to a sphere as it floats to the water surface. The common explanation for this is that because oil molecules do not H-bond with water molecules the oil cannot strongly interact with the bulk water phase. Another way to say this is that the oil disrupts the bulk (continuum) structure of water, and the water molecules at the oil interface then have to restructure to a new (more ordered) organization. This decrease in water entropy is energetically unfavorable according to the second law of thermodynamics. So, the oil minimizes its interfacial area with the water by coalescing into a sphere (a sphere has the lowest surface area for a given volume). This is called the hydrophobic effect (Tanford, 1978; Widom et al., 2003). It is not driven by the oil–water molecular interactions, but rather by the necessity to minimize the more structured (low entropy) organization of water molecules.

If we now take a surfactant molecule comprised of an "oily" segment and a polar (water-loving) segment, by shielding the oily phase from the water with the hydrophilic head groups, contact between oil and water is minimized. Figure I.1.6.4 illustrates some hydrophobic effect-driven supramolecular aggregate structures that lead to this energy minimization. Liposomes and block copolymer micelles are widely used in drug delivery, where the hydrophobic region (micelle core or liposome bilayer) or the aqueous center (liposome) can carry a hydrophobic drug or hydrophilic drug, respectively (see Chapter II.5.18). Bilayer sheets are used in biosensors to orient and stabilize receptor proteins.
FIGURE I.1.6.4 Lipid molecules with polar head groups (white) and hydrophobic tails (brown), when placed in water, organize themselves to minimize surface area contact between the hydrophobic tail (typically comprised of methylene units, -CH2-) and water. This minimization of contact area, depending on precise conditions, can lead to micelles, liposomes or bilayer sheets. (Modified from a public domain image on Wikimedia Commons.)

Hydrogels

The structured water within hydrogels has been discussed. Water structure associated with hydrogels has been implicated in their interactions with blood (Garcia et al., 1980; Tanaka and Mochizuki, 2004). Water structure in hydrogels is also thought to be important in the performance of hydrogel contact lenses, specifically the rate of lens dehydration (Maldonado-Codina and Efron, 2005).

Protein Adsorption. Protein adsorption is discussed in detail in Chapter II.1.2, and is critically important for understanding the performance of biomaterials. A question commonly posed is: "Why do proteins bind rapidly and tenaciously to almost all surfaces?" A model that can explain this considers structured water at interfaces. All surfaces will organize water structure differently from the bulk structure; this organization almost always gives more structured (lower entropy) water. If a protein can displace the ordered water in binding to the surface, the entropy of the system will increase as the water molecules are released and gain freedom in bulk water. This is probably the driving force for protein adsorption at most interfaces. There are some specially engineered surfaces referred to as "non-fouling" or "protein-resistant" (see Chapter I.2.10). These surfaces may resist protein adsorption by binding or structuring water so strongly that the protein molecule cannot "melt" or displace the organized or tightly bound water, and thus there is no driving force for adsorption.

Life

Living systems self-assemble from smaller molecular units. For example, think about the organizational processes in going from an egg, to a fetus, to a mature

creature. Much of this assembly is driven by hydropho-bic interactions (i.e., entropically by water structure). Another area where water structure has a major impact on life involves DNA and its unique binding of water (Khesbak et al., 2011). Also, consider enzymes that are so essential to life. A substrate molecule enters the active site of an enzyme by displacing water molecules. The unique mechanical properties of cartilage under com-pression can be modeled by considering water organi-zation. In fact, the average human is 57% by weight water, on a molar basis by far the major component in the human body. Thus we can well appreciate, as Hen-derson surmised in 1913, that water is essential to this phenomenon we call life. As you work through this text-book, think about how the phenomena you are reading about may be driven or controlled by water that com-prises such a large fraction of all biological systems.

Classes of Materials Used in Medicine

CHAPTER I.2.1 INTRODUCTION: THE DIVERSITY AND VERSATILITY OF BIOMATERIALS

Allan S. Hoffman

Professor of Bioengineering and Chemical Engineering, UWEB Investigator, University of Washington, Seattle, WA, USA

In Section I.2 the reader will find chapters covering the fundamental principles of the many diverse materials used in a great variety of implants, extracorporeal medical devices, dermal and mucosal treatments and devices, drug delivery systems, sensors, and diagnostic assays. When such biomaterial devices and systems are exposed to the biologic environment, it is their surfaces that first encounter biologic species such as proteins, which usually deposit a monolayer of protein. Subsequently, cells interact with the adsorbed protein monolayers on the surfaces of the biomaterials. Therefore, it is the fundamental compositions and "nanotextures" of those biomaterials surfaces that are expected to strongly influence the overall responses of the biological environment to the materials (as well as the responses of the biomaterials to the bioenvironment), as detailed in Section II.2. Section I.2 also includes chapters that cover the key technologies used to fabricate, modify, and characterize biomaterials and their surfaces. Thus, this section is fundamental to the entire spectrum of the science and engineering of biomaterials and their surfaces for many diverse applications.

In this section, the authors often include important historical details. The wide diversity and sophistication of materials currently used in medicine and biotechnology is testimony to the significant scientific and technological advances that have occurred over the past 50 years. From World War II to the early 1960s, a few pioneering surgeons were taking commercially available polymers and metals, fabricating implants and components of medical devices from them, and applying them clinically. There was little government regulation of this activity, and yet many of those earliest implants and devices had remarkable success. However, there were also some dramatic failures, often based on a poor choice or improper fabrication of the biomaterial components (see Chapters III.1.3 and III.1.5). This led the surgeons to enlist the aid of physical, biological, and materials scientists and engineers, and the earliest multidisciplinary "bioengineering" collaborations were born some time in the 1970s–1980s.

These teams of physicians and scientists and engineers not only recognized the need to control the composition, purity, and physical properties of the materials they were using, but they also recognized the need for new materials with new and special properties. This stimulated the development of many new materials, beginning in the 1970s. New materials were designed *de novo* specifically for medical use, such as biodegradable polymers, "medical grade" silicones, pyrolytic carbon, and bioactive glasses and ceramics. Some were derived from existing materials that were then fabricated using new technologies, such as polyester fibers that were knitted or woven in the form of tubes for use as vascular grafts or cellulose acetate plastic that was processed as bundles of hollow fibers for use in artificial kidney dialysers. Some materials were "borrowed" from unexpected sources, such as pyrolytic carbons or titanium alloys that had been developed for use in space and nuclear technology. Some were the result of serendipity, such as the use of titanium in dental implants. Other materials were specifically modified to provide special biological properties, such as immobilization of heparin for anticoagulant surfaces, one of the earliest "bioengineered" biomaterials.

In this section, the reader will find chapters on the five basic classes of biomaterials: Polymers (Chapter I.2.2, focused on synthetic polymeric biomaterials, including subsections on: (A) polyurethanes, (B) silicones, (C) fluorinated biomaterials, and (D) acrylics); metals (Chapter I.2.3, including subsections on: (A) titanium and nitinol (NiTi) and (B) stainless steels); ceramics and glasses (Chapter I.2.4, including subsections on: (A) natural and synthetic hydroxyapatites and (B) alumina); engineered natural materials (Chapter I.2.7, with special focus on hyaluronic acid and collagen); and carbons (Chapter I.2.8).

There are additional chapters on the special properties and compositions of biomaterials. For example, sometimes two different classes of materials are combined together into a composite material, such

as silica-reinforced silicone rubber or hydroxyapatite particle-reinforced poly(lactic acid). Such composites can be considered as a sixth class of biomaterials, and they are discussed in Composites (Chapter I.2.9). This chapter emphasizes the mechanical properties of polymers that have been reinforced with specially surface-treated particles, fibers, and fabrics.

It should be noted that some implants and devices, such as artificial heart valves, are comprised of more than one class of biomaterial. For example, the Starr-Edwards ball-in-cage heart valve includes the silicone rubber ball, the polyester fabric for fixation to the tissues, and the stainless steel struts; however, these implants should not be considered as "composites," even though one or more component may be a composite material (such as the silica-reinforced silicone rubber ball composite material in the Starr-Edwards ball-in-cage heart valve). These implants are considered in other sections and chapters in this text.

Another chapter on special forms and properties of synthetic polymers is Hydrogels (Chapter I.2.5). This chapter includes a wide variety of compositions and structures, but it does not include "smart hydrogels" or drug delivery from hydrogels, which are found in other chapters, e.g., Chapter I.2.11 in the section on "smart," environmentally-responsive polymers, and Chapter II.5.16, which is a very detailed chapter on drug delivery systems. Section I.2 also includes a chapter on bioresorbable

and bioerodible materials (Chapter I.2.6) that are a very important subclass of polymeric biomaterials.

Following these chapters, there are several chapters that focus on surfaces of biomaterials, including the principles of surface modification (Chapter I.2.12), surface-immobilized biomolecules (Chapter I.2.17), and surface patterning (Chapter I.2.13). These chapters are fundamental to the bioresponses of biomaterials.

Special fabrication processes and forms of materials are also considered in chapters on electrospinning of fibers (Chapter I.2.16), medical fibers and textiles (Chapter I.2.14), textured and porous materials (Chapter I.2.15), and micro- and nanoparticles (Chapter I.2.19). A chapter on biomimetic materials (Chapter I.2.18) is included, with special focus on bio-inspired designs and compositions of biomaterials.

More recently, biomaterials scientists and engineers have developed a growing interest in natural tissues and polymers in combination with living cells. This is particularly evident in the field of tissue-engineering, which focuses on the repair or regeneration of natural tissues and organs. This interest has stimulated the isolation, purification, and application of many different natural materials, including decellularized natural tissues and spider silk. The principles and applications of these biomaterials and modified biomaterials are critically described, discussed, and reviewed in Section II.6 of this text.

CHAPTER I.2.2 POLYMERS: BASIC PRINCIPLES

Daniel E. Heath and Stuart L. Cooper
William G. Lowrie Department of Chemical and Biomolecular Engineering, The Ohio State University, Columbus, OH, USA

INTRODUCTION

Polymer materials possess an array of unique properties which make them useful in a wide variety of biomaterial applications such as orthopedics, dental, hard and soft tissue replacements, and cardiovascular devices. In fact, polymers represent the largest class of materials used in medicine. This chapter introduces the basic principles in polymer science, illustrates how polymer materials can be specifically designed to fill needs in the biomaterials field, and provides examples of how this class of materials is currently used in medical applications.

The central idea of this chapter is structure–property relationships, which means molecular characteristics such as molecular architecture, molecular weight, and chemical composition are directly related to the physical and chemical properties of the macroscopic material. For instance, polymer scientists in other fields have been

able to exploit structure–property relationships to create non-stick coatings, pressure-sensitive adhesives, and the penetration-resistant materials used in bullet-proof vests. A biomaterials scientist aware of structure–property relationships can rationally engineer a polymer system for a specific need.

THE POLYMER MOLECULE

Molecular Structure of Single Polymer Molecules

The hallmark of polymer molecules is high molecular weight. A single polymer molecule could have a molecular weight of 200,000 Da compared to a water molecule, which has a molecular weight of 18 Da. Furthermore, polymer molecules are organized into very interesting architectures. Common shapes of polymer molecules are shown in Figure I.2.2.1. The simplest is the linear chain where there is a single molecular backbone. When linear chains of two different composition polymers (e.g., A and B) are linked together, the resultant polymer is called an A–B block copolymer. If another chain is added to the second chain, it may be called an A–B–C triblock copolymer, or more simply, an A–B–C block copolymer. Branched structures are also

possible where a central polymer backbone has smaller side chains extending from it. Branches can occur due to undesired side reactions during synthesis, or can be purposefully incorporated into the molecular structure. So far we have discussed polymer systems in which there are discrete polymer molecules. However, what would happen if you took a linear polymer molecule and covalently bonded it to the backbone of another linear

FIGURE I.2.2.1 Some of the molecular structures available for polymer molecules. In the schematic of the network, polymer open circles indicate cross-link sites.

chain? You would produce a branched structure. If you repeated this act many times over you would eventually link all of the polymer chains together into one very large *network* polymer. This is also possible by using small di- or tri-functional "cross-linker" molecules to react with pendant or terminal reactive groups on linear polymer chains, eventually yielding a network polymer.

Chemical Structure of Single Polymer Molecules

If you were able to see the individual atoms making up a polymer molecule, you would notice the same basic structure repeats over and over again. Figure I.2.2.2 shows a schematic of a linear polypropylene molecule. The polymer backbone is a series of carbon–carbon single bonds, while the hydrogen atoms and methyl group are *pendant groups*. The polymer chain is composed of many $-(-CH_2-CHCH_3-)-$ groups covalently linked end-to-end. This structure is called the *repeat unit* of a polymer molecule. Etymologically, polymer comes from the Greek "poly," meaning many, and "meros," meaning part – many parts. In polymer molecules the "mer" is
FIGURE I.2.2.2 Polypropylene repeat unit and different tactic isomers. In the schematic Me indicates a methyl group.

the repeat unit. The repeat unit can be controlled through polymer synthesis and plays a large role in the macroscopic behavior of the polymer. Figure I.2.2.3 shows the repeat units of several synthetic and natural polymers commonly used in the biomaterials field.

Copolymers

Sometimes it is advantageous to synthesize copolymers – polymers containing more than one chemically distinct repeat unit. For instance, a researcher may synthesize a
FIGURE I.2.2.3 Repeat unit of common polymer biomaterials.
FIGURE I.2.2.4 Some of the molecular structures available for copolymers.
Poly(tetrafluoroethylene-co-hexafluoropropylene) random copolymer
Poly(lactide-co-glycolide) random copolymer

FIGURE I.2.2.5 Repeat unit of two common copolymer biomaterials.

polymer which contains repeat units "A" and "B." As shown in Figure I.2.2.4, there are many different ways the repeat units could be organized. Random copolymers occur when the "A" and "B" repeat units have no order in the backbone; however, alternating, block, and graft copolymers are also possible and the arrangement of repeat units affects the physical behavior of the biomaterial. The repeat units of two random copolymers commonly used in the biomaterials field are shown in Figure I.2.2.5.

Determination of Chemical Composition

A researcher will often need to verify the chemical structure of polymers or determine the composition of copolymer systems. Two common techniques a scientist would use are nuclear magnetic resonance spectroscopy (NMR) and infrared spectroscopy (IR). NMR is an analytical technique which exploits the magnetic moments associated with nuclei containing an odd number of protons (most commonly the ^{1}H and ^{13}C isotopes). These protons are excited to a higher energy state through a burst of radiofrequency radiation. The nuclei relax to a lower energy state which is measured as an electric signal. Fourier transform analysis is used to convert this time domain electrical signal into the frequency domain. Due to shielding, protons attached to different structural units will display chemical shifts, meaning their peaks in the NMR spectrum will be at different frequencies. Through analysis of the peak placement and intensity, the chemical structure of molecules can be determined.

Infrared spectroscopy (IR) is also used to determine the chemical composition of polymers. The sample of interest is irradiated with infrared radiation and the sample adsorbs certain wavelengths, resulting in specific molecular motion (such as C–H stretching). The IR spectrum is created by plotting absorbance versus wavelength. Like NMR, analysis of the spectra can lead to the verification of a polymer's composition.

Often the chemical composition of the polymer surface is different from the bulk. For a medical implant the surface composition is highly important, since it will interface with the biological environment. To probe the surface composition X-ray photoelectron spectroscopy (XPS) – also known as electron spectroscopy for chemical analysis (ESCA) – is a common technique. A sample is bombarded with X-rays which results in the ejection of inner shell electrons from the atoms displayed on the material surface. The kinetic energies of the ejected electrons are measured and interpreted into information about the chemical composition of the surface (for more information on surface characterization techniques see Chapter I.1.5).

Tacticity

Tacticity describes the stereochemistry of the repeat units in polymer chains. To illustrate the discussion on tacticity let us consider a molecule of polypropylene (PP). When stretched into its *planar zigzag* form, as seen in Figure I.2.2.2, you can see that sometimes the methyl groups are all on one side of the backbone, sometimes they alternate from side to side, and sometimes they are randomly distributed. During routine synthesis, a polymer chemist would normally produce an *atactic* version of PP, one where the methyl group is randomly located in front of and behind the polymer backbone. However, when a special catalyst is used during synthesis a chemist can produce *isotactic* PP, where all the methyl groups are located on one side of the "stretched out" polymer backbone, or *syndiotactic* PP where the methyl groups regularly alternate from side to side. As will be discussed later, tacticity can drastically affect the physical behavior of the polymer system, largely by affecting the ability of the polymer molecules to crystallize. Tactic isomers occur whenever an atom in the polymer backbone has the capacity to form tetrahedral bonding and is bonded to four different ligands. Such atoms (generally carbon) are referred to as *asymmetric*.

MOLECULAR WEIGHT

The Molecular Weight Distribution and its Averages

During polymerization, polymer chains are built up from low molecular weight monomers. The number of monomer repeat units in each polymer chain is called the *degree of polymerization*. However, in a traditional free radical

or condensation polymerization synthesis, each polymer chain will not have the same degree of polymerization. For instance, in the free radical polymerization of polyethylene, one polymer chain may add 3000 monomers, a second may add 4500 monomers, and a third may only add 1500. Therefore, most polymer systems have a *distribution of molecular weights*. Since polymer materials are made from molecules with a variety of molecular weights, it is incorrect to talk about *the* molecular weight of a polymer system. Instead, a polymer system is described by different averaged values of molecular weight. The two most commonly used averages are the number average molecular weight (M_n) and the weight average molecular weight (M_w). The mathematical definitions of these averages are supplied in Equations 1 and 2, where N_i is the number of molecules with "i" repeat units and M_i is the molecular weight of a polymer chain with "i" repeat units. Since M_w is calculated using the square of the molecular weight it is always greater than or equal to M_n.

$$M_n = \frac{\sum_i N_i M_i}{\sum_i N_i} \tag{1}$$

$$M_w = \frac{\sum_i N_i M_i^2}{\sum_i N_i M_i} \tag{2}$$

The ratio of M_w to M_n is the polydispersity index (PDI) (Equation 3) which is a measurement of the breadth of the molecular weight distribution. If the PDI of a polymer system is unity the number average and weight average molecular weights are identical, meaning the polymer sample is monodisperse (all chains have the same degree of polymerization). For most condensation polymers, the PDI is approximately 2.

$$PDI = \frac{M_w}{M_n} \tag{3}$$

The higher the average molecular weight, the stronger a polymer material will be. However, the melt/solution viscosity also increases with increasing average molecular weight, making the material more difficult to process. Often a molecular weight range exists within which most desired physical behaviors are achieved, yet the material is still easily processed. Generally, a number average molecular weight range from 25,000 to 50,000 Da is suitable for condensation polymers, while values from about 50,000 Da up to hundreds of thousands are preferred for addition polymers.

Characterizing the Molecular Weight Distribution

Through understanding the importance of molecular weight and its distribution, polymer scientists have developed many methods for measuring average molecular weight values. For instance, M_n can be determined through techniques such as end-group analysis, vapor pressure lowering, and freezing point depression. In the following paragraphs we will first discuss common methods historically used to measure M_n (osmotic pressure) and M_w (light scattering). Although osmotic pressure and light scattering are powerful and useful techniques in the field of polymer science, they have been replaced in recent years by gel permeation chromatography (GPC), which gives much more detail about the molecular weight distribution, and does so much quicker. From the molecular weight distribution obtained by GPC, the first and second moments of the distribution, M_n and M_w, are readily determined.

In osmotic pressure experiments, a dilute polymer solution is separated from pure solvent by a semi-permeable membrane through which solvent can freely pass but which excludes polymer. The activity of the pure solvent differs from that of the solvent molecules in the solution phase resulting in a thermodynamic driving force – the osmotic pressure (π or p) causes molecules of pure solvent to diffuse across a membrane (which is permeable only to solvent) and into a compartment containing a solute (e.g., polymer) in solution. This causes the fluid level in the solution compartment to rise, resulting in a hydrostatic pressure head. Equilibrium is reached when the pressure head exactly offsets the osmotic pressure. By measuring the rise in fluid level, the osmotic pressure can be calculated and related to the number average molecular weight. A number of polymer solutions are prepared, each with a distinct concentration. The osmotic pressure is measured for each solution and plotted against concentration, the concentration is then extrapolated to zero, and the number average molecular weight can be determined from the intercept of the regression line.

Light scattering is a common technique to determine the M_w of a polymer system. In dilute solutions, the scattering of light is directly proportional to the number of molecules. The scattered intensity is observed at a distance r and angle Q from the incident beam, and is related to the size or weight average molecular weight of the molecule. The light scattering behavior of a series of polymer solutions with varying concentrations are measured and the data are extrapolated to zero concentration to determine M_w. Once the M_n and M_w values are determined, the PDI of the polymer system can be calculated.

Gel permeation chromatography (GPC) is the most commonly used molecular weight characterization technique in modern polymer science laboratories. Unlike osmotic pressure and light scattering, which provide *average* values of molecular weight, GPC provides the entire molecular weight distribution from which all the desired average values can be calculated. In GPC experiments, a dilute polymer solution flows through a column packed with solid separation media which contains pores on the

same size scale as the polymer molecules. As the polymer molecules flow though the column, smaller chains diffuse into the pores and are detained, while larger polymer chains move through the column faster since they are excluded from the pore structure, resulting in higher molecular weight material eluting from the column first, followed by lower molecular weight species. The concentration of the effluent stream is monitored and a plot of detector signal (which is proportional to polymer concentration) versus elution time can be generated. Elution time is converted to molecular weight though calibration with mono-disperse polymers of known molecular weights.

CONNECTING PHYSICAL BEHAVIOR WITH CHEMICAL CHARACTERISTICS

We have discussed the key characteristics of polymer molecules (molecular architecture, chemical composition, tacticity, and molecular weight). Now we will relate these molecular characteristics to macroscopic properties, and illustrate how these characteristics can be manipulated to create a polymer system with the desired behavior. We will focus on the tensile properties, hydrophilicity, and biodegradability of polymer systems.

Physical States of Linear Polymers. When designing a biomaterial, physical behavior is a key feature. For instance, if you were creating a cement for use in loadbearing bones (tibia or femur) you would have to ensure the material is both strong enough to act as a cement, but not so brittle that it would fail due to low fracture toughness. The physical properties of a polymer system stem from the intermolecular interactions occurring between individual polymer molecules; thus, the molecular characteristics we have discussed up to this point are of extreme importance. As you will see in the following text, the four most fundamental molecular characteristics of polymer chains which determine the physical behavior of a polymer are chain stiffness, chain composition or polarity, chain architecture or regularity, and molecular weight.

> The three fundamental molecular properties of polymer molecules are chain stiffness, chain polarity, and chain architecture. They determine two important temperatures that characterize polymer molecules: T_g, the glass transition temperature, and T_m, the crystalline melting temperature. T_m is only present when there are crystalline regions in a polymer.

In Figure I.2.2.2, we see polypropylene molecules extended into planar zigzags. Although this is a convenient way to draw polymer molecules, this type of extended structure is rarely seen in nature. More often, polymer molecules are found as unorganized and three-dimensional structures called the *random coil*. In an *amorphous* structure, each random coil is highly interpenetrated with its neighbors. Polymers in the rubbery state or the glassy state have this amorphous molecular arrangement. Under

certain conditions, some polymers will arrange themselves into highly organized crystalline domains resulting in a semi-crystalline material. Each of these states will now be explored in more depth.

The Rubbery State. Rubbery polymers are amorphous. However, the random coils have enough thermal energy for rotation to occur around single bonds. If you were able look at polymer molecules in the melt state, you would see that each random coil is continuously changing shape (conformation). This molecular motion becomes more intense as the thermal energy in the system increases. Macroscopically these materials are soft, flexible, and extensible, due to the molecular motion available to the molecules.

The Glassy State. As the polymer system is cooled, rotation around single bonds becomes hindered due to energy barriers created by a segment of a chain having to move (rotate) past a neighboring segment. As the temperature drops, the rate of rotation around main chain bonds in a polymer chain becomes slower and slower, and the chain gets stiffer and stiffer. Eventually, at a low enough temperature, single bond rotation ceases and the interpenetrated random coils become frozen in space. This is called the glassy state, and the temperature where single bond rotation ceases is called the glass transition temperature (T_g). A material below its T_g is called a glass because it is hard, stiff, and brittle. Molecules in the glassy state can no longer rearrange themselves under applied stress, so deformation results in straining the secondary interactions between molecules. The opposite occurs when an amorphous polymer is heated: the amorphous region goes from hard and glassy, to "leathery," to rubbery, and if the material is not cross-linked, it will eventually flow as a viscous fluid and can be processed into shapes.

Ramen Noodles: Glassy Versus Rubbery Polymer Chains

If you're reading this you are probably a college student, which means you are very familiar with Ramen Noodles. A package of noodles can be cooked in about 10minutes. When you first remove the noodles from the package, you will notice that the individual noodles are rather random in shape and intertwined with their neighbors. Furthermore, before boiling, these noodles are very rigid and fixed in relation to one another. This food product is a pretty good example of a polymer in the glassy state, where each noodle represents one polymer molecule. As the noodles are boiled they become flexible, and can easily change their shape and slip around; however, they retain their intertwined character. These noodles are a good example of a polymer material in the rubbery state.

The Semi-Crystalline State. All polymer systems form glasses at sufficiently low temperatures. However, as a melt is cooled, certain polymers have the ability to pack into a regular lattice, leading to the formation of stable crystalline domains. In polyethylene (PE), these stable crystalline domains are formed by chains in the planar zigzag conformation, while the crystalline chains in syndiotactic poly(vinyl chloride) (PVC) have a helical

conformation. Since only a portion of the long polymer chains can crystallize (some segments will not be able to pack into the crystallites) this state is called semi-crystalline. The temperature above which such crystalline regions will melt is called the crystalline melting point (T_m). Crystallites act to stiffen and reinforce the bulk material, and extend the stiffness and strength properties of a material well above the glass transition temperature until the crystallite melting point (T_m) is reached.

The Physical Behavior of Linear and Amorphous Polymers

Unlike metals which are held together by metallic bonds and atomic crystals which are held together by covalent bonds, polymer materials are held together by secondary interactions such as London forces, dipole–dipole inter-actions, and hydrogen bonding. For this reason, poly-mers are often mechanically weaker than other classes of materials; however, they can display physical behavior more similar to native tissue.

The simplest polymer system is an amorphous rub-bery or glassy polymer composed of linear polymer chains. When rubbery materials are strained, the poly-mer molecules are able to deform and extend resulting in a material which is macroscopically soft and weak, yet highly extensible. However, as the T_g of the material approaches and exceeds the environmental conditions, the material becomes a glass and is much stronger yet stiffer. The mechanical behavior of polymer systems is often probed through stress–strain analysis. From this analysis several key material properties can be deter-mined: modulus (a measurement of material stiffness); tensile strength (the stress at failure); and percent elonga-tion (the amount of deformation at failure). The room temperature mechanical properties of several polymeric biomaterials are presented in Table I.2.2.1.

The Physical Behavior of Other Physical States

Cross-linking, crystallinity, and copolymerization greatly affect the physical behavior of polymer systems, and con-trolling these parameters gives a polymer scientist ways of specifying the physical behavior of a polymer system. Figure I.2.2.6 illustrates how each of these affects polymer modulus as a function of temperature. In Figure I.2.2.6A we see the standard modulus–temperature behavior of a linear and amorphous polymer system (solid line). Below the T_g the material is a glass and has a high modulus. However, at the glass transition temperature we see a dramatic drop in modulus due to the increased mobility within the polymer structure. At temperatures just higher than the T_g, we see a plateau on the curve where modulus declines more slowly with temperature. This is called the rubbery plateau, and in this region the polymer is still solid-like but soft, flexible, and extensible. Eventually, as the temperature is increased more, we see the modulus curve take another drop corresponding to the material beginning to flow. Notice that amorphous materials do not have a melting temperature. Melting refers to the loss of crystallinity, and since these materials are non-crystalline they never truly melt. As we will discover later, the architecture of the polymer chains, especially where there is a specific tacticity, determines if segments of a polymer chain can pack together and form crystallites.

In Figure I.2.2.6A we can also see the modulus–temperature behavior of a semi-crystalline material. In this curve we see a small drop in the modulus at the glass transition temperature, due to the onset of backbone rotation in the amorphous regions of the polymer. Since crystallites are unaffected by the T_g, the magnitude of this drop is greatly affected by the amount of crystallinity in the system. After the T_g we see that the modulus holds steady until the melting point, illustrating that crystallinity

TABLE I.2.2.1	Physical Properties and Equilibrium Water Absorption of Common Polymeric Biomaterials			
Material	**Tensile Modulus (GPa)**	**Tensile Strength (MPa)**	**Elongation at Break (%)**	**Water Absorption (%)**
Polyethylene (PE)	0.8–2.2	30–40	130–500	0.001–0.02
Poly(methyl methacrylate) (PMMA)	3–4.8	38–80	2.5–6	0.1–0.4

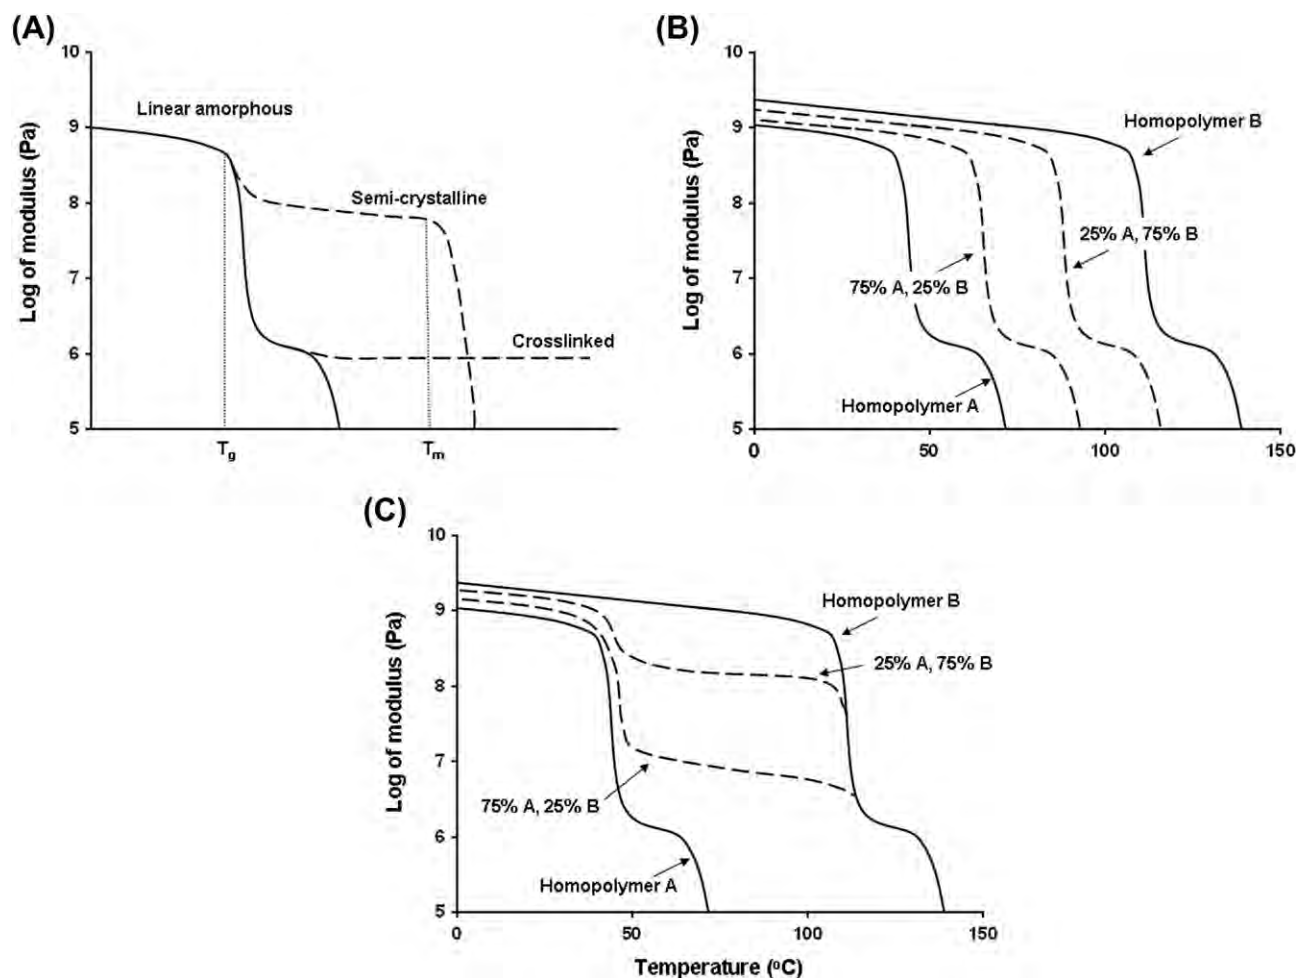

FIGURE I.2.2.6 Modulus versus temperature behavior for: (A) linear amorphous, semi-crystalline, and cross-linked polymer; (B) random copolymer; and (C) block or graft copolymer.

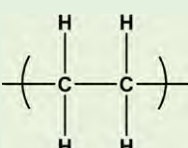
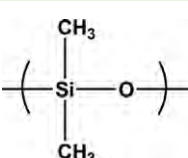
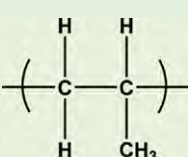
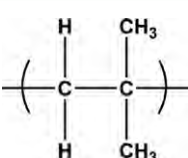
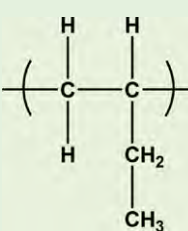
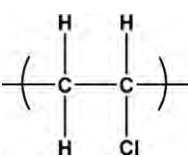
is a way to increase the window of temperatures in which a polymer can be employed. At T_m the crystallites melt and the polymer begins to flow. The ability of chains to crystallize is a special feature of chain architecture that is sometimes called "symmetry" or "regularity," i.e., a streamline profile in cross-section with small side groups that allows the chain segments to pack into crystallites. In special cases, a stereospecific property of some chains with asymmetric atoms is called tacticity; it can also control the ability of a polymer to crystallize. Polymers without asymmetric atoms in the backbone (and therefore having no tactic isomers) can crystallize along with isotactic and syndiotactic polymers. However, atactic materials cannot organize themselves into a lattice due to the irregularity in their chemical structure, and so are therefore permanently amorphous. Branched polymers have difficulty crystallizing, since the branch sites interfere with the ability of the polymer to organize into a lattice. In cases where branch sites are purposefully incorporated into the material they will lower the extent of crystallization (such as in the case of low density polyethylene).












Also in Figure I.2.2.6A you can see the modulus–temperature behavior of a cross-linked polymer. Again,

at the glass transition temperature you will see a decrease in modulus due to the onset of single bond rotation; however, above the T_g the modulus is relatively independent of temperature because the cross-links act to tether the polymer chains in place. In fact, the cross-linked polymer will not experience a large decrease in modulus until the temperature is high enough to begin thermally degrading the bonds holding the structure together.

Copolymerization of more than one monomer unit could also be used to control the physical behavior of a material. Figure I.2.2.6B shows modulus–temperature curves for a random copolymer system where the shape of the curve is maintained, but shifted laterally. If block or graft copolymers are produced, one would see the distinct transition of both materials used to generate the copolymer, as seen in Figure I.2.2.6C.

Table I.2.2.2 provides the repeat unit, T_g, and T_m of common polymers. Chemical characteristics that facilitate backbone rotation result in lower T_g materials, while structural characteristics that hinder backbone rotation result in higher T_g materials. For instance, the –Si–O– bond in polydimethylsiloxane is unhindered, and is a freely rotating bond down to very low temperatures, resulting in a

TABLE I.2.2.2	Structural Factors Affecting the Glass Transition Temperature and the Crystalline Melting Point of Polymers

[†]Isotactic.
*Decomposition temperature.

very low T_g. As pendant group bulkiness increases, the polymer chains along the backbone have more difficulty rotating due to steric hindrances, illustrated by the much higher T_g of polystyrene in comparison with polyethylene. However, pendant groups of four or more carbon atoms tend to create "free volume" around the polymer backbone, making main chain rotation easier, and the T_g may be lowered, as seen in the alkyl methacrylate family as the alkyl group increases in length. Increased polarity, especially where hydrogen bonds may act between side groups, increases the polar interactions between chains, slowing the rate of main chain rotations and resulting in a higher T_g. In general, the structural factors that affect the glass transition temperature (backbone flexibility, pendant group structure and polarity, main chain symmetry and polarity) similarly affect T_m, as illustrated by the data in Table I.2.2.2.

A Tragedy Caused by a Change in Temperature and its Effect on Tg and Polymer Properties

In 1986 the space shuttle *Challenger* broke apart during lift-off, killing the seven crew members aboard and halting all US space flights for the next two and a half years. This tragedy was caused by the failure of an O-ring - a polymer gasket – connecting the shuttle's external fuel tank to one of its solid rocket boosters. The O-ring failed, in part, due to the abnormally cold weather on the morning of the launch, causing stiffening of the gasket as the polymer approached its T_g, and that undermined its ability to form a tight seal. The gasket failure allowed a tongue of flame to reach both the solid rocket booster and the external fuel tank, and resulted in the structural failure of both. The shuttle then broke apart due to extreme aerodynamic loads. See NASA, 1986.

Characterizing a Polymer's Physical State and Behavior

Crystallinity plays a large role in determining polymer behavior. The *degree of crystallinity* – a measurement of how much of the polymer is incorporated into crystalline regions – can be studied with techniques such as measurement of density, X-ray diffraction (XRD), and infrared spectroscopy. In XRD experiments a polymer sample is bombarded with X-ray radiation and the intensity of the scattered X-rays is measured as a function of scattering angle. A fully amorphous material would produce a very broad peak, covering all scattering angles. However, crystalline materials will produce sharp peaks at specific angles. Furthermore, the placement of these peaks corresponds to a particular crystalline structure. By integrating the areas under the amorphous peak and the crystalline peaks, and then calculating the fractional area of the crystalline peaks relative to the total area, a researcher can determine the degree of crystallinity.

Stress–strain analysis provides information about the mechanical behavior of a polymeric biomaterial. In this test a polymer sample of known dimensions is deformed at a given rate, and the force needed to cause the deformation is recorded.

Measuring the Transition Temperatures Between States

Measuring transition temperatures (T_g and T_m) is important to understanding how a material will behave in a certain application. Two common methods for determining the transition temperatures in polymer systems are differential scanning calorimetry (DSC) and dynamic mechanical analysis (DMA). In DSC experiments a polymer sample is heated at a constant temperature rate (generally 10–20°C/min) and the amount of heat supplied to the sample to obtain the temperature increase is recorded. The output from this experiment is a plot of supplied heat versus temperature. The curves exhibit a step change at T_g due to a change in heat capacity at the onset of backbone rotation. An endothermic peak occurs in the DSC spectra at the melting point of the polymer due to the increased energy needed to melt the crystalline regions.

When performing a DMA experiment, one measures the modulus (stiffness) of the material over a temperature range, yielding the types of curves shown in Figure I.2.2.6. The glass transition temperature of the material is physically observed as the softening point of the material. In a DMA study the modulus drops by approximately three orders of magnitude at the T_g. At the T_m another drop is observed, associated with the softening due to melting of the polymer crystalline units and the onset of flow behavior.

Interactions with Water

Biomaterials are often employed in highly hydrated environments, so their interaction with water is an important design characteristic. Relatively non-polar and electrically neutral polymers such as polyethylene or poly(methylmethacrylate) are very hydrophobic and absorb <1 wt% water. However, as polarity and, in some cases, ionic character is incorporated into the polymer, it will imbibe more water due to polar (and coulombic) interactions. For instance, poly(hydroxyethyl methacrylate) (PHEMA) (the first soft contact lens) absorbs approximately 40 wt% water due to the polar hydroxyl moieties of the pendant groups. Eventually, if enough polarity or ionic character is incorporated into the material, it becomes water soluble, e.g., poly(ethylene glycol) and poly(methacrylic acid). The equilibrium water absorption of common biomaterials is presented in Table I.2.2.1.

One can tailor the interaction of a polymer with water in several ways, such as by controlling the ratio of hydrophobic and hydrophilic monomers in a copolymer. Also, crystalline regions in polymers usually resist infiltration of water molecules. If a polymer is processed in a way to control the degree of crystallization, the swelling character of the polymer can thereby be controlled. Cross-linked hydrophilic polymers generate hydrogels that can imbibe upwards of 200 wt% water. However, increasing the cross-link density can reduce the swelling of such a material, providing another method of tailoring the interactions of a polymer with water.

In addition to swelling behavior, the surface hydrophilicity of a polymer is also an important design feature. Though it is beyond the scope of this chapter, you will learn elsewhere in this text that a biomaterial surface can be physically or chemically coated with peptides or proteins to enhance cellular attachment and growth. Surfaces may also be treated to be "non-fouling," i.e., to resist protein adsorption and cell attachment.

Measuring the Hydrophilicity of Polymer Materials

Equilibrium swelling experiments are performed to study the interactions between bulk polymer and water. A dry sample of polymer of known mass is submerged in water, and the change in mass is recorded over time. Eventually the sample weight will become constant, and from this value the equilibrium water absorption can be calculated.

The surface hydrophilicity is probed through either static or dynamic contact angle experiments. In static experiments, a droplet of water is placed on a flat polymer surface and the angle the droplet makes with the material (as measured through the water phase) is measured. The degree to which water spreads on the surface is a measurement of the polarity of the interface. For instance, a material with a water contact angle of 20° has a *more polar* surface than a material with a water contact angle of 95°.

The surface composition of some materials can change depending on the external environment. For instance, a polymer may expose its hydrophobic portions to an air environment, yet it will reorganize its surface to display its hydrophilic portions when exposed to water (unless the interface has been oxidized to increase hydrophilicity). Dynamic contact angle experiments allow a researcher to probe the ability of the surface molecules to rearrange depending on the phase to which they are exposed. In such an experiment a polymer film is dipped into a bath of water and then removed. The force between the polymer sample and water is measured during immersion and retraction, and converted into contact angles. Materials with surface molecules that have the mobility to rearrange in air versus water will exhibit contact angle hysteresis, and the advancing and receding contact angles will not be the same. The advancing angle is always greater than the receding angle.

Degradation Characteristics

Depending on the application, one may desire a polymer material that is either biodegradable or biostable.

For instance, a polymer that will be used for a tissue engineered scaffold needs to be biodegradable, and to "disappear" as functioning tissue is regenerated by cells. However, some biomaterials, such as dental implants, vascular grafts, and intraocular lenses need to be bio-stable so that they retain their function for the lifetime of the patient. The main type of polymer degradation reaction occurring in the body is *hydrolysis*, i.e., the reaction of the polymer backbone bonds with water, which results in the hydrolysis of those bonds and loss of the polymer's mechanical properties. Eventually the polymer breaks up into small fragments that are metabolized and/or dissolve, and the residual molecules are eliminated from the body. The ultimate stability of polymers in the body depends on two key factors: water absorption and the susceptibility of main chain bonds to hydrolysis.

The carbon–carbon single bond is very stable and those materials with main chain C–C bonds, such as polyethylene, polypropylene or PMMA, do not lose their properties due to degradation of the backbone. However, the presence of other bonds in the polymer backbone (*heterochain* polymers) can lead to hydrolytic breakdown, and the rate of this hydrolysis is greatly affected by the polymer's molecular structure. For instance, the hydrolysis of amide bonds in Nylon 6,6 is so slow that it is almost non-existent at physiological conditions, making polyamide biomaterials relatively biostable. On the other hand, water can hydrolyze ester bonds (–CO–O–C–)

present in some polymers. For example, poly(lactide-co-glycolide) copolymers (Figure I.2.2.5) degrade by such hydrolysis. An exception to this is poly(ethylene terephthalate) or PET, which is crystalline and hydrophobic, so that even though it has main chain ester bonds, water absorption is so low it is resistant to hydrolysis. The reader is referred to Chapter II.4.1 on degradation of biomaterial implants and to Chapter II.5.16 on drug delivery from degradable matrices for further discussion of this important topic.

POLYMER SYNTHESIS

A polymer scientist who understands structure–property relationships can design polymer molecules to fit a particular application. In this section of we discuss synthesis of polymers.

Polymerization Mechanisms

Condensation and *addition polymerization* are the two most common methods for polymer synthesis. In organic chemistry, reactions are described which occur between different functional groups. For instance, a carboxylic acid group can react with an amine group to form an amide bond and liberate a water molecule. Table I.2.2.3 illustrates some of these major organic reactions. The same reactions as those seen in Table I.2.2.3 are used to produce condensation polymers. The only difference

TABLE I.2.2.3	Examples of Common Organic Reactions
Reactants	**Product**
R—OH + [epoxide] Alcohol epoxide	R—O—CH₂—CH₂—OH Ether bond
R—OH + HO—C(=O)—R' Alcohol carboxylic acid	R—O—C(=O)—R' Ester bond
R—C(=O)—OH + HN(H)—R' Carboxylic acid amine	R—C(=O)—N(H)—R' Amide bond
R—N(H)(H) + O=C=N—R' Amine isocyanate	R—N(H)—C(=O)—N(H)—R' Urea bond
R—OH + O=C=N—R' Alcohol isocyanate	R—O—C(=O)—N(H)—R' Urethane bond

is that instead of using monofunctional molecules (which contain only one functional group) difunctional monomers (which contain two functional groups) are used. Figure I.2.2.7A illustrates the formation of a poly(ethylene terephthalate) (PET) repeat unit through the reaction of ethylene glycol and dimethyl terephthalate, while Figure I.2.2.7B shows the production of a Nylon 6,6 repeat unit through the reaction of adipic acid and hexamethylenediamine. (In practice, PET is synthesized by an ester interchange reaction between dimethyl terephthalate and ethylene glycol, liberating methanol.) Notice that all of the monomers are difunctional molecules. Furthermore, the products from each reaction are also difunctional, allowing further, similar reactions to gradually produce higher molecular weight linear polymer chains.

The addition polymerization mechanism is quite different. A reactive center (most often a free radical, but sometimes an ion) is produced and reacts by adding across the C=C of vinyl monomers. The active center is not consumed during this reaction, and will continue reacting with carbon double bonds until it is terminated. High molecular weight chains are produced rapidly, and new chains are constantly being initiated. Figure I.2.2.8 is a schematic of a typical addition polymerization. First the reaction is initiated by the production of free radicals through a peroxide decomposition. The radical then propagates the polymer chain by consuming vinyl monomers. Finally the polymerization is terminated through a coupling reaction with a second radical (another method of termination called disproportionation is possible but is not discussed here) to produce a polymer molecule containing monomer repeat units.

There are newer polymerization techniques that are known as "controlled living free radical polymerizations" (or CRP) where the growth, chain transfer, and termination reactions are controlled to yield polymers with a desired molecular weight and narrow PDI. The two most popular of these techniques are known as ATRP, or Atom Transfer Radical Polymerization (Kato et al., 1995; Wang and Matyjaszewski, 1995) and RAFT,

(A)

Condensation reaction of ethylene glycol and dimethyl terephthalate to produce a repeat unit of poly(ethylene terephthalate) and the byproduct methanol.
(B)

Condensation reaction of adipic acid and hexamethylenediamine to produce a repeat unit of Nylon 6,6. First a Nylon salt is formed to ensure equimolar amounts of monomer. The Nylon salt is then polymerized to Nylon 6,6. Often acetic acid is used during synthesis to control molecular weight and thus act as a viscosity stabilizer.
FIGURE I.2.2.7 Condensation reaction between: (A) ethylene glycol and dimethyl terephthalate to produce a repeat unit of poly(ethylene terephthalate); and (B) adipic acid and hexamethylenediamine first form a 1:1 Nylon salt to ensure stoichiometric balance between monomers allowing polymerization to high molecular weights. Monomers present in the Nylon salt are then polymerized to produce a repeat unit of Nylon 6,6.

(A)

Initiation - free radicals are generated through the decomposition of benzoyl peroxide.

2 R
(B)

Propagation - free radicals produce polymer chains through addition across carbon-carbon double bonds. X denotes a generic side group.

$$R \ + \ \longrightarrow \ R-CH_2-\overset{\overset{\displaystyle H}{|}}{\underset{\underset{\displaystyle X}{|}}{C}}$$
(C)

Termination - two free radicals react to form a single bond through coupling to form one polymer chain.
FIGURE I.2.2.8 Addition polymerization of a vinyl monomer to a polymer chain: (A) the initiation step where the free radical is produced; (B) the propagation step where the free radical adds across the vinyl monomer's double bond; and (C) the termination step where two radicals react to produce dead polymer chains. In the schematic X represents a generic side group.

or Reversible Addition-Fragmentation Chain Transfer Polymerization (Chiefari et al., 1998).

The reader is referred to recent polymer textbooks (see Bibliography) for further reading on polymerization techniques.

Using Synthesis Conditions to Build the Desired Polymer

The first step towards producing a material with the desired behavior is selection of the appropriate monomer species. For instance, a researcher developing a bone cement could select a monomer with a bulky pendant group to produce a glassy polymer, while another biomaterials scientist creating a hydrogel could select a monomer with a polar pendant group to improve hydrogen bonding interactions with water.

Physical behavior can be further tailored through crystallinity and cross-linking. Addition polymers containing asymmetric carbon atoms are generally atactic, meaning the polymer will be predominantly amorphous. However, one can use special catalysts to produce isotactic or syndiotactic addition polymers that can crystallize.

In condensation polymerization, monomers containing two functional groups produce linear polymer chains. However, if one adds a small amount of a monomer with three or more functional groups,

cross-linked materials are produced. Similarly, addition of vinyl type monomers containing two or more vinyl groups can produce networked materials. Linear polymers can also be cross-linked after synthesis through techniques such as vulcanization, or UV or gamma ray irradiation.

So What is a Network Polymer?

A common example of a network polymer is an automobile tire. The main polymer component of tire tread is a polystyrene/polybutadiene copolymer (SBR). The individual SBR polymer chains are covalently cross-linked into a network polymer through reaction with sulfur (a process known as vulcanization). There are other additives in car tires (carbon black, for instance, which gives the tire its black color); however, the polymer component of the tire is actually one very large, covalently cross-linked molecule.

If degradation characteristics are desired they can be achieved through control of the composition of the backbone groups. Addition polymerization produces homochain polymers that are generally biostable. Sometimes condensation polymerization mechanisms may produce a water molecule. The reverse reaction can occur between the polymer bonds being formed and the water molecule, resulting in simultaneous degradation of the polymer. In that case, water must be removed as it is formed.

CASE STUDIES

We have discussed the basic molecular characteristics that govern polymer behavior, and how to exploit chemistry in order to build polymers with the desired characteristics. Table I.2.2.4 compiles the chemical characteristics of several polymeric biomaterials, and reports their clinical applications. We will also look in more depth at the development of three polymer biomaterials that have achieved clinical success.

THE PRESENT AND THE FUTURE

In the early days of biomaterials science, materials were not designed for biomedical applications. Pre-existing materials were used and their biocompatibility was empirically assessed. As you will learn through this book, much of the current work in the biomaterials field focuses on creating materials that exhibit specific interactions with biology to achieve improved performance and better healing.

Case Study	Resorbable Sutures

What problems can occur?
Sutures are often needed to hold tissue together after injury, incision, or surgery. If a non-biodegradable material is used to suture an internal wound, a secondary surgery would be necessary to remove the stitches after healing.

What properties are required of the biomaterial?
For a suture material, the most fundamental property required is appropriate tensile strength, so the wound does not reopen during healing. Also, the suture materials should degrade in the body during healing, making retrieval or removal unnecessary. Further, the degradation must occur at an appropriate rate, and the degradation products must be non-toxic.

What polymeric biomaterial is used?
Early resorbable sutures were made from sheep or beef gut. However, synthetics are more commonly used due to their ease of handling, low cost, consistent performance, and low chance of disease transfer. One commonly used material is a poly(lactide-co-glycolide) copolymer (PLGA). This is a random copolymer so the material is permanently amorphous; however, it still possesses the high tensile strength and flexibility required for this application. Also, the material biodegrades through hydrolysis of the ester bonds in the polymer backbone into lactic and glycolic acid. Both of these chemicals occur naturally in the body's metabolic pathway, and so are non-toxic in small amounts. Furthermore, the ester bonds in the lactide and glycolide repeat units hydrolyze at different rates, allowing the degradation rate to be tailored.

TABLE I.2.2.4	Common Polymeric Biomaterials with Their Applications and the Properties That Make Them Useful in the Medical Field	
Material	**Characteristics**	**Uses**
Poly(methyl methacrylate) (PMMA)	Hydrophobic polymer which is hard, rigid, and biostable. The amorphous material is clear allowing light transmittance	Bone cement Intraocular lenses Hard contact lenses
Polyacrylamide (PA)	Cross-linking produces a hydrogel with molecular-sized pores and allows the gel to be used as a separation medium	Separation gel used in electrophoresis
Poly(acrylic acid) (PAA)	The liquid monomer can be cured with a photo-initiator. If inorganic salts are added, ionic cross-linking can occur. The material is glassy and rigid, and has the potential to bond to enamel	Glass ionomer cement used in dental restoration
Polyethylene (high density) (PE)	Low density PE cannot withstand sterilization temperatures; however, high density PE has good toughness and wear resistance	Tubing for drains and catheters Prosthetic joints
Poly(vinyl chloride) (PVC)	PVC is plasticized to make flexible materials. This material is used for short-term applications since plasticizers can be leached resulting in embrittlement of the material	Tubing Blood storage bags
Polypropylene (PP)	Isotactic PP is semi-crystalline, has high rigidity and tensile strength, and good biostability	Non-degradable sutures Hernia repair
Polydimethylsiloxane (PDMS)	Due to its silicone backbone, this material has a very low T_g making it extremely flexible and providing it with good fatigue resistance at physiological conditions	Finger joints Heart valves Breast implants Ear, chin, and nose reconstruction
Poly(ethylene terephthalate) (PET)	The aromatic rings in the backbone generate a polymer with a high melting point ($T_m = 267°C$). It is semi-crystalline and possesses excellent tensile strength	Vascular grafts Fixation of implants Hernia repair Ligament reconstruction
Cellulose acetate (CA)	Unique transport properties make it excellent for use in the separation of complex biological mixtures	Dialysis membranes Osmotic drug delivery devices

---

Case Study | **Soft Contact Lenses**

What problem was addressed?

The first contact lens, developed in 1888, was made of glass, and could not be worn for long periods of time. A generation of PMMA lenses were developed (hard contact lenses) and experienced clinical success. However, these rigid lenses caused eye irritation, and did not allow enough oxygen to be transported to the cornea of the eye (an avascular tissue which must receive oxygen from the environment in order for normal metabolism to occur). The Czech scientists, Wichterle and Lim, wanted to make a lens which was more comfortable and would allow better transport of oxygen to the cornea. (Otto Wichterle and Drahoslav Lim, "Process for producing shaped articles from three-dimensional hydrophilic high polymers", US Patent 2,976,576, March 28, 1961.)

What properties were required of the biomaterial?

Strong mechanical properties were not a major factor in the design of soft contact lenses, since the device does not need to support large stresses. However, a successful lens needed to: (1) be transparent so that clear vision could be achieved; (2) be dimensionally stable to maintain the optical correction desired; (3) be soft and flexible to minimize eye irritation; (4) allow appropriate transport of oxygen and nutrients to the cornea; and (5) have sufficient surface wettability so as not to damage the corneal cells.

What polymeric biomaterial is used?

The major component of most modern soft contact lenses is loosely cross-linked poly(hydroxyethyl methacrylate) (PHEMA). Semi-crystalline polymers are often translucent due to light refracted by crystallites. Since PHEMA is atactic the polymer is transparent. When dry, PHEMA is glassy, allowing the lens to be fabricated through milling procedures (as is done with hard contact lenses). However, the hydroxyl-containing pendant group results in a hydrophilic polymer that imbibes 40 wt% water. The absorbed water plasticizes the polymer, producing a soft and supple material that is less irritating to the eye. Pure PHEMA lenses are not capable of providing the necessary oxygen to the cornea of the eye, so PHEMA is often copolymerized with other monomers, such as fluorinated or "siliconized" methacrylates, to improve oxygen transport either by increasing the oxygen solubility in the lens or by allowing the fabrication of a thinner lens.

Recently, much research in contact lens development has focused on the design of extended wear lenses (contacts that can be worn for up to 7–14 days without removal). A leading material for extended wear contacts is a silicone hydrogel that is composed of a silicone polymer network with an entrapped water-soluble polymer such as poly(vinyl pyrrolidone). This combination creates a material with excellent oxygen and ion permeability, and good lubricity of the lens against the cornea. (For example, see http://en.wikipedia.org/wiki/Contact_lens.)

Case Study | **Artificial Hip Joints**

What problem was addressed?

A surgeon may perform hip arthroplasty (implantation of an artificial hip) to alleviate the pain and stiffness of severe arthritis or to repair the joint after physical damage. An artificial hip implant has two pieces: the femoral ball and stem; and the acetabular cup. The femoral ball and stem implant is a metal shaft that inserts into the femoral bone core, and is capped by a ball that articulates with the acetabular cup.

What properties were required of the biomaterial?

Sir John Charnley – a British orthopedic surgeon – conceived the initial concept that led to the modern artificial hip. Focusing on the acetabular component, tribology (the study of friction, lubrication, and wear) is of utmost importance. The ideal polymer for use in an articulating joint would be low friction and resistant to wear.

What polymeric biomaterial was used?

Initially Charnley used poly(tetrafluoroethylene) (PTFE), a very non-polar and low-friction material, for the acetabular cup. He also used stainless steel for the femoral ball and stem. Two problems arose: first, PTFE did not have the necessary wear resistance, and small pieces of PTFE debris eroded from the surface of the cup, causing severe inflammation of the surrounding tissue. Second, Charnley had to force-fit the femoral stem into the femur, and it loosened during use. Although polyethylene (PE) is a higher-friction surface than PTFE, very high molecular weight PE is a superior biomaterial for this application, since the PE did not produce excessive wear debris. Also, the PE could be simultaneously gamma radiation-sterilized and cross-linked, increasing its wear resistance. It could also be machined to a fine smoothness to further minimize wear. Charnley was advised by Dennis Smith, a biomaterials chemist working on dental implants, to use PMMA dental cement to hold the femoral stem in place during wear, and that solved the second problem.

A. POLYURETHANES

Daniel E. Heath and Stuart L. Cooper
William G. Lowrie Department of Chemical and Biomolecular Engineering, The Ohio State University, Columbus, OH, USA

INTRODUCTION

Polyurethanes are widely used in medical devices such as pacemakers, artificial hearts, and other blood contacting applications. Their excellent mechanical properties, stability, and good biocompatibility give them a special place in medicine. Polyurethanes were developed in the 1930s. Around this time, Nylon 6,6 – a condensation polymer of hexamethylenediamine and adipic acid – was developed and patented by Du Pont. This polymer achieved commercial success due to its good mechanical properties and fiber-producing ability. German scientists led by Otto Bayer began to explore new polymerization techniques in the hope of creating a material competitive with nylon. Initial work reacted difunctional isocyanates and amines to produce polyureas; however, these materials were too hydrophilic to be used as plastics or textiles. Diisocyanates were also reacted with diols to produce polyurethanes. One nylon-like polyurethane produced through the reaction of 1,4-butanediol and hexamethylene diisocyanate, as shown in Figure A.1, was used commercially in Germany. Chemically the polymer is the same as nylon except for the two additional oxygens per repeat unit, and the properties are similar except that the polyurethane has a lower melting point. These early polyurethanes also had lower water absorption, and better electrical and mechanical stability upon aging compared to nylon. Subsequently block polymers including polyester or polyether polyols were developed both in Germany and the United States.

Today, polyurethanes (PUs) are a class of polymer which has achieved industrial relevance due to their tough and elastomeric properties, and good fatigue resistance. PUs are used as adhesives, coatings, sealants, rigid and flexible foams, and textile fibers. Furthermore, PUs have also been employed in biomaterial applications such as artificial pacemaker lead insulation, catheters, vascular grafts, heart assist balloon pumps, artificial heart bladders, and wound dressings.

ANATOMY OF A POLYURETHANE MOLECULE

The polyurethane molecule presented in Figure A.1 has a very simple architecture. Most commercially relevant PUs today are actually block copolymers (as seen in Chapter I.2.2, Figure I.2.2.4) meaning there are alternating segments in the polymer molecules composed of solely "A" or "B" repeat units. Furthermore, the materials are designed so that one of the segments – called the *hard segment* – is glassy or crystalline at the use temperature, while the other segment – referred to as the *soft segment* – is rubbery. If the monomers are appropriately selected, the hard and soft segments of the polyurethane will be incompatible, leading to phase separation and meaning that the composition of the bulk polymer will not be homogeneous. Instead, there will be nanometer-sized regions which are rich in hard segments, and other regions rich in soft segments. The unique block copolymer structure and phase separation of PUs results in unique and useful properties. One can consider the hard phase domains as providing highly efficient reinforcing microdomains which give rise to the unusual and very attractive properties of polyurethanes, such as strength and toughness.
FIGURE A.1 Synthesis scheme of a polyurethane through the condensation of 1,4-butanediol and hexamethylene diisocyanate. The repeat unit of the PU and of Nylon 6,6 are presented for comparison.

THE PHYSICAL PROPERTIES OF POLYURETHANES

Most polymer elastomers – such as rubber bands – are produced by lightly cross-linking a low T_g polymer into a loose network. When such a material is strained, the segments between cross-links can deform and elongate; however, when the load is removed the cross-links result in the material returning to its original form. Although these elastomers are useful, they are *thermosets*. Since the material is essentially one large molecule it cannot be dissolved, neither can it be made to flow through the introduction of heat and pressure. This means that once a thermoset elastomer is formed, it cannot be processed further. However, the unique segmented structure of PUs allows *thermoplastic elastomers* to be formed. When such materials are strained, the polymer segments in the soft phase will deform and elongate, while the hard phase will stabilize the structure, resulting in the recovery of the original form once the load is removed. However, unlike the covalent cross-links in thermosets, the physical cross-links present between hard segments can be undermined through the application of heat, and then reformed upon cooling, allowing the useful properties of elastomers to be combined with the simple processing procedures of thermoplastics. In addition to elastomeric properties, PUs have several useful interfacial characteristics. Foremost, PUs are abrasion- and impact-resistant, making them useful as coatings, and the materials also have good blood-contacting properties, making them useful in biomaterial applications.

TABLE A.1	Chemical Structure of Common Precursors used in Polyurethane Block Copolymer Synthesis: Diisocyanates, Chain Extenders, and Polyester or Polyether Diols

Diisocyanates
2,4-toluene diisocyanate (TDI)
Methylene-bis(4)phenyl isocyanate (MDI)

Diols
Polyester diol
Polyether diol

Chain extenders
HO—(CH$_2$)$_x$—OH NH$_2$—(CH$_2$)$_x$—NH$_2$
Diol Diamine
x = 2 to 6 carbons

POLYURETHANE SYNTHESIS

The Precursors

When synthesizing most PU block copolymers a two-step synthesis strategy is employed which involves three precursor molecules: diisocyanates; diols; and chain extenders. In the final polymer molecule the diisocyanates and chain extenders will form the hard segments, while the diols form the soft segments. Table A.1 illustrates the chemical structure of molecules often used to synthesize PU block copolymers.

The diisocyanate molecules used in polyurethane synthesis can be aliphatic (such as Figure A.1), but most often aromatics are used (Table A.1). The two most commonly used diisocyanates employed in PU synthesis are 2,4-toluene diisocyanate (TDI) and methylene-bis(4) phenyl isocyanate (MDI). The soft segments are formed from polyether or polyester diols (sometimes referred to as *polyols*). These molecules have a molecular weight of 1000 to 2000 Da, and are well above their T_gs and melting points at use conditions, which impart a rubbery character to the resulting polyurethane. The last precursor is the chain extender. These molecules are often short aliphatic diols or diamines containing 2 to 6 carbon atoms, and are used to build the polymer up to its final high molecular weight.

Synthesis Reactions

The isocyanate group contains two unsaturated bonds and is a highly reactive moiety. When reacted with a hydroxyl group, the result is a urethane bond, as illustrated in Figure A.1. The first step in PU synthesis reacts the diisocyanates with the polyether or polyester diols. Excess diisocyanate is used to ensure the resulting materials are end terminated with isocyanate groups, as seen in Figure A.2A. The result of this reaction is a *prepolymer* with a degree of polymerization commonly between 2 and 5. Next, the prepolymer is further reacted with the chain extenders to produce high molecular weight polyurethane molecules, as shown in Figure A.2B.

Tailoring Polyurethane Behavior

Many of the techniques described in Chapter I.2.2 to modulate polymer properties can easily be applied to polyurethanes. For instance, monomers with functionality greater than two can be used in order to produce cross-linked polymer structures. Also, as the cross-link density in thermosets controls material stiffness, the relative amounts of hard and soft segments in the PU can vary the modulus. Also, the length and chemical nature of the soft segment can be adjusted to further tune physical behavior.

For biostable biomaterial applications, MDI is generally used to form the hard segments, and polyether diols are often preferred to form the soft segments since they are more resistant to hydrolytic degradation than polyesters. However, PUs have been explored more recently as scaffolds for tissue engineering. For these applications, biodegradable PUs are required, the degradation rate must be controlled, and the degradation

Case Study | **What Problem was Addressed?**

An individual may require an artificial pacemaker to regulate their heartbeat. The pacemaker is an implanted device which monitors heartbeat and provides electrical stimulation to the muscles of the heart, resulting in muscle contraction when needed. The pacemaker is connected to the appropriate heart muscles through pacemaker leads, electrically conductive wires which are fed to the heart through the vasculature.

   The pacemaker leads require insulation. Initially poly(dimethyl siloxane) (PDMS) or polyethylene was used as the insulator for the leads. However, both of these materials resulted in a fibrous endocardial reaction. Furthermore, PDMS has a low tensile modulus and poor tear resistance.

What properties were required of the biomaterial?

A successful insulator for pacemaker leads would not elicit a fibrous reaction from the heart, and would have high tensile strength and resistance to tearing allowing for thinner lead insulations to be produced.

What polymeric biomaterial is used?

In 1978 polyurethane was introduced as a lead insulator. Although not as flexible as PDMS, the PU had superior tensile properties and tear resistance. This allowed much thinner lead insulations to be fabricated without compromising handling properties. The thinner insulation allows multiple leads to be inserted per vein, enabling sequential pacing. Furthermore, the PU surface has lower friction in contact with blood and tissue than the PDMS surface, allowing easier insertion of the leads.

   The search for the optimum lead insulation material is not over yet, however. In the 1980s it was found that metal-induced oxidation from lead metals resulted in undesired degradation of the polyurethane insulation. Lower ether content in the polyurethane was one solution to this problem, although this results in higher modulus insulation. In subsequent years there have been changes in the material used for the lead wire, and silicone rubber remains in use as well as polyurethanes for pacemaker insulation. Research is underway to find more biostable polyurethanes for this application.

---

products need to be non-toxic. Soft segment structure is often used to build in the appropriate degradability. For instance, soft segments containing polylactide, polyglycolide, and polycaprolactone have been investigated, all of which are susceptible to degradation and the degradation rates vary based on chemical composition. The aromatic diisocyanates can result in carcinogenic degradation products; therefore, PUs for tissue engineering applications require the use of diisocyanates other than MDI and TDI. New PU formulations have been synthesized using lysine-diisocyanate, hexamethylene diisocyanate, and 1,4 diisocyanatobutane which are believed to degrade into non-toxic products.

CONCLUDING REMARKS

Polyurethanes are a unique family of polymers with interesting properties which arise from their block copolymer nature and the resulting phase separation. These materials have achieved industrial success in everyday applications, as well as in the biomaterials field.

B. SILICONES

André Colas[1] and Jim Curtis[2]
[1] Dow Corning Europe S.A., Parc Industriel, Seneffe, Belgium
[2] Dow Corning Corporation, Midland, MI, USA

Silicone materials have been widely used in medicine for over 60 years. Available in a variety of material types, they have unique chemical and physical properties that manifest in excellent biocompatibility and biodurability for many applications. Silicone elastomers have remarkably low glass-transition temperatures and maintain their flexibility over a wide temperature range, enabling them to withstand conditions from cold storage to steam autoclaving. They have high permeability to gases and many drugs, advantageous respectively in wound care or in transdermal drug delivery. They have low surface tension and remarkable chemical stability, enabling biocompatibility and biodurability in many long-term implant applications.

   However, versatile as they are, present-day silicone materials still have limitations. The mechanical properties of silicone elastomers, such as tensile strength or tear

resistance, are somewhat lower than for other implantable elastomers such as polyurethanes (although generally speaking, polyurethanes are less biodurable). While resistant to a wide array of chemical environments, silicone elastomers are susceptible to degradation in very strongly basic or acidic conditions, such as those found in the stomach. Like all hydrophobic implant materials, silicones are quickly coated with proteins when placed in tissue contact; and a scar tissue capsule forms to surround an implant during wound healing, walling it off from the host. Additionally, silicone elastomers are thermosetting materials, requiring different processing from conventional thermoplastics, which can on occasion be seen as a drawback.

CHEMICAL STRUCTURE AND NOMENCLATURE

Silicones are a general category of synthetic polymers whose backbone is made of repeating silicon-to-oxygen bonds. In addition to their links to oxygen to form the polymeric chain, the silicon atoms are also bonded to organic groups, typically methyl groups. This is the basis for the name "silicones," which was assigned by Kipping based on their similarity with ketones, because in most cases there is on average one silicone atom for one oxygen and two methyl groups (Kipping, 1904). Later, as these materials and their applications flourished, more specific nomenclature was developed. The basic repeating unit became known as "siloxane," and the most common silicone is polydimethylsiloxane, abbreviated as PDMS.

$$-\left(\begin{array}{c} R \\ | \\ Si-O- \\ | \\ R \end{array}\right) \quad \text{and if R is } CH_3, \quad -\left(\begin{array}{c} CH_3 \\ | \\ Si-O- \\ | \\ CH_3 \end{array}\right)_n$$

"siloxane"   "polydimethylsiloxane"
Many other groups (e.g., phenyl, vinyl, and trifluoropropyl) can be substituted for the methyl groups along the chain. The simultaneous presence of organic groups attached to an inorganic backbone give silicones a combination of distinctive properties, making their use possible as fluids, emulsions, compounds, resins, and elastomers in numerous applications and diverse fields. For example, silicones are common in the aerospace industry, due principally to their low and high temperature performance. In the electronics field, silicones are used as electrical insulation, potting compounds, and other applications specific to semiconductor manufacture. Their long-term durability has made silicone sealants, adhesives, and waterproof coatings commonplace in the construction industry. Excellent biocompatibility makes many silicones well suited for use in numerous personal care, pharmaceutical, and medical device applications (see Chapter II.5.18).

Historical Milestones in Silicone Chemistry

Key milestones in the development of silicone chemistry, thoroughly described elsewhere by Lane and Burns (1996), Rochow (1945), and Noll (1968), are summarized in Table B.1.

Nomenclature

The most common silicones are the trimethylsilyloxy end-blocked polydimethylsiloxanes, with the following structure:

$$CH_3 - \underset{\underset{CH_3}{|}}{\overset{\overset{CH_3}{|}}{Si}} - O - \left(\underset{\underset{CH_3}{|}}{\overset{\overset{CH_3}{|}}{Si}} - O\right)_n - \underset{\underset{CH_3}{|}}{\overset{\overset{CH_3}{|}}{Si}} - CH_3,$$

$$(n = 0, 1, \dots)$$
These are linear polymers and liquids, even for large values of n. The main chain unit, $-(Si(CH_3)_2O)-$, is often represented by the letter D for $(CH_3)_2SiO_{2/2}$, because with the silicon atom connected to two oxygen atoms this unit is capable of expanding within the polymer in two directions. M, T, and Q units are defined in a similar manner, as shown in Table B.2.

The system is sometimes modified by the use of superscript letters designating nonmethyl substituents, for example, $D^H = H(CH_3)SiO_{2/2}$ and M^ϕ or M^{Ph}

TABLE B.1	Key Milestones in the Development of Silicone Chemistry
1824	Berzelius discovers silicon by the reduction of potassium fluorosilicate with potassium: $4K + K_2SiF_6 \rightarrow Si + 6KF$. Reacting silicon with chlorine gives a volatile compound later identified as tetrachlorosilane, $SiCl_4$: $Si + 2Cl_2 \rightarrow SiCl_4$.
1863	Friedel and Crafts synthesize the first silicon organic compound, tetraethylsilane: $2Zn(C_2H_5)_2 + SiCl_4 \rightarrow Si(C_2H_5)_4 + 2ZnCl_2$.
1871	Ladenburg observes that diethyldiethoxysilane $(C_2H_5)_2Si(OC_2H_5)_2$, in the presence of a diluted acid gives an oil that decomposes only at a "very high temperature."
1901–1930s	Kipping lays the foundation of organosilicon chemistry with the preparation of various silanes by means of Grignard reactions and the hydrolysis of chlorosilanes to yield "large molecules." The polymeric nature of the silicones is confirmed by the work of Stock.
1940s	In the 1940s, silicones become commercial materials after Hyde of Dow Corning demonstrates the thermal stability and high electrical resistance of silicone resins, and Rochow of General Electric finds a direct method to prepare silicones from silicon and methylchloride.

TABLE B.2	Shorthand Notation for Siloxane Polymer Units

M	D	T	Q
$(CH_3)_3SiO_{1/2}$	$(CH_3)_2SiO_{2/2}$	$CH_3SiO_{3/2}$	$SiO_{4/2}$

$= (CH_3)_2(C_6H_5)SiO_{1/2}$ (Smith, 1991). Further examples are shown in Table B.3.

Preparation

Silicone Polymers. The modern synthesis of silicone polymers is multifaceted. It usually involves the four basic steps described in Table B.4. Only step 4 in this table will be elaborated upon here.

Polymerization and Polycondensation. The linear [4] and cyclic [5] oligomers resulting from dimethyldichlorosilane [2] hydrolysis have chain lengths too short for most applications. The cyclics must be polymerized, and the linears condensed, to give macromolecules of sufficient length (Noll, 1968).

Catalyzed by acids or bases, cyclosiloxanes $(R_2SiO)_m$ are ring-opened and polymerized to form long linear chains. At equilibrium, the reaction results in a mixture of cyclic oligomers plus a distribution of linear polymers. The proportion of cyclics depends on the substituents along the Si–O chain, the temperature, and the presence of a solvent. Polymer chain length depends on the presence and concentration of substances capable of giving chain ends. For example, in the KOH-catalyzed polymerization of the cyclic tetramer octamethylcyclotetrasiloxane $(Me_2SiO)_4$ ([5] or D_4 in shorthand notation), the average length of the polymer chains depends on the KOH concentration:

$$x(Me_2SiO)_4 + KOH \rightarrow (Me_2SiO)_y + KO(Me_2SiO)_zH$$

A stable hydroxy-terminated polymer, $HO(Me_2SiO)_zH$, can be isolated after neutralization and removal of the remaining cyclics by stripping the mixture under vacuum at elevated temperature. A distribution of chains with different lengths is obtained. The reaction can also be made in the presence of $Me_3SiOSiMe_3$, which acts as a chain end-blocker:

$$\text{\wedge\wedge\wedge } Me_2SiOK + Me_3SiOSiMe_3$$
$$\rightarrow \text{\wedge\wedge\wedge } Me_2SiOSiMe_3 + Me_3SiOK$$
where \wedge\wedge\wedge represents the main chain.

TABLE B.3	Examples of Silicone Shorthand Notation

	MD_nM
	D_4
	TM_3
	$QM_2M^HM^{C_2H_5}$ or $QM_2M^HM^{Et}$

The Me_3SiOK formed attacks another chain to reduce the average molecular weight of the linear polymer formed.

The copolymerization of $(Me_2SiO)_4$ in the presence of $Me_3SiOSiMe_3$ with Me_4NOH as catalyst displays a surprising viscosity change over time (Noll, 1968). First a peak or viscosity maximum is observed at the beginning of the reaction. The presence of two oxygen atoms on each silicon in the cyclics makes them more susceptible to a nucleophilic attack by the base catalyst than the silicon of the end-blocker, which is substituted by only one oxygen atom. The cyclics are polymerized first into very long, viscous chains that are subsequently reduced in length by the addition of terminal groups provided by the end-blocker, which is slower to react. This reaction can be described as follows:

$$Me_3SiOSiMe_3 + x(Me_2SiO)_4 \xrightarrow{\text{cat}} Me_3SiO(Me_2SiO)_nSiMe_3$$
TABLE B.4	The Basic Steps in Silicone Polymer Synthesis
1. Silica reduction to silicon	$SiO_2 + 2C \rightarrow Si + 2CO$
2. Chlorosilanes synthesis	$Si + 2CH_3Cl \rightarrow \underset{[1]}{(CH_3)_2SiCl_2} + \underset{[2]}{CH_3SiCl_3} + \underset{[3]}{(CH_3)_3SiCl} + CH_3HSiCl_2 + \cdots$
3. Chlorosilanes hydrolysis	
4. Polymerization and polycondensation	

or, in shorthand notation:

$$MM + x\,D_4 \xrightarrow{\text{cat}} MD_nM$$

where $n = 4x$ (theoretically).

The ratio between D and M units defines the average molecular weight of the polymer formed.

Catalyst removal (or neutralization) is always an important step in silicone preparation. Most catalysts used to prepare silicones can also catalyze the depolymerization (attack along the chain), particularly at elevated temperatures in the presence of traces of water.

$$\text{vvv}(Me_2SiO)_n \text{ vvv} + H_2O$$
$$\xrightarrow{\text{cat}} \text{vvv}(Me_2SiO)_y H + HO(Me_2SiO)_z \text{ vvv}$$
It is therefore essential to remove all remaining traces of the catalyst, providing the silicone optimal thermal stability. Labile catalysts have been developed. These decompose or are volatilized above the optimum polymerization temperature, and consequently can be eliminated by a brief overheating. In this way, catalyst neutralization or filtration can be avoided (Noll, 1968).

The cyclic trimer $(Me_2SiO)_3$ has internal ring tension and can be polymerized without re-equilibration of the resulting polymers. With this cyclic, polymers with narrow molecular weight distribution can be prepared, as well as polymers only carrying one terminal reactive function (living polymerization). Starting from a mixture of cyclics with different internal ring tensions also allows preparation of block or sequential polymers (Noll, 1968).

Linears can combine when catalyzed by many acids or bases to give long chains by intermolecular condensation of silanol terminal groups (Noll, 1968; Stark et al., 1982).
A distribution of chain lengths is obtained. Longer chains are favored when working under vacuum or at elevated temperatures to reduce the residual water concentration. In addition to the polymers described above, reactive polymers can also be prepared. This result can be achieved when re-equilibrating oligomers or existing polymers to obtain a polydimethylmethylhydrogenosiloxane, $MD_zD^H_wM$.

$$Me_3SiOSiMe_3 + x(Me_2SiO)_4 + Me_3SiO(MeHSiO)_ySiMe_3$$
$$\xrightarrow{\text{cat}} \text{cyclics} + Me_3SiO(Me_2SiO)_z(MeHSiO)_wSiMe_3$$

[6]
Additional functional groups can be attached to this polymer using an addition reaction.

$$Me_3SiO(Me_2SiO)_z(MeHSiO)_wSiMe_3 + H_2C = CHR$$

$$[6]$$

$$\xrightarrow{\text{Pt cat}} Me_3SiO(Me_2SiO)_z(Me\underset{\underset{CH_2CH_2R}{|}}{Si}O)_wSiMe_3$$
All the polymers heretofore shown are linear or cyclic, comprising mainly difunctional units, D. In addition, branched polymers or resins can be prepared if, during hydrolysis of the chlorosilanes, a certain amount of T or Q units are included, which allow molecular expansion in three or four directions, as opposed to just two. For example, consider the hydrolysis of methyltrichlorosilane in the presence of trimethylchlorosilane, which leads to a branched polymer:

$$x\,Me - \underset{\underset{Me}{|}}{\overset{\overset{Me}{|}}{Si}} - Cl + y\,Me - \underset{\underset{Cl}{|}}{\overset{\overset{Cl}{|}}{Si}} - Cl \xrightarrow[-HCl]{+H_2O} z$$

$$[3] \qquad\qquad [2]$$

$$Me - \underset{\underset{Me}{|}}{\overset{\overset{Me}{|}}{Si}} - O - \underset{\underset{O}{|}}{\overset{\overset{Me}{|}}{Si}} - O - \underset{\underset{OH}{|}}{\overset{\overset{Me}{|}}{Si}} - O \;\backslash\!\backslash\!\backslash$$

$$Me - \underset{\underset{O}{|}}{\overset{\overset{|}{}}{Si}} - O \;\backslash\!\backslash\!\backslash$$

$$Me - \underset{\underset{Me}{|}}{\overset{\overset{|}{}}{Si}} - Me$$
The resulting polymer can be described as $(Me_3SiO_{1/2})_x$ $(MeSiO_{3/2})_y$ or M_xT_y, using shorthand notation. The formation of three silanols on the $MeSiCl_3$ by hydrolysis yields a three-dimensional structure or resin after condensation, rather than a linear polymer. The average molecular weight depends upon the number of M units that come from the trimethylchlorosilane, which limits the growth of the resin molecule. Most of these resins are prepared in a solvent and usually contain some residual hydroxyl groups. These groups could subsequently be used to cross-link the resin and form a continuous network.

Silicone Elastomers. Silicone polymers can easily be transformed into a three-dimensional network by way of a cross-linking reaction, which allows formation of chemical bonds between adjacent chains. The majority of silicone elastomers are cross-linked according to one of the following three reactions.

1. Cross-linking with radicals. Efficient cross-linking with radicals is achieved only when some vinyl groups are present on the polymer chains. The following mechanism has been proposed for the cross-linking reaction associated with radicals generated from an organic peroxide for the initiation, propagation, and termination steps (Stark et al., 1982):

$$R^{\cdot} + CH_2 = CH - Si \equiv \;\rightarrow\; R - CH_2 - CH^{\cdot} - Si \equiv$$

$$RCH_2 - CH^{\cdot} - Si \equiv + CH_3 - Si \equiv$$
$$\rightarrow\; RCH_2 - CH_2 - Si \equiv + \equiv Si - CH_2^{\cdot}$$

$$\equiv Si - CH_2^{\cdot} + CH_2 = CH - Si \equiv$$
$$\rightarrow\; \equiv Si - CH_2 - CH_2 - CH^{\cdot} - Si \equiv$$

$$\equiv Si - CH_2 - CH_2 - CH^{\cdot} - Si \equiv + \equiv Si - CH_3$$
$$\rightarrow\; \equiv Si - CH_2 - CH_2 - CH_2 - Si \equiv + \equiv Si - CH_2^{\cdot}$$

$$2 \equiv Si - CH_2^{\cdot} \;\rightarrow\; \equiv Si - CH_2 - CH_2 - Si \equiv$$
where $\equiv$ represents two methyl groups and the rest of the polymer chain.

This reaction has been used for high-consistency silicone rubbers (HCRs), such as those used in extrusion or compression and injection molding, which are cross-linked at elevated temperatures. The peroxide is added before processing. During cure, some precautions are needed to avoid the formation of voids by the volatile residues of the peroxide. Post-cure may also be necessary to remove these volatiles, which can catalyze depolymerization at high temperatures.

2. Cross-linking by condensation. Although mostly used in construction sealants and caulks, condensation-cure silicone materials have also found utility in medical device manufacturing as silicone adhesives (facilitating the adherence to materials of silicone elastomers), encapsulants, and sealants.

One-part products are ready to apply and require no mixing. Cross-linking starts when the product is squeezed from the tube or cartridge and comes into contact with moisture, typically from humidity in the ambient air. These materials are formulated from a reactive polymer prepared from a hydroxy end-blocked polydimethylsiloxane and a large excess of methyltriacetoxysilane.

$$HO - (Me_2SiO)_x - H + excess\,MeSi(OAc)_3$$

$$\xrightarrow[-2AcOH]{}(AcO)_2MeSiO(Me_2SiO)_xOSiMe(OAc)_2$$

$$[7]$$
$$\text{where } Ac = -\overset{\overset{CH_3}{|}}{C} = O$$

Because of this excess, the probability of two different chains reacting with the same silane molecule is remote. Consequently, all the chains are end-blocked with two acetoxy functional groups. The resulting product is still liquid and can be packaged in sealed tubes and cartridges. Upon opening and exposing the sealant to room humidity, acetoxy groups are hydrolyzed to give silanols, which allow further condensation to occur.

$$\backslash\!\backslash\!\backslash O - \underset{\underset{OAc}{|}}{\overset{\overset{Me}{|}}{Si}} - OAc \xrightarrow[-AcOH]{+H_2O} \backslash\!\backslash\!\backslash O - \underset{\underset{OAc}{|}}{\overset{\overset{Me}{|}}{Si}} - OH$$

$$[7] \qquad\qquad\qquad [8]$$

$$\begin{array}{ccc} Me & & Me \\ | & & | \\ \text{\textasciitilde}O-Si-OH + AcO- & & Si-O\text{\textasciitilde} \\ | & & | \\ OAc & & OAc \end{array}$$

$$[\,8\,] \qquad\qquad [\,7\,]$$

$$\xrightarrow[-AcOH]{} \quad \begin{array}{ccc} & Me & Me \\ & | & | \\ \text{\textasciitilde}O- & Si-O- & Si-O\text{\textasciitilde} \\ & | & | \\ & OAc & OAc \end{array}$$
In this way, two chains have been linked, and the reaction continues from the remaining acetoxy groups. An organometallic tin catalyst is normally used, and the cross-linking reaction requires moisture to diffuse into the material. Accordingly, cure will proceed from the outside surface inward. These materials are called one-part RTV (room temperature vulcanization) sealants, but actually require moisture as a second component. Acetic acid is released as a by-product of the reaction. Problems resulting from the acid can be overcome by using other cure (cross-linking) reactions developed by replacing the methyltriacetoxysilane $MeSi(OAc)_3$ with oximosilane $RSi(ON = CR')_3$ or alkoxysilane $RSi(OR')_3$.

Condensation curing is also used in some two-part products where cross-linking starts upon mixing the two components (e.g., a hydroxy end-blocked polymer and an alkoxysilane such as tetra-n-propoxysilane, $Si(OnPr)_4$) (Noll, 1968):

$$\begin{array}{ccc} & Me & nPr \\ & | & | \\ & O \\ 4\ \text{\textasciitilde}Si-OH & + nPrO- & Si-OnPr \\ & | & | \\ & Me & O \\ & & nPr \end{array}$$

$$\xrightarrow[-4nPrOH]{cat} \quad \begin{array}{c} Me \\ | \\ Me-Si\,\text{\textasciitilde} \\ | \\ \begin{array}{ccc} Me & O & Me \\ | & | & | \\ \text{\textasciitilde}Si-O-Si-O-Si\,\text{\textasciitilde} \\ | & | & | \\ Me & O & Me \end{array} \\ | \\ Me-Si\,\text{\textasciitilde} \\ | \\ Me \end{array}$$
Here, no atmospheric moisture is needed. Usually an organotin salt is used as a catalyst, but it also limits the stability of the resulting elastomer at high temperatures. Alcohol is released as a by-product of the reaction, leading to some shrinkage after cure at room temperature (0.5–2% linear shrinkage). Silicones with this cure system may not be suitable for the fabrication of parts with precise tolerances.

3. Cross-linking by addition. Use of an addition-cure reaction for cross-linking can eliminate the shrinkage problem mentioned above. In addition-cure, cross-linking

is achieved by reacting vinyl end-blocked polymers with $\equiv$ Si–H groups carried by a functional oligomer such as described above [6] (Stark et al., 1982):

$$\begin{array}{c} Me \\ | \\ \text{\textasciitilde}O-Si-CH=CH_2 + H-Si\equiv \\ | \\ Me \end{array}$$

$$[5]$$

$$\xrightarrow{cat} \quad \begin{array}{c} Me \\ | \\ \text{\textasciitilde}O-Si-CH_2-CH_2-Si\equiv \\ | \\ Me \end{array}$$
where $\equiv$ represents the remaining valences of the Si in [6].

The addition occurs mainly on the terminal carbon and is catalyzed by Pt or Rh metal complexes, preferably as organometallic compounds to enhance their solubility. The following mechanism has been proposed (oxidative addition of the $\equiv$ Si-H to the Pt complex, H transfer to the double bond, and reductive elimination of the product):

$$\begin{array}{c} \equiv Si-CH=CH_2 + H-Si\equiv \xrightarrow{Pt} \\ \equiv Si-CH=CH_2 \\ | \\ Pt \\ / \ \backslash \\ \equiv Si \quad H \\ \rightleftarrows \ \equiv Si-CH_2-CH_2-Pt-Si\equiv \\ \xrightarrow[-Pt]{} \equiv Si-CH_2-CH_2-Si\equiv \end{array}$$
where, to simplify, other Pt ligands and other Si substituents are omitted.

There are no by-products with this reaction. Molded silicone elastomer components cured at room temperature by this addition-reaction mechanism are very accurate in terms of dimensional tolerance (i.e., there is no shrinkage). At elevated temperatures, some shrinkage occurs because of the thermal expansion during cure. However, handling these two-part products (i.e., Si–Vi polymer and Pt complex in one component, Si–Vi polymer and SiH oligomer in the other) requires some precautions. The Pt in the complex is easily bonded to electron-donating substances such as amine or organosulfur compounds to form stable complexes with these "poisons," rendering the catalyst complex inactive and inhibiting the cure.

The preferred cure system can vary by application. For example, silicone medical bonding adhesives use acetoxy cure (condensation cross-linking), while platinum cure (cross-linking by addition) is used for precise silicone parts with no by-products.

4. Elastomer filler. In addition to the silicone polymers described above, most silicone elastomers incorporate "filler." Besides acting as a material extender, as the name implies, filler acts to reinforce the cross-linked matrix. The strength of silicone polymers without filler is unsatisfactory for most applications (Noll, 1968). Like most other noncrystallized synthetic elastomers, the addition of reinforcing fillers reduces the tackiness of the silicone, increases its hardness, and enhances its

mechanical strength. Fillers might also be employed to affect other properties; for example, carbon black is added for electrical conductivity, or barium sulfate to increase radiopacity. These and other materials are used to pigment the otherwise colorless elastomer; however, care must be taken to select only pigments suitable for the processing temperatures and end-use application.

Generally, the most favorable reinforcement is obtained by using fumed silica, such as Cab–O–Sil®, Aerosil®, or Wacker HDK®. Fumed silica is produced by the vapor phase hydrolysis of silicon tetrachloride vapor in a hydrogen/oxygen flame:

$$SiCl_4 + 2H_2 + O_2 \xrightarrow{1800°C} SiO_2 + 4HCl$$
Unlike many naturally occurring forms of crystalline silica, fumed silica is amorphous. The very small spheroid silica particles (in the order of 10 nm in diameter) fuse irreversibly while still semi-molten, creating aggregates. When cool, these aggregates become physically entangled to form agglomerates. Silica produced in this way possesses remarkably high surface area (100–400 m²/g), as measured by the BET method developed by Brunauer, Emmett, and Teller (Brunauer et al., 1938; Noll, 1968; Cabot Corporation, 1990).

The incorporation of silica filler into silicone polymers is accomplished prior to cross-linking, by mixing the silica into the silicone polymers on a two-roll mill, in a twin-screw extruder, or in a Z-blade mixer capable of processing materials with this rheology.

Reinforcement occurs with polymer adsorption encouraged by the large surface area of the silica, and when hydroxyl groups on the filler surface lead to hydrogen bonds between the filler and the silicone polymer. In this way, reinforcing filler contributes to the high tensile strength and elongation capability of silicone rubber (Lynch, 1978). The addition of filler increases the already high viscosity of the polymer. Uncured silicone elastomers can have viscosities from 10,000 to well over 100,000 mPa·s. Chemical treatment of the silica filler with silanes enhances its incorporation in, and reinforcement of, the silicone elastomer, resulting in increased material strength and tear resistance (Lane and Burns, 1996) (Figure B.1).

Silicone elastomers for medical applications normally use fumed silica as filler, and occasionally appropriate pigments or barium sulfate. Because of their low glass transition temperatures, these compounded and cured silicone materials are elastomeric at room and body temperatures without the use of plasticizers, unlike other medical materials such as PVC, which might contain phthalate additives.

---

5. Processing of silicone elastomers. In addition to the polymer blend with amorphous silica filler, other ingredients are needed: an initiator or cross-linker plus catalyst. To avoid premature cure during shipment and
FIGURE B.1 Silicone elastomer/silica network.

storage, these ingredients must be separated. Consequently, products for making silicone elastomers are generally supplied as two components or two-part kits, for example, a base and a peroxide paste, or a kit made of Part A containing polymer and catalyst, and Part B containing polymer and cross-linker. These two components are mixed at a fixed ratio at the point of use and formed into the desired shape before cure.

Silicone elastomers are thermosetting materials. They must be formed into the appropriate shape and configuration prior to cross-linking. Unlike a thermoplastic, which can be remelted and formed again, a cured silicone elastomer part cannot be reprocessed. Suitable processing methods for shaping silicone elastomers include casting, extrusion, and molding. The process selected depends on the viscosity of the feedstock elastomer material, and the shape and configuration of the desired cured elastomer product.

High Consistency Rubber (HCR). If very high molecular weight silicone polymers are used (silicone "gums" in the trade), the result is high consistency rubbers, which are desirable as they allow for high tear strengths and tensile elongations. Uncured HCRs are putty-like materials that require high shear equipment for processing. These are usually supplied in two parts to be mixed prior to use, either as a silicone base plus a peroxide initiator or as two-part kit using a Pt cure system. These parts are combined using high shear two-roll mills. The mixed material is then shaped into "preforms" before use in compression, transfer or injection molding at elevated temperature. *Compression molding* requires the simplest equipment: a preform is inserted in a mold and cured under high pressure at elevated temperature. The preform must be of an approximate shape that corresponds well to the mold cavity. This allows sufficient material to fill the cavity without producing excessive flash, the overflow material that remains attached to the parts from around the edge of the mold. Removal of flash requires post-processing. *Transfer molding* requires less preparation of the preform: a more precise but simply shaped preform is transferred from a receiving cavity to the mold cavity. *Injection molding* allows for more automation: an extruder system is used to inject a simple ribbon preform directly into the mold cavity. Typical considerations in this case are controlling the exact amount of material sent to the molding cavity to avoid flash, and maximizing speed but avoiding "scorching" (premature cure before the mold cavity is properly

filled). HCRs are also used for *extrusion* to produce tubing, as they have enough "green strength" or mechanical integrity when leaving a cooled extruder and prior to enter a curing oven. When peroxides are used, post-cure in a well-ventilated oven is necessary to remove peroxide by-products, which could bloom at the surface and can reduce the stability of the cured elastomer. One part HCR materials, for which all ingredients have been premixed by the supplier, are also available, but have limited shelf-life depending on the cure system.

Liquid Silicone Rubber (LSR). If lower molecular weight silicone polymers are used, the silicone polymer/silica blend viscosities are lower, leading to liquid silicone rubber. These LSRs are provided as two-part materials that can be used in liquid injection molding – pumped, metered, mixed, and then directly injected in the molding cavity. Processing is eased by the shear-thinning effect that occurs during pumping and injection, reducing the viscosity of the LSR blend and the injection pressures compared to HCR processing. LSRs are particularly well-suited for long automated production runs. Mixing LSR Parts A and B from two 200-liter drums is typically automated using a static mixer prior to direct injection of the precise amount needed. In contrast with the handling of small quantities of HCR on a two-roll mill, preforming, and molding, LSR processing allows more automation. Yet liquid injection molding requires higher investment in the equipment to control the injected amount (to avoid under- or over-filling the mold) precisely. Precise mold cavity temperature control is needed, as cold material is quickly and repeatedly injected into a hot mold. With LSRs, complex molds are needed, preferably with cold runners to avoid premature cure in the feeding lines between injection cycles, with tight specifications still allowing venting (air escape from the mold cavity during injection). The molds may be equipped with complex ejectors to remove parts quickly at the end of the cure, enabling the processing of the next part without loosing thermal control of the mold. The acquisition cost of liquid injection molding machines and sophisticated molds is usually justified for large production runs, as they provide for more efficiency in terms of mold cycle time, overall processing time, and material usage. Cycle time is dependant on operator skills, equipment, and the part to be cured. Typical conditions for LSRs are 0.3–3.0 seconds injection time, 150–200°C cure temperature, and 3–5 sec/mm thickness cure time, depending on formulations (Sommer, 2003).

> Fabricators of silicone elastomer parts should be aware that these LSRs and other addition-cure products contain an inhibitor, a substance that weakly bonds to the platinum catalyst to moderate its activity, permitting sufficient pot life by avoiding premature cure. If contamination occurs with substances capable of bonding more strongly to the platinum catalyst (e.g., amino or thio compounds), the catalyst (which is present in only minute quantities, typically about 10ppm) may lose activity, resulting in inhibition of elastomer cure.

Room Temperature Vulcanizing (RTV) elastomers. In addition to HCRs and LSRs, which are designed to cure by exposure to heat, other silicone elastomers, known as RTVs, are intended to be cured at room temperature. Typically, RTV elastomers are provided in two-part systems and can be viewed as a variation of the LSRs, but with lower viscosity and less inhibitor. They can be mixed with a spatula and cast after de-airing, and are typically used for laboratory trials and commercially in medical applications for dental impression molding. RTVs are also available as one-part silicone elastomers provided ready to use, usually as adhesives. These materials rely on a condensation reaction and on moisture in the air as the second component to achieve cure.

Silicone Gels. Silicone gels are typically composed of a very lightly cross-linked silicone elastomer whose polymer network has been swollen with silicone fluids; however, these gels contain no silica or other fillers. Medical applications for silicone gels include breast, testicular, and other soft-tissue implants for tissue augmentation or to help restore one's appearance after cancer surgery. In addition, silicone gel external breast prostheses can be worn in or attached to garments, such as brassieres, for similar purposes. Silicone gel is often supplied in a two-part fluid system and cures via a platinum-catalyzed addition reaction. Parts A and B are mixed at a desired ratio and cured (usually by exposure to elevated temperature) to yield a sticky, cohesive mass of the desired consistency. The consistency of the material can be controlled by the degree of cross-linking, as well as quality and quantity of swelling fluid. After mixing but before curing, the mixture is still liquid and can be pushed through a large gauge needle, enabling the filling of a silicone elastomer implant shell or the thermoformed pouch of an external breast prosthesis made of a thin polyurethane film.

Beyond gel implants and external prostheses, silicone gels find application in skin-contacting sheet goods in wound and scar care.

In addition to gels composed entirely of silicone materials, the gel used in some gel pads for the prevention of pressure sores or for orthotic applications are comprised of a cross-linked silicone polymer network swollen with non-silicone fluids such as mineral oil.

Silicone Adhesives. Three basic types of silicone adhesives are used in medical applications: bonding, pressure-sensitive, and gel.

1. *Bonding adhesives.* Silicone bonding adhesives are used to attach components together and to seal seams and junctions. Electrical components can also be encapsulated and insulated using silicone bonding adhesive. Silicone bonding adhesives are most commonly formulated as one-part RTV elastomer systems that use a condensation cross-linking reaction, as described earlier in this chapter.
2. *Pressure-sensitive adhesives.* Silicone PSAs are typically formulated in solvent. A silanol end-blocked

POLYMER   **RESIN**

PSA

FIGURE B.2 Three-dimensional representation of eicosamethylnonasiloxane, $Me_3SiO(SiMe_2O)_7SiMe_3$ or MD_7M. *(Courtesy T. Lane, Dow Corning.)*
PDMS undergoes a polycondensation reaction with a silicate resin in the presence of ammonia as catalyst. The ammonia is stripped with heat, and usually the solvent is exchanged.

In some applications, a hot melt silicone PSA is used ostensibly without solvent.

Silicone PSAs have properties that make them well-suited for application in the medical area. Besides their biocompatibility, the materials are highly flexible and permeable to moisture vapor, CO_2, and oxygen. Silicone PSAs can provide strong adhesion to the skin, facilitating the attachment of hairpieces, prosthetics, and other devices to the body, and they are widely used in transdermal drug delivery. Due to compatibility concerns with amine-containing drugs, an additional class of silicone PSAs have been generated by the further reaction of the PSA with hexamethyldisilazane to convert the pendant $\equiv$ SiOH groups into $\equiv$ SiOSi(CH$_3$)$_3$.

3. *Gel adhesives.* Silicone gel adhesives, also known as soft skin adhesives, are used in wound care, and are found to be gentler and less traumatic on removal than the pressure-sensitive types. Unlike PSAs, which are typically formulated in solvent, silicone gel adhesives are supplied in solventless two-part systems. In addition to wound care applications, the materials are also used in the treatment of hypertrophic and keloid scars. Evidence suggests this therapy may reduce scar height and appearance (O'Brien and Pandit, 2006).

Silicone Film-in-Place, Fast-Cure Elastomers. In addition to the cured silicone elastomers in skin contact applications, *in situ* cure materials have been developed. These materials form films when spread or sprayed on the skin, and then undergo RTV cure. Products such as spray-on wound dressings or drug-loaded lotions have been evaluated. The ability of silicone to spread and form films is related to its low surface tension as described in the Physico-Chemical Properties section below (Maxon et al., 2004).

Physico-Chemical Properties

The position of silicon just under carbon in the periodic table led to a belief in the existence of analog compounds
where silicon would replace carbon. Most of these analog compounds do not exist, or behave very differently from their carbon counterparts. There are few similarities between Si–X bonds in silicones and C–X bonds (Stark et al., 1982; Corey, 1989; Hardman, 1989; Lane and Burns, 1996).

Between any given element and Si, bond lengths are longer than for the element and C. The lower electronegativity of silicon ($\chi_{Si} \approx 1.80$, $\chi_C \approx 2.55$) leads to a very polar Si–O bond compared to C–O. This bond polarity also contributes to strong silicon bonding; for example, the Si–O bond is highly ionic and has a high bond energy. To some extent, these values explain the stability of silicones. The Si–O bond is highly resistant to homolytic scission. On the other hand, heterolytic scissions are easy, as demonstrated by the re-equilibration reactions occurring during polymerizations catalyzed by acids or bases.

Silicones exhibit the unusual combination of an inorganic chain similar to silicates and often associated with high surface energy, but with side methyl groups that are very organic and often associated with low surface energy (Owen, 1981). The Si–O bonds are moderately polar, and without protection would lead to strong intermolecular interactions (Stark et al., 1982). Yet, the methyl groups, only weakly interacting with each other, shield the main chain (see Fig. B.2).

The surface activity of silicones is evident in many ways (Owen, 1981):

- Polydimethylsiloxanes have low surface tension (20.4mN/m) and are capable of wetting most surfaces. With the methyl groups pointing to the outside, this configuration gives very hydrophobic films and a surface with good release properties, particularly if the film is cured after application. Silicone surface tension is also in the most promising range considered for biocompatible elastomers (20–30mN/m) (Baier, 1985).
- Silicones have a critical surface tension of wetting (24mN/m), higher than their own surface tension. This means silicones are capable of wetting themselves, which promotes good film formation and surface coverage.

- Silicone organic copolymers can be prepared with surfactant properties, with the silicone as the hydrophobic part (e.g., in silicone glycol copolymers).

The low intermolecular interactions in silicones have other consequences (Owen, 1981):

- Glass transition temperatures are very low (e.g., 146°K for a polydimethylsiloxane compared to 200°K for poly-isobutylene, the analog hydrocarbon).
- The presence of a high free volume compared to hydrocarbons explains the high solubility and high diffusion coefficient of gas into silicones. Silicones have a high permeability to oxygen, nitrogen, or water vapor, even though liquid water is not capable of wetting a silicone surface. As expected, silicone compressibility is also high.
- The viscous movement activation energy is very low for silicones, and their viscosity is less dependent on temperature compared to hydrocarbon polymers. Furthermore, chain entanglements are involved at higher temperature, and contribute to limit viscosity reduction (Stark et al., 1982).

This shielding is made easier by the high flexibility of the siloxane chain. Barriers to rotation are low, and the siloxane chain can adopt many configurations. Rotation energy around a $H_2C–CH_2$ bond in polyethylene is 13.8 kJ/mol, but is only 3.3 kJ/mol around a $Me_2Si–O$ bond, corresponding to a nearly free rotation. In general, the siloxane chain adopts a configuration so that the chain exposes a maximum number of methyl groups to the outside, whereas in hydrocarbon polymers, the relative rigidity of the polymer backbone does not allow selective exposure of the most organic or hydrophobic methyl groups. Chain-to-chain interactions are low, and the distance between adjacent chains is also greater in silicones. Despite a very polar chain, silicones can be compared to paraffin, with a low critical surface tension of wetting (Owen, 1981).

CONCLUSION

Polydimethylsiloxanes are often referred to as silicones. They are used in many applications because of their stability, low surface tension, and lack of toxicity. Methyl group substitution or introduction of tri- or tetrafunctional siloxane units leads to a wide range of structures. Polymers are easily cross-linked at room or elevated temperature to form elastomers, without losing their advantageous properties.

C. FLUORINATED BIOMATERIALS

Fang Liu[1] and David W. Grainger[1,2]
[1]Departments of Pharmaceutics and Pharmaceutical Chemistry, University of Utah, Salt Lake City, UT, USA
[2]Bioengineering, University of Utah, Salt Lake City, UT, USA

INTRODUCTION

Fluorinated biomaterials have a long history of biomedical device and biomaterials applications. These materials are generally carbon-based polymers, liquids, and gas precursors to films that all contain large amounts of chemically bonded fluorine (i.e., perfluorocarbons). Fluorinated materials can be solids, liquids, thin films, coatings or gels, depending on their chemistry, processing, and mode of use. Fluoropolymers in general are thermoplastic polymers analogous to hydrocarbon-based polyethylene (PE), but highly fluorinated; some or all of the hydrogen atoms attached to the PE carbon polymer chain are replaced by fluorine (F) or fluorinated alkyl (perfluorocarbon) side groups. In some cases other halogen atoms (e.g., chlorine, Cl) are also included with F to slightly modify polymer properties (Drobny, 2005). Notably, fluoropolymers show unique propertiesnot achievable by other polymer materials, including chemical inertness, extreme hydrophobicity and solvent resistance, low coefficients of friction, high design tolerances for device fabrication, and temperature resistance (Drobny, 2005). These properties facilitate fluoropolymer use in specific technologies where most hydrocarbon-based materials do not perform well, either in device manufacturing or their applications. Nevertheless, as with all biomaterials, fluoropolymers perform best only in certain biomedical applications, and often carry a considerably greater cost than their hydrocarbon analogs into medical device designs.

Just two years after the first commercial launch of completely fluorinated polytetrafluoroethylene (PTFE), as DuPont's now well-known Teflon™ product, after World War II ended, this new polymer was implanted in animals for the first time (Leveen and Barberio, 1949). However, early PTFE materials processing difficulties limited device capabilities. In 1963, Japanese researchers reported a new process for expanding PTFE films to produce highly uniform, continuous fibrous porous structures that, after thermal processing, retained this microstructure with vastly improved mechanical strength (Oshige, 1967). In 1972, this expanded fibrous material was first used experimentally as a venous graft substitute (Soyer et al., 1972), and a year later as an arterial bypass implant (Matsumoto et al., 1973). Several years later (1976), expanded PTFE (ePTFE) was refined to production scales by Gore, allowing increased access and clinical use of this more versatile PTFE form in commercialized biomedical products (Gore, 1976). This enabled fluorinated biomaterials to be employed in biomedical applications both inside and outside the living host, facilitating entry as an important class of polymeric biomaterials that are seen in the field today.

Biomedical interest in fluorinated biomaterials focuses on several unique properties: lubricity; high sizing tolerances for device fabrication; and select aspects of reasonable biocompatibility resulting from both unique chemical and morphological properties. Understanding certain aspects of fluorinated chemistry is important to appreciate their material properties and broad utility in biomedical products.

INTERESTING FLUOROPOLYMER CHEMICAL AND PHYSICAL PROPERTIES DERIVED FROM THEIR POLYMER CHEMISTRY, MOLECULAR STRUCTURE, AND BONDING

Replacing large amounts of hydrogen in C–H and C–C bonds in organic materials with fluorine as C–F chemistry, using several different chemical means, results in dramatic changes to the fluoromaterial's physical and chemical properties. Technologically desirable characteristics of perfluorinated materials are identified from how they interact distinctly with other media (e.g., heated fabrication machines and device extruding dyes, as well as tissue, blood, proteins, and other polymers). Single fluorine bonds with carbon are the strongest carbon bonds, some 25 kcal/mol^{-1} stronger than C–Cl (Smart, 1994). Fluorination also strengthens adjacent aliphatic bonds: the CF_3–CF_3 bond is 10 kcal/mol^{-1} stronger than the CH_3–CH_3 bond (Smart, 1994). This makes alkyl fluorides 10^2–10^6 times more stable than the corresponding alkylchlorides in solvent and thermal reactions (Smart, 1994). Exceptional thermal and chemical stabilities observed for perfluorinated materials then result. Fluorine's high ionization potential energy and low polarizability provide relatively weak intermolecular forces, low interfacial energies, and low refractive indices in fluorinated materials. This is important to interfacial applications, (see section on Surfaces Modified by Fluorination Treatments below). Fluorine's larger atomic radius compared to hydrogen provides a rational basis for the observed structural differences between perfluorocarbons and hydrocarbons; chain movement energies (i.e., C–C chain rotational barriers) for various fluorine-substituted bonds are significantly higher than barriers in analogous hydrocarbon systems (Smart, 1994). Partially fluorinated commercial polymers, polyvinylidene fluoride (PVDF) and ethylene-trifluoroethylene copolymer (ETFE), have zig-zag polymer chain conformations with different C–F dipole alignments along the chain (Smart, 1994), while perfluorocarbons with only C–F bonds (e.g., PTFE, see below) assume helical chain orientations with C–F dipoles distributed axially around the chain helix (Doeff and Lindner, 1989; Zhang et al., 1989; Sun et al., 1994a,b; Kobayashi and Owen, 1995; Bar et al., 1997;

Stone et al., 1998). PTFE, for example, as a model for high molecular weight perfluorocarbon chains, is known to have a rich phase diagram of several distinct helical solid phases (Scheirs, 1997). This polymer helix basically encases the inner carbon–carbon polymer backbone with a tight outer shell of fluorine groups, protecting the carbon bonds from reactants, and also contributing to unique chain–chain interactions in PTFE and helical fluorinated polymers. Although most fluoropolymers share unique properties (e.g., thermal and chemical stability, lubricity), their mechanical properties are slightly different, depending on whether they are fully fluorinated or contain some hydrogen atoms. Generally, partially hydrogenated fluoropolymers exhibit higher stiffness than fully fluorinated polymers (i.e., perfluoropolymers). Perfluoropolymers exhibit greater elongation and higher maximum service temperatures that benefit device engineering and thermal processing.

DISTINGUISHING THE DIFFERENT FLUOROPOLYMERS

Fluoropolymers can be classified into homopolymers and copolymers by the monomer(s) used in their polymerization. They are divided into either "partially fluorinated" or "perfluorinated" (i.e., 100% C–F bonds) based on the amounts of fluorine in the polymer chain. Figure C.1 lists currently available commercial biomedical fluoropolymers. Polymer chemical composition affects the resulting materials' properties; only certain fluoropolymers exhibit properties attractive for biomedical products. As one selection criteria, Figure C.2 (Scheirs, 1997) compares some selected mechanical properties for different biomedical fluoropolymers (Drobny, 2005).

Polytetrafluoroethylene (PTFE)

PTFE (DuPont trade-name Teflon™) is perhaps the most commonly analyzed fluoropolymer. As described above, fluorine's large size and mutual repulsion of adjacent fluorine atoms causes PTFE macromolecule chains to exhibit a twisting helix, comprising 13 CF_2 groups per 180° turn, distinct from the classic planar zigzag chain typical

for PE (Bunn and Howells, 1954). Figure C.3 shows this important conformational chain distinction that imparts certain unique physical properties to the fluoropolymer. Helical PTFE chains are often of very high molecular weight ($>10^6$) from their polymerization by reactive TFE gas. The helical polymer chains pack into solid crystallites like long, parallel, stiff molecular rods; individual PTFE polymer molecules can slip on each other as quasi-cylinders sliding under shear stress. Tight helical packing and chain–chain slip make PTFE the most lubricious polymer available, with a low coefficient of friction (0.1). This is a major selection criterion for manufacturing fluoropolymer tubing for catheters. Unfortunately, this also makes PTFE solids very susceptible to cold flow (creep) under stress – a major reason for their contraindication in mechanical applications (i.e., poor bearing and joint surfaces) (see Box 1). Mutual repulsive forces of adjacent fluorine atoms keep the PTFE chain backbone from bending. Low energy barriers to chain–chain slip events result from low chain–chain interaction energies. PTFE's very high bulk solid fractional crystallinity means that it scatters most visible light wavelengths, resulting in its characteristic opaque white color. PTFE's high molecular weight and rigid helical chain conformation also produce high melt viscosities (e.g., 10^{12} Pa/s), ~6 times higher than most thermoplastic polymers. This viscosity

BOX 1	Sir John Charnley and the PTFE Replacement Hip Bearing

Convinced that hip joint repair could not use metal-on-metal bearings, Professor Sir John Charnley's early work on hip arthroplasty techniques in the early 1950s used a Teflon™-on-Teflon solid bearing to resurface the arthritic femoral head and acetabulum. These Teflon™-on-Teflon bearings failed within two years from mechanical creep and particulate issues. His further innovations created a femoral stem and metal head articulating against a Teflon cup-socket inserted into the acetabulum. High Teflon wear occurred with joint articulation, producing severe osteolysis, loosening in the surrounding bone and, as a result, requiring many revision surgeries. Teflon's poor performance in this articulating joint application prompted the adoption of high molecular weight polyethylene as a better bearing surface – an innovation that persists to today.

is excessive for conventional melt processing fabrication methods for thermoplastic medical devices (e.g., extrusion and injection molding). This requires a high continuous service temperature (~260°C) for processing PTFE into devices. Therefore, as PTFE does not dissolve in any solvents, PTFE processing technologies are similar to those of powder metallurgy. This involves form casting of pre-polymerized PTFE granulated powders or latex formulations, followed by mold compression and thermal sintering. PTFE's high thermal stability is key to success under the extreme processing conditions required for molded device parts (Drobny, 2005).

Fluorinated Ethylene Propylene (FEP)

FEP is a copolymer of tetrafluoroethylene (TFE) and hexafluoropropylene (HFP), first produced by DuPont in 1956 (Teflon™ FEP) to reduce PTFE's high crystallinity and melt viscosity. This improves FEP processing characteristics while maintaining high perfluorination. Bulky FEP perfluoromethyl groups produce defects in solid fluoropolymer crystallites, reducing polymer melting point, impeding chain slip, and reducing solid cold flow (Drobny, 2001). FEP combines the unique mechanical and chemical properties of PTFE with the melt-processability of more conventional polymers. FEP has a maximum service temperature of 204°C, and a slightly higher coefficient of friction than PTFE. It is used in biomedical devices in place of PTFE.

Polyvinylidene fluoride (PVDF)

PVDF is a homopolymer of the vinylidene monomer (CH_2CF_2), and is sold as Kynar™. PVDF has the highest flexural modulus of all fluoropolymers, due to the interpenetration of larger CF_2 groups crystallizing with adjacent smaller CH_2 groups on adjacent chains. Unlike other fluoropolymers, PVDF is soluble in highly polar solvents (dimethylformamide, tetrahydrofuran), acetone, and esters (Drobny, 2005). PVDF's unique high dielectric constant, high dielectric loss factor, and interesting piezoelectric behavior under certain conditions result from this chemistry and result in solid state structures. Fluorine's shielding effects to all neighboring CH_2 groups

provides PVDF with good chemical resistance and thermal stability (Scheirs, 1997; Drobny, 2001). These are all valuable properties sought in specific medical device applications.

Fluoropolymer Melt Processing

Because most perfluorinated polymers do not dissolve in many solvents, their bio-medical products are often made by melt extrusion, where polymers develop flow upon melting in normal extrusion equipment. This technique, common to all polymer devices and chemistries, exposes fluoropolymers to very high temperatures in order to reduce their viscosity and improve flow characteristics for extended device production runs and product lengths. Fluoropolymers FEP and PVDF will readily melt flow when heated, typically above 260°C. This permits uninterrupted feed of fluoropolymer resin into the parts extruder to produce long continuous lengths of product (i.e., medical tubing). By contrast, PTFE extrusion is limited due to difficulties in its materials handling, size of the stock pre-forms, and tubing. However, PTFE's poor melt processing presents an important opportunity: PTFE tubing can be manufactured to very small dimensions, with wall thicknesses as small as 2.54×10^{-3} cm and tolerances of $\pm 1 \times 10^{-3}$ cm. This engineering benefit is largely due to PTFE's inability to melt flow, allowing more precise control over its use in small dimensional, high-tolerance extrusion forms. This unique PTFE property is essential for producing medical products requiring tight size tolerances, such as small diameter and multi-lumen tubing with multiple precision passages for advanced catheters.

Original Gore-Tex™ and Generic Equivalents (ePTFE)

PTFE film extrusion under anisotropic loading conditions produces expanded Teflon™ (ePTFE). Its micro-architecture exhibits pores axially aligned along the stretch direction, resulting in a unique fluoropolymer fabric material with an oriented microporous architecture. This was originally commercialized as the fabric-like Gore-Tex™ material (Gore, 1976). ePTFE's porous structure is characterized by regular PTFE nodes interconnected by PTFE fibrils (Figure C.4A), distinct from solid PTFE shown in Figure C.4B. In ePTFE internodal spacing or distance (i.e., PTFE fibril length between solid PTFE nodes) is important to control device implant behavior (McClurken et al., 1986), and this can be controlled from 1 to 100 microns (Santiago et al., 1981) while retaining some properties similar to PTFE, e.g., biological adsorption, low tensile strength, low modulus of elasticity, water penetration control, and easy sterilizability. Porous ePTFE structures also allow important mechanical modulus-matching properties in tissue sites better than other polymers for many soft biological
FIGURE C.4 (A) Scanning electron micrograph of ePTFE showing regular node-fiber open materials structure (scale bar, lower right corner = 10 microns). (We kindly acknowledge B. Wagner, W. L. Gore & Associates, Flagstaff, AZ, USA, for ePTFE micrographs). (C) Dense continuous top surface (scale bar = 25 microns).

tissue applications (Mole, 1992). Porosity also importantly encourages in-growth of tissue, and hence moderate levels of tissue mechanical fixation. Bulk PTFE does not exhibit this property. The micropores also present active sites for stable blood clotting, an important property for conditioning implanted vascular graft surfaces to limit their chronic blood coagulation.

Surfaces Modified by Fluorination Treatments (Grainger and Stewart, 2001)

Bulk perfluorinated materials' intrinsically higher costs and often substandard mechanical properties limit their applications. When only fluorinated polymer interfacial properties are desired, then fluorinated surface layers can

be chemically deposited or coated over other mechanically superior substrates to impart fluorinated properties only at the surface. This surface application limits bulk fluorocarbon costs and their performance liabilities. As developed further below, fluorinated surfaces can be produced by plasma deposition of gaseous precursor monomers, direct solid powder or solution overcoating and casting/evaporation, and solution phase fluorinated component blooming. High surface fluorocarbonation produces unique interfacial properties, imparting specific, technologically attractive features including low solid-state surface free energy (or low water wettability and permeability), surface lubricity, and chemical resistance and durability, to device surfaces. Table C.1 shows that perfluorinated polymer surfaces exhibit low interfacial energies (indicated by Zisman γ_c values), correlating directly with their utility as low adhesion, low water-wetting, and low friction surfaces. Substituting either hydrogen or another halogen for fluorine along the polymer backbone results in significant increases in γ_c values (as seen in comparisons of PTFE with high-density polyethylene (HDPE)), PVDF:poly(CH_2CHF) has a $\gamma_c \sim 25$ mN/m, approaching that for polyethylene (HDPE, see Table C.1). Another important outcome of this low interfacial fluoromaterial energy is that fluorinated species thermodynamically prefer to coat a material's surface exposed to air. Hence, fluorinated components will migrate from deep inside fluid coating mixtures to "bloom" and enrich as a coated overlayer at the solid–air interface.

Surface-enriched films of fluorinated components reside at surfaces even if fluorinated components are doped only at trace or minority components into bulk coating materials. Therefore, fluorinated surfaces can be fabricated using minority fluorinated components added to a bulk material if they are allowed to move to that material's surface (e.g., from coating solutions), off-setting the intrinsically high costs of fluorinated materials. Emphasis on surface-fluorinated coatings and films has therefore increased as technological needs drive new, improved, and less expensive methods to put this chemistry over biomaterial surfaces. Several coating strategies have sought to create, organize, and orient $-CF_3$ and $-SF_5$ terminal groups from films over any surface to provide such properties. High surface density and organization of these groups is necessary to achieve their technological properties. Alignment of perfluorinated chains terminating in this $-CF_3$ or $-SF_5$ chemistry at the surface is required. Orienting the side chains in fluoroalkyl side-chain acrylate and methacrylate films enriches surfaces with side chain-terminating $-CF_3$ groups (Bunn and Howells, 1954; Clark and Muus, 1962; Russell et al., 1986; Naselli et al., 1989), and lowers solid interfacial energies. Perfluoroalkyl-grafted polysiloxanes also exhibit side chain orientation of their perfluorinated chemistry, sometimes with spontaneous perfluorinated group organization as a film or coating (Hare et al., 1954; Pittman, 1972; Schneider et al., 1989; Tsao et al., 1997; Clark, 1999). Gas plasma-deposited thin fluorinated coatings are also well-developed for this purpose (D'Agostino,

1990), representing a mature industry and biomedically relevant materials treatment (e.g., for vascular devices and intraocular lenses; Ratner, 1995).

BIOMEDICAL APPLICATIONS

Biomedical applications of fluoropolymers, fluorocarbon coatings, and perfluorinated fluids and gels all include clinical interventional and luminal access devices (catheters in many forms), and more permanent implants (cardiovascular (Stanley, 1982), dental (Ratner, 1993), ocular (Legeais et al., 1998), craniofacial (Valdevit et al., 2000), urological (Reid et al., 1995), and abdominal (Grannis and Wagman, 1995) applications) as well as substantial non-implanted medical tubing and biotechnology components (protein blotting and filtration membranes). Annually, millions of perfluorinated polymer components are used worldwide in biological milieu both *in vitro* and *in vivo*. PTFE (Teflon™) and ePTFE (Gore-Tex™) are widely used in medical tubing, advanced catheters, vascular grafts, meshes, sutures, and other medical implants. PVDF is used for biotechnology blotting/separation membranes. Table C.2 provides biomedical applications of more popular fluoropolymers. Clinically, ePTFE vascular grafts, including dialysis-access grafts, and Teflon™-FEP catheter components are the most widely used fluorinated material medical devices. Other biomedical applications are described below.

Fluorinated Material Biological Response

Fluoropolymers are often regarded as chemically inert under most biological conditions. As noted above, they have some mechanical shortcomings under cyclic or continuous shear (creep). This makes applications in loadbearing situations (i.e., joint replacement, wear surfaces) difficult. Additionally, fluoropolymer surfaces are not inert to host

TABLE C.2	Fluorinated Biomaterials Biomedical Applications
Decade	**Biomedical Applications**
1970s	Implantable vascular grafts, peripheral catheters, and catheter introducers
1980s	Guiding catheters, protein blotting membranes, tissue meshes, tubing
1990s	Endoluminal stents, blood substitutes
2000s	Drug-eluting stents

biological reactions, including protein adsorption and blood clotting, either *in vitro* or *in vivo*. In fact, extremely tight binding of serum albumin to fluoroplasma-deposited surfaces (Kiaei et al., 1992), high levels of fibronectin and hemoglobin on PVDF (Paynter and Ratner, 1985), and various serum proteins (Dekker et al., 1991) including significant fibrinogen (Chandy et al., 2000), and high levels of both fibronectin and albumin (Grainger et al., 2003) on PTFE are observed *in vitro*. Importantly, protein adsorption to fluoropolymers is also observed *in vivo* (van Wachem et al., 1985; Roald et al., 1994), including fibrinogen activation, fibrin deposition, and platelet activation from blood, often deliberately promoted to stabilize blood reactivity on ePTFE vascular graft materials *in vivo* (Hoffman et al., 1986; Callow, 1988; Roald et al., 1994). Therefore, non-specific protein adsorption is significant, often irreversible, on fluoropolymer surfaces, leading to their desired utility as efficient protein blotting membranes. But different proteins from different media (i.e., serum versus plasma versus blood) produce different interfacial reactions to fluorinated surfaces. From serum *in vitro* for example, substantial amounts of albumin adsorption hinder serum-mediated cell attachment to fluoropolymers. This albumin passivation against further biological reactivity helps render the surface bio-fouling resistant. Clinical human cell-based vascular graft endothelialization to improve their blood compatibility is also generally poor on non-porous fluoropolymer chemistries (Kempczinski et al., 1985; Callow, 1988; Dekker et al., 1991; Schmidt et al., 1991; van Kooten et al., 1992; Roald et al., 1994; Legeais et al., 1998). This poor cell–fluoropolymer attachment has often been interpreted as "biological inertness," but results instead from substantial plasma protein adsorption on fluoropolymers (Baier et al., 1984) that does not support cell attachment and growth. Serum albumin, the most abundant protein in blood, blocks most cell attachment and other protein binding (Kesler et al., 1986; Zilla et al., 1989). Fibronectin, collagens, and other trace matricellular proteins (e.g., osteopontin, laminin, vitronectin) are cell-adhesive proteins. The observed general inability of non-porous fluoropolymers to support cell attachment has been related to excessive adsorption of albumin over cell-adhesive proteins (e.g., fibronectin) from serum – a media lacking clot-forming fibrinogen (Grainger et al., 2003). Pre-adsorption of specific cell-adhesive proteins (e.g., collagen or fibronectin) to fluoropolymers is used

to promote reliable cell adhesion (McClary et al., 2000; Koenig et al., 2003). Therefore, little evidence suggests that fluoropolymers can be intrinsically "biologically inert." In fact, the opposite is true; solid fluoropolymers are intrinsically reactive and adsorptive to most every protein studied, and the nature of what types of proteins are adsorbed dictates the fluoropolymer's biological reactivity. For example, porous fluoropolymers with 60–80 μm voids, including ePTFE, can facilitate rapid blood clotting, cell and bacterial in-growth in blood. These interactions occur by blood-based protein adsorption, clotting, and cell/bacterial adhesion, with additional physical integration and engagement into the ePTFE pores (Clark et al., 1974; Clowes et al., 1986).

PTFE (Teflon™) Mesh and Fabric Vascular Implants

The innovation that enabled the spinning of PTFE paste into a fiber that could be woven or knitted into fabric or mesh produced a fabric-like fluorinated material (Berry, 1951). Attracted by solid PTFE's reported "blood compatibility" claimed in early animal acute *in vivo* studies, PTFE weaves were applied early in vascular grafts (Edwards, 1959). However, these early woven vascular grafts exhibited both high early failure rates and substantial late failure rates. Graft thrombosis was the most frequent early complication, accompanied by a high mortality rate (Boyd and Midell, 1971). Gore-Tex™ (ePTFE) vascular grafts supplanted these earlier PTFE weaves in this application and are discussed below. Thrombosis is a general property of fluoropolymer meshes and weaves in blood, passivating surfaces rapidly for acute short-term use, but limiting long-term blood-contacting applications.

ePTFE and Teflon™ Soft Tissue Repair Meshes

Teflon™ fibrous mesh has been used to repair abdominal wall defects (Ludington and Woodward, 1959) and hernias (Gibson and Stafford, 1964; Snijders, 1969; Kalsbeek, 1974). However, it does not reliably integrate into body tissues, is not sufficiently infection-resistant, and exhibits wound complication rates too high for routine hernia or abdominal repair use. ePTFE mesh is clinically used to repair hernias of many types (DeBord, 1998), reducing risks of several complications (DeGuzman et al., 1995; Lo Monte et al., 2009) (see Box 2). Infection and intestinal obstructions remain an issue for ePTFE mesh. However, they are better controlled with antibiotic therapies without mesh removal. ePTFE meshes have also been used as abdominal surgery barriers against surgical adhesions (Tulandi, 1997; Morris-Stiff and Hughes, 1998). ePTFE is also FDA-approved for many different plastic surgical facial defect reconstructions and augmentations, but is contraindicated in cosmetic lip augmentation, temporomandibular joint reconstruction, cardiovascular defects, and dermal placement (Levine and

Berman, 1995). Nonetheless, commercial sources for these plastic surgery materials are discontinued.

ePTFE Vascular Implants

Because of abundant protein adsorption, ePTFE's porous inner surface is often claimed in vascular implants (blood) to clot blood rapidly to stabilize further surface coagulation and promote formation of a host "pseudo-intimal lining" that maintains blood compatibility under high flow, high shear applications. Its porous outer surface promotes peri-graft cell and tissue infiltration that mechanically stabilizes the prosthesis in place, preventing kinking (White, 1988). Unlike most animal models, humans do not reliably form stable cellular "neo-intimal" endothelial cell linings in these grafts, limiting their success. ePTFE is currently used most widely to fabricate medium sized (4–10 micron internode) vascular grafts for use in specific clinical blood vessel replacement indications (Kannan et al., 2005), including major vessels affected by disease or trauma, and arteriovenous hemodialysis grafts (Jenkins, 1976; Konner, 2005). ePTFE vascular prostheses are most clinically successful in high blood flow, low resistance conditions (i.e., large peripheral arteries >5–6 mm diameter, such as the descending aorta). They are generally not suitable for smaller arterial reconstructions (e.g., coronary circulation and peripheral vascular placements) under high resistance, low flow conditions that allow continued clotting and loss of patency. Typically, ePTFE suffers from thrombosis, poor healing, lack of compliance, and excessive intimal and anastomotic hyperplasia leading to stenotic complications. Their routine placement in high flow vascular environments allows them to remain patent despite their thrombus generation (see Box 3).

Arteriovenous ePTFE Grafts for Dialysis Access

Hemodialysis – essential for patients with end-stage renal disease – often requires regular, repeated (weekly) access to large blood vessels capable of producing high flow rates through an external artificial kidney device.

Hemodialysis patients typically undergo cannula puncture of skin, underlying tissue, and vasculature to provide this access to the external artificial kidney. Repeated trauma to patient skin, tissue, and blood vessels from 13–17 gauge access needles produces notable complications including hyperplasia, thrombosis, hematoma, occlusion, infection, and other morbidities. Vascular access complications remain the main reason for hemodialysis patient hospitalization. Synthetic ePTFE arteriovenous (A–V) grafts are surgically placed across the basilic vein and brachial artery to permit cannula access and reduce tissue trauma complications. A–V prosthetic graft failure rates are substantial (>50%), leading to increasing use of native fistulas and catheters (Li et al., 2008). However, synthetic grafts reliably provide high blood flow rates shortly after placement, as they do not require maturation before use. In A–V ePTFE grafts, stenosis occurs most commonly at the graft–venous anastomosis. Histologically, macrophages are seen in large numbers in the

adventitial and medial layers in the anastomotic tissues from A–V ePTFE grafts (Kapadia et al., 2008).

Multi-Lumen Catheters

Fluoropolymers are important for biomedical tubing, and are central to advanced multi-lumen small gauge medical-grade tubing required in many new minimally invasive catheters. These catheters permit surgeons to perform several invasive procedures through several lumens in a single inserted catheter device without removing one entire catheter to insert another. Catheter *in vivo* exposures are usually short-term, typically using endoluminal access, and increasingly are minimally invasive. As described above, PTFE's unique properties and stable thermal processing methods allow PTFE multi-lumen tubing precision manufacture unlike any other material, and this is a very important fluoropolymer in this particular use.

Guiding Catheters

An important clinical device with a long track record, the guiding catheter helps the clinician deliver stents and other devices endo-luminally. Central to the guiding catheter is a PTFE inner liner with its superior lubricity and low friction coefficient that slides within an outer lumen. Lubricity is so critical to this device function that FEP, as the second-most lubricious material available, is insufficient as a catheter liner. During catheter construction, PTFE is chemically bonded onto the tube's outer diameter to enable slip. Bonding is accomplished by using an FEP heat-shrinkable fusing sleeve. After depositing PTFE over the liner the FEP mold is removed from the device, leaving a smooth outer PTFE jacket on the liner within the catheter outer liner.

PTFE Catheter Introducers

Now over three decades old, the PTFE "introducer" facilitates catheter insertion into a patient's vein, taking full advantage of PTFE's endoluminal lubricity and precision tubing processing. Once the catheter is inserted, the PTFE outer sheath can be removed from the patient, leaving the implanted catheter behind. The introducer exploits PTFE processing that molecularly orients the fluoropolymer material in the tubing-based sleeve over the catheter. This allows PTFE tubing to be readily split and torn longitudinally from the catheter *in situ*, enabling the surgeon to remove a PTFE introducer from a patient while the primary catheter remains in place.

Perfluorocarbon Liquids and Emulsions as Oxygen Carrying Blood Substitutes

Low molecular weight perfluoro-fluids can be aspirated into the lungs directly or injected as submicron-sized emulsion droplets into the blood to facilitate oxygen transport, exploiting their high oxygen carrying capacities (Winslow, 2005). Liquid perfluorocarbons in the lung eliminate the gas–lung interface, acting to reduce tension in the lung alveolus, and reducing mechanical work required to breathe during respiratory distress and lung surfactant deficiency. Emulsions made from dispersing perfluoro fluids into water using interfacial droplet stabilizers (emulsifiers) create sub-micron perfluoro-droplets, much smaller than red blood cells. This provides enormous oxygen carrying capacity in blood to supplement normal oxygenation in microcirculation. Several commercial products have been clinically available, most recently Oxygent™ (Alliance Pharmaceutical, USA), consisting of two different perfluorocarbon fluids stabilized as a micro-emulsion using egg phospholipids. The product is eliminated from the blood after injection by macrophage/monocyte clearance, and is exhaled eventually from the lung.

Fluorinated Liquids in the Eye as Experimental Vitreous Substitutes

Detached retinal repair and other ophthalmic surgeries require oxygen-permeable viscous liquid vitreous substitutes. Perfluorinated oils and polymers have intrinsic high oxygen permeabilities and solubilities with suitable viscosity control. Perfluoropolyethers, perfluorinated alkanes, and perfluorinated silicone oils have all been studied in ocular vitreous applications, but still lack convincing safety, toxicity or efficacy to date to produce an approved product in this context.

Fluorinated (Meth)Acrylates and (Meth)Acrylated Perfluoroalkyl Silicones as Cross-Linked Polymer Cores for Soft Contact Lenses

Exploiting the intrinsic high oxygen permeability well known for perfluorinated materials, rigid gas permeable contact lenses (RGPs) have used many variations on cross-linked perfluorinated acrylates and perfluorinated polyether silicone gels as lens cores to improve extended-wear contact lens on-eye performance. Increased ocular acuity under high-throughput inexpensive but precise lens fabrication methods, with high lens oxygen transport, is sought. Many patents describe many fluorinated polymer gels in this regard, with most major lens manufacturers developing these lens core materials.

Fluorinated Materials as Anti-Fouling Coatings for Intraocular Lenses (IOLs)

General cellular reactions to implanted polymer intraocular lenses replacing cataracts can result in cell migration onto, and adhesion to, the lens, with optical interference (clouding) requiring IOL replacement. To prevent cells

from migrating onto and coating the IOL's optical lens surface (typically a thermoplastic), thin optically transparent plasma-deposited fluorocarbon films or layers of other fluorinated polymers are deposited on the IOL rear surface. Several patents describe this approach and application.

PTFE Paste Injectable Bulking Agent

Teflon™ particles formulated as an injectable paste have been reported for the treatment of vesico-ureteric reflux (VUR) (Puri, 1995), corrected by sub-ureteric injection of a PTFE paste (Puri and O'Donnell, 1984). Sub-ureteric paste injection by endoscopy has successfully addressed primary and secondary VUR in children for nearly two decades (Le Guillou et al., 1984; Dodat and Paulhac, 1987; Puri, 2000). Similarly, PTFE paste was introduced nearly 4 decades ago to treat female stress urinary incontinence (Beckingham et al., 1992; Politano, 1992; Meschia et al., 2002). However, this device does not have regulatory approval, due to high risks for PTFE microparticle migration and granuloma induction, especially in lymph nodes, kidneys, lungs, and brain (Aaronson et al., 1993). Applications of Teflon™ paste injection are still reported (Harrison et al., 1993; Lopez et al., 1993; Herschorn and Glazer, 2000), but its side-effect concerns limit clinical use.

Ligament Replacement

The Gore-Tex™ ligament prosthesis comprises a single long fiber of ePTFE woven into loops. Mechanical testing shows that the resulting ultimate tensile strength is ~3 times that of the human anterior cruciate ligament (ACL). Creep and bending fatigue testing validate this ePTFE device as a strong synthetic ACL replacement material (Bolton and Bruchman, 1985). The Gore-Tex™ ACL prosthesis is currently FDA-approved for use in patients with failed autogenous intra-articular graft procedures (Mascarenhas and Macdonald, 2008). However, while acute performance shows promising stability in the knee, extended use and implant time produce significant ligament loosening, and other knee stability problems.

Sutures

PTFE also finds limited use as a suture fiber in various forms. Both PTFE monofilament and ePTFE fibers are surgically proven, with clinically accepted surgeon handling and lubricity properties. Additionally, PTFE is blended into other common surgical sutures used for myocardial heart valve prostheses fixation. Poly(ethylene terephthalate) (PET polyester) braided sutures are impregnated with PTFE polymer to limit wrinkling of the braid and consequent swelling. PTFE hydrophobic properties likely help protect the polyester braid from water uptake and hydrolysis (Bhat, 2002).

THE MONEY JOINT

Most biomaterials used for jaw joint reconstruction were introduced to markets prior to the 1976 Medical Devices Amendment Act that required device manufacturers to prove that their devices were safe and effective. A legal loophole that required manufacturers only to prove that their devices were "substantially equivalent" to a pre-Amendment device allowed temporal mandibular joint (TMJ) implants marketed soon after 1976 to enter the market without testing. Two designs widely used as TMJ replacement surfaces were Dow Corning's Silastic® and Vitek's Proplast-Teflon product. Vitek developed and sold Proplast sheeting (Teflon™ FEP film laminated with a porous composite material of PTFE and carbon) in the 1970s. Implants modified in the 1980s comprised Teflon™ film laminated to PTFE and aluminum oxide. These implants, ~1 cm² in size, were cut from sheets in the operating room and sutured into the TMJ joint. In 1983, the FDA allowed Vitek to market a pre-cut disc because, under the law, the company needed only to convince the FDA that its device was "substantially equivalent" to Dow's Silastic® disc marketed years earlier. In 1986, several reports of catastrophic biomechanical failure of the PTFE implant were linked to a giant cell reaction leading to bone resorption and pain. Further analysis documented device failure rates of 10–25%. By 1992, implant success rates below 20% were reported. Animal studies performed only after failures in humans began showed complete erosion of the TMJ implant within a "few months." In early 1990, with implant failures increasing, the FDA recalled Vitek's products. Predictably, Vitek declared bankruptcy with its rising product litigation costs, but continued to market their TMJ implants. Surgeons continued to implant them until eventually the FDA seized all products from Vitek, as well as its subsidiaries.

SUMMARY

Due to their unique chemistry, fluorinated materials, primarily fluoropolymers, have attractive properties of biomaterials interest, including chemical stability, low adhesion/friction, non-wetting, high protein adsorption, high oxygen permeability, and precision tubing manufacturing. Low cell adhesion in serum and high intrinsic blood coagulation in plasma and blood both result from distinct media-dependent protein adsorption treatments and the physical form of the material. Expanded PTFE provides fabric-like properties with controlled pores and high surface area to alter device-related mechanics, processing, and tissue responses, while promoting rapid blood clotting. Solid fluoropolymers also have attractive precision engineering and device processing properties essential to producing several medical device classes where fine dimensional tolerances and biocompatibility are required. This enables fabrication of multi-lumen, high-tolerance, small dimensional tubing for advanced catheters.

GLOSSARY

Blooming: a term used to describe the spontaneous enrichment of certain chemistries at the surface of a bulk matrix, usually associated with the surface enrichment by low surface energy chemistry-like fluorinated materials.

This phenomenon is used to promote a surface enriched in trace components like expensive added fluorinated chemistry by allowing them to spontaneously diffuse from the bulk material to the surface.

Blotting membrane: a thin, porous, hydrophobic, high protein-binding capacity polymer membrane (e.g., PVDF) used to transfer proteins from a gel electrophoresis separation process for further probing with antibodies to identify the proteins as a blot or spot.

ePTFE: expanded polytetrafluoroethylene, produced from PTFE films under anisotropic stretching to yield a unique node-fibril microporous morphology in a fabric-like sheet form deemed important to biomedical utility in implanted biomaterials.

Fluorinated biomaterial: a material intended for a biomedical application made from a base material that contains significant amounts of chemically bonded fluorine.

Fluoropolymer: a fluorinated polymer, also perfluoropolymer, usually thermoplastic, with high content of fluorine atoms replacing hydrogen atoms along the carbon-based polymer chain.

Perfluorinated material: a material wherein all hydrogen atoms are replaced with fluorine, generally making C–F bonds.

PTFE: polytetrafluoroethylene, a high molecular weight, highly crystalline perfluoropolymer solid also known as Teflon™, discovered at DuPont in 1938, with unique solid properties and processing requirements.

D. ACRYLICS

Joe Antonucci[1] and Sabine Dickens[2]

[1]National Institute of Standards and Technology, Gaithersburg, MD, USA

[2]American Dental Association Foundation Pattenbarger Research Center, Gaithersburg, MD, USA

INTRODUCTION

The modern development of tooth-colored dental polymeric composites owes much to R. L. Bowen of the American Dental Association for his pioneering studies at the National Bureau of Standards, now the National Institute of Standards and Technology. His recognition of the excellent matrix-forming potential of epoxy resins (oxiranes), as well as their poor ambient polymerization characteristics (slow under anionic catalysis and uncontrollable under the more rapid cationic catalysis then available) led him to the discovery of a unique hybrid monomer which combined the low polymerization contraction of epoxy resins with the excellent setting behavior of acrylic monomers (Bowen, 1956). His classical synthesis of the bulky, thermosetting dimethacrylate, Bis-GMA, 2,2-bis[p(2′-hydroxy-3′-methacryloxypropoxyphenyl)] propane (Figure D.1), his preparation of silica fillers that combined translucency and radiopacity while matching the refractive indices of the resin matrix, and his utilization of the technology of silane coupling agents, ushered in the modern era of esthetic dental composites (Bowen, 1963).

MONO- AND MULTI-METHACRYLATE MONOMERS

Acrylics based on the monofunctional monomer methyl methacrylate (MMA) combined with poly(methyl methacrylate) (PMMA) and a low viscosity dimethacrylate for cross-linking are mainly used in orthodontic appliances, e.g., bionator, bite plates, palatal expanders, retainers, and for removable prosthetic devices, such as partial and full dentures, temporary crowns, and bridges. Basic MMA/PMMA mixtures activated with chemical initiators have been widely used as bone cements for orthopedic applications (Shalaby et al., 2007). Further development has led to the incorporation of PMMA fibers, resulting in composites with moderately increased moduli and improved toughness (Gilbert et al., 1995). MMA and other monomethacrylates of moderate size and viscosity are only occasionally incorporated into dental restorative materials due to their relatively high molar double-bond concentration, and thus, increased polymerization shrinkage. However, functional monomethacrylates are widely used in adhesive formulations, and as coupling agents in composites, and are discussed below.

Base and Diluent Monomers

In preventive and restorative dentistry a variety of di- or multimethacrylates are photo and/or chemically cured into polymers that function as pit and fissure sealants, adhesives, veneer materials, and when combined with fillers, as esthetic or loadbearing composite restoratives. Typically, dental resins are composed of mixtures of two or more monomers that combine a relatively high viscosity dimethacrylate (base) monomer with a low viscosity dimethacrylate comonomer such as triethylene glycol dimethacrylate (TEGDMA) to obtain resins with workable rheologies. The base resins 2,2-bis[p-(2′-hydroxy-3′-methacryloxypropoxy) phenylene]propane (Bis-GMA), ethoxylated bisphenol A dimethacrylate (EBPADMA) or 1,6-bis(methacryloxy-2-ethoxycarbonylamino)-2,4,4-trimethylhexane (UDMA) (Figure D.1) are among those
FIGURE D.1 Structures of commonly used base and diluent monomers.

most commonly employed in commercial dental resin-based materials.

When cured at ambient temperature, free radicals convert the resin to a cross-linked three-dimensional polymer network. The free radicals are generated chemically from benzoyl peroxide and a tertiary aryl amine or through visible light irradiation using a photoinitiator, such as acyl-and bis-acylphosphine oxides, that yield radicals by photo cleavage or redox photoinitiator systems comprising camphorquinone or phenylpropanedione combined with aromatic or aliphatic tertiary amines that yield radicals by electron/hydrogen transfer mechanisms. For dental applications, rapid and efficient polymerization, in particular photopolymerization enabling on-command cure of dental resins, is a critical aspect of the clinical use of adhesives, sealants, and composites. Moreover, optimized cure is one of the most crucial parameters that govern the long-term performance of the polymeric material, affecting the biocompatibility by limiting the leaching of potentially cytotoxic materials from the cured polymers (Yoshii, 1997; Geurtsen et al., 1998). The extent of cure also affects the mechanical properties, e.g., fracture toughness, elastic moduli, flexural strength, and hardness (Cook, 1991; Ferracane et al., 1998). The base monomers are used in dental resin mixtures to enhance the physical and mechanical properties of the resulting polymers. Moreover, they minimize polymerization shrinkage and related stresses due to their relatively low methacrylate double-bond molar concentrations (Patel et al., 1987; Bogdal et al., 1997). While the addition of diluent monomers compromises the shrinkage, they are needed to reduce the viscosity of the base monomers to enable maximum filler loading, and to improve conversion and the physical and mechanical properties of the composite resins. When dental base monomers are combined with various proportions
FIGURE D.2 Log viscosity of mixtures of Bis-GMA, EBPADMA, and UDMA with TEGDMA with linear regression and 95% confidence intervals (R^2 = 0.987, 0.995, and 0.998, respectively).

of the diluent monomer TEGDMA, the difference in their H-bonding potential results in compositions covering a broad range of viscosities (Figure D.2), and significantly different photopolymerization kinetics (Dickens et al., 2003). The structures of the individual monomers, and consequently the resin viscosities of the comonomer mixtures, strongly influence both the rate and extent of conversion of the photopolymerization process (Figure D.3). When compared at similar diluent concentrations, UDMA resins are significantly more reactive than Bis-GMA and EBPADMA resins. At higher diluent concentrations, EBPADMA resins provide the lowest photopolymerization reactivities. Optimum reactivities in the UDMA and EBPADMA resin systems are obtained with the addition of relatively small amounts of TEGDMA, whereas the Bis-GMA/TEGDMA resin system

FIGURE D.4 Hydrophilic monomers: 2-hydroxyethyl methacrylate (HEMA); glycerol dimethacrylate (GDM).
FIGURE D.3 Thermograms (a), and rate/conversion profiles (b), of the DSC homo-polymerizations of the three base resins and the diluent monomer TEGDMA (light intensity: 100 μW/cm²). The early onset of the autoacceleration is particularly noticeable for UDMA and EBPADMA, while Bis-GMA and TEGDMA demonstrate a sluggish polymerization onset with very low conversion for Bis-GMA, and low polymerization rates.

requires near equivalent mole ratios for highest reactivity (Dickens et al., 2003).

Modified Base Monomers

Analogs and modifications of Bis-GMA and UDMA have been reported resulting in somewhat improved properties (Khatri et al., 2003; Kim et al., 2006). Derivatives of Bis-GMA having pendant n-alkyl urethane substituents exhibited lower viscosities and were more hydrophobic than Bis-GMA. Generally, the viscosity of these experimental monomers decreased with increasing chain length of the alkyl urethane substituent. Photopolymerization of the new monomers gave higher degrees of vinyl conversion compared to Bis-GMA, yet yielded lower polymerization shrinkage than Bis-GMA when compared at equivalent degrees of vinyl conversion (Antonucci and Stansbury, 1997; Peutzfeldt, 1997; Moszner and Salz, 2001, 2007). Modified urethane dimethacrylates have also been developed as alternatives for Bis-GMA; however, the improvements in physical properties were moderate, showing small changes in flexural strength and reduction in water uptake (Moszner et al., 2008).

Alternative Monomers with Improved Reactivity

In the late 1980s and early 1990s oxy bis-methacrylates were developed and evaluated as potential monomers for dental applications. It was found that these monomers undergo cyclopolymerization, resulting in polymers with high conversion yet low shrinkage (Stansbury, 1990).
Other work by Stansbury introduced cyclic carbonates as highly reactive diluent monomers for dental applications (Berchtold et al., 2008).

Functionalized Monomers with Adhesive Properties

Adhesive Monomers. Currently, there are three main classes of free radical polymerizable restoratives available: (1) resin composites, which are mainly based on the methacrylate resins described above; (2) resin-modified glass ionomer cements, which are hybrids of polyacrylic acids having pendant methacrylate groups for free radical polymerization, while the carboxylic acid groups provide the means for an acid/base setting reaction with specialty ion-leachable aluminum fluorosilicate glasses; and (3) polyacid-modified composite resins based on carboxylic acid-containing methacrylates, also known as compomers. In contrast to resin composites, groups 2 and 3 contain, in addition to methacrylate or acrylate groups, carboxylic acid groups that are attached either to a backbone (group 2) or to the center core of the monomer (group 3). The acid groups are also capable of forming ionic bonds to apatitic calcium phosphate mineral and also strong hydrogen bonds to collagen, and thus promote adhesion to both enamel and dentin. Thus, acidic monomers together with other hydrophilic monomers (Figures D.4–D.6) are significant components of adhesive primers and bonding resins. In order to form durable bonds between a resin-based restorative and tooth structure it is essential to use an adhesive system that wets enamel and dentin well. Bonding to enamel is primarily achieved by micromechanical adhesion. Formation of resin tags in patent dentin tubules, but most importantly, mechanical interlocking of dentinal substrate and adhesive resins as a result of penetration of the adhesive into the intertubular dentin is believed to be responsible for durable dentin adhesion (Nakabayashi et al., 1982). The most widely used monomers in adhesives and bonding resins are the highly hydrophilic 2-hydroxyethyl methacrylate (HEMA) and monomers that contain one or more carboxylic acid group, carboxylic acid anhydride or phosphoric acid groups (Figures D.4–D.6). The hydrophilic monomer HEMA and the acidic monomers have solubility parameters with high polar and hydrogen
FIGURE D.5 Structures of selected carboxylic acid dianhydrides and monomers: BPDA = biphenyl dianhydride; PMDA = pyromellitic dianhydride; ODPDA = oxydiphthalic dianhydride; TMA = trimellitic anhydride. The adhesive monomers 4-META, PMDM, and PMGDM are also shown. They are formed by the reaction between TMA chloride and HEMA, PMDA, and HEMA or PMDA and GDM, respectively.
FIGURE D.6 Exemplary structures of phosphate monomers: (a) HEMA-phosphate (R=H), glycerol dimethacrylate phosphate (R= –O–CO–C(CH_3) = CH_2); (b) MDP (methacryloyldecyldihydrogen phosphate); (c) Bis-GMA-phosphate.

bonding components, resulting in high total cohesive energy density values. It has been demonstrated that bonding will be enhanced if fractional polarity and solubility parameters match those of the conditioned bonding substrate (Asmussen and Uno, 1993). Monomers with carboxylic acid groups (Figure D.5) are usually synthesized by reacting HEMA, glyceroldimethacrylate or other hydroxylated (meth)acrylate monomers with mono- or dicarboxylic acid anhydrides (Takeyama et al., 1978; Bowen et al., 1982; Venz and Dickens, 1993; Hammesfahr, 1997; Lopez-Suevos and Dickens, 2008). An adhesive monomer (4-META) with anhydride functionality is prepared from HEMA and trimellitic acid chloride (Figure D.5). To achieve improved interaction of

adhesive monomers and tooth substrate beta cyclodextrines with multi-methacrylate/carboxylic-acid groups have been examined (Bowen et al., 2000; Hussain et al., 2004, 2005; Bowen et al., 2009). To improve the hydrolytic stability of monomer/polymer systems acrylamide/phosphonates have been proposed (Catel et al., 2008; Yeniad et al., 2008).

Silane Coupling Agents

Except for pure gold fillings, all dental restoratives are multiphase materials having a composite microstructure involving one or more interfaces or interphases. Polymeric dental composites are interconnected heterogeneous
FIGURE D.7 Structure of γ-methacryloxypropyltrimethoxysilane.

materials that generally have three discernable phases: (1) a polymeric matrix or continuous phase formed by polymerization of a resin system consisting of one or more monomers/oligomers activated for chemical/photochemical polymerization; (2) a higher modulus dispersed phase consisting of fillers of various types (silica, ceramic, organic, etc.), sizes, shapes, and morphologies; and (3) an interface or interphase (usually derived from silane coupling agents) that mediates bonds between the continuous soft and the hard dispersed phases, thereby enhancing the moduli and mechanical properties of the relatively low modulus polymer phase, and also facilitating stress transfer between these phases by forming a unitary material. Adhesion of lower moduli polymeric matrices to higher moduli inorganic fillers can occur as a result of van der Waals forces, ionic interactions, hydrogen bonding, ionic or covalent bonding, interpenetrating polymer network formation and, for certain types of fillers, by a micromechanical interlocking mechanism. For most mineral reinforced dental composites, the primary interphasial linkage between the polymer matrix and the filler phase is by chemical bond formation, mediated through a dual functional organosilane (Antonucci et al., 2005). The most commonly used silane coupling agent, γ-methacryloxypropyltrimethoxysilane (MPTMS), is shown in Figure D.7.

Monomers for Low Shrinking Polymers

Methacrylate Monomers: General Considerations. All methacrylate monomers undergo shrinkage when they polymerize. The volume a monomer occupies is governed by the monomer's molecular structure, and by the inherent van der Waals forces that keep monomer molecules at distinct intermolecular distances. During polymerization the double bonds of neighboring (meth) acrylate groups are converted to covalently bonded single bonds, thereby linking individual mers and forming macromers. If di- or multimethacrylates are present, a three-dimensional polymer network is formed. After the initiation of polymerization, the free radical chain growth of multimethacrylates initiated by commonly used chemical or photoinitiators is hindered by the rapid formation of the three-dimensional network, increasing the viscosity of the gel and decreasing the mobility of the monomer or short chain polymer molecules, which then limits the vinyl conversion. Thus, residual monomer and pendant double bonds are commonly present in these types of polymers to various degrees (Ruyter, 1985; Dickens et al., 2003). Monomer and short chain oligomers (a limited number of linked monomer units) not incorporated into the polymer network can potentially leach out, and both unsaturated residual and pendant

methacrylate groups act as internal plasticizers that may influence the biocompatibility, physical properties, and longevity of the material (Asmussen, 1982; Ruyter, 1985). As polymerization shrinkage and remaining double bonds are directly correlated, these properties ought to be considered together when characterizing "low shrinking" materials. The polymerization process results in a reduction in free volume, measurable as linear or volumetric polymerization shrinkage. Polymerization contraction stresses occur as a consequence of polymerization shrinkage. For highly cross-linked systems, the majority of shrinkage stress develops during and after the vitrification stage (Lu et al., 2005), and is a significant concern in numerous dental applications. The most detrimental effect caused by shrinkage stress is debonding at the composite/tooth interface, which results in gap formation and microleakage that provides a route for bacterial infiltration that can contribute to secondary caries. Strategies to reduce the polymerization shrinkage in resin-based materials comprise varying the monomer structure and resin composition, increasing the number of atoms between methacrylate groups, and modifying type, size, size distribution, and amount of fillers added to the resin matrix. Most highly filled resin composites shrink between 2% and 3%.

Molecular Structure and Size Effects. In the last decade, modifications in the monomer structure for reducing the shrinkage and related stresses included hyperbranched monomers (Holter et al., 1997), liquid crystalline methacrylates (Hammesfahr, 1997; Satsangi et al., 2005), and dendritic monomers (Viljanen et al., 2005). However, these types of resins have given mixed results with respect to the physical and mechanical properties of their composites. Other recent strategies to lowering the polymerization shrinkage and stresses included use of high molecular weight bis(vinylcyclopropane)-based monomers containing a cholesteryl group (Choi et al., 2005), and dimer acid-based monomers (Trujillo-Lemon et al., 2006). It was found that these monomers contributed to significantly reduced shrinkage. The dimer acid-based monomers have found application in a commercial composite.

Thiol-ene Systems. Recently, novel photopolymerizable monomer systems have been developed which are based on thiol-ene resin chemistry involving free radical step growth rather than chain growth polymerization (Cramer and Bowman, 2001). These systems, especially oligomeric thiol-ene materials, produce polymers having high conversion and dramatically reduced polymerization shrinkage stress (Carioscia et al., 2005; Lu et al., 2005; Carioscia et al., 2007). While these systems undergo more rapid reaction with higher functional group conversion, they are mechanically inferior to current Bis-GMA/TEGDMA resins. Other work reported the application of thiol-allyl ether-methacrylate ternary systems (Kilambi et al., 2007) with an interesting approach using a two-stage polymerization process.

During the first stage, highly functional oligomeric methacrylates are formed. Because this process occurs in the pre-gel stage, it does not contribute to shrinkage stress. The allyl ether conversion and shrinkage stress develop subsequently, and thus these systems have high cross-link density and improved mechanical properties, yet significantly reduced shrinkage stress when compared to previously developed thiol-ene systems.

Ring Opening Monomers: Spiroorthocarbonates. To reduce polymerization shrinkage while maintaining high conversion and acceptable material properties, non-methacrylated ring opening spiroorthocarbonate (SOC) monomers were evaluated (Thompson et al., 1979; Bailey, 1990; Byerley et al., 1992; Eick et al., 1993). Modified vinyl SOCs in combination with methacrylate monomers achieved tensile strengths that were comparable to their SOC-free controls (Stansbury, 1992). Re-examining the concept of potentially expanding resins, Stansbury et al. investigated a number of tetraoxaspirononanes either with cationic initiation alone or a combined cationic/free radical initiation (Ge et al., 2005), while others used tetraoxaspiroundecanes in combination with siloranes (Chappelow et al., 2007). Both studies confirmed the ring-opening mechanism. However, it was pointed out that even a trace amount of moisture had a significant adverse impact on both the reaction kinetics and the polymerization course of the hydrolytically vulnerable tetraoxaspirononanes (Ge et al., 2005).

Monomers Containing Silicon and/or Epoxy Functionality. Various approaches have been taken to include silicon-based monomers in addition to the silane coupling agents into dental composites. The chemistry of functional organosilanes (or silane coupling agents as they are commonly known) can be quite complex, involving hydrolytically initiated self-condensation reactions in solvents (including monomers) that can culminate in oligomeric silsesquioxane structures, exchange reactions with hydroxylated or carboxylated monomers to form silyl ethers and esters, as well as the formation of silane-derived interfaces by adhesive coupling with siliceous mineral surfaces (Antonucci et al., 2005). Examples of silsesquioxane oligomeric structures (together with MPTMS) are shown in Figure D.7. It was recently shown that the fluorinated silsesquioxane oligomers, when added to EBPADMA, led to similarly acceptable mechanical properties as the silsesquioxane-free control, while exhibiting significantly reduced polymerization shrinkage stresses (Dickens et al., 2009). It is hypothesized that the bulky nature of the oligomeric additive, possibly in combination with fluoridated pendant chains being repelled from the more hydrophilic bulk, increased the free volume of the oligomers, and thus contributed to the low shrinkage stresses in these composites. Adding 2% of the novel organic/inorganic hybrid monomer POSS-MA (polyhedral oligomeric silsesquioxane methacrylate) into Bis/TEGDMA resins showed moderate improvement of the mechanical properties. However,

due to the high number of polymerizable methacrylate groups, the polymerization shrinkage was not improved (Fong et al., 2005). Cycloaliphatic epoxy (oxiranes) monomers formulated with polyol network extenders and cured with cationic onium/camphorquinone initiators have been considered as potential candidates to reduce polymerization shrinkage (Tilbrook et al., 2000). They exhibit lower polymerization shrinkage, no oxygen inhibition layer, higher strength, equivalent hardness, and acceptable glass transition temperatures as many methacrylate-based resins. However, the water uptake of these epoxy-polyol materials when immersed in water was nearly twice that of the Bis-GMA/TEGDMA control.

Even lower shrinkage and shrinkage stress values have been reported for a new class of methacrylate-free photocationically polymerizing low-shrinkage composite resins (Weinmann et al., 2005; Ilie et al., 2007). The monomers are named siloranes, indicating that their chemical structure comprises a combination of siloxanes and oxiranes. The reduction in polymerization shrinkage and resulting shrinkage stresses is based on two principles: epoxy-ring opening during setting of a large cyclic siloxane monomer core structure; and relatively slow polymerization kinetics resulting in somewhat delayed gelation and the possibility of stress relaxation. Physical properties of silorane-based materials match those of conventional composite resins. The silorane-based composites require special bonding and coupling agents based on the same chemistry to allow copolymerization between bonding agent and resin matrix, and also between the silanized reinforcing glass filler and the resin matrix.

Anticariogenic Strategies. To combat biofilm attachment to restoration surfaces and recurrent caries, a family of fluoride-releasing resins has been developed for adhesive applications, temporary crowns, and removable acrylic devices. These resins contain fluoride ions, which are covalently bound to positively charged sites within the polymer network and can be released via an exchange mechanism involving anions from oral fluids (Rawls, 1987). More recent approaches include tetrabutylammonium tetrafluoroborate incorporated into a hydrophilic monomer system (Glasspoole et al., 2001); complexing zirconium fluoride with a chelating monomer (Ling et al., 2009); or incorporating antibacterial functionality into monomers as demonstrated for methacryloyloxydodecyl-pyridinium bromide monomer (Imazato et al., 1994; Imazato, 2009).

SUMMARY

Dental resin chemistry has made significant progress in the last decade in improving clinical performance and addressing some of the most pertinent problems in restorative dentistry, i.e., polymerization shrinkage and shrinkage stress that potentially affect recurrent caries through bacterial ingress into marginal crevices around dental restorations. Thus, the most significant improvements for better dental health are the successful reduction of polymerization shrinkage and polymerization shrinkage stresses for improved marginal integrity; the development of resin chemistries that enhance the hydrolytic stability of the restoratives; and the development of monomers with antibacterial properties designed to increase the resistance of tooth structure to bacterial attack.

CHAPTER I.2.3 METALS: BASIC PRINCIPLES

John B. Brunski
Division of Plastic & Reconstructive Surgery, Department of Surgery, School of Medicine, Standford University, Standford, CA, USA

INTRODUCTION

Since large segments of the medical device industry rely on implants with one or more metallic parts – e.g., stents, heart valves, orthopedic hips and knees, plus oral/maxillofacial implants – metals have a highly significant place in the biomaterials market. In view of this wide utilization of metallic biomaterials, this chapter provides some basic principles underlying the quantification and design-related manipulation of composition, structure, and properties of metallic biomaterials. Major themes are the metallurgical principles underlying structure–property relationships, and the larger problem of design, production, and proper utilization of medical devices.

STEPS IN THE FABRICATION OF METALLIC BIOMATERIALS

Understanding the structure and properties of metallic implant materials requires an appreciation of the metallurgical significance of the material's processing history. Typically, any metallic medical device will differ in exactly how it is manufactured, so it is useful to look briefly at some generic processing steps in implant manufacture (Figure I.2.3.1A).

Metal-Containing Ore to Raw Metal Product

With the exception of noble metals such as gold (which do not represent a major fraction of implant metals), metals exist in the Earth's crust in mineral form, wherein the metal is chemically combined with other elements, as in the case of metal oxides. These mineral deposits, or "ore," must be located, mined, separated, and enriched for further processing into pure metal or various alloys. For example, in the case of titanium, certain mines in the southeastern United States yield sands containing common quartz along with mineral deposits of zircon, titanium, iron, and rare earth elements. The sandy mixture can be concentrated by using water flow and gravity to isolate titanium-containing compounds such as rutile (TiO_2) and ilmenite ($FeTiO_3$). To obtain rutile, which is particularly good for making metallic titanium, further processing typically involves electrostatic separations. Then, to extract titanium metal from the rutile, one method involves treating the ore with chlorine to make titanium tetrachloride liquid, which in turn is treated with magnesium or sodium to produce chlorides of the latter metals along with bulk titanium "sponge" according to the Kroll process. At this stage, the titanium sponge is not of controlled purity, so depending on the purity ("grade") of the final titanium product that is sought, it is necessary to refine it further by using vacuum furnaces, remelting, and additional steps. All of this is critical in producing titanium with the appropriate properties, as exemplified in the production of the most common grades of commercially pure (CP) titanium; these grades differ in oxygen content by only tenths of a percent, yet these small differences in oxygen content make major differences in mechanical properties, including yield, tensile and fatigue strength of titanium.

After extraction steps, the resulting raw metal product eventually emerges in some type of bulk form, such as ingots, which can be supplied to raw materials' vendors or metal manufacturers. For instance, in the case of multicomponent metallic implant alloys (i.e., made up of more than one element), the raw metal product will usually have to be further processed both chemically

and physically. Processing steps can include remelting, addition of specific alloying elements, and controlled solidification from the melt, in order to produce an alloy that meets certain chemical and metallurgical specifications. For example, to make ASTM (American Society for Testing and Materials) F138 316L stainless steel, iron is alloyed with specific amounts of carbon, silicon, nickel, and chromium; and to make ASTM F75 or F90 alloy, cobalt is alloyed with specific amounts of chromium, molybdenum, carbon, nickel, and other elements. Table I.2.3.1 lists ASTM designations and typical properties of common metallic alloys for surgical implants.

Raw Metal Product to Stock Metal Shapes

A metal supplier will typically further process the bulk raw metal product (metal or alloy) into stock bulk shapes, such as bars, wire, sheet, rods, plates, tubes or powders. These stock shapes may then be sold to implant manufacturers, who typically want a stock shape that is closer to the final implant shape, e.g., a maker of screw-shaped dental implants would often buy rod stock of the appropriate metal as feedstock for screw-manufacturing machines.

A metal supplier might transform the raw metal product into stock shapes by a variety of processes, including

(A)

MINERAL DEPOSITS (ORE)

MINING
ORE SEPARATION/CONCENTRATION
CHEMICAL EXTRACTION OF METAL
REFINING OF "PURE" METAL
ALLOYING TO SPECIFICATIONS

METALLIC RAW MATERIAL

MARKET

FIGURE I.2.3.1 (A) Generic processing history of a typical metallic implant device, in this case a hip implant.

FIGURE I.2.3.1 (B) Image of one step during the investment casting ("lost wax") process of manufacturing hip stems; a rack of hip stems can be seen attached to a system of sprues through which molten metal can flow. At this point, ceramic investment material composes the mold into which the molten metal will flow and solidify during casting, thereby replicating the intended shape of a hip stem.

remelting and continuous casting, hot rolling, forging, cold drawing through dies, etc. Depending on the metal there might also be heat-treating steps (i.e., carefully controlled heating and cooling cycles) designed to: facilitate further working or shaping of the stock; relieve the effects of prior plastic deformation (e.g., as in annealing) or produce a specific microstructure and properties in the stock material. Because of the high chemical reactivity of some metals at elevated temperatures, high temperature processing may require vacuum conditions or inert atmospheres to prevent unwanted uptake of oxygen by the metal, all of which can add to the cost of production. For instance, in the production of fine powders of ASTM F75 Co-Cr-Mo alloy, molten metal is ejected through a small nozzle to produce a fine spray of atomized metal droplets that solidify while cooling in an inert argon atmosphere.

Typically, stock shapes are chemically and metallurgically tested at this early stage to ensure that the chemical composition and microstructure of the metal sold to an implant company conforms to industry standards for surgical implants (e.g., ASTM Standards), as discussed later in this chapter. It makes sense that an implant manufacturer will demand quality assurance that they are buying an appropriate grade of metal from the supplier of the raw metal stock.

Stock Metal Shapes to Preliminary and Final Metal Devices

Typically, an implant manufacturer will buy stock material and then fabricate preliminary and final forms of the device. Specific steps depend on a number of factors, including the final geometry of the implant, the forming and machining properties of the metal, and the costs of alternative fabrication methods. Typical fabrication methods include investment casting (the "lost wax" process), conventional and computer-based machining (CAD/CAM), forging, powder metallurgical processes (e.g., hot isostatic pressing or HIP), and a range of grinding and polishing steps. A variety of fabrication methods are required because not all implant alloys can be feasibly or economically fabricated into a final form in the same way. As one example, cobalt-based alloys are extremely difficult to machine into the complicated shapes of some implants by conventional machining methods. Therefore, many cobalt-based alloys are frequently shaped into implant forms by investment casting (e.g., Figure I.2.3.1B) or by powder metallurgy. On the other hand, titanium is relatively difficult to cast, and is therefore often machined.

Other aspects of fabrication (which to some degree more accurately fall under the heading of surface treatment) involve the application of macro-, micro-, and/or nano-level coatings on implants, often with the intent of producing certain ranges of surface roughness. Such surface modifications have become more popular in recent years as a means to improve fixation of implants in bone or to improve interfacial bone growth. The surface coating or roughening can take various forms, and can require different fabrication technologies. In some cases, modifications to the surface have the potential to negatively affect the metallurgical properties of the underlying bulk implant metal. For example, in the case of alloy beads or "fiber metal" coatings for macro-porous implants, the manufacturer may employ high temperature sintering to apply the coating over specific regions of the implant surface (e.g., on the proximal portion of a femoral hip stem). Sintering involves heating the coating and substrate to about half (or more) of the alloy's melting temperature in order to encourage diffusion, which in turn helps form the necks that join the beads to one another and to the implant's surface. Such reasonably high temperatures can modify the underlying metallic substrate by allowing grain growth or other mechanisms, which could negatively affect the properties. An alternative to sintering is plasma or flame spraying a metal onto an implant's surface. In this process, hot, high velocity gas plasma is charged with a metallic powder and directed at appropriate regions of

TABLE I.2.3.1 | **Typical Mechanical Properties of Implant Metals[a]**

Material	ASTM Designation	Condition	Young's Modulus (GPa)	Yield Strength (MPa)	Tensile Strength (MPa)	Fatigue Endurance Limit Strength (at 10^7 cycles, $R = -1$[c]) (MPa)
Stainless steel	F745	Annealed	190	221	483	221–280
	F55, F56, F138, F139	Annealed	190	331	586	241–276

[c] R is defined as $\sigma_{min}/\sigma_{max}$.

an implant surface. The powder particles fully or partially melt, and then fall onto the substrate surface, where they solidify rapidly to form a tough coating. This has the advantage of not excessively heating the substrate.

Still more surface treatments are available, including ion implantation (to produce better surface properties), nitriding, and coating with a thin diamond film. For example, in nitriding, a high energy beam of nitrogen ions is directed at the implant under vacuum so that nitrogen atoms penetrate the surface and come to rest at sites in the substrate. Depending on the alloy, this process can produce enhanced properties, such as improved surface hardness and wear properties. (Many examples of different levels of surface modifications – ranging from the nanolevel on up to the macro level – can be seen by perusing the advertisements for oral and maxillofacial implants in any one of the many journals devoted to such implants.)

Finally, a manufacturer of a metallic implant device will normally perform a set of finishing steps. These vary with the metal and manufacturer, but typically include chemical cleaning and passivation (i.e., rendering the metal inactive if exposed to a corrosive environment). Electrolytically-controlled treatments may also be used to remove machining chips or impurities that may have become embedded in the implant's surface. As a rule, these steps are conducted according to good manufacturing practice (GMP), and ASTM specifications for cleaning and finishing implants. Notably, these finishing steps can be extremely important to the overall biological performance of the implant because they can affect the detailed surface properties of the medical device – which govern the surface of the device that comes in direct contact with the blood and other tissues at the implant site.

MICROSTRUCTURES AND PROPERTIES OF IMPLANT METALS

In order to understand the properties of each alloy system in terms of microstructure and processing history, it is essential to know: (1) the chemical and crystallographic identities of the phases present in the microstructure; (2) the relative amounts, distribution, and orientation of these phases; and (3) the effects of the phases on properties. This section of the chapter emphasizes mechanical properties of metals used in implant devices, even though other properties, such as surface properties and wear properties, must also be considered and may in some instances be more critical to control. (Surface properties of materials are reviewed in more depth in Chapter I.1.5 of this textbook.) The basic principles are illustrated here in the context as applied to the stainless steels, cobalt-based alloys, and titanium-based alloys – which are very commonly used in medical devices. (More detailed discussions follow in the separate chapters in this textbook on stainless steel (Chapter I.2.3.B) and titanium (Chapter I.2.3.A).)

Microstructure and Mechanical Properties

There are many ways to manipulate microstructures and properties of metallic biomaterials. The following sections highlight just a few of the more commonly-encountered principles that apply to the most common

metallic biomaterials, including the stainless steels, Co-Based alloys, and Ti-based alloys.

316L Stainless Steel. In this alloy, two common strengthening methods are cold-working and controlling grain size. The basis of each method is the idea of increasing the difficulty of slip of dislocations. In cold-working, the idea is to introduce more and more plastic deformation such that additional plastic flow becomes even more difficult. In decreasing grain size, the idea is to have more grain boundaries to interfere with the flow of dislocations on slip systems within each grain.

With 316L stainless (ASTM F138), typically it is used in a 30% cold-worked state, because this cold-worked metal has a markedly increased yield, ultimate tensile, and fatigue strength relative to the annealed state (Table I.2.3.1). The trade-off in this case is decreased ductility of the cold-worked metal, but ordinarily this is not a major concern in implant products. In dealing with grain size in 316L, the recommended grain size is ASTM #6 or finer, in which the grain size number n is defined in the formula $N = 2^{n-1}$, where N is the number of grains counted in a 1 in^2 area at 100 × magnification (0.0645 mm^2 actual area). As an example, when $n = 6$, the grain size is about 100 micrometers. The emphasis on a fine grain size is explained by the well-known Hall–Petch-type relationship (Hall, 1951; Petch, 1953), which relates mechanical yield stress and grain diameter as follows:

$$t_y = t_i + kd^{-m}$$

where t_y and t_i are the yield and friction stress, respectively; d is the grain diameter; k is a constant associated with propagation of deformation across grain boundaries; and m is approximately 0.5. This equation indicates that a higher yield stress may be achieved by a metal with a smaller grain diameter d, all other things being equal. A key determinant of grain size is manufacturing history, including details on solidification conditions, cold-working, annealing cycles, and recrystallization.

Cobalt-Based Alloys. Cobalt-based alloys include Haynes-Stellite 21 and 25 (ASTM F75 and F90, respectively), forged Co-Cr-Mo alloy (ASTM F799), and multiphase (MP) alloy MP35N (ASTM F562). The F75 and F799 alloys are virtually identical in composition, each being about 58–70% Co and 26–30% Cr, with the key difference in their processing history. The other two alloys, F90 and F562, have slightly less Co and Cr, but more Ni (F562) or more tungsten (F90).

To consider the example of F75 alloy (which has a long history in both the aerospace and biomedical implant industries), the main attribute of this alloy is corrosion resistance in chloride environments, which is related to its bulk composition and surface oxide (nominally Cr_2O_3). When F75 is cast into shape by investment casting (e.g., the "lost wax" process; Figure I.2.3.1B), the alloy is first melted at 1350–1450°C and then poured or pressurized into ceramic molds of the desired shape (e.g., femoral stems for artificial hips, oral implants, dental

partial bridgework). The sometimes intricately-shaped molds are made by fabricating a wax pattern to near-final dimensions of the implant and then coating (or "investing") the pattern with a special ceramic, which then holds its shape after the wax is burned out prior to casting – hence the name "lost wax" for the process. Molten metal is poured into the ceramic mold through sprues, or pathways, and then, once the metal has solidified into the shape of the mold, the ceramic mold is cracked away and processing of the metal continues toward the final device.

Depending on the exact details of the casting process, at least three microstructural features can come into play as strong determinants of implant properties. First, as-cast F75 alloy typically consists of a Co-rich matrix (alpha phase) plus interdendritic and grain boundary carbides (primarily $M_{23}C_6$, where M represents Co, Cr or Mo). Overall, the relative amounts of the alpha and carbide phases should be approximately 85% and 15%, respectively, but due to non-equilibrium cooling, it is possible that a "cored" microstructure may develop. In this situation, the interdendritic regions become rich in solute (Cr, Mo, C) and contain carbides, while the dendrites become depleted in Cr and richer in Co. This creates an unfavorable electrochemical situation, with the Cr-depleted regions being anodic with respect to the rest of the microstructure. (This is also an unfavorable situation if a porous coating will subsequently be applied by sintering to this bulk metal.) Subsequent solution-annealing heat treatments at 1225°C for 1 hour can help alleviate this situation.

A second issue with F75 solidification is that dendrites will form, along with a relatively large grain size. This is generally undesirable because it decreases the yield strength via a Hall–Petch relationship between yield strength and grain diameter (recall the discussion from the section on stainless steel above). An example of dendritic growth and large grain diameter (approximately 4 mm) can be easily seen in Figures I.2.3.2A and I.2.3.2B, which show metallographic cross-sectional views through a femoral hip stem, and also a dental implant (Figures I.2.3.2C, I.2.3.2D) manufactured by investment casting.

A third issue with cast F75 is that casting defects may arise, e.g., Figure I.2.3.2B shows an inclusion in the middle of the cross-section through the distal third of the femoral hip stem. The inclusion was a particle of the ceramic mold (investment) material, which presumably broke off and became trapped within the interior of the mold while the metal was solidifying. This contributed to a fatigue fracture of the implant device *in vivo*, most likely because of stress concentrations and crack initiation sites associated with the ceramic inclusion. For similar reasons, it is also desirable to avoid macro- and microporosity arising from metal shrinkage upon solidification of castings. As an example of such porosity, Figures I.2.3.2C and I.2.3.2D exemplify a markedly dendritic microstructure with large grain size and
FIGURE I.2.3.2 (A) Macrophoto of a metallographically polished and etched cross-section of a cast Co–Cr–Mo ASTM F75 femoral hip stem, showing dendritic structure and large grain size. (B) Macrophoto of the fracture surface of the same Co–Cr–Mo ASTM F75 hip stem as in (A). Arrow indicates large inclusion within the central region of the cross section. Fracture of this hip stem occurred *in vivo*. (C), (D) Scanning electron micrographs of the fracture surface from a cast F75 subperiosteal dental implant. Note the large grain size, dendritic microstructure, and interdendritic microporosity (arrows).

microporosity at the fracture surface of a dental implant fabricated by investment casting.

To avoid problems such as the ones described above with cast F75, powder metallurgical techniques have been designed and used by some implant manufacturers.

For example, in hot isostatic pressing (HIP), a fine powder of F75 alloy is compacted and sintered together under appropriate pressure and temperature conditions (about 100 MPa at 1100°C for 1 hour) and then forged to final shape. The typical microstructure shows a much smaller

grain size than with casting (e.g., about 8 microns), which has the benefit of a much higher yield strength (via the Hall–Petch relationship), and better ultimate and fatigue properties than the as-cast alloy (Table I.2.3.1).

One final example with F75 alloy is the issue of porous-coated implants made by sintering. Here the idea is to sinter (join) the beads together, and to the underlying bulk substrate. With Co-based alloys like F75, however, sintering can be difficult, requiring temperatures near the melting point (1225°C), which in turn can decrease the fatigue strength of the substrate alloy. For example, cast/solution-treated F75 alloy has a fatigue strength of about 200–250 MPa, but this strength can decrease to about 150 MPa after porous coating treatments – evidently from further phase changes in the non-equilibrium cored microstructure in the original cast F75 alloy. On the other hand, it has been found that a modified sintering treatment can return the fatigue strength back up to about 200 MPa (Table I.2.3.1).

Titanium-Based Alloys. Commercially pure (CP) titanium (ASTM F67) and extra-low interstitial (ELI) Ti-6AI-4V alloy (ASTM F136) are the two most common titanium-based implant biomaterials (although within the category of CP Ti there are four grades). F67 CP Ti is 98.9–99.6% Ti. The oxygen content of CP Ti, as well as the content of other interstitial elements (e.g., C and N), affect its yield, tensile, and fatigue strengths significantly. With Ti-6AI-4V ELI alloy, the individual Ti-AI and Ti-V phase diagrams suggest the effects of the alloying additions in the ternary alloy; since Al is an alpha (HCP) phase stabilizer and V is a beta (BCC) phase stabilizer, Ti-6AI-4V alloy used for implants is an alpha-beta alloy.

For CP titanium implants (as exemplified by many current dental implants) typical microstructures are made up of single-phase alpha titanium (having the HCP structure), in which there is typically mild (30%) cold-work and grain diameters in the range of 10–150 microns, depending on manufacturing. The nominal mechanical properties are listed in Table I.2.3.1. Beyond cold-work, interstitial elements (O, C, N) in both CP titanium and the Ti-6AI-4V alloy strengthen the metal through interstitial solid solution strengthening mechanisms, with nitrogen having approximately twice the hardening effect (per atom) of either carbon or oxygen. As noted earlier, the oxygen content of CP Ti (and the interstitial content generally) affects its yield, tensile, and fatigue strengths significantly. For example, data available in the ASTM standard show that at 0.18% oxygen (grade 1), the yield strength is about 170 MPa, whereas at 0.40% (grade 4) the yield strength is about 485 MPa.

Likewise, the ASTM standard shows that the tensile strength increases with oxygen content. The literature also reveals that the fatigue limit of unalloyed CP Ti is typically increased by interstitial content, in particular the oxygen content. For example, Figure I.2.3.3A shows data from Beevers and Robinson (1969), who tested

FIGURE I.2.3.3 (A) S–N curves (stress amplitude–number of cycles to failure) at room temperature for CP Ti with varying oxygen content (see text for O content of Ti 160, 130, and 115), from Beevers and Robinson (1969). (B) S–N curves at room temperature for CP Ti with varying oxygen content (see text), from Turner and Roberts (1968a). (C) Ratio of fatigue limit to yield stress in unalloyed Ti at 300°K as a function of at% oxygen and grain size, from Conrad et al. (1973). See Bibliography for details of references given within this figure.

vacuum-annealed CP Ti having a grain size in the range 200–300 microns in tension-compression at a mean stress of zero, at 100 cycles/sec. The 10^7 cycle endurance limit, or fatigue limit, for Ti 115 (0.085 wt% O, grade 1), Ti 130 (0.125 wt% O, grade 1), and Ti 160 (0.27 wt% O, grade 3) was 88.3, 142, and 216 MPa, respectively. Figure I.2.3.3B shows similar results from Turner and Roberts' (1968a) fatigue study on CP Ti (tension-compression, 160 cycles/sec, mean stress equals zero) having a grain size in the range 26–32 micrometers. Here the fatigue limit for "HP Ti" (0.072 wt% O, grade 1), Ti 120 (0.087 wt% O, grade 1), and Ti 160 (0.32 wt% O, grade 3) was 142, 172, and 295 MPa, respectively – again showing an increasing endurance limit with increasing oxygen content. Also, for grade 4 Ti in the cold-worked state, Steinemann et al. (1993) reported a 10^7 endurance limit of 430 MPa. Other workers (Conrad et al., 1973) have reported fatigue studies on CP Ti at 300°K, and noted that the ratio of fatigue limit to yield stress is relatively constant at about 0.65, independent of interstitial content and grain size (Figure I.2.3.3C). The work of Turner and Roberts also reported that the ratio f (defined as fatigue limit/ultimate tensile strength) – also referred to as the "fatigue ratio" in materials design textbooks (e.g., see Charles and Crane, 1989, p. 106) – was 0.43 for the high-purity Ti (0.072 wt% O), 0.5 for Ti 120 (0,087 wt% O), and 0.53 for Ti 160 (0.32 wt% O). It seems clear that interstitial content affects the yield and tensile and fatigue strengths in CP Ti.

At the same time, cold-work appears to increase the fatigue properties of CP Ti. For example, Disegi (1990) quoted bending fatigue data for annealed versus cold-worked CP Ti in the form of un-notched 1.0 mm thick sheet, and showed a moderate increase in ultimate tensile strength (UTS) and "plane bending fatigue strength," when comparing annealed versus cold-rolled Ti samples. Based on these data, the ratio of fatigue strength to ultimate tensile strength ("endurance ratio" or "fatigue ratio," see paragraph above) varied between 0.45 and 0.66. On the other hand, the *ASM Handbook Fatigue and Fracture* (Wagner et al., 1996) noted that the fatigue limit for high purity Ti only increased about 10% relative to the annealed material, while Disegi's data showed that the fatigue strength increased by about 28%, on average, with cold-work.

CONCLUDING REMARKS

Metallurgical structure–property relationships inform materials selection in medical implant design, just as they do in the design of any well-engineered product. Although this chapter's emphasis has been on mechanical properties (for the sake of specificity), other properties – including surface properties – are receiving increasing attention in relation to biological performance of implants. Examples of this latter theme are efforts to

attach relevant biomolecules to metallic implant surfaces to promote certain desired interfacial activities, and attempts to develop special surface textures on implants to guide molecular and cellular reactions; these subjects can be researched further based on the following Bibliography.

Another point to remember is that the intrinsic material properties of metallic implants – e.g., Young's elastic modulus, yield strength, or fatigue strength – are not the sole determinant of implant performance and success; overall implant design is also critical. So while it is certainly true that inadequate attention to intrinsic material properties can doom a device to failure, it is also true that even with the best intrinsic properties, a device may still fail because of faulty structural properties, inappropriate use of the implant, surgical error or overall inadequate mechanical design of the implant. As an illustration of this latter point, Figure I.2.3.4 shows a plastically-deformed 316L stainless steel Harrington spinal distraction rod (*circa* 1980s) that failed *in vivo* because of metallurgical fatigue. A failure analysis of this case concluded that failure did not occur because of any shortcomings in the rod's 316L cold-worked stainless steel; rather, the fracture occurred because of a combination of other factors, namely: (1) the surgeon plastically bent the rod to make it fit a bit better in the patient's back (and the rod company sold rod-bending jigs!), but

(A)   **(B)**
FIGURE I.2.3.4 The smooth part of a 316L stainless steel Harrington spinal distraction rod that fractured by fatigue *in vivo*. Note the bend in the rod (the rod was originally straight) and (insert) the relationship of the crack initiation zone of the fracture surface to the bend. The inserted photo shows the nature of the fatigue fracture surface, which is characterized by a region of "beach marks" and a region of sudden overload failure. (Photo courtesy of Brunski, J. B., Hill, D. C. & Moskowitz, A. (1983). Stresses in a Harrington distraction rod: Their origin and relationship to fatigue fractures *in vivo*. *J. Biomech. Eng.*, **105**, 101–107.)

the bend in the rod increased the bending moment and bending stresses on the rod at the first ratchet junction, which was a known problem area in terms of fractures *in vivo*; (2) the stress concentrations at the fracture site at the ratchet end of the rod were severe enough to significantly increase the tensile stresses at the first ratchet junction, which was the eventual site of the fatigue fracture; and (3) spinal fusion did not occur in the patient, which contributed to relatively persistent loading of the rod over several months post-implantation, thus further predisposing the implant to fatigue fracture. Here the point is that all three of these factors could have been anticipated and considered in the original design of the rod, during which both structural and material properties could have been considered in various stress analyses to forestall fatigue failure. While this example comes from spinal implants, there are many similar examples with the same theme in the orthopedic, oral, and maxillofacial areas. The take-home message here is that implant design is generally a multifaceted problem in which biomaterials selection is only a part of the overall design problem.

Titanium and its alloys have attracted much attention in the medical implants field, not only because of their unique mechanical properties and resistance to corrosion, they do not initiate an allergenic response and have the probably the best tolerance among metallic biomaterials in the body. Currently only three alloy systems have extensive use in the industry, specifically commercially pure titanium (cpTi), Ti-6Al-4V, and Ti-6A1-7Nb. These alloy systems represent a very significant percentage of the market for titanium biomaterials.

In its elemental form, titanium has a hexagonal closed packed crystal structure (hcp), named α, up to a temperature of 882.5°C, where it transforms into a body centered cubic structure (bcc), named β, up to its high melting point temperature at 1668°C (Collings, 1994). Due to this allotropic change, and depending on the alloying elements, titanium alloys are classified as α, near-α, α + β, metastable β, or stable β, depending on the phase and microstructure stabilized at room temperature (Polmear, 1981). Alloying elements are classified as α-stabilizers, such as Al, O, N, C; β-stabilizers, such as Mo, V, Nb, Ta, Fe, W, Cr, Si, Co, Mn, H; and neutral, such as Zr. α and near α alloys exhibit superior corrosion resistance, but find limited applications as biomaterials due to their low room temperature strength. The α + β alloys exhibit higher strength (with an elastic modulus around 110 GPa) due to the combination of both phases, whereas the β alloys exhibit a unique combination of low elastic modulus (Young's modulus around 60 GPa) and superior corrosion resistance (Bania, 1993; Schutz, 1993). The final properties of the alloy depend on the chemical composition which affects the α and β phase relative proportions that can be modified by thermal treatment, and thermo-mechanical processing conditions.

FABRICATION

Ti and Ti alloys are fabricated into semi-finished bulk products by conventional plastic forming methods, such as forging, rolling, pressing, and drawing. Most Ti materials are processed to avoid an excessive intake of O, N, and H during heating and annealing, since these interstitial elements may induce embrittlement. The hot-working temperature for fabrication has to be carefully selected, since this depends on the alloy composition, and has to be controlled in order to obtain the desired mechanical properties and grain structure. Machining of Ti alloys is to some extent more difficult than that of austenitic stainless steels since they yield under the tool pressure due to

their low Young's modulus. For this same reason the tools used in machining tend to stick to the material. Therefore, sharp tools, rigid setups, heavy feeds, slow speeds, and abundant coolant are required (Breme and Biehl, 1998).

Metallic macroporous structures in orthopedic implants are attracting increasing attention because they combine high strength, which is important to avoid deformation or fracture, relatively low stiffness that reduces the stress-shielding effect, high toughness that prevents brittle fracture, and porosity that allows full bone in-growth and stable long-term fixation. Some fabrication methods used to obtain both open-cell or closed-cell porous metallic structures include sintering of Ti powder, plasma spraying, combustion synthesis, replication, and rapid prototyping (Bansiddhi et al., 2008; Ryan et al., 2008).

CORROSION RESISTANCE

To some extent, interest in Ti and its alloys for biomaterials applications stems from their superior corrosion resistance when compared to other metals and alloys. This is attributed to the spontaneous formation of a few nm thick titanium dioxide film that protects the metal from further oxidation (Textor et al., 2001). This behavior depends on alloy composition and corrosive medium (Steinemann et al., 1993): anodic polarization tests indicate that Ti-12Mo-6Zr-2Fe protective oxide has a breakdown resistance equal to that of Ti-6Al-4V, whereas for Ti-5Mo-5Zr-3Al alloy, corrosion current densities are lower than for cpTi (Steinemann et al., 1993; Wang et al., 1993). In addition, electrochemical measurements for Ti-13Nb-13Zr also confirmed the potential of Ti, Nb, and Zr to develop highly protective passive layers, resulting in a better corrosion resistance compared to Ti-6Al-4V (Mishra et al., 1993; Cai et al., 2003).

BIOCOMPATIBILITY AND SURFACE MODIFICATION

The biocompatibility of a metallic alloy has to be understood in terms of both the biocompatibility of the alloy itself, which is closely associated with its corrosion resistance, and the biocompatibility of its by-products as a result of corrosion. It is generally accepted that Ti and its alloys are relatively "bioinert," and exhibit acceptable *in vitro* and *in vivo* responses for the desired application. When implanted in bone, tissue heals in close apposition to the metal, although there maybe a thin fibrous layer separating the metallic implant and the bone. In order to improve osteointegration, bioactivity, biocompatibility, and corrosion resistance, several surface treatments based on chemical and physical modifications have been developed (Liu et al., 2004). Methods include chemical and electrochemical treatment, sol-gel, chemical vapor deposition (CVD), and biochemical modification, while physical methods include machining, grinding, polishing, blasting, thermal and plasma spraying, physical vapor deposition, and ion

implantation and deposition, among others. The aim of all these methods is to obtain specific surface topography and chemistry to improve either the mechanical bone/implant interlocking, or the deposition of an apatite or another calcium phosphate bioactive layer to promote direct material–bone bonding, or the activation of particular cell responses by the use of specific biomolecules, such as peptides and proteins (Endo, 1995; Sargeant et al., 2008).

MECHANICAL PROPERTIES

Ti and its alloys are very attractive for use in different biomedical devices, particularly orthopedics, due to their elastic modulus which is closer to that of bone in comparison to other alloys. The mechanical properties of cpTi and some Ti-based alloys are summarized in Table A.1. The Young's moduli of α + β and β-type titanium alloys for biomedical applications such as Ti-6Al-4V and Ti-35Nb-5Ta-7Zr are much lower than those of stainless steel and Co-based alloys. However, their Young's moduli are still significantly higher than that of cortical bone. Much effort is currently being carried out to develop new alloys with low elastic modulus that mimic that of bone tissue. Some Ti-based alloys within systems such as Ti–Zr, Ti–Mo, Ti–Ta, Ti–Ta–Zr, Ti–Nb–Hf, Ti–Nb–Zr, Ti–Nb–Sn, Ti–Nb–Ta–Zr, Ti–Fe–Ta, Ti–Mo–Zr–Sn, Ti–Sn–Nb–Ta, Ti–Mo–Zr–Fe, Ti–Mo–Nb–Si, Ti–Mo–Ga, Ti–Mo–Ge, and Ti–Mo–Al have recently been reported as potential biomaterials (Niinomi 1999; Nitta et al., 2001). Many of these alloys are β-type, and contain rather large percentages of Nb, Ta, Zr, Mo, and/or Sn, as these elements are relatively non-toxic and non-allergenic, as reported in previous studies (Ahmed et al., 1995; Steinemann 1980).

Among the alloys under investigation, the Ti–Nb–Ta–Zr system known as Gum metal (Ti-29Nb-13Ta-4.6Zr) (Saito, 2001) is gaining attention in the field because of its "super elastic" properties. This alloy has a Young's

modulus of 40 GPa, and an elastic strain of 2.5% (Niinomi et al., 2002). Another alloy, Ti-35Nb-7Zr-5Ta, also known as TiOsteum® β-Ti alloy, is an alloy that has shown enhanced osseointegration, improved ductility, adequate mechanical strength, optimal hot and cold workability, and low elastic modulus (55 GPa)(Jablokov et al., 2005).

NiTi ALLOY

Nitinol (*Nickel-Titanium Naval Ordnance Laboratory*), an equiatomic alloy of nickel and titanium with shape memory properties, was discovered in the early 1960s by Buehler and his co-workers (Buehler and Wang, 1967). Since then, intensive research has been carried out in order to elucidate the mechanics of its basic behavior. Although NiTi had been proposed and used in different clinical applications, such as clamps for orthopedic and traumatological bone fixation, filters to retain emboli in vascular surgery or orthodontic wires, it was only in the mid-1990s that the first widespread commercial NiTi stents made their appearance. At present, NiTi alloys have been introduced in the medical implant field for their superelastic and shape memory alloy properties, despite related drawbacks associated with Ni ionic release (Huang et al., 2003). Ni is allergenic at high concentrations, and thus the use of Ti–Ni shape memory alloys is quite restrictive (Cederbrant et al., 2003). NiTi shape memory alloy also exhibits two different temperature-dependent crystal structures or phases, named martensite, low temperature phase, and austenite, high temperature or parent phase. When martensite NiTi is heated, it transforms into austenite. The temperature at which this phenomenon starts is called austenite start temperature (A_s). The temperature at which this phenomenon is completed is called austenite finish temperature (A_f). When austenite NiTi is cooled, it transforms into martensite. The temperature at which this

TABLE A.1	Titanium Alloys Developed for Orthopedic Applications and Their Mechanical Properties (Adapted from Long and Rack, 1998)			
Alloy	Microstructure	Elastic Modulus E (GPa)	Yield Strength YS (MPa)	Ultimate Strength UTS (MPa)
cpTi	α	105	692	785

Bone	–	10–40		90–140
FIGURE A.1 Schematic of the shape memory effect created when the surrounding temperature changes; NiTi alloy modifies its shape to a preprogrammed structure due to the austenite-to-martensite phase transformations.

TABLE A.2	Mechanical Properties of NiTi Alloy (Duerig and Pelton, 1994)	
	NiTi	
	Austenitic	**Martensitic**
Ultimate tensile strength (MPa)	800–1500	103–1100
Tensile yield strength (MPa)	100–800	50–300
Modulus of elasticity (GPa)	70–110	21–69
Elongation at failure (%)	1–20	up to 60

phenomenon starts is called martensite start temperature (M_s). The temperature at which martensite is again completely reverted is called martensite finish temperature (M_f) (Buehler and Wang, 1967).

A_s, A_f, M_s, and M_f depend on the chemical composition of the alloy, and can be adjusted by introducing small variations in the almost equiatomic composition of these alloys. The unique behavior of NiTi is based on the temperature-dependent austenite-to-martensite phase transformations on an atomic scale, which is also called thermoelastic martensitic transformation, and causes the shape recovery as a result of the need for the crystal lattice structure to accommodate to the minimum energy state for a given temperature (Otsuka and Wayman, 1998). As a consequence, the shape memory effect is created when the surrounding temperature changes; NiTi alloy modifies its shape to a preprogrammed structure (see Figure A.1).

Superelasticity (or pseudoelasticity) refers to the ability of NiTi to return to its original shape upon unloading after substantial deformation. This is based on stress-induced martensite formation. The application of an external stress causes macroscopic deformation which is accommodated by the formation of martensite at temperatures higher than M_s. When the stress is released, the martensite transforms back into austenite, and the specimen returns back to its original shape. Superelastic NiTi can be strained several times, i.e., cycled, without being plastically deformed, reflecting a rubber-like behavior. While most metals sustain plastic deformation by slip or dislocation movement, NiTi sustains large elastic deformations by simply changing the orientation of its crystal structure through the movement of twin boundaries. This phenomenon is only observed over a specific range of temperatures. The highest temperature at which

martensite can no longer be stress induced is called M_d. Above M_d, NiTi alloy deforms in the austenite phase by slipping, like ordinary metals. Below A_s, the material is martensitic and does not recover. Superelasticity appears in a temperature range around A_f up to M_d. The ability to recover is maximal when temperature is close to A_f (Duerig and Pelton, 1994).

The mechanical properties of NiTi depend on the phase which is present at a certain temperature (Buehler and Wang, 1967; Van Humbeeck et al., 1998). Fully austenitic NiTi material generally has suitable properties for surgical implantation. The common mechanical properties of martensitic and austenitic NiTi are presented in Table A.2 (Buehler and Wang, 1967; Honma, 1987; Breme and Biehl, 1998; Van Humbeeck et al., 1998).

NiTi has unique high fatigue and ductile properties, which are also related to its martensitic transformation. These properties are favorable for their use in orthopedic implants. However, wear resistance has been reported to be lower when compared to the Co–Cr–Mo alloys (Sekiguchi, 1987). Moreover, NiTi is a non-magnetic alloy and consequently, magnetic resonance imaging is possible.

SURFACE MODIFICATIONS OF NiTi

It is well known that titanium is well tolerated when implanted in the human body; however, it is also known that certain nickel levels are toxic and may trigger allergic responses. NiTi alloys form a passive titanium oxide layer that improves the metal resistance to corrosion, and acts as a barrier to Ni oxidation and release. The original NiTi surface has shown a tendency towards preferential oxidation of titanium. This behavior is in agreement with the fact that free enthalpy formation of titanium oxides is negative, and exceeds in absolute value the enthalpy formation of nickel oxides by at least two to three times (Chan et al., 1990). As a result, Ni is mostly present in an ionic state on the NiTi surfaces. Various approaches are currently under development to prevent undesirable Ni release and improve NiTi tolerance in the body. Laser and plasma treatment, ion implantation, hydroxyapatite, as well as TiN and TiCN chemical vapor deposits, have been used to modify the surface of NiTi alloys (Averback and Kirk, 1985; Filip et al., 1997; Villermaux et al., 1997). Induction or development of bioactive surfaces

by immersion of the material in either simulated body fluid (SBF) or Hank's solution, and protein coatings are also strategies for improving NiTi biocompatibility and reducing Ni release. In addition, techniques such as oxidation in air/oxygen atmosphere, oxidation in boiling water and steam, and chemical/electrochemical passivation have been successfully used (Michiardi et al., 2005).

APPLICATIONS

Superelasticity is a unique property of great interest in the biomedical field, and this is the reason why NiTi alloy has been proposed for different applications, such as orthopedic plates, screws and staples; cardiovascular devices, mainly stents; surgical instruments, such as surgical endoscopic tools and orthodontic devices (Duerig et al., 1999).

Since superelasticity and shape memory effect are highly advantageous, but the risk of metallic allergy is still high, investigations in developing Ni-free superelastic and shape memory titanium alloys containing non-toxic elements are of significant interest to researchers in the field. Some candidates that are currently investigated include the Ti–Nb–Sn system alloy. The martensite transformation temperature (M_s) of this system decreases by increasing the amount of Nb or Sn, and the shape memory effect is recognized when the alloy is deformed below austenite transformation temperature (A_f) similar to the case of Ti–Ni. It has been reported that superelastic strain of 3.5% is obtained at the composition of Ti-18Nb-4Sn (Nitta et al., 2001). Other systems being investigated also include Ti–Mo–Ga, Ti–Mo–Ge or Ti–Mo–Al, Ti–Ta, Ti–Ta–Zr, and Ti–Sc–Mo (Niinomi, 2003).

B. STAINLESS STEELS

Phillip J. Andersen
Andersen Metallurgical, LLC

INTRODUCTION

There are a large number of stainless steels available commercially but only a few of these alloys are used as biomaterials for implantable devices. Use of stainless steel implants began in the 1920s and 1930s; stainless steel applications have expanded as new medical procedures and improved materials were developed.

The performance of these alloys depends on their chemical composition and processing history. While 316L is the most common stainless steel, alloys with enhanced corrosion resistance and mechanical properties are available.

METALLURGICAL AND CHEMICAL CONSIDERATIONS

Implantable stainless steels all have a crystal structure known as face centered cubic (models of metallic crystal structures are shown in Figure I.3.1.1, Chapter I.1.3); in steels this crystal structure is called austenite. Austenitic stainless steels are essentially non-magnetic; this is crucial since patients may be exposed to high intensity magnetic fields during MRI examinations. It should be noted that modest amounts of heating and displacement can occur for these alloys under MRI exposure. Under some processing conditions, it is possible to form different phases within the austenitic alloys such as delta ferrite (which is magnetic); the presence of these additional phases is deleterious and is not allowed under the standard specifications that control these materials for implant use.

Table B.1 shows the chemical composition ranges specified for several common implantable stainless steels. Chromium is present in these alloys, primarily to form a protective Cr_2O_3 surface layer (passive film) that is crucial to their corrosion resistance. Since chromium stabilizes the magnetic ferrite (body centered cubic) structure, other alloying elements must be added to stabilize the desired austenite phase. This role is filled primarily by additions of nickel, manganese, and nitrogen. Nitrogen additions also increase mechanical strength and corrosion resistance. Molybdenum additions have a beneficial impact on the pitting corrosion resistance of stainless steels.

Carbon is controlled to be at low levels to prevent the formation of chromium carbides (the "L" in 316L designates low carbon). Formation of these carbides can result in a phenomenon known as sensitization. If enough carbon is available, chromium carbides can form when austenitic stainless steels are held at temperatures in the range of 450°C to 815°C; the time required to form these carbides depends on the temperature. Under these conditions, carbides tend to form preferentially along grain boundaries, leaving the adjacent areas with depleted chromium levels which are prone to attack by corrosion. Slow cooling after welding is a classic process that can cause sensitization if time and cooling rates are not controlled.

Examination of the chemical compositions in Table B.1 reveals some trends that have changed over time in the chemical composition of implantable stainless steels. While 316 and 316L stainless steels have been used successfully for implants for more than 50 years, stronger and more corrosion-resistant alloys have been developed. The alloys known as Rex 734 (also known as Ortron 90) and 22-13-5 were developed in the 1980s. These alloys contain higher levels of chromium, manganese,

TABLE B.1	Compositions of Common Implantable Stainless Steels (Weight Percent)											
Alloy	Cr	Ni	Mn	Mo	C	N	Nb	V	Si	Cu	P	S
316L ASTM F138, ISO 5832-1	17–19	13–15	<2 max	2.25–3	<0.030	<0.10	–	–	<0.75	<0.5	<0.025	<0.010
22-13-5 ASTM F1314	20.5–23.5	11.5–13.5	4–6	2–3	<0.030	0.2–0.4	0.1–0.3	0.1–0.3	<0.75	<0.5	<0.025	<0.010
Rex 734, Ortron 90 ASTM F1586 ISO 5832-9	19.5–22	9–11	2–4.25	2–3	<0.08	0.25–0.5	0.25–0.8	–	<0.75	<0.25	<0.25	<0.010
BioDur® 108 ASTM F 2229	19–23	<0.050	21–24	0.5–1.5	<0.08	0.85–1.10	–	–	<0.75	<0.25	<0.03	<0.010

and nitrogen than 316L, leading to improved mechanical properties and corrosion resistance. Recent concern about patients with an allergic response to nickel (see Orthopedic Applications, Chapter II.5.6 for additional discussion of this topic) has led to development of stainless steels which are essentially nickel free. One example is an alloy known as BioDur®108, which uses additions of manganese and nitrogen instead of nickel to stabilize the austenite phase. The nitrogen level in this alloy (1%) is much higher than the level found in the prior implantable stainless steels.

Empirical formulas have been developed to describe the contribution of alloying elements to pitting corrosion resistance of austenitic stainless steels; this is known as the Pitting Resistance Equivalent number or PRE. The formula for PRE depends on several factors, including the amount of nitrogen in the alloy. At low nitrogen levels an appropriate approximation of the PRE is: PRE = %Cr + 3.3 × %Mo + 16 × %N; at nitrogen levels nearing 1% a more appropriate approximation is: PRE = %Cr + 3.2 × %Mo + 8 × %N (Gebeau and Brown, 2001). Higher PRE numbers indicate improved resistance to pitting corrosion.

MECHANICAL PROPERTIES

The mechanical properties of metals and alloys depend on their chemical composition and processing history. To understand how these factors influence mechanical properties it is important to consider the mechanisms involved when permanent deformation takes place (plastic deformation). Plastic deformation occurs primarily by movement of dislocations within the material ("slip"). Dislocations are defects or disturbed regions in the crystal lattice. If the resistance to dislocation motion is increased, strength properties such as yield strength increase, while deformation capacity (ductility) decreases.

Chemical composition also influences strength by a process known as solid solution strengthening. In stainless steels the metallic alloying elements (Cr, Ni, etc.) replace iron atoms at random locations within the crystal structure. Since the various atoms are not the same size, additions of alloying elements lead to distortion of the crystal lattice. This distortion makes deformation of the material more difficult (dislocation movements), thus increasing strength (and generally decreasing ductility). Smaller atoms, such as N, fit within the gaps between the larger metallic atoms; for this reason they are often referred to as interstitials. Additions of these atoms lead to large strength increases due to the interactions between the solute atom and dislocations.

Another strengthening mechanism available for these materials involves work hardening (also known as "cold-working"). Processes commonly used to change the mechanical properties of other alloys such as aging reactions during heat treatment are not applicable to austenitic stainless steels.

Work hardening occurs due to the increased difficulty of dislocation motion, as more and more dislocations interact within the material. As the material is deformed, increasing quantities of dislocations develop within the grains of the alloy. If the deformation process takes place at high temperatures (which is typical of the large-scale processes used to produce metal products), or if the material is heated above its recrystallization temperature after deformation, the dislocations are removed by formation of new, annealed grains (recrystallization). Deformation at lower temperatures does not eliminate dislocations. As the density of dislocations within the material increases, they begin to interact making further dislocation motion more difficult. This leads to increases in strength and reductions in ductility. More information on solid solution strengthening and work hardening can be found in a number of materials science textbooks (Hosford, 2005; Meyers & Chawla, 2008).

Evidence of deformation within the grains of a moderately cold-worked 316L sample is shown in Figure B.1, which compares the structure of annealed and ~30% cold-worked 316L. The amount of cold-work is routinely specified by the percentage reduction of area; this is calculated by $(A_i - A_f/A_i) \times 100$, where A_i is the initial cross-sectional area of the product and A_f is the final cross-sectional area. As the amount of cold-work
FIGURE B.1 Microstructures of annealed 316L (left), and ~30% cold-worked 316L (right). Deformation within many of the grains of the cold-worked material is evident.

increases, strength parameters (yield strength and ultimate strength) increase (along with hardness), while the ductility decreases. This behavior gives designers the ability to specify a wide range of mechanical properties by proper selection of the alloy composition, processing temperature, and the amount of cold-work. Table B.2 lists approximate tensile and fatigue strength properties for some implantable stainless steels produced under different conditions. The influence of chemical composition and amount of cold-work on mechanical properties is evident in these data.

It should be noted that there are limits to the uniformity of the cold-working response which is a function of the cross-sectional area of the material. In practical terms, this means that a large cross-section may have a gradient in the amount of cold-work; thus the outer regions of the material may be more heavily worked than the interior. Another effect of cold-working is that heavily worked stainless steels, such as 304 and 305, can become magnetic due to a

stress-induced transformation of crystal structure from austenite (non-magnetic) to martensite (magnetic). This can result in negative clinical results if fragments of these alloys, which are routinely used as guide wires, break off during a procedure (FDA Public Health Notification, 2008). It is also important to realize that elevated temperature processes such as welding will result in softening of a cold-worked material, and reduction of mechanical properties to annealed levels.

A high level of fatigue strength is necessary for many stainless steel medical devices (see Chapter I.1.3 of this volume for more information on fatigue). The fatigue properties of metallic materials depend on a number of factors including: composition; grain size; processing history; surface finish; and test method. The fatigue data shown in Table B.2 provide approximate values; these data should not be used for implant design purposes since the properties of specific devices are strongly influenced by manufacturing processes, product design features, the inherent variation from batch to batch of raw

material, and variability in the processes used to produce the device.

CORROSION BEHAVIOR

With the exception of noble metals such as gold or platinum, the common implantable metals and alloys rely on the formation of protective oxide films to control corrosion of the material to acceptable levels. These oxides are commonly referred to as passive films. They are very thin (typically less than 100 microns), dense, and adhere strongly to the underlying substrate. They limit transport of metallic ions to the implant surface. The alloys that contain substantial amounts of chromium (austenitic stainless steels and implantable cobalt base alloys) form a Cr_2O_3 layer while alloys rich in titanium (titanium alloys and Nitinol) form a TiO_2 layer. More detailed information on passive layers is presented in Chapter II.5.6 Orthopedic Applications. Chapter II.4.4 Degradative Effects of the Biological Environment on Metals and Ceramics includes a great deal of information on corrosion of implant metals.

In general terms, the austenitic stainless steels are not considered to be quite as corrosion resistant as either cobalt–chromium alloys or titanium alloys. The more recent alloys (22-13-5, Rex 734, and BioDur®108) exhibit improved corrosion resistance when compared to 316L, due to their higher levels of Cr and N. One measure of relative corrosion resistance is the pitting potential, as determined in an anodic polarization test; pitting potential varies somewhat depending on the testing conditions, but one author found it was 346 mV for 316L, 1030 mV for 22-13-5, and 1120 mV for BioDur®108 (Zardiackas et al., 2003). Another factor which influences the corrosion of stainless steels is the presence of foreign particles, known as inclusions. These are typically oxide particles such as alumina or silicates which are formed during the initial melting of the alloy and become trapped within the material during subsequent processing. Since these inclusions have different corrosion behavior than the alloy, they can act as corrosion initiation sites if they are found at the surface of a component. Careful control of alloy melting practice and subsequent processing is required to minimize the number of inclusions within these alloys. The ASTM specifications for implantable stainless steels include sections that limit the number and size of inclusions.

SUMMARY

A limited group of austenitic stainless steels are routinely implanted because they offer sufficient corrosion resistance and mechanical strength for long-term applications in the human body. Although 316L is one of the oldest and most common alloys in use, more recent developments have led to stainless steels with improved mechanical strength and corrosion resistance. The corrosion resistance and mechanical properties of these materials are determined by chemical composition, and the processing used to produce the component.

The ability to choose from a range of properties is advantageous. A soft, ductile, annealed condition can be specified for a component that must be contoured in the operating room, while a higher strength, less ductile, work-hardened material may be used for devices that must withstand higher fatigue loads. A long history of success in an application may also be a factor in the use of stainless steels in some devices.

CHAPTER I.2.4 CERAMICS, GLASSES, AND GLASS-CERAMICS: BASIC PRINCIPLES

Larry L. Hench[1], Serena M. Best[2]
[1]Imperial College, London, UK
[2]University of Cambridge, Cambridge, UK

Ceramics, glasses, and glass-ceramics include a broad range of inorganic/nonmetallic compositions. In the medical industry, these materials have been essential for eyeglasses, diagnostic instruments, chemical ware, thermometers, tissue culture flasks, and fiber optics for endoscopy. Insoluble porous glasses have been used as carriers for enzymes, antibodies, and antigens, offering the advantages of resistance to microbial attack, pH changes, solvent conditions, temperature, and packing under high pressure required for rapid flow (Hench and Ethridge, 1982). Insoluble glasses have also been developed as a microinjectable delivery system for radioactive isotopes for *in situ* treatment of tumors. The glass microspheres go to the site of the tumor by way of the blood supply, and the radiation kills the cancer cells with very little damage to the other tissues, saving thousands of patients (Hench et al., 2010). Ceramics are also widely used in dentistry as restorative materials, such as in gold–porcelain crowns, glass-filled ionomer cements, and dentures. These dental ceramics are discussed by Phillips (1991). Glass-ceramics are also widely used for dental restorations, including inlays, onlays, crowns, and multi-unit bridges. This is one of the most rapidly growing applications of this class of biomaterials (Hench et al., 2010).

This chapter focuses on ceramics, glasses, and glass-ceramics used as implants. Although dozens of compositions have been explored in the past, relatively few have achieved clinical success. This chapter examines differences in processing and structure, describes the chemical and microstructural basis for their differences in physical properties, and relates properties and tissue response to particular clinical applications. For a historical review of these biomaterials, see Hulbert et al. (1987). For a summary of clinical applications see Hench (1998) and Hench et al. (2004).

TYPES OF BIOCERAMICS: TISSUE ATTACHMENT

It is essential to recognize that no one material is suitable for all biomaterial applications. As a class of biomaterials, ceramics, glasses, and glass-ceramics are generally used to repair or replace skeletal hard connective tissues. Their success depends upon: (1) achieving a stable attachment to connective tissue when used as bulk implants; or (2) stimulating repair and regeneration of bone when used as particulates for bone grafting.

The mechanism of tissue attachment is directly related to the type of tissue response at the implant–tissue interface. No material implanted in living tissue is inert because all materials elicit a response from living tissues. There are four types of tissue response (Table I.2.4.1) and four different means of attaching prostheses to the skeletal system (Table I.2.4.2).

A comparison of the relative chemical activity of the different types of bioceramics, glasses, and glass-ceramics is shown in Figure I.2.4.1. The relative reactivity that is shown in Figure I.2.4.1A correlates very closely with the rate of formation of an interfacial bond of ceramic, glass or glass-ceramic implants with bone (Figure I.2.4.1B). Figure I.2.4.1B is discussed in more detail in the section on bioactive glasses and glass-ceramics in this chapter.

The relative level of reactivity of an implant influences the thickness of the interfacial zone or layer between the material and tissue. Analyses of implant material failures often show failure originating at the biomaterial–tissue interface. When biomaterials are nearly inert (type 1 in Table I.2.4.2 and Figure I.2.4.1) and the interface is not chemically or biologically bonded, there is relative movement and progressive development of a fibrous capsule in soft and hard tissues. The presence of movement at the biomaterial–tissue interface eventually leads to deterioration in function of the implant or the tissue at the interface, or both. Wear particles can accelerate the deterioration of the tissue–implant interface. The thickness of the non-adherent capsule varies, depending upon both material (Figure I.2.4.2) and extent of relative motion.

The fibrous tissue at the interface of dense Al_2O_3 (alumina) implants is very thin. Consequently, if alumina devices are implanted with a very tight mechanical fit and are loaded primarily in compression, they are very successful. In contrast, if a type 1 nearly inert implant is loaded so that interfacial movement can occur, the fibrous capsule can become several hundred micrometers thick, and the implant can loosen very quickly.

The mechanism behind the use of nearly inert microporous materials (type 2 in Table I.2.4.2 and Figure I.2.4.1) is the ingrowth of tissue into pores on the surface or throughout the implant. The increased interfacial area between the implant and the tissues results in an increased resistance to movement of the device in the tissue. The interface is established by the living tissue in the pores. Consequently, this method of attachment is often termed "biological fixation." It is capable of withstanding more complex stress states than type 1 implants

TABLE I.2.4.1	Types of Implant–Tissue Response
If the material is toxic, the surrounding tissue dies.	
If the material is nontoxic and biologically inactive (nearly inert), a fibrous tissue of variable thickness forms.	
If the material is nontoxic and biologically active (bioactive), an interfacial bond forms.	
If the material is nontoxic and dissolves, the surrounding tissue replaces it.	

TABLE I.2.4.2	Types of Bioceramic Tissue Attachment and Their Classification
1. Dense, nonporous, nearly inert ceramics attach by bone growth into surface irregularities by cementing the device into the tissues or by press-fitting into a defect (termed "morphological fixation").	Al_2O_3 (single crystal and polycrystalline)
2. For porous inert implants, bone ingrowth occurs that mechanically attaches the bone to the material (termed "biological fixation").	Al_2O_3 (polycrystalline) Hydroxyapatite-coated porous metals
3. Dense, nonporous surface-reactive ceramics, glasses, and glass-ceramics attach directly by chemical bonding with the bone (termed "bioactive fixation").	Bioactive glasses Bioactive glass-ceramics Hydroxyapatite
4. Dense, nonporous (or porous) resorbable ceramics are designed to be slowly replaced by bone.	Calcium sulfate (Plaster of Paris) Tricalcium phosphate Calcium–phosphate salts
FIGURE I.2.4.1 Bioactivity spectra for various bioceramic implants: (A) Relative rate of bioreactivity; (B) Time-dependence of formation of bone bonding at an implant interface.

FIGURE I.2.4.2 Comparison of interfacial thickness (μm) of reaction layer of bioactive implants of fibrous tissue of inactive bioceramics in bone.

with "morphological fixation." The limitation with type 2 porous implants, however, is that for the tissue to remain viable and healthy, it is necessary for the pores to be greater than 50 to 150 μm (Figure I.2.4.2). The large interfacial area required for porosity is due to the need to provide a blood supply to the ingrown connective tissue (vascular tissue does not appear in pore sizes less than 100 μm). Also, if micromovement occurs at the interface of a porous implant and tissue is damaged, the blood supply may be cut off, the tissues will die, inflammation will ensue, and the interfacial stability will be destroyed. When the material is a porous metal, the large increase in surface area can provide a focus for corrosion of the implant and loss of metal ions into the tissues. This can be mediated by using a bioactive ceramic material such as hydroxyapatite (HA) as a coating on the metal. The fraction of large porosity in any material also degrades the strength of the material proportional to the volume fraction of porosity. Consequently, this approach to solving interfacial stability works best when materials are used as coatings or as unloaded space fillers in tissues.

Resorbable biomaterials (type 4 in Table I.2.4.2 and Figure I.2.4.1) are designed to degrade gradually over a period of time, and to be replaced by the natural host tissue. This leads to a very thin or nonexistent interfacial thickness (Figure I.2.4.2). This is the optimal biomaterial solution, if the requirements of strength and short-term performance can be met, since natural tissues can repair and replace themselves throughout life. Thus, resorbable biomaterials are based on biological principles of repair that have evolved over millions of years. Complications in the development of resorbable bioceramics are: (1) maintenance of strength and the stability of the interface during the degradation period and replacement by the natural host tissue; and (2) matching resorption rates to the repair rates of body tissues (Figure I.2.4.1A) (e.g., some materials dissolve too rapidly and some too slowly). Because large quantities of material may be replaced, it is also essential that a resorbable biomaterial consist only of metabolically acceptable substances. This criterion imposes considerable limitations on the compositional design of resorbable biomaterials. Successful examples of resorbable polymers include poly(lactic acid) and poly(glycolic acid) used for sutures, which are metabolized to CO_2 and H_2O and therefore are able to function for an appropriate time and then dissolve and disappear. Porous or particulate calcium phosphate ceramic materials such as tricalcium phosphate (TCP) have proved successful for resorbable hard tissue replacements when low loads are applied to the material.

Another approach to solving problems of interfacial attachment is the use of bioactive materials (type 3 in Table I.2.4.2 and Figure I.2.4.1). Bioactive materials are intermediate between resorbable and bioinert. A bioactive material is one that elicits a specific biological response at the interface of the material, resulting in the formation of a bond between the tissues and the material. This concept has now been expanded to include a large number of bioactive materials with a wide range of rates of bonding and thicknesses of interfacial bonding layers (Figures I.2.4.1 and I.2.4.2). They include bioactive glasses such as 45S5 Bioglass; bioactive glass-ceramics such as A-W glass-ceramic; dense HA and bioactive composites such as HA-polyethylene. All of these materials form an interfacial bond with adjacent tissue. However, the time dependence of bonding, the strength of bond, the mechanism of bonding, and the thickness of the bonding zone differ for the various materials. Relatively small changes in the composition of a biomaterial can dramatically affect whether it is bioinert, resorbable or bioactive. These compositional effects on surface reactions are discussed in the section on bioactive glasses and glass-ceramics.

CHARACTERISTICS AND PROCESSING OF BIOCERAMICS

The types of implants listed in Table I.2.4.2 are made using different processing methods. The characteristics and properties of the materials, summarized in Table I.2.4.3, differ greatly, depending upon the processing method used.

The primary methods of processing ceramics, glasses, and glass-ceramics are summarized in Figure I.2.4.3. These methods yield five categories of microstructures:

1. Glass;
2. Cast or plasma-sprayed polycrystalline ceramic;
3. Liquid-phase sintered (vitrified) ceramic;
4. Solid-state sintered ceramic;
5. Polycrystalline glass-ceramic.

Differences in the microstructures of the five categories are primarily a result of the different thermal processing steps required to produce them. Alumina and calcium phosphate bioceramics are made by fabricating the product from fine grained particulate solids. For example, a desired shape may be obtained by mixing the particulates with water and an organic binder, then pressing them in a mold. This is termed "forming." The formed piece is called green ware. Subsequently, the temperature is raised to evaporate the water (i.e., drying) and the binder is burned out, resulting in bisque ware. At a very much higher temperature, the part is densified during firing. After cooling to ambient temperature, one or more finishing steps may be applied, such as polishing. Porous ceramics are produced by adding a second phase that decomposes prior to densification, leaving behind holes or pores (Schors and Holmes, 1993) or transforming natural porous organisms, such as coral, to porous HA by hydrothermal processing (Roy and Linnehan, 1974).

FIGURE I.2.4.3 Relation of thermal processing schedules of various bioceramics to equilibrium phase diagram.

The interrelation between microstructure and thermal processing of various bioceramics is shown in Figure I.2.4.3, which is a binary phase diagram consisting of a network-forming oxide such as SiO_2 (silica), and some arbitrary network modifier oxide (MO) such as CaO. When a powdered mixture of MO and SiO_2 is heated to the melting temperature T_m, the entire mass will become liquid (L). The liquid will become homogeneous when held at this temperature for a sufficient length of time. When the liquid is cast (paths 1B, 2, 5), forming the shape of the object during the casting, either a glass or a polycrystalline microstructure will result. Plasma spray coating follows path 1A. However, a network-forming oxide is not necessary to produce plasma-sprayed coatings such as hydroxyapatites, which are polycrystalline (Lacefield, 1993).

If the starting composition contains a sufficient quantity of network former (SiO_2), and the casting rate is sufficiently slow, a glass will result (path 1B). The viscosity of the melt increases greatly as it is cooled, until at approximately T_1, the glass transition point, the material is transformed into a solid.

If either of these conditions is not met, a polycrystalline microstructure will result. The crystals begin growing at T_L and complete growth at T_2. The final material consists of the equilibrium crystalline phases predicted by the phase diagram. This type of cast object is not often used commercially, because the large shrinkage cavity and large grains produced during cooling make the material weak and subject to environmental attack.

If the MO and SiO_2 powders are first formed into the shape of the desired object and fired at a temperature T_3, a liquid-phase sintered structure will result (path 3). Before firing, the composition will contain approximately 10–40% porosity, depending upon the forming process used. A liquid will be formed first at grain boundaries at the eutectic temperature, T_2. The liquid will penetrate between the grains, filling the pores, and will draw the grains together by capillary attraction. These effects decrease the volume of the powdered compact. Since the mass remains unchanged and is only rearranged, an increased density results. Should the compact be heated for a sufficient length of time, the liquid content can be predicted from the phase equilibrium diagram. However, in most ceramic processes, liquid formation does not usually proceed to equilibrium owing to the slowness of the reaction and the expense of long-term heat treatments.

The microstructure resulting from liquid-phase sintering (or vitrification as it is commonly called) will consist of small grains from the original powder compact surrounded by a liquid phase. As the compact is cooled from T_3 to T_2, the liquid phase will crystallize into a fine-grained matrix surrounding the original grains. If the liquid contains a sufficient concentration of network formers, it can be quenched into a glassy matrix surrounding the original grains.

A powder compact can be densified without the presence of a liquid phase by a process called solid-state sintering. This is the process usually used for manufacturing alumina and dense HA bioceramics. Under the driving force of surface energy gradients, atoms diffuse to areas of contact between particles. The material may be transported by grain boundary diffusion, volume diffusion, creep, or any combination of these, depending upon the temperature or material involved. Because long-range migration of atoms is necessary, sintering temperatures are usually in excess of one-half of the melting point of the material: $T > T_L/2$ (path 4).

The atoms move to fill up the pores and open channels between the grains of the powder. As the pores and open channels are closed during heat treatment, the crystals become tightly bonded together, and the density, strength, and fatigue resistance of the object improve greatly. The microstructure of a material that is prepared by sintering consists of crystals bonded together by ionic-covalent bonds with a very small amount of remaining porosity.

The relative rate of densification during solid-state sintering is slower than that of liquid-phase sintering, because material transport is slower in a solid than in a liquid. However, it is possible to solid-state sinter individual component materials such as pure oxides, since liquid development is not necessary. Consequently, when high purity and uniform fine-grained microstructures are required (e.g., for bioceramics) solid-state sintering is essential.

The fifth class of microstructures is called glass-ceramics, because the object starts as a glass and ends up as a polycrystalline ceramic. This is accomplished by first quenching a melt to form the glass object. The glass is transformed into a glass-ceramic in two steps. First, the glass is heat treated at a temperature range of 500–700°C (path 5a) to produce a large concentration of nuclei from which crystals can grow. When sufficient nuclei are present to ensure that a fine-grained structure will be obtained, the temperature of the object is raised to a range of 600–900°C, which promotes crystal growth (path 5b). Crystals grow from the nuclei until they impinge and up to 100% crystallization is achieved. The resulting microstructure is nonporous and contains fine-grained, randomly oriented crystals that may or may not correspond to the equilibrium crystal phases predicted by the phase diagram. There may also be a residual glassy matrix, depending on the duration of the heat treatment, called ceraming. When phase separation occurs (indicated by composition B in Figure I.2.4.3), a nonporous, phase-separated microstructure can be produced that consists of glass phases suspended in a glass matrix. Crystallization of phase-separated glasses results in very complex microstructures, as reviewed in Höland and Beal (2005). Glass-ceramics can also be made by pressing powders and a grain boundary glassy phase (Kokubo, 1993). For additional details on the processing of ceramics, see Reed (1988) or Onoda and Hench (1978), and for processing of glass-ceramics, see Höland and Beal (2005).

NEARLY INERT CRYSTALLINE CERAMICS

High-density, high-purity (>99.5%) alumina is used in the articulating surfaces of total joint prostheses because of its excellent corrosion resistance, good biocompatibility, high wear resistance, and high strength (Hulbert et al., 1987; Christel et al., 1988; Hulbert, 1993; Miller et al., 1996). Most Al_2O_3 devices are very fine-grained polycrystalline α-Al_2O_3 ceramics produced by pressing and sintering at T = 1600–1700°C. A very small amount of MgO (< 0.5%) is used to aid sintering and limit grain growth during sintering.

Strength, fatigue resistance, and fracture toughness of polycrystalline α-Al_2O_3 ceramics are a function of grain size and percentage of sintering aid (i.e., purity). Al_2O_3 ceramics with an average grain size of <4 µm and >99.7% purity exhibit good flexural strength and excellent compressive strength. These and other physical properties are summarized in Table I.2.4.4, along with the International Standards Organization (ISO) requirements for alumina implants. Extensive testing has shown that alumina implants that meet or exceed ISO standards have excellent resistance to dynamic and impact fatigue, and also resist subcritical crack growth (Dörre and Dawihl, 1980). An increase in average grain size to >17 µm can decrease mechanical properties by about 20%. High concentrations of sintering aids must be avoided, because they remain in the grain boundaries and degrade fatigue resistance.

Methods exist for lifetime predictions and statistical design of proof tests for loadbearing ceramics. Applications of these techniques show that load limits for specific prostheses can be set for an Al_2O_3 device based upon the flexural strength of the material and its use environment (Ritter et al., 1979). Loadbearing lifetimes of 30 years at 12,000 N loads have been predicted (Christel et al., 1988). Results from aging and fatigue studies show that it is essential that Al_2O_3 implants be produced at the highest possible standards of quality assurance, especially as they are often used as orthopedic prostheses in younger patients. Alumina has been used in orthopedic surgery for >30 years (Miller et al., 1996). Its use has been motivated largely by its exceptionally low coefficient of friction and low wear rates.

The superb tribiologic properties (friction and wear) of alumina occur only when the grains are very small (<4 µm) and have a very narrow size distribution. These conditions lead to very low surface roughness values Ra <0.02 µm (Table I.2.4.4). If large grains are present, they can pull out and lead to very rapid wear of bearing surfaces owing to local dry friction.

Alumina on alumina loadbearing, wearing surfaces, such as in hip prostheses, must have a very high degree of sphericity, which is produced by grinding and polishing the two mating surfaces together. For example, the alumina ball and socket in a hip prosthesis are polished together and used as a pair. The long-term coefficient of friction of an alumina–alumina joint decreases with time and approaches the values of a normal joint. This leads to wear on alumina-articulating surfaces being nearly 10 times lower than metal–polyethylene surfaces (Figure I.2.4.4), and eliminates formation of polyethylene wear particles that are associated with aspetic loosening of total joint prostheses, as discussed elsewhere in this textbook.

Low wear rates have led to widespread use in Europe of alumina noncemented cups press-fitted into the acetabulum of the hip. The cups are stabilized by the growth of bone into grooves or around pegs. The mating femoral ball surface is also made of alumina, which is bonded to a metallic stem. Long-term results in general are good, especially for younger patients. However, Christel et al. (1988) caution that stress shielding, owing to the high elastic modulus of alumina, may be responsible for cancellous bone atrophy and loosening of the acetabular cup in old patients with senile osteoporosis or rheumatoid arthritis. Consequently, it is essential that the age of the patient, nature of the disease of the joint, and biomechanics of the repair be considered carefully before any prosthesis is used, including alumina ceramics.

TABLE I.2.4.4	Physical Characteristics of Al_2O_3 Bioceramics	
	High Alumina Ceramics	**ISO Standard 6474**

FIGURE I.2.4.4 Time dependence of coefficient of friction and wear of alumina–alumina versus metal–polyethylene hip joint (*in vitro* testing).

Yttria-stabilised zirconia was also used in a similar way to alumina for articulating applications in hip and knee replacement (Hench and Wilson, 1993). However a series of implant failures around the year 2000, resulted in the withdrawal of zirconia for these applications. Today, there is significant interest in the use of zirconia toughened alumina implants due to the potential to enhance strength and toughness properties over those of alumina. Zirconia is used widely for dental applications due to aesthetic and mechanical benefits the material offers.

Other clinical applications of alumina prostheses reviewed by Hulbert et al. (1987) include knee prostheses; bone screws; alveolar ridge and maxillofacial reconstruction; ossicular bone substitutes; keratoprostheses (corneal replacements); segmental bone replacements; and blade, screw, and post-dental implants.

POROUS CERAMICS

The potential advantage offered by a porous ceramic implant (type 2, Table I.2.4.2, Figures I.2.4.1 and I.2.4.2) is its inertness combined with the mechanical stability of the highly-convoluted interface that develops when bone grows into the pores of the ceramic. The mechanical requirements of prostheses, however, severely restrict the use of low-strength porous ceramics to nonloadbearing applications. Studies reviewed by Hench and Ethridge (1982), Hulbert et al. (1987), and Schors and Holmes (1993) have shown that when loadbearing is not a primary requirement, porous ceramics can provide a functional implant. When pore sizes exceed 100 μm, bone will grow within the interconnecting pore channels near the surface and maintain its vascularity and long-term viability. In this manner, the implant serves as a structural bridge or scaffold for bone formation.

Commercially available porous products originate from two sources: hydroxyapatite converted from coral or animal bone. The optimal type of porosity is still uncertain. The degree of interconnectivity of pores may be more critical than the pore size. Eggli et al. (1988) demonstrated improved integration in interconnected 50–100 μm pores compared with less connected pores with a size of 200–400 μm. Similarly Kühne et al. (1994) compared two grades of 25–35% porous coralline apatite with average pore sizes of 200 and 500 μm, and reported bone ingrowth to be improved in the 500 μm pore sized ceramic. Holmes (1979) suggests that porous coralline apatite when implanted in cortical bone requires interconnections of osteonic diameter for transport of nutrients to maintain bone ingrowth. The findings clearly indicate the importance of thorough characterization of porous materials before implantation, and Hing (1999) has recommended a range of techniques that should be employed.

Porous materials are weaker than the equivalent bulk form in proportion to the percentage of porosity, so that as the porosity increases, the strength of the material decreases rapidly. Much surface area is also exposed, so that the effects of the environment on decreasing the strength become much more important than for dense, nonporous materials. The aging of porous ceramics, with their subsequent decrease in strength, requires bone ingrowth to stabilize the structure of the implant. Clinical results for nonloadbearing implants are good (Schors and Holmes, 1993).

BIOACTIVE GLASSES AND GLASS-CERAMICS

Certain compositions of glasses, ceramics, glass-ceramics, and composites have been shown to bond to bone (Hench and Ethridge, 1982; Gross et al., 1988; Yamamuro et al., 1990; Hench, 1991; Hench and Wilson, 1993). These materials have become known as bioactive ceramics. Some specialized compositions of bioactive glasses will bond to soft tissues as well as bone (Wilson et al., 1981). A common characteristic of bioactive glasses and bioactive ceramics is a time-dependent, kinetic modification of the surface that occurs upon implantation. The surface forms a biologically-active carbonated HA layer (HCA) that provides the bonding interface with tissues. Materials that are bioactive develop an adherent interface with tissues that resist substantial mechanical forces. In many cases, the interfacial strength of adhesion is equivalent to or greater than the cohesive strength of the implant material or the tissue bonded to the bioactive implant.

Bonding to bone was first demonstrated for a compositional range of bioactive glasses that contained SiO_2, Na_2O, CaO, and P_2O_5 in specific proportions (Hench et al., 1971) (Table I.2.4.5). There are three key compositional features to these bioactive glasses that distinguish them from traditional soda–lime–silica glasses: (1) less than 60 mol% SiO_2; (2) high Na_2O and CaO content; and (3) a high CaO/P_2O_5 ratio. These features make the surface highly reactive when it is exposed to an aqueous medium.

Many bioactive silica glasses are based upon the formula called 45S5, signifying 45 wt.% SiO_2 (S = the network former) and 5:1 ratio of CaO to P_2O_5. Glasses with lower ratios of CaO to P_2O_5 do not bond to bone. However, substitutions in the 45S5 formula of 5–15 wt.% B_2O_3 for SiO_2 or 12.5 wt.% CaF_2 for CaO or heat treating the bioactive glass compositions to form glass-ceramics has no measurable effect on the ability of the material to form a bone bond. However, adding as little as 3 wt.% Al_2O_3 to the 45S5 formula prevents bonding to bone.

The compositional dependence of bone and soft tissue bonding on the Na_2O–CaO–P_2O_5–SiO_2 glasses is illustrated in Figure I.2.4.5. All the glasses in Figure I.2.4.5 contain a constant 6 wt.% of P_2O_5. Compositions in the middle of the diagram (region A) form a bond with bone. Consequently, region A is termed the bioactive bone-bonding boundary. Silicate glasses within region B (e.g., window or bottle glass or microscope slides) behave as nearly inert materials and elicit a fibrous capsule at

the implant–tissue interface. Glasses within region C are resorbable and disappear within 10 to 30 days of implantation. Glasses within region D are not technically practical, and therefore have not been tested as implants.

The collagenous constituent of soft tissues can strongly adhere to the bioactive silicate glasses that lie within the dashed line region in Figure I.2.4.5. The interfacial thicknesses of the hard tissue–bioactive glasses are shown in Figure I.2.4.2 for several compositions. The thickness decreases as the bone-bonding boundary is approached.

Gross et al. (1988) and Gross and Strunz (1985) have shown that a range of low-alkali (0 to 5 wt.%) bioactive silica glass-ceramics also bond to bone. They found that small additions of Al_2O_3, Ta_2O_5, TiO_2, Sb_2O_3 or ZrO_2 inhibit bone bonding (Table I.2.4.5, Figure I.2.4.1). A two-phase silica–phosphate glass-ceramic composed of apatite [$Ca_{10}(PO_4)_6(OH_1F_2)$] and wollastonite [CaO, SiO_2] crystals and a residual silica glassy matrix, termed A-W glass-ceramic (A-WGC) (Nakamura et al., 1985; Yamamuro et al., 1990; Kokubo, 1993), also bonds with

bone. The addition of Al_2O_3 or TiO_2 to the A-W glass-ceramic also inhibits bone bonding, whereas incorporation of a second phosphate phase, B-whitlockite (3CaO, P_2O_5), does not.

Another multiphase bioactive phosphosilicate containing phlogopite (Na, K) $Mg_3[AlSi_3O_{10}]F_2$ and apatite crystals bonds to bone even though Al is present in the composition (Höhland and Vogel, 1993). However, the Al^{3+} ions are incorporated within the crystal phase, and do not alter the surface reaction kinetics of the material. The compositions of these various bioactive glasses and glass-ceramics are compared in Table I.2.4.5. The important compositions that are used in the clinic are 45S5 Bioglass and A/W glass-ceramic.

The surface chemistry of bioactive glass and glass-ceramic implants is best understood in terms of six possible types of surface reactions (Hench and Clark, 1978). A high-silica glass may react with its environment by developing only a surface hydration layer. This is called a type I response. Vitreous silica ($SiO2$) and some inert glasses at the apex of region B (Figure I.2.4.5) behave in this manner when exposed to a physiological environment.

When sufficient SiO_2 is present in the glass network, the surface layer that forms from alkali–proton exchange can repolymerize into a dense SiO_2-rich film that protects the glass from further attack. This type II surface is characteristic of most commercial silicate glasses, and their biological response of fibrous capsule formation is typical of many within region B in Figure I.2.4.5.

At the other extreme of the reactivity range, a silicate glass may undergo rapid, selective ion exchange of alkali ions, with protons or hydronium ions leaving a thick but highly porous and nonprotective SiO_2-rich film on the surface (a type IV surface). Under static or slow flow conditions, the local pH becomes sufficiently alkaline (pH > 9) that the surface silica layer is dissolved at a high rate, leading to uniform bulk network or stoichiometric

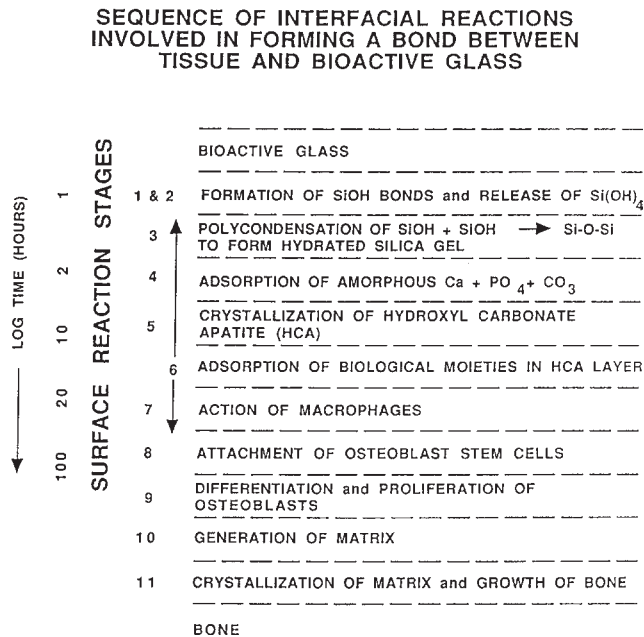
SEQUENCE OF INTERFACIAL REACTIONS INVOLVED IN FORMING A BOND BETWEEN TISSUE AND BIOACTIVE GLASS


FIGURE I.2.4.6 Types of silicate glass interfaces with aqueous or physiological solutions.

dissolution (a type V surface). Both type IV and V surfaces fall into region C of Figure I.2.4.5.

Type IIIA surfaces are characteristic of bioactive glasses. The first five reaction stages depicted in Figure I.2.4.6 are characteristic of Type IIIA bioactive glasses such as 45S5 Bioglass. A CaO-P$_2$O$_5$ layer forms on top of the alkali-depleted SiO$_2$-rich film. When multivalent cations such as Al^{3+}, Fe^{3+}, and Ti^{4+} are present in the glass or solution, multiple layers form on the glass as the saturation of each cationic complex is exceeded, resulting in a type IIIB surface, which does not bond to tissues.

A general equation describes the overall rate of change of glass surfaces and gives rise to the interfacial reaction profiles shown in Figure I.2.4.1. The reaction rate (R) depends on at least four terms (for a single-phase glass). For glass-ceramics, which have several phases in their microstructures, each phase will have a characteristic reaction rate, R_i

$$R = -k_1 t^{0.5} - k_2 t^{1.0} - k_3 t^{1.0} + k_4 t^y + k_n t^z \quad (1)$$

The first term describes the rate of alkali extraction from the glass, and is called a stage 1 reaction. A type II nonbonding glass surface (region B in Figure I.2.4.5) is primarily undergoing stage 1 attack. Stage 1, the initial or primary stage of attack shown in Figure I.2.4.6, is a process that involves an exchange between alkali ions from the glass and hydrogen ions from the solution, during which the remaining constituents of the glass are not altered. During stage 1, the rate of alkali extraction from the glass is parabolic ($t^{1/2}$) in character.

The second term describes the rate of interfacial network dissolution that is associated with a stage 2 reaction. A type IV surface is a resorbable glass (region C in Figure I.2.4.5), and experiences a combination of stage 1

and stage 2 reactions. A type V surface is dominated by a stage 2 reaction. Stage 2, the second stage of attack, is a process by which the silica structure breaks down, and the glass totally dissolves at the interface. Stage 2 kinetics are linear ($t^{1.0}$).

A glass surface with a dual protective film is designated type IIIA. The thickness of the secondary films can vary considerably – from as little as 0.01 μm for Al$_2$O$_3$–SiO$_2$-rich layers on inactive glasses, to as much as 30 μm for CaO–P$_2$O$_5$-rich layers on bioactive glasses (Figure I.2.4.2). A type III surface forms as a result of the repolymerization of SiO$_2$ on the glass surface by the condensation of the silanols (Si-OH) formed from the stage 1 reaction. For example:

$$Si-OH+OH-Si \rightarrow Si-O-Si+H_2O \quad (2)$$
Stage 3 protects the glass surface. The SiO$_2$ polymerization reaction contributes to the enrichment of surface SiO$_2$-rich gel layer, Figure I.2.4.6. It is described by the third term in Eq. (1). This reaction is interface controlled with a time dependence of $+k_3 t^{1.0}$. The interfacial thickness of the most reactive bioactive glasses shown in Figure I.2.4.2 is largely due to this reaction.

The fourth term in Eq. (1), $+k_4 t^y$ (stage 4), describes the precipitation reactions that result in the multiple films characteristic of type III glasses. When only one secondary film forms, the surface is type IIIA. When several additional films form, the surface is type IIIB.

In stage 4, an amorphous calcium phosphate film precipitates on the silica-rich layer and is followed by crystallization to form carbonated HA crystals, Figure I.2.4.6. The calcium and phosphate ions in the glass or glass-ceramic provide the nucleation sites for crystallization. The most bioactive glasses reach completion of this stage of surface reaction very rapidly. Thus, the biological response of living cells at the interface with the bioactive glass is to the presence of the growing HCA layer, and not a foreign-body. Carbonate anions (CO$_3$$^{2-}$) substitute for OH$^-$ in the apatite crystal structure to form a carbonate hydroxyapatite (HCA) similar to that found in living bone (see the following section for details). Incorporation of CaF$_2$ in the glass results in incorporation of fluoride ions in the apatite crystal lattice. Crystallization of HCA occurs around collagen fibrils present at the implant interface, and results in interfacial bonding.

In order for the material to be bioactive and form an interfacial bond, the kinetics of reaction in Eq. (1), and especially the rate of stage 4, must match the rate of biomineralization that normally occurs *in vivo*. If the rates in Eq. (1) are too rapid, the implant is resorbable, and if the rates are too slow, the implant is not bioactive. The interfacial reaction rates for 45S5 Bioglass are summarized in Figures I.2.4.1 and I.2.4.6.

By changing the compositionally-controlled reaction kinetics (Eq. (1)), the rates of formation of hard tissue at an implant interface can be altered, as shown in Figure I.2.4.1. Thus, the level of bioactivity of a material can

be related to the time for more than 50% of the interface to be bonded ($t_{0.5bb}$) (e.g., I_B index of bioactivity: = ($100/t_{0.5bb}$)) (Hench, 1988). It is necessary to impose a 50% bonding criterion for an I_B, since the interface between an implant and bone is irregular (Gross et al., 1988). The initial concentration of macrophages, osteoblasts, chondroblasts, and fibroblasts at an implant site varies as a function of the fit of the implant or particle size if the implant is a bone graft particulate, and especially the nature of the bony defect. Consequently, all bioactive implants require an incubation period before bone proliferates and bonds. The length of this incubation period varies widely, depending on the composition of the implant.

The compositional dependence of I_B indicates that there are isoI_B contours within the bioactivity boundary, as shown in Figure I.2.4.5 (Hench, 1988). The change of I_B with the $SiO_2/(Na_2O + CaO)$ ratio is very large as the bioactivity boundary is approached. The addition of multivalent ions to a bioactive glass or glass-ceramic shrinks the isoI_B contours, which will contract to zero as the percentage of Al_2O_3, Ta_2O_5, ZrO_2 or other multivalent (M^{n+}) increases in the material. Consequently, the isoI_B boundary shown in Figure I.2.4.5 indicates the contamination limit for bioactive glasses and glass-ceramics. If the composition of a starting implant is near the I_B boundary, it may take only a few parts per million of multivalent cations to shrink the I_B boundary to zero and eliminate bioactivity. Also, the sensitivity of fit of a bioactive implant and length of time of immobilization postoperatively depends on the I_B value and closeness to the $I_B = 0$ boundary. Implants near the I_B boundary require more precise surgical fit and longer fixation times before they can bear loads. In contrast, increasing the surface area of a bioactive implant by using them in particulate form for bone augmentation expands the bioactive boundary. Small (<200 μm) bioactive glass granules behave as a partially resorbable implant and stimulate new bone formation (Hench, 1994). Slow dissolution of the bioactive glass particles provides ionic stimuli to osteoprogenitor cells and leads to enhanced osteogenesis, as described below.

Bioactive implants with intermediate I_B values do not develop a stable soft tissue bond; instead, the fibrous interface progressively mineralizes to form bone. Bioactive materials with this level of activity are referred to as Class B bioactive. Consequently, there appears to be a critical isoI_B boundary beyond which bioactivity is restricted to stable bone bonding and growth of bone along the bioactive material interface, termed osteoconduction. Inside the critical isoI_B boundary, the bioactivity includes both stable bone and soft-tissue bonding, depending on the progenitor stem cells in contact with the implant. Such bioactive materials are considered to exhibit Class A bioactivity and possess properties of both osteoconduction and osteostimulation, discussed below. This soft tissue-critical isoI_B limit for Class A bioactivity is shown by the dashed contour in Figure I.2.4.5.

The thickness of the bonding zone between a bioactive implant and bone is proportional to its I_B (compare Figure I.2.4.1 with Figure I.2.4.2). The failure strength of a bioactive bond is inversely dependent on the thickness of the bonding zone. For example, 45S5 Bioglass with a very high I_B develops a gel bonding layer of 200 μm, which has relatively low shear strength. In contrast, A-W glass-ceramic, with an intermediate I_B value, has a bonding interface in the range of 10–20 μm and a very high resistance to shear. Thus, the interfacial bonding strength appears to be optimum for I_B values of ~4. However, it is important to recognize that the interfacial area for bonding is time dependent, as shown in Figure I.2.4.1. Therefore, interfacial strength is time-dependent and is a function of such morphological factors as the change in interfacial area with time, progressive mineralization of the interfacial tissues, and resulting increase of elastic modulus of the interfacial bond, as well as shear strength per unit of bonded area. A comparison of the increase in interfacial bond strength of bioactive fixation of implants bonded to bone with other types of fixation is given in Figure I.2.4.7 (Hench, 1987).

Clinical applications of bioactive glasses and glass-ceramics are reviewed by Yamamuro et al. (1990), Hench and Wilson (1993), (Hench 1998), and Hench et al. (2004). The high level of clinical success of 20-year use of A-W glass-ceramic in vertebral surgery (Yamamuro et al., 1990), 45S5 Bioglass in endosseous ridge maintenance (Stanley et al., 1996), and middle-ear replacement are important accomplishments of this field. Table I.2.4.6 lists the clinical applications of 45S5 bioactive glass. Use of 45S5 Bioglass in repair of periodontal defects (Wilson and Low, 1992; Wilson, 1994; Hench and Wilson, 1996; Lovelace et al., 1998; Mengle et al., 2003) and in a variety of dental, maxillo-facial, and orthopedic applications is summarized in Hench et al. (2004). This 2004 review includes an extensive bibliography of 800 references listed chronologically since the first paper by Hench et al. (1971) described bone bonding to bioactive glasses. The year 2009 heralded the 40th anniversary of the discovery
FIGURE I.2.4.7 Time dependence of interfacial bond strength of various fixation systems in bone. (After Hench, 1987.)

of 45S5 Bioglass, and the landmark sales of the one millionth dose of the bone graft product (NovaBone) and the one millionth tube of toothpaste containing 445S5 particulate (NovaMin) designed to occlude dentinal tubules and remineralize the surface of teeth, thereby eliminating the cause of dentinal hypersensitivity. The excellent clinical success of this bioactive material is due to the stimulation of osteogenesis, as summarized above, and a clinical response equivalent to use of autogeneous bone grafts without second site morbidity (Ilharreborde et al., 2008; Ameri et al., 2009).

BIOACTIVITY REACTION STAGES

There is a sequence of 11 reaction stages that occur at the surface of a Class A bioactive glass, as summarized in Figure I.2.4.6. The log time axis shown in Figure I.2.4.6 is based upon studies of surface reaction rates, as discussed above. The first five stages of surface reactions occur very rapidly and go to completion within 24 hours for the Class A bioactive glasses with highest levels of bioactivity, e.g., 45S5 Bioglass. The effect of the surface reactions is rapid release of soluble ionic species from the glass into the interfacial solution. A high surface area hydrated silica and polycrystalline hydroxyl-carbonate apatite (HCA) bilayer is formed on the glass surface within hours (Figure I.2.4.6, Stages 1–5). The reaction layers enhance adsorption and desorption of growth factors produced by the cells (Figure I.2.4.6, Stage 6), and decrease greatly the length of time macrophages are required to prepare the implant site for tissue repair (Figure I.2.4.6, Stage 7).

Attachment of osteoprogenitor stem cells (Figure I.2.4.6, Stage 8) and synchronized proliferation and differentiation of the cells towards the mature osteoblast phenotype (Figure I.2.4.6, Stage 9) rapidly occurs on the surface of Class A bioactive materials. Several weeks are required for similar cellular events to occur on the surface of Class B bioactive materials. Differentiation of progenitor cells into a mature osteoblast phenotype does not occur on bioinert materials, because of the lack of ionic stimuli. In contrast, osteoprogenitor cells colonize the surface of Class A bioactive materials within 24–48 hours, and begin production of various growth factors which stimulate cell division, mitosis, and production of extracellular matrix proteins (Figure I.2.4.6, Stage 10). Mineralization of the matrix follows soon thereafter and mature osteocytes, encased in a collagen-HCA matrix, are the final product by 6–12 days *in vitro* and *in vivo* (Figure I.2.4.6, Stage 11).

A rapid completion of all 11 reaction stages shown in Figure I.2.4.6 is the key to regenerative repair of bone, which involves: (1) control of the population of cells that are capable of entering into active phases of the cell cycle; (2) complete mitosis of cells with accurate replication of genes (cell proliferation); and (3) cellular differentiation into a phenotype capable of synthesizing a full complement of extracellular proteins that constitute mature osteocytes.

Such osteoblast cell cycle control is achieved *in vivo* by the controlled release of critical concentrations of Ca and Si ionic dissolution products from 45S5 bioactive glass particulate (Buttery et al., 2001; Xynos et. al., 2000, 2001) or 58S bioactive gel-glass (Christodoulou et al., 2005). Osteoprogenitor cells colonize the surface of the bioactive glass (Figure I.2.4.6), and slow release of the critical concentration of soluble Si and Ca ions at the cell–solution interface activates seven families of genes responsible for osteogenesis in the cells. Controlled rates of dissolution of the glass provide the critical concentration of the biologically active ions to the cells via the interfacial solution. The families of genes that are upregulated and/or activated are shown in Table I.2.4.7.

The upregulated genes encode nuclear transcription factors and potent growth factors, especially IGF-II, along with IGF-binding proteins and proteases that cleave IGF-II from their binding proteins. The growth

factors are present in a biologically active state, as confirmed by analysis of the upregulation of IGF-II mRNA with quantitative real-time PCR (Buttery, 2001; Hench, 2003). Similar bioactive induction of the transcription of extracellular matrix components and their secretion and self-organization into a mineralized matrix is responsible for the rapid formation and growth of bone nodules and differentiation of the mature osteocyte phenotype. Details are given in Xynos et al. (2000, 2001), and reviewed in Hench (2003).

CALCIUM PHOSPHATE CERAMICS

Bone typically consists by weight of 25% water, 15% organic materials, and 60% mineral phases. The mineral phase consists primarily of calcium and phosphate ions, with traces of magnesium, carbonate, hydroxyl, chloride, fluoride, and citrate ions. Hence, calcium phosphates occur naturally in the body, but they also occur within nature as mineral rocks, and certain compounds can be synthesized in the laboratory. Table I.2.4.8 summarizes the mineral name, chemical name, and composition of various phases of calcium phosphates.

Within the past 20–30 years interest has intensified in the use of calcium phosphates as biomaterials, but only certain compounds are useful for implantation in the body, since both their solubility and speed of hydrolysis increase with a decreasing calcium-to-phosphorus ratio. Driessens (1983) stated that those compounds with a Ca/P ratio of less than 1:1 are not suitable for biological implantation.

The main crystalline component of the mineral phase of bone is a calcium deficient carbonate hydroxyapatite, and a wide variety of methods have been investigated to produce synthetic hydroxyapatite. The most commercially popular routes are based on aqueous precipitation or conversion from other calcium compounds. The first reports appeared in the literature in the 1960s, and since then there have been many approaches based on those original methods. Aqueous precipitation is most often performed in one of two ways: a reaction between a calcium salt and an alkaline phosphate (Collin et al., 1963; Eanes et al., 1965; Jarcho et al., 1976; Kijima and Tsutsumi, 1979; Denissen et al., 1980; Young and Holcomb, 1982; Bonel et al., 1987) or a reaction between calcium hydroxide or calcium carbonate and phosphoric acid (Mooney, 1961; Rao and Boehm, 1974; McDowell et al., 1977; Akao et al., 1981; Irvine, 1981; Nagai et al., 1985). Since these papers were published there have been many reports of alternative wet chemical routes, but most of these are, in fact, based on similar reactants to those first described in the 1960s, 1970s, and 1980s.

Other routes include those based on solid-state processing (originally described by Lehr et al., 1967; Fowler, 1974; Rootare et al., 1978; Monma et al., 1981; Young and Holcomb, 1982), hydrolysis (Schleede et al., 1932; Perloff et al., 1956; Morancho et al., 1981; Young and Holcomb, 1982) or hydrothermal synthesis (Perloff and Posner, 1960; Roy, 1971; Skinner, 1973; Fowler, 1974; Arends et al., 1979; Young and Holcomb, 1982).

The route and conditions under which synthetic HA is produced will greatly influence its physical and chemical characteristics. Factors that affect the rate of resorption of the implant include physical factors, such as the physical features of the material (e.g., surface area, crystallite size), chemical factors, such as atomic and ionic substitutions in the lattice, and biological factors, such as the types of cells surrounding the implant and location, age, species, sex, and hormone levels.

The thermodynamic stability of the various calcium phosphates is summarized in the phase diagram shown in Figure I.2.4.8. The binary equilibrium phase diagram between CaO and P_2O_5 gives an indication of the compounds formed between the two oxides, and by comparing this with Table I.2.4.8 it is possible to identify

TABLE I.2.4.8	Calcium Phosphates		
Ca:P	**Mineral Name**	**Formula**	**Chemical Name**
1.0	Monetite	$CaHPO_4$	Dicalcium phosphate (DCP)
1.0	Brushite	$CaHPO_4 \cdot 2H_2O$	Dihydrate (DCPD) Dicalcium phosphate
1.33	—	$Ca_8(HPO_4)_2(PO_4)_4 \cdot 5H_2O$	Octocalcium phosphate (OCP)
1.43	Whitlockite	$Ca_{10}(HPO_4)(PO_4)_6$	
1.5	—	$Ca_3(PO_4)_2$	Tricalcium phosphate (TCP)
1.67	Hydroxyapatite	$Ca_{10}(PO_4)_6(OH)_2$	
2.0		$Ca_4P_2O_9$	Tetracalcium phosphate

the naturally occurring calcium phosphate minerals. The diagram does not indicate the phase boundaries of apatite due to the absence of hydroxyl groups. However, from the binary diagram an indication may be obtained of the stability of other calcium phosphates with temperature.

The stoichiometry of HA is highly significant where thermal processing of the material is required. Slight imbalances in the stoichiometric ratio of calcium and phosphorus in HA (from the standard molar ratio of 1.67) can lead to the appearance of either α- or β-tricalcium phosphate on heat treatment. Many early papers concerning the production and processing of HA powders reported problems in avoiding the formation of these extraneous phases (Jarcho et al., 1976; Peelen et al., 1978; De With et al., 1981a,b). However, using stoichiometric hydroxyapatite it should be possible to sinter, without phase purity problems, at temperatures in excess of 1300°C.

X-ray diffraction and infrared spectroscopy should be used to reveal the phase purity and level of hydroxylation of hydroxyapatite (Figures I.2.4.9 and I.2.4.10). Kijima and Tsutsumi (1979) used these techniques to study hydroxyapatite sintered at different temperatures, and reported that after sintering at 9000°C the material was fully hydroxylated, but after sintering at temperatures higher than this, dehydroxylation occurred. In fact, the dehydration of hydroxyapatite, produced by processes such as high temperature solid-state reactions, result in the formation of oxyhydroxyapatite: $Ca_{10}(PO_4)_6(OH)_{2-2x}O_xV_x$, (where V is a hydroxyl vacancy). Hydroxyapatite has a $P6_3/_m$ space group: this signifies that the lattice is primitive Bravais,

there is a six-fold axis parallel to the c-axis and a 1/2 (3/6) translation along the length of the c-axis (a screw axis) with a mirror plane situated perpendicular to the screw axis and the c-axis. The lattice parameters for hydroxyapatite have been determined to be 0.9418 nm and 0.6884 nm for the a and c parameters, respectively (JCPDS #09-0432).

The structure assumed by any solid is such that, on an atomic level, the configuration of the constituents is of the lowest possible energy. In phosphates, this energy requirement results in the formation of discrete subunits within the structure, and the PO_4^{3-} group forms a regular tetrahedron with a central P^{5+} ion and O^{2-} ions at the four corners. In a similar manner, the $(OH)^-$ groups are also ionically bonded. In terms of the volume occupied, oxygen ions exceed all other elements in phosphates. Any other elements present may therefore be considered as filling the interstices, with the exact position being determined by atomic radius and charge (see Figure I.2.4.11).
FIGURE I.2.4.11 Unit cell of hydroxyapatite (from PhD thesis, University of Cambridge, H. Chappell 2008).

The hydroxyapatite lattice contains two kinds of calcium positions: columnar and hexagonal. There is a net total of four "columnar calcium" ions that occupy the [1/3, 2/3, 0] and [1/3, 2/3, 1/2] lattice points. The "hexagonal calcium" ions are located on planes parallel to the basal plane at $c = 1/4$ and $c = 3/4$, and the six PO_4^{3-} tetrahedra are also located on these planes. The (OH)⁻ groups are located in columns parallel to the c-axis, at the corners of the unit cell, which may be viewed as passing through the centers of the triangles formed by the "hexagonal calcium" ions. Successive hexagonal calcium triangles are rotated through 60° (see Figure I.2.4.12).

Defects and impurities in hydroxyapatite may be identified as either substitutional or discrete extraneous crystalline phases (as discussed above). Methods of detection of impurities include X-ray diffraction, infrared spectroscopy, and spectrochemical analysis. It is important to make a full spectrochemical analysis of hydroxyapatite, since contact with any metal ions during production can lead to high levels of impurties in the product. Typical data for one commercial hydroxyapatite powder are shown in Table I.2.4.9.

Other ions which may be incorporated into the HA structure, either intentionally or unintentionally, include carbonate ions (substituting for hydroxyl or phosphate groups), fluoride ions (substituting for hydroxyl groups), silicon or silicate ions (substituting for phosphorus or phosphate groups), and magnesium ions substituting for calcium (e.g., Newsley, 1963; Le Geros, 1965; Barralet, 1997; Jha et al., 1998; Gibson et al., 1999).

Based on the research work performed by Carlisle in the 1970s, in which the nutritional effects of silicon were studied, Bonfield, Best, and co-workers later reported the development of silicate-substituted hydroxyapatites (Si-HA) (Gibson et al., 1999; Patel et al., 2002; Porter et al., 2003). *In vivo* studies comparing the rates of bone apposition to HA and Si-HA ceramic implants demonstrated a significant increase in the amount of bone apposition and organization around silicon-substituted HA (Si-HA) implants, illustrating their potential as bone graft materials (Patel et al., 2002). Several other groups have also investigated the production and characterization of Si-HA and Si-TCP (Ruys, 1993; Balas et al., 2003; Gasqueres et al., 2008).

Silicate-substituted HA (Si-HA) may be prepared via a variety of synthesis routes. Gibson et al. (1999) produced phase-pure Si-HA via an aqueous precipitation route, and proposed the substitution mechanism given the equation below:

$$10Ca^{2+} + (6-x)PO_4^{3-} + xSiO_4^{4-} + (2-x)OH^-$$
$$\rightarrow Ca_{10}(PO_4)_{6-x}(SiO_4)_x(OH)_{2-x}$$
Structural analysis has confirmed that silicate (SiO_4^{4-}) ions can substitute for the PO_4 sites in HA.

TABLE I.2.4.9	Trace Elements in a Commercial Hydroxyapatite
Trace Element	**PPM**
Al	600
Cu	1
Fe	1000
Ge	100
Mg	2000
Mn	300
Na	3000
Pb	4
Si	500
Ti	30

This substitution results in changes in the crystal lattice dimension, with a decrease in the a-axis and an increase in the c-axis (Gibson et al., 1999; Patel et al., 2002). This work led to a significant level of interest in silicate-substituted apatite-based bone grafts, and these materials are now used in a range of orthopedic applications (Waked and Grauer, 2008).

The presence of carbonate may be observed directly, using infrared spectroscopy, in the form of weak peaks at between 870 and 880 cm^{-1}, and a stronger doublet between 1460 and 1530 cm^{-1}, and also through alterations in the hydroxyapatite lattice parameters from X-ray diffraction (LeGeros, 1965; Rootare and Craig, 1978; Barralet et al., 1997). The substitution of electronegative anions such as fluorine and chlorine for (OH)$^-$ have also been reported to alter the lattice parameters

TABLE I.2.4.10	Typical Mechanical Properties of Dense Hydroxyapatite Ceramics
Theoretical density	3.156 g cm^3
Hardness	500–800 HV, 2000–3500 Knoop
Tensile strength	40–100 MPa
Bend strength	20–80 MPa
Compressive strength	100–900 MPa
Fracture toughness	approx. 1 Mpa m$^{0.5}$
Young's modulus	70–120 GPa

of the material (e.g., Kay et al., 1964; Young and Elliot, 1966; see also Elliot, 1994).

Hydroxyapatite may be processed as a ceramic using compaction (die pressing, isostatic pressing, slip casting, etc.) followed by solid-state sintering (discussed earlier in this chapter). When reporting methods for the production and sintering of hydroxyapatite powders, it is very important to adequately characterize the morphology of the product including the surface area, particle size distribution, mean particle size, and physical appearance of the powders, since this will greatly influence the handling and processing characteristics of the material (Best and Bonfield, 1994). There is a great deal of variation in the reported mechanical performance of dense hydroxyapatite ceramics, dependent on phase purity, density and grain size, but the properties cited generally fall in the range shown in Table I.2.4.10.

The bonding mechanism of dense HA implants appear to be very different from that described above for bioactive glasses. The bonding process for HA implants has been described by Jarcho (1981). A cellular bone matrix from differentiated osteoblasts appears at the surface, producing a narrow amorphous electron-dense band only 3 to 5 μm wide. Between this area and the cells, collagen bundles are seen. Bone mineral crystals have been identified in this amorphous area. As the site matures, the bonding zone shrinks to a depth of only 0.05 to 0.2 μm (Figure I.2.4.2). The result is normal bone attached through a thin epitaxial bonding layer to the bulk implant. TEM image analysis of dense HA bone interfaces shows an almost perfect epitaxial alignment of some of the growing bone crystallites with the apatite crystals in the implant. A consequence of this ultra-thin bonding zone is a very high gradient in elastic modulus at the bonding interface between HA and bone. This is one of the major differences between the bioactive apatites and the bioactive glasses and glass-ceramics. The implications of this difference for the implant interfacial response to Wolff's law are discussed in Hench and Ethridge (1982), Chapter 14.

CALCIUM PHOSPHATE COATINGS

The clinical application of calcium phosphate ceramics is largely limited to bone grafting applications or, if in the form of a monolithic or porous component, to non-major

loadbearing parts of the skeleton. This is because of relatively poor mechanical strength and toughness, and inferior mechanical properties, and it was partly for this reason that interest was directed toward the use of calcium phosphate coatings on metallic implant subtrates. Good reviews of the production of calcium phosphate coatings have been published by de Groot et al. (1998), Sun et al. (2001), and Heimann (2006). Many techniques are available for the deposition of hydroxyapatite coatings, including electrophoresis, sol–gel routes, electrochemical routes, biomimetic routes, and sputter techniques, but the most popular commercial routes are those based on plasma spraying. In plasma spraying, an electric arc is struck between two electrodes and a stream of gases is passed through the arc. The arc converts the gases into plasma with a speed of up to 400 m/sec and a temperature within the arc of 20,000°K. The ceramic powder is suspended in the carrier gas and fed into the plasma, where it can be fired at a substrate. There are many variables in the process including the gases used, the electrical settings, the nozzle/substrate separation, and the morphology, particle size, and particle size distribution of the powder. Because of the very high temperatures but very short times involved, the behavior of the hydroxyapatite powder particle is somewhat different than might be predicted in an equilibrium phase diagram. However, according to the particular conditions used, it is likely that at least a thin outer layer of the powder particle will be in a molten state and will undergo some form of phase transformation, but by careful control of the operating variables the transformed material should represent a relatively small volume fraction of the coating, and the product should maintain the required phase purity and crystallinity (Mayer et al., 1986; Cook et al., 1988; Wolke et al., 1992).

Early work on plasma sprayed coatings established that there are a number of factors that influence the properties of the resulting coating, including coating thickness (this will influence coating adhesion and fixation – the agreed optimum now seems to be 50–100 μm) (de Groot et al., 1987; Soballe et al., 1993), crystallinity (this affects the dissolution and biological behavior) (Le Geros et al., 1992; Klein et al., 1994a,b; Clemens, 1995), biodegradation (affected by phase purity, chemical purity, porosity, crystallinity) (Tang et al., 2010), and adhesion strength (these may range between 5 and 65 MPa (de Groot, 1998).

Plasma sprayed coatings have been found to be highly successful, and are now widely used in hip joint replacement, particularly for younger patients (Sun et al., 2001). However, the mechanical mismatch between the coating and the substrate can lead to high levels of residual interfacial stress. For this reason, a number of other "low temperature" and thin film deposition techniques been investigated, including electrophoresis, sol–gel routes, electrochemical routes, biomimetic routes,

electrohyhdrodynamic spray deposition sputter techniques, and bone-like apatite coatings through simulated body fluid treatments.

Sputtering results in thin (<1 micron) coatings on metallic, ceramic or polymeric substrates (Hulshoff et al., 1996, 1997; Lo et al., 2000; Ong, 2002; Boyd et al., 2003; Cairns et al., 2008). Pure calcium phosphate coatings need to be deposited using magnetron sputtering. Using a combination of two or more targets allows the co-deposition of Si with the calcium phosphate, and the resulting films have been found to exhibit enhanced biological performance (Thian et al., 2005, 2006). However, further investigation of sputtered coatings is required to provide better understanding of their potential long-term clinical performance.

The preparation of SiHA films via sol–gel routes (Hijon et al., 2006) and pulsed laser deposition techniques (Garcia-Sanz et al., 1997) has also been investigated. Fluoride-substituted HA coatings on metallic surfaces using a sol–gel method (Wang et al., 2007). Biomimetic approaches have also been investigated. Substrates are immersed in a supersaturated or metastable solution at 37°C with ion concentrations and pH value similar to human blood plasma. After several days, the formation and growth occurs of a thin "bone-like" apatite layer (Ohtsuki et al., 1991). Biomimetic coatings are generally produced using simple, low cost, low temperature processes. However, long induction and growth periods are required to form the coatings, and adhesion strength between the coating and substrate still requires optimization.

Electrostatic spray deposition allows the fabrication of dense, porous or nanostructured CaP coatings (Leeuwenburgh et al., 2003; Huang et al., 2005; Lim et al., 2005; Ahmad et al., 2006; Huang et al., 2008). Research indicates that this route offers the potential for using CaP coatings as carriers for a variety of drugs (Siebers et al., 2004, 2006).

CALCIUM PHOSPHATE IMPLANTS: MECHANICAL PROPERTIES AND POROSITY

The mechanical behavior of calcium phosphate ceramics strongly influences their application as implants. Tensile and compressive strength and fatigue resistance depend on the total volume of porosity. Porosity can be in the form of micropores (<1 μm diameter, due to incomplete sintering) or macropores (>100 μm diameter, created to permit bone growth). The dependence of compressive strength (σ_c) and total pore volume (V_p) is described in de Groot et al. (1990) by:

$$\sigma_c = 700 \exp - 5V_p \text{ (in MPa)} \tag{3}$$

where (V_p is in the range of 0–0.5.

Tensile strength depends greatly on the volume fraction of microporosity (V_m):

$$\sigma_t = 220\exp - 20\ V_m (\text{in MPa}) \qquad (4)$$

The Weibull factor (n) of HA implants is low in physiological solutions ($n = 12$), which indicates low reliability under tensile loads. Consequently, in clinical practice, calcium phosphate bioceramics should be used: (1) as powders; (2) in small, unloaded implants such as in the middle ear; (3) with reinforcing metal posts, as in dental implants; (4) as coatings (e.g., composites) or (5) in porous implants where bone growth acts as a reinforcing phase.

There are a number of commercially available porous products on the market, and these originate from three main sources: hydroxyapatite that has been chemically synthesized (e.g., Apapore®); material has been converted from synthetic sources; coral (e.g., Pro Osteon®, Interpore®, Bio Eye®) or animal bone (e.g., Endobon®). There has been some discussion in the literature regarding the optimum "type" of porosity, and a number of authors have suggested that the degree of interconnectivity is more critical than the pore size. Eggli et al. (1988) demonstrated improved integration in interconnected 50–100 μm pores compared with less connected pores with a size of 200–400 μm. Similarly, Kühne et al. (1994) compared two grades of 25–35% porous coralline apatite with average pore sizes of 200 and 500 μm and reported bone ingrowth to be improved in the 500 μm pore sized ceramic. Holmes (1979), who also studied a porous coralline apatite, suggested that when implanted in cortical bone interconnections of osteonic diameter were required for transport of nutrients to the bone ingrowth. The findings clearly indicate the importance of thorough characterization of the porous materials before implantation, and Hing (1999) has recommended a range of techniques which should be employed.

RESORBABLE CALCIUM PHOSPHATES

Resorption or biodegradation of calcium phosphate ceramics is caused by three factors:

1. Physiochemical dissolution, which depends on the solubility product of the material and local pH of its environment. New surface phases may be formed, such as amorphous calcium phosphate, dicalcium phosphate dihydrate, octacalcium phosphate, and anionic-substituted HA.
2. Physical disintegration into small particles as a result of preferential chemical attack of grain boundaries.
3. Biological factors, such as phagocytosis, which causes a decrease in local pH concentrations (de Groot and Le Geros, 1988).

Ideally, one might wish for a replacement material to be slowly resorbed by the body once its task of acting as a scaffold for new bone has been completed. Degradation or resorption of calcium phosphates *in vivo* occurs by a combination of phagocytosis of particles and the production of acids. However, when selecting a resorbable material for implantation, care must be taken to match the rate of resorption with that of the expected bone tissue regeneration. Where the solubility of calcium phosphates is higher than the rate of tissue regeneration, they will not be of use to fill bone defects. As mentioned previously, the rate of dissolution increases with decreasing calcium-to-phosphorus ratio and, consequently, tricalcium phosphate, with a Ca:P ratio of 1.5, is more rapidly resorbed than hydroxyapatite. Tricalcium phosphate has four polymorphs: α; β; γ; and super α. The γ polymorph is a high pressure phase, and the super α polymorph is observed at temperatures above approximately 1500°C (Nurse et al., 1959). Therefore, the most frequently observed polymorphs in bioceramics are α- and β-TCP. X-ray diffraction studies indicate that the β polymorph transforms to the α polymorph at temperatures between 1120°C and 1290°C (Gibson et al., 1996).

All calcium phosphate ceramics biodegrade to varying degrees; the rate of biodegradation increases as:

1. Surface area increases (powders > porous solid > dense solid);
2. Crystallinity decreases;
3. Crystal perfection decreases;
4. Crystal and grain size decrease;
5. There are ionic substitutions of CO^{-3}_2, Mg^{2+}, and Sr^{2+} in HA.

Factors that tend to decrease the rate of biodegradation include: (1) F⁻ substitution in HA; (2) Mg^{2+} substitution in β-TCP; and (3) lower β-TCP/HA ratios in biphasic calcium phosphates.

CALCIUM PHOSPHATE BONE CEMENTS

In the 1980s, calcium phosphate bone cements were developed. These materials offer the potential for *in situ* molding and injectability. There are a variety of different combinations of calcium compounds (e.g., α-tricalcium phosphate and dicalcium phosphate) which are used in the formulation of these bone cements, but the end product is normally based either on a calcium deficient hydroxyapatite (Fernandez et al., 1998, 1999a,b) or on brushite (although *in vivo* these tend to convert to hydroxyapatite) (Lemaitre et al., 1987; Constantz et al., 1998). In the development and production of the bone cements a number of factors need to be considered, including the processing parameters (such as solid and liquid component composition, particle size, and liquid-to-powder ratio), setting properties, cohesion time, and the injectability of the paste (Doroszhkin, 2009). These will in turn significantly

influence the microstructure and porosity, and hence mechanical behavior of the cement.

The cements have been found to perform well *in vivo*, and are now commercially available (Bohner, 2000). There is considerable interest in the future potential for these materials to be used for drug delivery (Ginebra et al., 2001).

CLINICAL APPLICATIONS OF HA

Calcium phosphate-based bioceramics have been used in medicine and dentistry for over 20 years (Jarcho, 1981; de Groot, 1983; Hulbert et al., 1987; Le Geros, 1988; de Groot, 1988; de Groot et al., 1990; Le Geros and Le Geros, 1993). Applications include dental implants, periodontal treatment, alveolar ridge augmentation, orthopedics, maxillofacial surgery, and otolaryngology (Table I.2.4.6).

Most authors agree that HA is bioactive, and it is generally agreed that the material is osseoconductive, where osseoconduction is the ability of a material to encourage bone growth along its surface when placed in the vicinity of viable bone or differentiated bone-forming cells. Good reviews of porous hydroxyapatite from different sources for eventual clinical application have been prepared by Hing et al. (1998, 2005), and Damien and Revell (2004). Hing et al. (1998) observed that there are a large number of "experimental parameters," including specimen, host, and test parameters, which need to be carefully controlled in order to allow adequate interpretation of data.

Hydroxyapatite has been investigated and used in a range of different forms for clinical applications. It has been utilized as a dense, sintered ceramic for middle ear implant applications, (van Blitterswijk, 1990) and alveolar ridge reconstruction and augmentation (Quin and Kent, 1984; Cranin et al., 1987), in porous form for orbital implants (Suter et al., 2002), as granules for filling bony defects in dental and orthopaedic surgery, such as for spinal fusion and impaction grafting (Froum et al., 1986; Galgut et al., 1990; Oonishi et al., 1990; Wilson and Low, 1992; Aoki, 1994; Fujishiro, 1997; Bolder et al., 2002; Hing et al., 2007; Wheeler al., 2007; Coathup et al., 2008), and as a coating on metal implants (de Groot, 1987; Cook et al., 1992a,b; Camazzola et al., 2009). There are now numerous reports of the successful use of hydroxyapatite coated femoral prostheses and acetabular cups, and clinical results indicate that these implants are especially successful for younger patients (Stack et al., 2006; Shah, 2009).

Another successful clinical application of hydroxyapatite has been in polymer composites. The original concept of a bioceramic filler in a polymer composite was introduced by Bonfield et al. (1981) with the aim of producing an analog of the mineral-reinforced organic matrix in cortical bone. The material developed by Bonfield and co-workers contains up to 50 vol% hydroxyapatite in a polyethylene matrix, has a stiffness similar to cortical bone, has high toughness, and has been found to exhibit bone-bonding *in vivo*. The material has been used as an orbit implant for orbital floor fractures and volume augmentation (Tanner et al., 1994), and is now in used in middle ear implants, commercialized under the trade name, HAPEX® (Bonfield, 1996).

Other approaches have been made to produce bioactive and either bioresorbable or biodurable composites. The incorporation of glass ceramics A-W and Bioglass® have been investigated within a wide variety of polymer matrices (Thompson et al., 1998; Rea et al., 2004). Another recent advance has been in the development of a compositionally-graded mineralized collagen-GAG scaffold for cartilage and ligament repair (Lynn et al., 2005).

A. NATURAL AND SYNTHETIC HYDROXYAPATITES

Adele L. Boskey
Starr Chair in Mineralized Tissue Research, Hospital for Special Surgery and Professor, Weill Medical College of Cornell University; BME Faculty, Sibley School of Mechanical Engineering, Cornell, Ithaca

INTRODUCTION

The mineral in bone and dentin and some pathologic deposits is a poorly-crystalline analog of the geologic mineral hydroxylapatite ($Ca_{10}(PO_4)_6(OH)_2$), HAP. The analogy was recognized from X-ray diffraction analyses performed almost a century ago. The crystal structure of a single crystal of stoichiometric hydroxylapatite was solved in 1964 (Kay et al., 1964). More recent refinements have been made on powder diffraction patterns based on neutron diffraction data (Leventouri et al., 2003) and by Reitfeld refinement (Wilson et al., 2004). The salient features of the structure have not changed and are summarized in Figure A.1 as a projection on the x,y plane (i.e., the a and b axes are in the plane of the paper). The elevations shown in each symbol relate to the positions along the c-(needle) axis. Transmission electron microscopy (TEM) shows that the crystals (depending on how they are viewed) are needle- or plate-like (Landis et al., 1991); however, a plate-like crystal on its side resembles a needle, and *vice versa*. Nanocrystalline HAP crystals that are synthesized in the laboratory have structural properties similar to bone HAP, and range in size from 30 to 50 nm in length, with a diameter, based on TEM, of about 10 nm (Jäger et al., 2006).

As can be seen from the wide angle X-ray powder diffraction patterns (Figure A.2), the peaks for bone are broader than those for the highly crystalline hydroxyapatite, but are more similar to that of a synthetic apatite made at room temperature. The CaP ceramic shown in the figure has peaks that are distinct from both bone apatite and hydroxylapatite. The broadening of the peaks is caused by the imperfections in the crystal lattice and the small size of the crystals. The crystallite size (and perfection) can be estimated by the Scherrer equation (Eq. 1):

$$\beta 1/2 = K\lambda/(d\cos\Theta) \qquad (1)$$

where $\beta 1/2$ is the peak width at half maximum in degrees 2 Θ, K is a constant (usually 0.9 for HAP), λ is the wavelength of the X-ray source used (in Angstroms), d is the average domain size (assumed to be crystallite size), and Θ is the position of the reflection peak in radians. For HAP examined with Cu Kα radiation, the wavelength is 1.541, the 002 reflection (used to measure c-axis length) is 25.85 degrees 2 Θ.

In general, bone apatite is hydroxide deficient (Boskey, 2007), and hence is called hydroxyapatite or "apatite." Detailed analyses of the structure of synthetic and bone mimetic-apatites have shown them to be calcium deficient, with magnesium, sodium, carbonate, and fluoride substitutions. They may also be phosphate deficient, and lattice vacancies are also found (Legeros, 2002; Tampieri et al., 2005). The lack of stoichiometry of bone apatite has been confirmed by chemical analyses, which finds Ca/P molar ratio distinct from the predicted 1.67, ranging from 1.4:1 to 2.0:1.

Substitution of foreign ions and vacancies into the hydroxyapatite crystal structure are common, especially in biologic apatites, and adsorption of foreign ions and molecules onto the surfaces of the crystals is equally common, because of the relatively small size and large surface area of the biologic apatites. The most common vacancies are in the calcium positions; carbonate can substitute for either phosphate or hydroxyl; fluoride substitutes for hydroxyl; and the cations substitute in the calcium positions. Substitution of calcium by lead (Ellis et al., 2006), sodium and potassium (De Maeyer et al., 1996), zinc (Tampieri et al., 2005), magnesium (Bertoni et al., 1998), silicon (Gibson et al., 1999; Pietak et al., 2007), and strontium (O'Donnell et al., 2008) destabilizes the structure, increasing the solubility of the substituted apatites. Since the clinical application of HAP ceramics is bone and tooth repair, it is important to note that some of the substituted apatites have been shown to enhance bone cell growth in

FIGURE A.1 Structure of hydroxyapatite projected on the x, y plane. (*Adapted from* Kay et al., 1964.)

FIGURE A.2 X-ray diffraction powder patterns for (top to bottom) - poorly crystalline HAP (HAPp), bovine cortical bone (Bone), HAP ceramic, and highly crystalline HAP (HAPx).

culture and *in situ* (Table A.1). Substitution of hydroxyl and/or phosphate groups by carbonate increases the apatite solubility (Okazaki and Takahashi, 1999). Carbonate substitution is said to enhance osteoconduction (Spence et al., 2008), but the mechanism of this effect is unknown. The most common hydroxyl ion substituents are chloride and fluoride (LeGeros et al., 2002), both of which significantly change the HAP

crystal structure. In the case of chloride, the symmetry of the structure changes and hydroxyapatite becomes closer to the monoclinic chloroapatite structure (Baikie et al., 2007). Fluoride substitution shortens the HAP crystals' c-axis length and, due to hydrogen bonding, decreases the hydroxyapatite solubility (Bertoni et al., 1998). As discussed below, each of these ionic substitutions has been included alone or in combination, in

TABLE A.1	Effect of Ionic Substitution on Synthetic HA Properties		
Ion	Effect on Unit Cell	Effect on Bone Growth	Effect on Bone Remodeling
Si	Shorter a-axis; longer c-axis; decreased crystallinity[a,b]	Enhanced osteoblast growth	
Sr	Increased a and c axis[c]; increased crystallinity[c]	Enhanced osteoblast gene expression[d]	Decreased osteoclast activity[d]
CO_3	Decreased c-axis[e]	Enhanced osteogenesis[f]	Enhanced resorption[f]
Mg		Decreased osteogenesis[g]	
Fe		Inhibits growth[h]

HAP ceramics in an effort to optimize the ceramics' functional properties.

APPLICATIONS OF HAP CERAMICS

The HAP ceramics are designed to mimic the mineral in bone or other mineralized tissues. The ideal HAP mimetic should be biocompatible, easy to work with, and preferably osteoinductive. Most of the HAP ceramics, however, are osteoconductive at best. Osteoinductivity refers to the ability to generate bone. In contrast, osteoconductivity indicates that bone will grow on the surface of the material in question, but will not penetrate the structure. Biocompatibility refers to the ability of the material to respond appropriately in its desired *in situ* function, of which the HAP ceramics have many.

Clinical applications of HAP ceramics are quite varied, and range from prosthetic grafts in orthopedic surgery (Bucholz, 2002; Sing et al., 2004; Adachi et al., 2005; Trinkha et al., 2005; Huber et al., 2006), including spine (Khan et al., 2005), plastic (Isago et al., 2004), and reconstructive surgery (Ono et al., 1999; Schmitz et al, 1999; Reynolds et al., 2003), orbital and cranial reconstruction (Kundu et al., 2005), and oral surgery (Turhani et al., 2005), to their use as an embolic material (Kubo et al., 2003) in which capillary beds in tumors are occluded. Along with these clinical applications, HAP ceramics have also been tried as and drug delivery devices, for example for delivery of insulin (Paul et al., 2002), antibiotics (Sudo et al., 2008), and anti-tumor vaccines (Ciocca et al., 2007). Preclinical models have also examined the release of growth factors and cytokines from HAP ceramics (Sogo et al., 2007; Jones et al., 2008), but few of these are in clinical use (Yoshikawa et al., 2009). The HAP ceramics are used in a variety of forms (beads, pastes, chips, pre-formed structures), depending on application. In some cases the HAP ceramics are reported to be too brittle unless porosity is introduced (Yoshikawa et al., 2009). HAP ceramics are used to coat metallic prostheses to improve mechanical strength, while encouraging osteointegration. Addition of pores of sufficient size that penetrate the ceramic has been a challenge in the synthesis of HAP ceramics. A detailed review of the history of HAP clinical applications was recently published (LeGeros and LeGeros, 2008). HAP ceramics are also used in chromatographic columns, and as abrasives (LeGeros and LeGeros, 2008), conjugated with quantum dots for *in vivo* imaging (Guo et al., 2008).

SYNTHESIS OF HAP CERAMICS

There are two categories of HAP ceramics, those with minimal porosity (dense ceramics) and those in to which porosity is introduced (porous ceramics). In general, both types of HAP ceramics are prepared by sintering, and because the strength of the ceramics decreases as the sintering temperature increases (Ruys et al., 1995) a variety of techniques, discussed below, have been introduced to improve the ceramics' mechanical strengths. Sintered HAPs have higher crystallinity and lack carbonate substitution in contrast with bone apatites (Peters et al., 2000). Often the synthesis can involve two heating processes: calcining, which refers to the heating of the material turning it into ash (usually done at a lower temperature); and sintering, derived from the word for "cinder" which by definition is a method for making objects from powders by heating them below their melting point until they adhere to one another. Sintering can be done with pressure (referred to as hot pressing or hot isostatic

pressuring) and without added pressure, which is usually done for nanoparticles.

Several distinct processes can be used to make HAP ceramics (LeGeros and LeGeros, 2008). These include solid-state reactions in which calcium- and phosphate-containing compounds are mixed, compressed, and sintered above 950°C; hydrothermal reactions in which the reactants of the solid-state reactions are heated under pressure; sol–gel reactions in which solutions (sol) or colloids are mixed to form a colloid solution (gel), which is then aged, dried, and sintered (Chai et al., 1995); and variants thereof. A number of calcium phosphate phases can serve as starting materials for the preparation of HAP ceramics. The list includes alpha-tricalcium phosphate (TenHuisen and Brown, 1998) which can be hydrolyzed to form a calcium deficient HAP; carbonate-containing hydroxyapatite that loses its carbonate on heating (Ellies et al., 1988), and hydroxyapatite itself. These starting phases are listed in Table A.2. While a number of phases are listed, the most common are HA and ACP, but only HA, whitlokite, and brushite ($CaHPO_4.2H_2O$) persist in the body, the other phases are remodeled or dissolved. It is important to note that not every calcium phosphate ceramic is HAP, requiring analysis of the phases present before clinical use (ASTM F1185-03). For example, because the ceramics are prepared by sintering at high temperatures, depending on starting material they may contain calcium oxide or calcium carbonate (Qian et al., 2008) or some of the other phases listed in Table A.2.

To make the HAP starting material, variations of the Tiselius direct precipitation method (Tiselius et al., 1956), in which a calcium source and a phosphate source are mixed in solution at pH >7.4 and heated above 60°C, are used. A hydrolysis method wherein non-apatitic calcium phosphates (Table A.2) are hydrolyzed in base is also used frequently. Amorphous calcium phosphate (ACP) prepared from 0.4 M calcium chloride and 0.3 M ammonium chloride mixed in pH 7.4 buffer converts to HAP at room temperature in a few hours (Boskey, 1997). ACP, which can be recognized from the total lack of features in its X-ray diffraction pattern, can be flame sprayed or otherwise heated to generate the ceramic. HAP has been made by addition of phosphoric acid into a calcium hydroxide suspension followed by spray drying the suspension. The powder thus formed is calcined at 700°C and jet-milled for conditioning (Kubo et al., 2003). Recently, calcium nitrate tetrahydrate was mixed with triethyl phosphate following the sol gel method, after which the gel was dried slowly and calcined at 600°C, yielding a CaO-free HAP (Hsieh et al., 2001). Preparing the HAP particles in an autoclave with stirring results in variation in particle size and shape (Kothanpalli et al., 2005). Specifically, the aspect ratio of the particles increased with the reaction temperature. The length of the HA particles increased with increasing temperature when the temperature was below 170°C, and decreased above that temperature.

HAP ceramics can be made by sintering bovine bone (Joschek et al., 2000), coral (Chiroff et al., 1975), red algae (Turhani et al., 2005) or egg shells (calcium carbonate) mixed with phosphoric acid (Lee et al., 2007). In some cases bone is soaked in sodium pyrophosphate before calcining to provide a mixture of HAP and the more soluble (biodegradable) beta-TCP (Jun et al., 2003). Recently, bacterial synthesis has been used to produce HAP (Medina Ledo et al, 2008). While oral bacteria are known to produce HAP (van Dijk et al., 1998), in this novel approach the bacterium *Serratia* forms a biofilm on polyurethane, and then is incubated in calcium chloride and 2-glycerophosphate to produce HAP in bulk. The bacteria hydrolyze the phosphate and the initial precipitate formed is a calcium deficient HAP. Sintering increases the crystallite length.

The sintered bovine bone product, which retains the shape and porosity of the starting material is marketed as Bio-Oss® (Osteohealth, Luitpold Pharmaceuticals, Inc, Luitpold, NY); the coral product as Pro-Osteon and Interpore 200 (Interpore Cross Int); and the algae based product as C GRAFT/Algipore (Clinician's Preference LLC, Golden, CO). This is just a sample of the commercially-available HAP ceramics (see Box 1); in addition there are several that are mixtures of HAP and beta-tricalcium phosphate, the so-called biphasic calcium phosphates (BCPs) (e.g., KGBONE (Kasios, La Croix, France) or TRICOSS (Baxter, US)). The physicochemical characteristics of 14 CaP bone substitutes available in

TABLE A.2	Calcium Phosphate Phases Used to Prepare HAP Ceramics		
Compound	**Formula**	**Acronym**	**Geologic Name**
Alpha-tricalcium phosphate	$Ca_3(PO_4)_2$	α-TCP	
Amorphous calcium phosphate	$(Ca_3(PO_4)_2)$	ACP	
Anhydrous monocalcium phosphate	$Ca(H_2PO_4)_2$	MCPA	
Beta-tricalcium phosphate	$Ca_3(PO_4)_2$	β-TCP	B-Whitlokite
Dicalcium phosphate anhydrous	$CaHPO_4$	DCPA	Monetite
Dicalcium phosphate dihydrate	$CaHPO_4.2H_2O$	DCPD	Brushite
Hydroxyapatite	$Ca_5(PO_4)_6OH$	HAP, HA	Hydroxylapatite
Monocalcium phosphate monohydrate	$(Ca(H_2PO4)_2.H_2O$	MCPM	
Octacalcium phosphate	$Ca_8(HPO_4)_2(PO_4)_4.5H_2O$	OCP	
Tetracalciumphosphate	$Ca_4(PO_4)_2O$	TTCP	

BOX 1	Commercially Available HAP Ceramics
Product	**Made From**
Aperceram	Synthetic
Bio-Oss	Bovine bone (not sintered)
Bioroc	Synthetic
BONECERAM	Synthetic
Calcibon	Synthetic
Calcititek	Synthetic
C GRAFT/Algipore	Algae and starfish
Cerament	HAP + Ca sulfate
Collapat	Synthetic on bovine type I collagen fibrils
Cortoss	Synthetic
Endobon	Bovine bone (sintered)
FRIOS	Marine fluoroapatite
HAPEX	HAP + polymer
Hapset	HA + Ca sulfate
Healos	HAP + collagen composite
Interpore 200	Coral
Perossal	Synthetic
Nano-XIM	Synthetic
NuOSS	Bovine cortical bone
Ostogen	Synthetic (unsintered)
Osteograft	Bovine bone (sintered)
Ostim	Synthetic (unsintered)
Osprovit	Synthetic
Pro-Osteon	Coral (incomplete conversion)
Radiesse	Synthetic
Truebone	Bovine bone (sintered)

2004 were described in detail by Tadic and Epple (2004), and those available in Japan in 2008 were reviewed by Yoshikawa et al. (2009).

Ideally, a HAP ceramic that is clinically useful must be made from a material that is mechanically strong enough to bear the load on bones and teeth, while being sufficiently porous to allow cell penetration. In addition, the pores should be interconnected so that the cells can invade the entire construct and also receive nutrition. To improve the mechanical properties, as sintered HAP tends to be very brittle (Barralet et al., 2002), reinforcement with magnesium (Landi et al., 2005), zirconium (Kim et al., 2005), aluminum (Jun et al., 2003), lithium (Vaz et al., 1999), and a variety of trace metals (Kokubo et al., 2003) has been applied. Addition of PMMA (Yao et al., 2005) has been used to increase the strength of the HAP ceramics. Coating HAP ceramics on metallic surfaces or on pliable scaffolds (biotemplates) has also been used to increase mechanical toughness. There are also composite materials consisting of both HAP ceramics and synthetic or naturally-occurring polymers (such as bovine collagen, silk or tree bark) as biotemplates (Qian et al., 2008), and multilayered ceramics with various porosities and mechanical properties within the different layers (Vaz et al., 1999).

To allow cells to penetrate the HAP ceramic, pores are introduced into the sintered material. Pore diameters must be >100 um (Jones et al., 2009). Smaller connecting pores are satisfactory for nutrient flow into and fluid flow out of the cells, but not for cell penetration or new matrix synthesis. A variety of methods for increasing porosity have been described including, but not limited to, microwave processing at 1150 to 1200°C for short periods of time (1 to 5 minutes); heating in the presence of activated charcoal (Li et al., 2009); using starting materials with different morphology, adjusting density, changing sintering time and temperature; and mixing ammonium carbonate in the HAP powder during the consolidation process. The ammonia and carbon dioxide gases that are released on heating generate the pores. Pore-forming agents such as polyvinyl butyl and polyvinyl polyacrylate, which are also removed on heating, have been used to generate more uniform pore sizes (Liu, 1997; Vaz et al., 1999). HAP slurries have been impregnated into cellulose sponges which were then calcined at 1280°C (Fabbri et al., 1995). These processes are reviewed in detail elsewhere (Tadic et al., 2004). Other organic materials such as carbon beads (Kawata et al., 2004) have used to produce uniform porosities. "Super porous" HAP ceramics with interconnecting pores were made by including surfactants during the heating process (Sakamoto et al., 2007). The sol–gel can also be infiltrated into "biotemplates," and subsequently sintered at elevated temperatures to obtain porous HA ceramics. A "foam–gel" method that involves preparing an HAP gel in a cross-linking slurry (made from polyethyleneimine), casting the foamy slurry, and after removal from the mold drying and sintering, yields uniformed size interconnecting pores and a compressive strength of 12 Mpa, is currently in clinical trial in Japan (Yoshikawa et al., 2009).

Porosity alters the microstructure (Barralet et al., 2002), and the mechanical strength of HAP ceramics is dependent both on the number and size of the pores (Le Huec et al., 1995). The surface area and porosity of HAP ceramics decrease with increasing preparation temperature (Salver and Hall, 1989), while crystal size increases (Habibovic et al., 2005). The surface area of HAP ceramics is ~5–7 m^2/g at 1000°C and ~70–80 m^2/g at 400°C (Patel et al., 2001). The HAP structure degrades if sintered at temperatures higher than 1300°C (Lin et al., 2000), while an inflammatory response develops if sintering is performed at too low a temperature (Lu et al., 2004). With this in mind, HAP ceramics sintered at 1100–1200°C are reported to be the most osteogenic (Wang et al., 2004; Habibovic et al., 2005). Table A.3 compares some mechanical properties of cortical and cancellous bone to that of dense and porous HAP ceramics. Increasing porosity decreases compressive strength (Le Huec et al., 1995); hence, both dense and porous ceramics have advantages, which may be addressed by composites of the two.

Recently, emphasis has been placed on non-sintered HAP materials that are porous, but more similar in crystal

TABLE A.3	Mechanical Properties of Adult Human Cortical and Cancellous Bones and HAP Ceramics*		
Property	Cortical Bone	Cancellous Bone	HAP Ceramics*

size and composition to bone apatite. Tadic et al. (2004) produced such a nanomaterial ceramic by synthesizing HAP from mixtures of 5:1 $(NH_4)_2PO_4$, $(NH_4)_2CO_3$, and $Ca(NO_3)_2$, such that the Ca/P molar ratio was 1.67:1. Following ball milling and sieving of the powder that was formed to 250–400 μm, it was mixed with polyvinylalcohol fibers and NaCl crystals and cold isostatically pressed at room temperature. The NaCl and polyvinylalcohol were extracted in warm water, but the mechanical stability was markedly decreased, with compressive strength about 1/10th to 1/20th of that of the material without the pores.

The porous and nanomaterial HAP ceramics can be prepared in a variety of forms, depending on the desired use. These forms (Table A.4) are made by molding, grinding, three-dimensional printing or mixing with other materials. Some, like the injectable Radiesse, which is a dermal filler in a carrier gel made up of water, glycerin, and carboxymethylcellulose, combine multiple forms. To enhance cellular ingrowth, cell proliferation, and even vascular ingrowth, growth factors and cytokines, e.g., bone morphogenetic proteins, endothelial elements, and vascular endothelial growth factor (VEGF) have been included within the porous ceramics (Lieberman et al., 2002; Holt et al., 2005; Moioli et al., 2008; Schussele et al., 2009). Modification of surface texture, which increases surface area, has also been used to enhance cell interactions with implants (Harding et al., 2005).

STRUCTURE CHARACTERIZATION OF HAP CERAMICS

The American Society for Testing of Materials (ASTM) mandates analyses of HAP ceramics and related materials. Analyses can be done by X-ray and electron diffraction, vibrational spectroscopy, electron microscopy, and NMR. Changes in the composition of bone and synthetic apatites and apatite ceramics can be detected by infrared and Raman spectroscopy (Carden and Morris, 2000; Tadic and Epple, 2004; Boskey and Mendelsohn, 2005). The FTIR (Figure A.3) and Raman (Figure A.4) spectra for the same materials analyzed by X-ray diffraction in Figure A.2 are presented. The peak assignments for these spectra are summarized in Table A.5. As in the X-ray diffraction patterns, the "gold standard" method for analyses of these materials, the peaks for the synthetic and
FIGURE A.3 Infrared spectra of (top to bottom): - poorly crystalline HAP (HAPp), bovine cortical bone (Bone), HAP ceramic, and highly crystalline HAP (HAPx).
FIGURE A.4 Raman spectra of (top to bottom): - poorly crystalline HAP (HAPp), bovine cortical bone (Bone), HAP ceramic, and highly crystalline HAP (HAPx).

bone apatites are broadened relative to the geologic apatite and the HAP ceramic. The broadening of the peaks in the vibrational spectra indicate changes in the environment of the bond being analyzed. A more ordered environment leads to a sharper line. Both the sharpening of the band at 631 cm^{-1} in the infrared and the peak area and intensity ratios of sub-bands at 1030 cm^{-1} and 1020 cm^{-1} (Gadaleta et al., 1996) have been used as a measure of crystal size and perfection (Blumenthal et al., 1975). Other peaks can be used to indicate the presence

of additional phases or impurities in the material. When the template (be it natural or a biotemplate) is included, the vibrations from organic moieties can reveal the relative content of proteins, proteoglycans, lipids, and nucleotides.

NMR spectroscopy can also be used to analyze the composition of the HAP containing tissues and synthetic

materials (Figure A.5). As in the other methods, the peaks characteristic of highly crystalline apatites are broadened due to the change in the environment of the processing nuclide. One advantage of this technology is that it can be used in real-time to monitor the mass of the implant independent of the presence of native bone (Ramanathan and Ackerman, 1999).

TEM and other high resolution microscopic tools, such as scanning electron microscopy (SEM) and atomic force microscopy (AFM) are also used to characterize bones, teeth, and the HAP ceramics. AFM is used to determine the average sizes of ceramic crystals, pore morphology, surface topology, and nanoindentation modulus (Chowdhury et al., 2005; Covani et al., 2007; Teixeira et al., 2007). TEM and SEM are used to determine the crystallite size, interaction of cells with the cements, and other morphometric features (LeGeros and LeGeros, 2008; Qian et al., 2008; Sato et al., 2008; Li et al., 2009).

STABILITY, BIOCOMPATIBILITY, AND OSTEOINTEGRATION OF HAP CERAMICS

It is highly desirable that the HAP ceramic is replaced by native tissue (bone or dentin), and the implant dissolves slowly as the new tissue forms. The relatively large crystal size, small specific surface, and low porosity of the HAP ceramics makes them relatively insoluble. Modification of any of these properties tends to increase the solubility. In general, of the calcium phosphates, at physiologic pH based on solubility products, brushite, tetracalcium phosphate, and amorphous calcium phosphate are the most soluble, followed by alpha- and beta-tricalcium phosphate and then HAP. Solubility is dependent on the solution properties (pH, buffer concentration, degree of saturation, HAP/solution ratio, temperature, etc.), as well as on the crystallite size, nature of substituents, and porosity of the cement (LeGeros and LeGeros, 2008).

The HAP ceramics dissolve when there is mineral–cell contact, due to the phagocytic capability of the bone resorbing cells, the osteoclasts (Wenisch et al., 2003), and the low pH they produce in their environment. Thus, when new bone forms within the implant, there is remodeling and replacement of the implant ceramic

FIGURE A.5 NMR spectra of highly crystalline and nanocrystalline HAP. (Courtesy of Prof. Jaeger.)

by the patient's own tissue. Factors that control implant solubility and osteoclastic activity were reviewed by Heymann et al. (1999) and Detsch et al. (2008). The problem is that most of the sintered HAP ceramics, even the porous ones, have such large crystals that they are difficult to remodel. The biphasic calcium phosphates tend to be more soluble, but are less osteoinductive. The nanocrystalline HAP materials are more soluble, and hence may be more osteogenic (Webster et al., 2000).

Excellent biocompatibility of HAP ceramics has been consistently reported in bone, soft tissues, and other organs (Okumura et al, 1984; Costantino et al., 1991; Yoshikawa and Myoui, 2005). There are, however, reports of immune response, perhaps to proteins that adhere to the ceramic particles (van der Meulen and Koerten, 1994; Otto and Ogilvie 1998; Lu et al., 2005). The immune response usually takes the form of inflammation, which has not been reported to be severe, and which subsides rapidly. The optimal ceramic implants will dissolve slowly and be replaced by native bone, thus maximizing the mechanical properties of the tissues. Osteogenic activity of the bone and tooth implant materials is their most important property. This activity is dependent on the pore size, pore structure, pore volume, and amount of pore interconnectivity. Thus, selection of the optimal HAP ceramic may involve compromise as those that are stronger are unlikely to be those that are the most porous or the most osteoconductive. The osteoconductive properties are most frequently examined with bone forming or bone resorbing cells in culture, followed by analyses in preclinical animal models.

INTRODUCTION

Aluminum oxide or alumina has been used since 1970 as a material for manufacture of components of prostheses and surgical devices. It is very inert and resistant to corrosion in an *in vivo* environment. It elicits minimal response from the tissues and remains stable for many years of service. It is found in nature as corundum in emery, topaz, and emerald, and as the precious gemstones ruby and sapphire. Commercially it is extracted from ores such as bauxite and cryolite using the Bayer process. Its most significant use is in the production of aluminum metal. Other than applications in prostheses and surgical devices, it is commonly used as an abrasive due to its hardness, and as a refractory material due to its high melting point.

PRODUCTION OF ALUMINA

Commercially, alumina is extracted from bauxite using the Bayer process. The Bayer process can be considered in three stages:

1. Extraction: The aluminum-bearing minerals in bauxite are selectively extracted from the insoluble components by dissolving them in a solution of sodium hydroxide.

$$Al(OH)_3 + Na^+ + OH^- \rightarrow Al(OH)^{4-} + Na^+$$
2. Precipitation: Crystalline aluminum trihydroxide is precipitated. This is the reverse of the extraction process, except the chemistries are well-controlled.

$$Al(OH)^{4-} + Na^+ \rightarrow Al(OH)^3 + Na^+ + OH^-$$

3. Calcination: Aluminum trihydroxyde is calcined to form alumina. The water is driven off to form alumina. This process dictates the properties of the final product.

$$2Al(OH)_3 \rightarrow Al_2O_3 + 3H_2O$$

STRUCTURE OF ALUMINA

The alumina obtained by the Bayer process is recrystallized, based on the application for which it will be used. Alumina exists in many crystal phases: α, δ, γ, η, θ, ϱ, and χ, depending on the heat-treatment conditions. However, α-alumina or corundum is most thermodynamically stable form, and hence is used as a biomaterial. It has has a rhombohedral structure (a = 4.758 Å and c = 12.991 Å) (Figure B.1). The structure of can be viewed as a hexagonal close-packed array of O$^-$ atoms with 2/3 of the octahedral sites occupied
FIGURE B.1 Crystal structure of alumina (O: aluminum; ●: oxygen).

by Al^{3+} ions. Thus, each Al^{3+} ion is bonded to six O$^-$ atoms in a distorted octahedron. Each such octahedron shares a face with one on the upper and one on the lower layers. The distortion is caused by repulsion between Al^{3+} ions in octahedra sharing the faces. Such close packing of the aluminum and oxygen atoms within this structure leads to its good mechanical and thermal properties.

PROPERTIES OF ALUMINA

α-alumina is dense (specific gravity of 3.97), nonporous, and nearly inert. It is extremely hard and scratch-resistant (9 on the Mohs scale, next only to diamond). It has excellent corrosion resistance in *in vivo* environments. The physical properties of alumina such as strength, fatigue resistance, and fracture resistance depend on the grain size, porosity, and purity. Further, alumina exhibits high surface wettability, resulting in a low coefficient of friction. These excellent wetting characteristics are due to an outer surface of alumina that adsorbs a molecular film of water and biological molecules. The low coefficient of friction and wear rates of alumina occur only when the surface roughness is less than 0.02 μm, i.e., grain size is smaller than 4 μm with a very narrow size distribution. If the surface roughness is higher than 0.02 μm, large grains can pull out and lead to very rapid wear of loadbearing surfaces. Table B.1 lists some of the mechanical properties of 99.5% pure alumina.

The porosity of the alumina can be changed by how it is processed

Two primary synthetic processes are used for the production of alumina:

1. The traditional ceramic powder process: This processing involves three basic steps: powder-processing, shape-forming, and densification, often with a final mechanical finishing step. The ceramic produced by this technique is very dense, with virtually 0% porosity.
2. The solution–gelation or "sol–gel" process: This process is primarily used for the production of porous alumina or alumina coatings with porosity up to 40%. It involves four basic steps: dispersion, gelation, drying, and firing.

TABLE B.1	Mechanical Properties of 99.5% Alumina
Density	3.97 gm/cm^3
Flexural strength	345 MPa
Elastic modulus	300 GPa
Shear modulus	124 GPa
Bulk modulus	172 GPa
Poisson's ratio	0.21
Compressive strength	2100 MPa
Hardness	1000 kg/mm^2
Fracture toughness	3.5 MPa.m$^{1/2}$

The environmental impact of alumina and alumina-based ceramics is in general negligible; however, this is not true for the processing methods. Both of the above processes can have a significant environmental impact. For the traditional ceramic powder process, the most direct environmental impact arises from the shape-forming process where various binders, solvents, and other potentially toxic agents are used. For the sol–gel process, strong acids, plasticizers, binders, and solvents are used. Depending on the firing conditions, variable amounts of organic materials such as binders and plasticizers may be released as combustion products, causing significant environmental impact.

ALUMINA AS A BIOMATERIAL

Alumina is very inert and resistant to corrosion in an *in vivo* environment (Christel, 1992). It elicits minimal response from the tissues, and remains stable for many years of service. It is not bioresorbable; hence, the body does recognize it as a foreign material and attempts to isolate it by forming a fibrous capsule around the implant. However, as soon as a device made from alumina is implanted, within minutes proteins and other biomolecules adsorb on the surface, thus protecting the implant from the body's immune system. Further, the interface between alumina and the tissue can be engineered, preventing formation of a fibrous capsule around the implant. Although alumina is biocompatible, alumina particles formed by wear of the implant can induce a considerable foreign-body reaction (Tateiwa et al., 2008).

Nanoporous alumina (Popat et al., 2005; Swan et al., 2005a,b)

Cylindrical and planar anodized alumina nanoporous templates with pore diameters ranging from 10 to 130 nm can be fabricated using dilute solutions of either sulfuric or oxalic acid with anodizing voltages of approximately 8 V to 100 V. Pore length is determined by the thickness of the resultant alumina layer, and can vary from nanometers to several tens of microns. A two-step anodization process is used to ensure high pore uniformity. The aluminum substrate is first anodized in an oxalic or sulfuric acid solution. The anodization is stopped after consuming a few microns of aluminum, and the porous alumina film is removed through etching. The etchant, a mixture of chromic acid and phosphoric acid, is highly selective attacking alumina much faster than aluminum. The remaining aluminum is dimpled, with the dimples serving as a uniform seed layer upon which a highly uniform porous layer can then be achieved through a second anodization step. The exact pore size and pore structure is determined in this second anodization through control of the anodizing voltage. The pore diameter increases with anodization voltage, at ≈1.29 nm/volt. Constant anodizing voltages result in straight uniform pores, while step-wise changes in the anodizing voltage can be used to introduce branching channels with smaller diameters, enabling fabrication of a nanoscale tree-like structure. Such nanoporous templates can either be used as coatings for orthopedic implants to enhance osseointegration or as membranes for protein or virus separation (Figure B.2).

ALUMINA IN JOINT REPLACEMENTS

In the 1970s it was first realized that the properties of alumina ceramics could be exploited to provide better implants for orthopedic applications. Since then, alumina has often been used for wear surfaces in joint replacement prostheses due to its excellent wear resistance and ability to create smooth and polished surfaces. Typically, alumina is used to fabricate femoral heads for hip replacement implants and wear plates for knee replacement implants. To date more than 2.5 million alumina femoral heads have been implanted (Lang et al., 2008). Figure B.3 shows a schematic of total hip replacement and knee replacement implants. In hip replacements, the alumina femoral head is used in conjunction with a metallic femoral stem and an acetabular cup made from ultra-high molecular weight polyethylene (UHMWPE) or alumina for the opposing articulating surface. The success of such joint replacement implants depends on two factors:

1. The frictional and wear behavior of materials;
2. The reliability of the anchorage of the implant to the natural tissue.

Studies have shown that wear rates for alumina on UHMWPE are almost 20 times lower than those for metal on UHMWPE, resulting in less debris formation (Andreiotelli et al., 2009). Wear debris leads to complicated conditions such as osteolysis, resulting in long-term failure of the implants. An alumina–alumina ceramic bearing couple is superior to alumina–UHMWPE or metal, resulting in better wear resistance and preventing the inflammatory response elicited by polyethylene particles. Further, studies have also shown that ceramic debris is less inflammatory than that from UHMWPE. Fracture rates of alumina heads range between 0% for ceramics manufactured after 1990 and 13.4% for ceramics manufactured before 1990. The high fracture rates for alumina heads prior to 1990 were caused as low-density alumina with a very coarse microstructure was used. Over the years, material scientists have substantially improved the fabrication strategies of alumina, thus resulting in improved mechanical strength. The current generation is an alumina that is hot isostatic pressed,
FIGURE B.2 Nanoporous alumina fabricated using the anodization process (left and center). Osteoblast interaction with the nanoporous architecture (right).

FIGURE B.3 Total hip replacement (left) and total knee replacement (right) implants.

laser marked, and proof tested. This material has been on the market since 1994. The fracture rate for femoral heads is 0.004%. In total knee replacements, alumina is used in portions that come in contact with bone, and a combination of alumina and UHMWPE is used in sliding portions. In such implants, problems caused by polyethylene debris are much more severe than in hip implants (Figure B.3).

Alumina is not the optimal material for orthopedic applications. The Young's modulus for medical grade alumina is 380–420 GPa. This is much higher than that of cancellous bone (0.05–0.5 GPa) or cortical bone (7–25 GPa) (Young's modulus also depends on the age of the person, and the location of the bone tissue in the body). Thus, there is a mismatch in the mechanical properties of bone and alumina. Alumina implant will shield the bone from any mechanical loading, and the entire load will be carried by the implant. This mechanical shielding will result in compressive stresses on the bone, leading to resorption and weakening of the bone which will eventually result in failure of the implant.

ALUMINA IN BONE SPACERS

Alumina with more than 30% porosity can be used as bone spacers to replace sections of bone that have been removed due to cancer or traumatic injury (Huckstep, 1987). Bone spacers are inserted in natural tissue using metallic pins. The interconnected porous nature of the implant allows for bone cell infiltration into the implant,

FIGURE B.4 Ceramic dental implants.

eventually resulting in new bone formation. Typical pore sizes are greater than 100 μm. This will not only allow the new bone to grow, but will also encourage vascularization. Porous alumina is fabricated using either the sol–gel process or a hydrothermal exchange process in which microstructures of certain corals are used to cast the interconnected porous network. Porous alumina is weaker than the dense form of alumina, with its strength decreasing with increase in porosity.

ALUMINA IN DENTAL APPLICATIONS

Dense alumina has been used in dental applications, specifically for replacement of teeth (Figure B.4). Single crystal alumina is used for dental implants, since polycrystalline alumina can be fractured while inserting the implant in the dental root. Single crystal alumina has a higher bending strength (13,000 kg/cm^2) compared to that of polycrystalline alumina (3500 kg/cm^2). Typically, dental implants are made of single crystal alumina cylindrical core around which polycrystalline alumina is fused. There are several disadvantages of alumina dental implants. They have a high modulus of elasticity

compared to the native tissue, and cannot bend like metal implants. Thus, alumina dental implants are currently declining in popularity and being replaced by material such as dental porcelain (Della Bona and Kelly, 2008).

OTHER APPLICATIONS OF ALUMINA

Apart from joint replacements, bone spacers, and dental implants, alumina has been used for ENT applications and in maxillo-facial surgery. Alumina implants have also been used for neurosurgical operations such as cranioplasty (Kobayashi et al., 1987). Alumina has also been used in keratoprostheses (corneal replacement) (Polack and Heimke, 1980). Porous alumina has also been used for controlled delivery of hormones, vaccines, and drugs over long periods of time.

ALUMINA MATRIX COMPOSITES

Alumina matrix composites are composed of alumina, which represents 82% of the volume of the overall material. Nanoparticles of zirconium oxide (zirconia) are added to the alumina matrix and represent 17% of the volume (Cavalcanti et al., 2009). These particles are stabilized in the tetragonal phase, since it provides the best mechanical performance. The composites are reinforced in three different forms:

1. *In situ* formation of elongated crystals of strontium oxide in the alumina matrix, deflecting any subcritical cracks;
2. The addition of homogeneously dispersed small zirconia particles in the alumina matrix, creating a transformation toughening;
3. The creation of a solid solution of alumina with chromium oxide, resulting in increased hardness.

The US FDA has approved alumina matrix composites for use in ball heads of implant as a replacement for UHMWPE. The first clinical trials were performed in 2000, since then more than 65,000 ball heads have been implanted all over the world.

CONCLUSION

Alumina is very inert and resistant to corrosion in an *in vivo* environment. It elicits minimal response from the tissues, and remains stable for many years of service. Most of the alumina used for implant applications is polycrystalline, although some dental implants are single crystal. It is widely used in loadbearing applications due to its excellent biocompatibility, corrosion resistance, high wear resistance, and high compressive strength. Further, alumina has the tribological properties most suitable for articulating surfaces in orthopedic implants. However, high elastic modulus, slow crack growth, cyclic failure, low toughness, and sensitivity to tensile strength are some of the concerns for high loadbearing applications. The recent development

FIGURE B.5 BIOLOX®* delta ceramic femoral head.

of alumina matrix ceramics may extend the implant life beyond the current 10–12 years. It is expected that the use of alumina will continue to grow in orthopedic, dental, and maxillo-facial applications in the near future.

BIOLOX®* Delta Ceramic Femoral Head

The new alumina matrix composite, BIOLOX® delta developed by CeramTec AG, is used by Zimmer Inc. to fabricate femoral heads. This composite has excellent biocompatibility, low wear rates, high hardness, and is very stable in *in vivo*-like environments. The implant made from this composite meets the increasing demands of development of a durable implant for young and active patients. The heads fabricated from this ceramic have improved mechanical properties compared to standard alumina heads. The composite consists of about 75% alumina, 24% zirconia, and 1% chromium oxide. Alumina provides the hardness and the wear resistance, while zirconia along with chromium oxide provides improved mechanical properties. The pink color of the implant is also derived from chromium oxide (Figure B.5).

CHAPTER I.2.5 HYDROGELS

Nicholas A. Peppas[1] and Allan S. Hoffman[2]
[1]Chemical Engineering Department, University of Texas, Austin, TX, USA
[2]Professor of Bioengineering and Chemical Engineering, UWEB Investigator, University of Washington, Seattle, WA, USA

INTRODUCTION

Hydrogels have received significant attention because of their high water contents and related potential for many biomedical applications. Hydrogels are polymeric structures held together as water-swollen gels by: (1) primary covalent cross-links; (2) ionic forces; (3) hydrogen bonds; (4) affinity or "bio-recognition" interactions; (5) hydrophobic interactions; (6) polymer crystallites; (7) physical entanglements of individual polymer chains; or (8) a combination of two or more of the above interactions. The classic book by Andrade (1976) offers some of the best work that was available prior to 1975 (e.g., Ratner and Hoffman, 1976). Since then, numerous reviews and several books have addressed the preparation, structure, characterization, and applications of hydrogels (e.g., Peppas 1987, 2001; Brannon-Peppas and Harland, 1990; Lee and Mooney, 2001; Qiu and Park, 2001; Hennink and van Nostrum, 2002; Jeong et al., 2002; Miyata et al., 2002; Drury and Mooney, 2003; Patterson et al., 2010). In this chapter we focus on the preparation and characterization of the structure, and chemical and physical properties of *synthetic* hydrogels. Many natural polymers such as collagen, gelatin, fibrin, hyaluronic acid, heparin, alginates, pectins, chitosan, and others can be used to form hydrogels, and some of these gels have been used in biomedical applications. Details on these types of materials can be found throughout this textbook in other chapters.

CLASSIFICATION AND BASIC STRUCTURES OF HYDROGELS

Depending on their method of preparation, ionic charge, or physical structure features, hydrogels may be classified in several categories. Based on the method of preparation, they may be: (1) *homopolymer hydrogels*; (2) *copolymer hydrogels*; (3) *multi-polymer hydrogels*; and (4) *interpenetrating network* (IPN) *hydrogels*. *Homopolymer hydrogels* are cross-linked networks of one type of hydrophilic monomer unit, whereas *copolymer hydrogels* are produced by cross-linking of chains composed of two comonomer units, at least one of which must be hydrophilic to render them water swellable. *Multi-polymer hydrogels* are produced from three or more comonomers reacting together (e.g., Lowman and Peppas, 1997 and 1999). Finally, *interpenetrating network* (IPN) *hydrogels* are produced by two methods, one within a pre-formed network and the other in solution; the most common method is to polymerize one monomer within a different cross-linked hydrogel network. The monomer polymerizes to form a polymer or a second cross-linked network that is intermeshed with the first network.

There are several other ways that hydrogels may be classified. *Ionic hydrogels*, with ionic charges on the backbone polymers, may be classified as: (1) *neutral hydrogels* (uncharged); (2) *anionic hydrogels* (having negative charges only); (3) *cationic hydrogels* (having positive charges only); or (4) *ampholytic hydrogels* (having both positive and negative charges). These last gels may end up with a net negative, positive or neutral charge.

Based on physico-chemical structural features of the network, hydrogels may also be classified as: (1) *amorphous hydrogels* (having covalent cross-links); or (2) *semi-crystalline hydrogels* (may or may not have covalent cross-links). In amorphous hydrogels, the macromolecular chains are arranged randomly. Semi-crystalline hydrogels are characterized by self-assembled regions of ordered macromolecular chains (crystallites).

Another type of classification of hydrogels includes the "*complexation*" *hydrogels*, which are held together by specific types of secondary forces. These include hydrogen bonds, hydrophobic group associations, and affinity "complexes" (e.g., (1) hetero-dimers (peptide/peptide interactions called "coil–coil"); (2) biotin/streptavidin; (3) antibody/antigen; (4) conA/glucose; (5) poly(D-lactic acid)/poly(L-lactic acid) (PDLA/PLLA) stereo-complexes; and (6) cyclodextrin (CD) inclusion complexes). The physical properties of the gels held together by such secondary associations are critically dependent on the network density of these interactions, as well as on the many environmental conditions that can affect them. Hydrogels may also be classified as stable or degradable, with the latter further categorized as hydrolytically or enzymatically degradable.

Structural evaluation of hydrogels reveals that ideal networks are only rarely observed. Figure I.2.5.1a shows an ideal macromolecular network (hydrogel) indicating tetra-functional cross-links (junctions) produced by covalent bonds. However, in real networks it is possible to encounter multi-functional junctions (Figure I.2.5.1b) or physical molecular entanglements (Figure I.2.5.1c) playing the role of semi-permanent junctions. Hydrogels with molecular defects are always possible. Figures I.2.5.1d and I.2.5.1e indicate two such effects: unreacted functionalities with partial entanglements (Figure I.2.5.1d) and chain loops (Figure I.2.5.1e).

The terms "cross-link," "junction" or "tie-point" (shown by an open circle symbol in Figure I.2.5.1d) indicate the covalent or secondary connection points of several chains. In the case of covalent linkages, these junctions may be carbon atoms, but they are usually small chemical bridges (e.g., an acetal bridge in cross-linked poly(vinyl alcohol), or an ethylene glycol diester bridge in the polyHEMA contact lens gel) with molecular weights much smaller than those of the cross-linked

polymer chains. In other situations, a junction may be crystallites or other secondary interactions, such as described above, of a permanent or semi-permanent nature. Thus, in reality, the junctions should never be considered as points without volume, which is the usual assumption made when developing theoretical models for prediction of the properties of cross-linked hydrogels (Flory, 1953). Instead, they have a finite size and contribute to the physical properties during biomedical applications.

SYNTHESIS OF HYDROGELS

Covalently cross-linked hydrogels are usually prepared by bringing together small multi-functional molecules such as monomers and oligomers, and reacting to form a network structure. Sometimes large polymer molecules may be cross-linked with the same small multi-functional molecules. Such cross-linking may be achieved by reaction of two chemical groups on two different molecules, which can be initiated by catalysts, by photo-polymerization or by radiation cross-linking (see reviews by Peppas et al. 2000; Hoffman, 2002; Ottenbrite et al., 2010; Jin & Dijkstra, 2010).

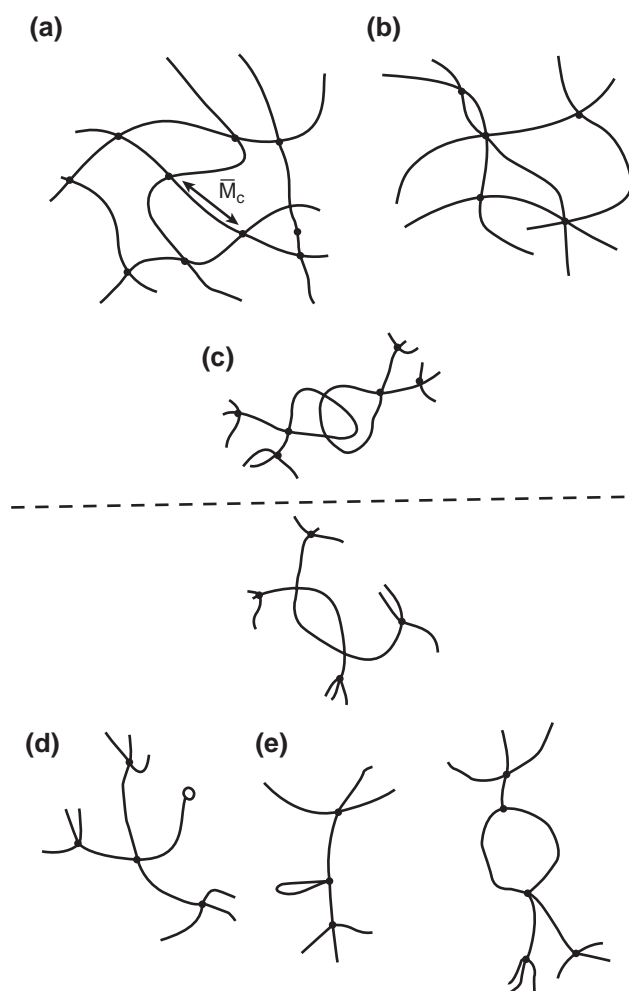
Several methods for forming cross-linked hydrogels are based on free radical reactions. The first involves a copolymerization-cross-linking reaction between one or more monomers and one multi-functional monomer that are present in relatively small quantities. In a related method, two water-soluble polymers may be cross-linked together by formation of free radicals on both polymer molecules, which combine to form the cross-link (Figure I.2.5.2). These reactions are free radical polymerization or cross-linking reactions, and such processes for synthesis of cross-linked hydrogels can be initiated by decomposition of peroxides or azo compounds, or by using ionizing radiation or UV light. Ionizing radiation methods utilize electron beams, gamma rays or X-rays to excite a polymer and produce a cross-linked structure via free radical reactions (e.g., Chapiro, 1962). Such free radical reactions can lead to rapid formation of a three-dimensional network, and are usually carried out


FIGURE I.2.5.1 (a) Ideal macromolecular network of a hydrogel; (b) Network with multifunctional junctions; (c) Physical entanglements in a hydrogel; (d) Unreacted functionality in a hydrogel; (e) Chain loops in a hydrogel.
FIGURE I.2.5.2 Synthesis of hydrogels by free radical polymerization reactions and cross-linking reactions. (Hoffman, 2002.)

in the absence of oxygen or air (note: some polymers are degraded by radiation, especially in air).

In another method, chemical cross-linking calls for direct reaction of a linear or branched polymer with a di-functional or multi-functional, small molecular weight, cross-linking agent. This agent usually links two longer molecular weight chains through its di- or multi-functional groups (Figure I.2.5.3a). There are a number of well-known reactions that can be used for linking hydrophilic polymers together with each other or with cross-linkers to form hydrogels, including some recent methods with growing popularity, such as the Michael addition of dithiol compounds with divinyl compounds (e.g., see Schoenmakers et al., 2004; van de Wetering et al., 2005) and the reaction of alkynes plus azides to form triazoles (Click reaction; see Kolb et al., 2001). The reader is referred to the excellent, comprehensive book detailing such chemistries, *Bioconjugate Techniques* (Hermanson, 2008).

A similar method involves the reaction of a small bi-functional molecule and linear polymeric chains having pendant or terminal reactive groups such as $-OH$, $-NH_2$, NCO, or $-COOH$ that are cross-linked by the bi-functional molecule (Figure I.2.5.3b). Natural polymers such as proteins can also be cross-linked in a similar way by using enzymes. For example, transglutaminase catalyses the reaction of protein glutamine amide groups with lysine amino groups (or with pendant or terminal amine groups on a synthetic polymer backbone) (Sperinde and Griffith, 1997 and 2000). This reaction is:

$$- (CH_2)_3 - \textbf{CONH}_2 + - (CH_2)_4 - NH_2 + transglutaminase \rightarrow$$
$$- (CH_2)_3 - \textbf{CONH} - (CH_2)_4 - \; + NH_3$$

Hydrogel Network

FIGURE I.2.5.3 (a) Synthesis of hydrogels by cross-linking reactive polymers with multi-functional cross-linkers. (Hoffman, 2002.) (b) Synthesis of hydrogels by cross-linking of multi-functional polymers with small bi-functional molecules. (Hoffman, 2002.)

In another enzyme-catalysed cross-linking reaction, hydroxyphenylpropionic acid (tyramine) was conjugated to gelatin and cross-linked to form a hydrogel by the horseradish peroxidase (HRP)-catalysed oxidation reaction with hydrogen peroxide (H_2O_2) (Wang et al., 2010; Jin and Dijkstra, 2010).

Formation of hydrogel networks may also result from physico-chemical interactions, and some examples are highlighted below.

Poly(ethylene glycol) (PEG) molecules or block polymers containing PEG can "thread" through cyclodextrins (CDs), and sequences of CDs threaded on different PEG molecules can then self-associate, helping to hold together the hydrogel that is formed (Harada et al., 1992; Li et al., 2001, 2003a,b, 2006). Hetero-dimer peptide sequences that are conjugated as pendant groups on different polymer chains can complex together in "coil–coil" associations, and thereby "tie" chains together to form hydrogels (Yang et al., 2006; Xu and Kopecek, 2008). Stereo-complexes can form between D and L forms of poly(lactic acid) (known as PDLA/PLLA stereo-complexes); this complexation can lead to hydrogel formation if block copolymers that contain both PDLA and PLLA blocks, along with hydrophilic blocks as PEG are mixed together (Jin and Dijkstra, 2010).

Figure I.2.5.4 shows the formation of interpenetrating network (IPN) hydrogels. Figure I.2.5.5 shows how hydrogels can be formed by ionic interactions. Figures I.2.5.6a and I.2.5.6b show how hydrogels can be formed by affinity recognition reactions (see also Miyata, 2010, for more on formation of affinity recognition hydrogels).

SWELLING BEHAVIOR OF HYDROGELS

The physical behavior of biomedical hydrogels is dependent on their dynamic swelling and equilibrium in water and in aqueous solutions. Much of the water within swollen hydrogels may be bound to the polymer chains by either polar or hydrophobic interactions (e.g., Ilavsky, 1982). Many solutes can diffuse into and through hydrogels only within unbound or "free" water channels. Solutes that are chaotropic may diffuse into and through hydrogels by destructuring such bound water layers around the polymer chains.

The Flory–Huggins theory is an ideal thermodynamic description of polymer solutions, and it does not consider network imperfections or the real, finite volumes of network chains and cross-links, and in the case of aqueous solutions it does not consider the presence of "bound" (versus "free") water around the network chains. It can be used to calculate thermodynamic quantities related to that mixing process. Flory (1953) developed the initial theory of the swelling of cross-linked polymer gels using a Gaussian distribution of the polymer chains. His model describing the equilibrium degree of cross-linked polymers postulated that the degree to which a polymer network swelled was governed by the elastic retractive
FIGURE I.2.5.4 Two methods for formation of an interpenetrating network (IPN) hydrogel. (Hoffman, 2002.)

forces of the polymer chains and the thermodynamic compatibility of the polymer and the solvent molecules. In terms of the free energy of the system, the total free energy change upon swelling was written as:

$$\Delta G = \Delta G_{elastic} + \Delta G_{mix} \qquad (1)$$

Here, $\Delta G_{elastic}$ is the contribution due to the elastic retractive forces and ΔG_{mix} represents the thermodynamic compatibility of the polymer and the swelling agent (water).

Upon differentiation of Equation (1) with respect to the water molecules in the system, an expression can be derived for the chemical potential change of water in terms of the elastic and mixing contributions due to swelling.

$$\mu_1 - \mu_{1,0} = \Delta \mu_{elastic} + \Delta \mu_{mix} \qquad (2)$$

Here, μ_1 is the chemical potential of water within the gel and $\mu_{1,0}$ is the chemical potential of pure water.

At equilibrium, the chemical potentials of water inside and outside of the gel must be equal. Therefore, the elastic and mixing contributions to the chemical potential will balance one another at equilibrium. The chemical potential change upon mixing can be determined from the heat of mixing and the entropy of mixing. Using the

Flory–Huggins theory, the chemical potential of mixing can be expressed as:

$$\Delta\mu_{mix} = RT\left(\ln(1 - v_{2,s}) + v_{2,s} + \chi_1 v_{2,s}^2\right) \tag{3}$$

where χ_1 is the polymer–water interaction parameter, $v_{2,s}$ is the polymer volume fraction of the gel, T is absolute temperature, and R is the gas constant.

This thermodynamic swelling contribution is counterbalanced by the retractive elastic contribution of the cross-linked structure. The latter is usually described by the rubber elasticity theory and its variations (Peppas, 1987). Equilibrium is attained in a particular solvent at a particular temperature when the two forces become equal. The volume degree of swelling, Q (i.e., the ratio of the actual volume of a sample in the swollen state divided by its volume in the dry state) can then be determined from Equation (4).

$$v_{2,s} = \frac{volume\ of\ polymer}{volume\ of\ swollen\ gel} = \frac{V_p}{V_{gel}} = 1/Q \tag{4}$$

Researchers working with hydrogels for biomedical applications prefer to use other parameters in order to define the equilibrium-swelling behavior. For example, Yasuda et al. (1969) introduced the use of the so-called hydration ratio, H, which has been accepted by those researchers who use hydrogels for contact lens applications (Peppas and Yang, 1981). Another definition is that of the weight degree of swelling, q, which is the ratio of the weight of the swollen sample over that of the dry sample.

In general, highly water-swollen hydrogels include those of cellulose derivatives, poly(vinyl alcohol), poly(N-vinyl 2-pyrrolidone) (PNVP), and poly(ethylene glycol), among others. Moderately and poorly swollen hydrogels are those of poly(hydroxyethyl methacrylate) (PHEMA) and many of its copolymers. In general, a basic hydrophilic monomer can be copolymerized with other more or less hydrophilic monomers to achieve desired swelling properties. Such processes have led to a wide range of swellable hydrogels, as Gregonis et al. (1976), Peppas (1987, 1997), and others have noted. Park and coworkers have developed a family of high water content, rapid swelling hydrogels (Omidian and Park, 2010) and superabsorbent hydrogels (Mun et al., 2010). Knowledge of the swelling characteristics of a polymer is of utmost importance in biomedical and pharmaceutical applications since the equilibrium degree of swelling influences: (1) the solute diffusion coefficient through these hydrogels; (2) the surface properties and surface molecule mobility; (3) the optical properties, especially in relation to contact lens applications; and (4) the mechanical properties.

DETERMINATION OF STRUCTURAL CHARACTERISTICS

The parameter that describes the basic structure of the hydrogel is the molecular weight between cross-links, $\overline{M}_c$ (as shown in Figure I.2.5.1a). This parameter defines the

average molecular size between two consecutive junctions regardless of the nature of those junctions and can be calculated by Equation (5).

$$\frac{1}{\overline{M}_c} = \frac{2}{\overline{M}_n} - \frac{(v/V_1)\left[\ln(1 - v_{2,s}) + v_{2,s} + \chi_1 v_{2,s}^2\right]}{\left(v_{2,s}^{1/3} - \frac{v_{2,s}}{2}\right)} \tag{5}$$

An additional parameter of importance in structural analysis of hydrogels is the cross-linking density, ρ_x, which is defined by Equation (6).

$$\rho_x = \frac{1}{\overline{v}\overline{M}_c} \tag{6}$$

In these equations, v is the specific volume of the polymer (i.e., the reciprocal of the amorphous density of the polymer), and $\overline{M}_n$ is the initial molecular weight of the uncross-linked polymer.

BIOMEDICAL HYDROGELS

Acrylic Hydrogels

Hydrogels with desired physical or chemical properties for a specific biomedical application may be "molecularly engineered" by choosing among the many types of acrylic monomers and cross-linkers available. This has led to many publications, describing a large family of acrylic hydrogels (e.g., Peppas et al., 2000; Peppas, 2001; Ottenbrite et al., 2010).

The most widely used hydrogel is water-swollen, cross-linked PHEMA, which was introduced as a biological material by Wichterle and Lim (1960). The hydrogel is inert to normal biological processes, shows resistance to degradation, is permeable to metabolites, is not absorbed by the body, is biocompatible, withstands heat sterilization without damage, and can be prepared in a variety of shapes and forms. The swelling, mechanical, diffusional, and biomedical characteristics of PHEMA gels have been studied extensively. The properties of these hydrogels are dependent upon their method of preparation, polymer volume fraction, degree of cross-linking, temperature, and swelling agent (Michalek et al., 2010).

Other acrylic hydrogels of biomedical interest include polyacrylamides and their derivatives. Tanaka (1979) has done extensive studies on the abrupt swelling and de-swelling of partially hydrolyzed acrylamide gels with changes in swelling agent composition, curing time, degree of cross-linking, degree of hydrolysis, and temperature. These studies have shown that the ionic groups produced in an acrylamide gel upon hydrolysis give the gel a structure that shows a discrete transition in equilibrium-swollen volume with environmental changes.

Discontinuous swelling in partially hydrolyzed polyacrylamide gels has been studied by Gehrke et al. (1986). Copolymers of HEMA and acrylamides with methacrylic

acid (MAA) and methyl methacrylate (MMA) have proven useful as hydrogels in biomedical applications (see below).

Small amounts of MAA as a comonomer have been shown to dramatically increase the swelling of PHEMA polymers. Owing to the hydrophobic nature of MMA, copolymers of MMA and HEMA have a lower degree of swelling than pure PHEMA (Brannon-Peppas and Peppas, 1991a). One particularly interesting IPN is the double network (DN) hydrogel of Gong and Murosaki (Murosaki and Gong, 2010). These DN hydrogels are composed of two interpenetrating cross-linked networks of PAAm and PAMPS, and exhibit the unusual combination of exceptionally strong mechanical properties and high water contents. All of these materials have potential uses in advanced technology applications, including biomedical separations, drug delivery devices, and as scaffolds for tissue engineering.

Poly(vinyl alcohol) (PVA) Hydrogels

Another hydrophilic polymer that has received much attention is poly(vinyl alcohol). This material holds great promise as a biological drug delivery matrix because it is non-toxic. Two methods exist for the preparation of PVA gels. In the first method, linear PVA chains are cross-linked using glyoxal, glutaraldehyde or borate. In the second method, semi-crystalline gels are prepared by exposing aqueous solutions of PVA to repeated freezing and thawing (Peppas and Hassan, 2000). The freezing and thawing induces crystal formation in the materials and allows for the formation of a network structure cross-linked with the quasi-permanent crystallites. The latter method is the preferred method for preparation as it allows for the formation of a "pure" network without the need to add cross-linking agents. Ficek and Peppas (1993) used PVA gels for the release of bovine serum albumin using novel PVA microparticles.

Poly(ethylene glycol) (PEG) Hydrogels

Hydrogels of poly(ethylene oxide) (PEO) and poly(ethylene glycol) (PEG) have received increasing attention recently for biomedical applications because of the non-toxic behavior of PEG, and its wide use in PEGylation of nanoscale drug carriers (e.g., Graham, 1992; Harris, 1992; Griffith and Lopina, 1995; Kofinas et al., 1996; Lee and He, 2010; Oishi and Nagasaki, 2010).

Three major techniques exist for the preparation of PEG networks: (1) chemical cross-linking between PEG chains, such as reaction of di-functional PEGs and multi-functional cross-linking agents; (2) radiation cross-linking of PEG chains to each other; and (3) physical interactions of hydrophobic blocks of triblock copolymers containing both hydrophobic blocks and PEG blocks (e.g., see Jeong et al., 2002, and Lee and He, 2010 for detailed discussion of pioneering work by S.W. Kim and co-workers on such block copolymer hydrogels. See also discussions of PEG hydrogels in the sections on Degradable Hydrogels and Temperature-Sensitive Hydrogels in this chapter.)

The advantage of using radiation-cross-linked PEG networks is that no toxic cross-linking agents are required. However, it is difficult to control the network structure of these materials. Stringer and Peppas (1996) prepared PEG hydrogels by radiation cross-linking. In this work, they analyzed the network structure in detail. Additionally, they investigated the diffusional behavior of smaller molecular weight drugs, such as theophylline, in these gels. Kofinas et al. (1996) have prepared PEG hydrogels by a similar technique. In this work, they studied the diffusional behavior of various macromolecules in these gels. They noted an interesting, yet previously unreported, dependence between the cross-link density and protein diffusion coefficient, and the initial molecular weight of the linear PEGs.

Lowman et al. (1997) described a method for the preparation of PEG gels with controllable structures. In this work, highly cross-linked and tethered PEG gels were prepared from PEG-dimethacrylates and PEG-monomethacrylates. The diffusional behavior of diltiazem and theophylline in these networks was studied. The technique described in this work has been used for the development of a new class of functionalized PEG-containing gels that are used for a variety of drug release applications.

Degradable Hydrogels

Hydrogels may degrade and dissolve by either of two mechanisms: hydrolysis or enzymolysis of main chain, side chain, or cross-linker bonds (e.g., Gombotz and Pettit, 1995). Degradable hydrogels have mainly been designed and synthesized for applications in drug delivery and, more recently, as tissue engineering scaffolds (e.g., Park, 1993; Atzet et al., 2008; Garcia et al., 2010).

Hydrolytically degradable hydrogels have been synthesized from triblock copolymers of A–B–A structure that form hydrogels held together by hydrophobic forces, where A (or B) may be PLA, PLGA or other hydrophobic polyesters that form hydrophobic blocks, and B (or A) is PEG, a hydrophilic block. These polyester hydrogels degrade into natural, endogenous metabolites such as lactic or glycolic acids, and the PEG block is then excreted through the kidneys (e.g., Lee and He, 2010; Jeong et al., 2002). A variation of this type of degradable hydrogel is formed by an A–B–A triblock copolymer composed of PEG-degradable polyester-PEG blocks mixed with cyclodextrin (CD) molecules, which thread onto the PEG blocks, after which the CDs self-assemble, forming the hydrogel (e.g., see the work of

Harada et al., 1992; Li et al., 2001, 2003(a,b), 2006; Li, 2009).

Polymerizable, cross-linked and degradable PEG gels have been prepared from acrylate- or methacrylate-terminated block copolymers that include PEG as a hydrophilic block (see the work of Hubbell and co-workers, e.g., Sawhney et al., 1993; Schoenmakers et al., 2004; van de Wetering et al., 2005; Lutolf and Hubbell, 2005; Raeber et al., 2005; Patterson et al., 2010; Patterson and Hubbell, 2010). These gels may have the simple A–B–A triblock structure of (methacrylate)–PEG–methacrylate which is photo-polymerized and later degrades by hydrolysis of the ester bonds linking PEG to the methacrylate cross-links. Another gel was formed with a more elaborate structure, (methacrylate–oligolactide–PEG–oligolactide–methacrylate), which is photo-polymerized, and later degrades and dissolves mainly by hydrolysis of the PLA in the main chains (see also Atzet et al., 2008; Kloxin et al., 2009). A third type of PEG gel may include a fibrin peptide cross-linking block, where the peptide is sequenced from fibrin that is a substrate for a naturally-occuring, fibrinolytic enzyme. The peptide block reacts by thiol addition of HS–peptide–SH to the acrylate vinyl groups, cross-linking the (acrylate)–PEG–acrylate triblock, to form: {–peptide–S–acrylate–PEG–acrylate–S–peptide–}, which then degrades and dissolves by proteolysis of the peptide by a natural, endogenous fibrinolytic enzyme.

Star Polymer and Dendrimer Hydrogels

Dendrimers and star polymers (Dvornik and Tomalia, 1996; Oral and Peppas, 2004) are exciting new materials because of the large number of functional groups available in a very small molecular volume. Such systems could have great promise in drug targeting applications. In 1993 Merrill published an exceptional review of PEO star polymers and applications of such systems in the biomedical and pharmaceutical fields. Griffith and Lopina (1995) prepared gels of controlled structure and large biological functionality by irradiation of PEO star polymers. Such structures could have particularly promising drug delivery applications when combined with emerging new technologies such as molecular imprinting.

Self-Assembled Hydrogel Structures

Recently there have been new, creative methods of preparation of novel hydrophilic polymers and hydrogels that may have significant drug delivery applications in the future (e.g., Li et al., 2001, 2003(a,b); Yang et al., 2006; Jin and Dijkstra, 2010; Wang et al., 2010; Miyata, 2010). In one unusual example, Stupp et al. (1997) synthesized self-assembled triblock copolymer nanogels having well-defined molecular architectures.

Hydrogels usually exhibit swelling behavior dependent on the external environment. Over the last 30 years there has been a significant interest in the development and analysis of environmentally-responsive hydrogels. These types of gels show large and significant changes in their swelling ratio due to small changes in environmental conditions, such as pH, temperature, ionic strength, nature and composition of the swelling agent (including affinity solutes), light (visible versus UV), electrical, and magnetic stimuli (e.g., Peppas, 1991, 1993; Hoffman, 1997; Hoffman et al. 2000; Yoshida and Okano, 2010). In most responsive networks, a critical point exists at which this transition occurs. These gels are sometimes referred to as "smart" or "intelligent" hydrogels.

"SMART" OR "INTELLIGENT," STIMULI-RESPONSIVE HYDROGELS AND THEIR APPLICATIONS

An interesting characteristic of numerous stimuli-responsive "smart" gels is that the mechanism causing the network structural changes can be entirely reversible in nature. The ability of pH- or temperature-responsive gels to exhibit rapid changes in their swelling behavior and pore structure in response to changes in environmental conditions lends these materials favorable characteristics as carriers for delivery of drugs, including peptides and proteins. This type of behavior may also allow these materials to serve as self-regulated, pulsatile or oscillating drug delivery systems (Yoshida and Okano, 2010).

pH-Sensitive Hydrogels

One of the most widely studied types of physiologically-responsive hydrogels is pH-responsive hydrogels. These hydrogels are swollen ionic networks containing either acidic or basic pendant groups. In aqueous media of appropriate pH and ionic strength, the pendant groups can ionize and develop fixed charges on the gel, leading to rapid swelling. All ionic hydrogels exhibit both pH and ionic strength sensitivity, especially around the pK of the pH-sensitive group. These gels typically contain ionizable pendant groups such as carboxylic acids or amine groups. The most commonly studied ionic polymers include poly(acrylic acid) (PAA), poly(methacrylic acid) (PMAA), poly(diethylaminoethyl methacrylate) (PDEAEMA), and poly(dimethylaminoethyl methacrylate) (PDMAEMA). The swelling and drug delivery characteristics of anionic copolymers of PMAA and PHEMA (PHEMA–co–MAA) have been investigated. In acidic media, the gels did not swell significantly; however, in neutral or basic media, the gels swelled to a high degree due to ionization of the pendant acid group (this is similar behavior to that of polymers used as enteric coatings). Brannon-Peppas and Peppas (1991b) have also studied the oscillatory swelling behavior of these gels.

One interesting example of pH-responsive "smart" polymers with great sensitivity to pK is the behavior of two poly(alkylacrylic acids): poly(ethylacrylic acid) (PEAA) (Tirrell et al., 1985) and poly(propylacrylic acid) (PPAA) (Cheung et al., 2001). These polymers phase separate sharply as pH is lowered below their pK, and this can lead to lipid bilayer membrane disruption in acidic liposome solutions or within the acidic environments of endosomes and lysosomes of cells, where the membranes of those vesicles contain proton pumps. This behavior makes such polymers very useful for endosomal escape and cytosolic delivery of biomolecular drugs such as protein and nucleic acid drugs (Stayton and Hoffman, 2008).

The swelling forces developed in pH-responsive gels are significantly increased over non-ionic hydrogels. This increase in swelling is due to the presence of mobile counter-ions (such as Na^+) that electrostatically balance the fixed charges on the polymer backbone. The concentration of such counter-ions will be dependent on the concentration of the fixed polymer charges, which in turn will be dependent on the composition of the network polymer and the pH. As a result, the water content and mesh size of an ionic polymeric network can change significantly with small changes in pH, as the osmotic pressure of the counter-ions within the gel changes.

pH-Responsive Complexation Hydrogels

Another promising class of hydrogels that exhibit responsive behavior is complexing hydrogels. Bell and Peppas (1995) have discussed a class of graft copolymer gels of PMAAc grafted with PEG: poly(MAAc–g–EG). These gels exhibited pH-dependent swelling behavior due to the presence of acidic pendant groups and the formation of interpolymer H-bonded complexes at low pH between the ether groups on the graft chains and protonated pendant groups. In these covalently cross-linked, complexing poly(MAA–g–EG) hydrogels, complexation resulted in the formation of temporary physical cross-links due to hydrogen bonding between the PEG grafts and the pendant and protonated -COOH groups in PMAAc. The physical cross-links were reversible in nature and dependent on the pH and ionic strength of the environment. As a result, these complexing hydrogels exhibit drastic changes in their mesh size in response to small changes of pH, which could be useful for drug delivery in varying pH environments in the body, such as in the GI tract, mouth and vagina, and on the skin.

In another study of complexation hydrogels, Hayashi et al. (2007) formed gels from PEGylated papain and PAAc at low pH. They showed how the molecular weight of the PEG and the addition of free PEG significantly affected the release rate of the PEGylated protein from the gel. A complexation gel formed as a result of H-bonding between PAAc and PAAm chains at low pH. It was unusual in that it exhibited temperature-responsive behavior, and went from a gel to a solution state as temperature rose above 30°C (Katono et al., 1991).

Temperature-Sensitive Hydrogels

Another class of environmentally-sensitive gels exhibits sharp temperature-sensitive swelling-de-swelling behavior due to a change in the polymer/swelling agent compatibility over the temperature range of interest. Temperature-sensitive polymers typically exhibit a lower critical solution temperature (LCST), below which the polymer is soluble. Above this temperature, the polymers may lose their hydrophobically-bound water, and phase separate, causing the gel to collapse. Below the LCST, the cross-linked gel re-swells to significantly higher degrees because of the increased hydrophobic bonding with water. Poly(N-isopropyl acrylamide) (PNIPAAm) has been the most widely studied temperature-responsive polymer and hydrogel, with an LCST around 32–34°C (Dong and Hoffman, 1986; Park and Hoffman, 1990, 1992; Kim, 1996; Hoffman et al., 2000; Yoshida and Okano, 2010).

Some of the earliest work with PNIPAAm hydrogels was carried out by Dong and Hoffman (1986). They immobilized an enzyme in copolymer hydrogels of NIPAAm and AAm, and observed a maximum in the specific activity of the enzyme in each hydrogel as the temperature was raised. They concluded that above the maximum the gel collapsed as the copolymer LCST was surpassed, and the collapse blocked substrate diffusion into, and product out of, the gel. As the ratio of AAm/NIPAAm increased, the maximum shifted to higher temperatures due to the increasing hydrophilicity, which caused the increase in LCST of the copolymer hydrogel. Most interesting was the fact that the curves were reversible up to the maximum reached for the highest AAm/NIPAAm ratio; above that LCST the enzyme was denatured due to the high temperature.

In other early work, Hirotsu et al. (1987) synthesized cross-linked PNIPAAm gels and determined that the LCST of the gels was 34.3°C; below this transition temperature significant gel swelling occurred. They noted that the de-swelling-swelling above and below the LCST was reversible. Similar to Dong and Hoffman (1986), they also noted that the transition temperature was raised by copolymerizing PNIPAAm with small amounts of hydrophilic ionic monomers. Dong and Hoffman (1991) prepared heterogeneous PNIPAAm gels containing silicone polymer regions; these unusual gels collapsed at significantly faster rates than homopolymers of PNIPAAm. Park and Hoffman (1990, 1992) studied the effect of temperature cycling on the efficiency of enzyme turnover in a temperature-controlled packed bed of PNIPAAm hydrogel microparticles containing the enzyme. They noted a significant increase in productivity of the reactor with thermal cycling of temperatures from above to below the LCST, where the increased efficiency was due to the

collapse of the gel particles above the LCST, "squeezing" out the product followed by the re-swelling of the gel below the LCST, enhancing uptake of substrate.

Yoshida et al. (1995) and Kaneko et al. (1996) developed an ingenious method to prepare comb-type graft hydrogels of PNIPAAm chains grafted to a PNIPAAm hydrogel network. Under conditions of gel collapse (above the LCST), hydrophobic regions were developed in the pores of the gel by the collapse of the grafted chains, drawing the network chains together with the collapsing grafted chains, resulting in a very rapid collapse of the gel. These materials had the ability to collapse from a fully swollen conformation in less than 20 minutes, while comparable gels that did not contain graft chains required up to a month to fully collapse. Such systems show promise for rapid or oscillatory release of drugs such as peptides and proteins.

There is a whole class of thermally-sensitive hydrogels based on physical interactions of hydrophobic blocks of triblock copolymers that also contain PEG blocks. Pluronic® block polymers (e.g., PPO–PEO–PPO) form such gels, but they are not degradable. The most interesting block copolymers for biomedical applications are hydrolytically degradable since they contain blocks of PLA or PLGA (e.g., PLGA–PEG–PLGA or PEG–PLA–PEG), which hydrolyze and release PEG chains that can be eliminated through the kidneys. These thermally-gelling block copolymers form *in situ* gels when injected subcutaneously, and act as drug delivery depots, releasing entrapped drugs as they degrade (e.g., see Jeong et al., 2002, and Lee and He, 2010 for detailed discussion of pioneering work by S. W. Kim and co-workers on such block copolymer hydrogels). One very interesting class of such degradable block copolymer hydrogels is formed by stereocomplexation of the two stereoisomers of PLA in PLLA–PEG and PDLA–PEG block copolymers (Fujiwara et al., 2010).

Affinity Hydrogels

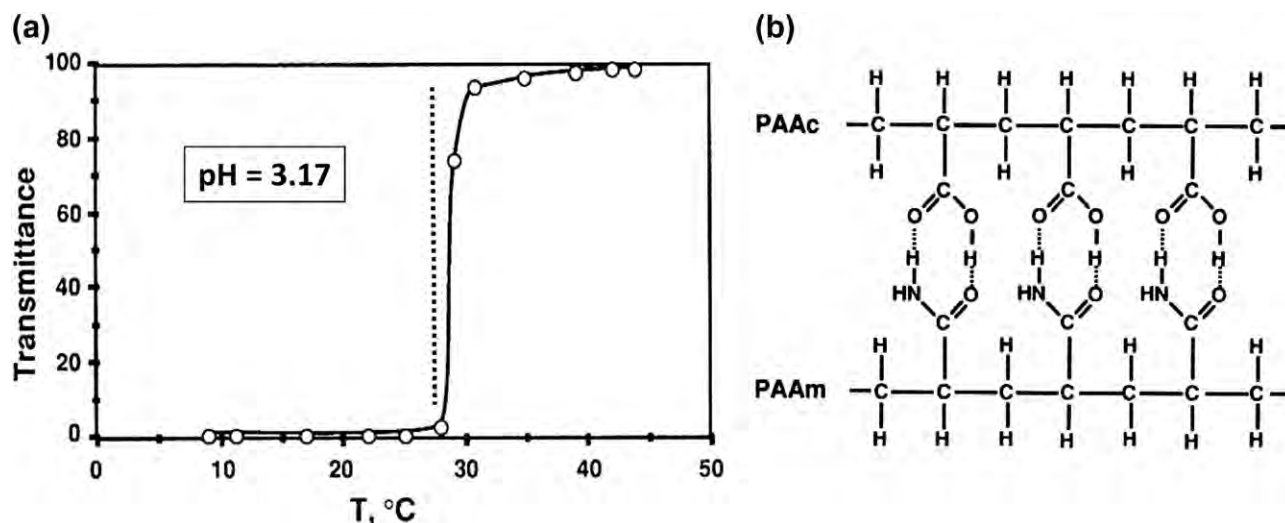
Some hydrogels may exhibit environmental sensitivity due to the formation of complexes between chains that hold them together as a gel. Polymer complexes are macromolecular structures formed by the non-covalent association of groups on multi-functional molecules or on polymer chains that exhibit affinity for different groups on another polymer molecule. Sometimes this complexation is due to affinity recognition interactions, such as between streptavidin, with four binding sites for biotin, and a polymer with multiple pendant biotins (see Figure I.2.5.7a and Morris et al., 1993), or Concanavalin A with four binding sites for glucose and a polymer with multiple pendant glucose units (see Figure I.2.5.7b and Miyata et al., 1996), or an antibody with two binding sites for its antigens (Miyata, 2010). The complexes may form by association of repeating units on different chains (interpolymer complexes) or on separate regions of the same chain (intrapolymer complexes). The stability of these affinity hydrogels is dependent on such factors as the affinity constant of the association, the concentration of a competing, mobile affinity agent, temperature, pH, ionic strength, network composition, and structure, especially the length of the network polymer chains between association points. In these types of hydrogel, complex formation results in the formation of physical cross-links in the gel. As the degree of such physical cross-linking is increased, the network mesh size and degree of swelling will be significantly reduced. As a result, if such hydrogels are used as drug carriers, the rate of drug release will decrease dramatically upon the formation of inter-polymer complexes.


FIGURE I.2.5.7 Temperature dependence of light transmission for two H-bonded polymers, PAAc (Polyacrylic acid) and PAAm (Polyacrylamide) at pH 3.17; (a) shows the temperature dependence of light transmission and (b) shows the hypothetical H-bonded structure that would exist at low pH and at temperatures below 30°C, where the COOH groups are protonated and the polymer chains are complexed. The H-bonding is disrupted as temperature rises above 30°C. Data are for an aqueous solution at pH 3.17 (adjusted by HCl). Polymer concentration (wt. %): PAAc, 0.5%; PAAm, 0.5%. (Katono et al., (1991).

The hydrophilic character of hydrogels makes them attractive for a variety of biomedical and pharmaceutical applications. Because of their normally high water contents, hydrogels have been useful for delivering drugs from ingested tablets and osmotic pumps. Further, they have been successful as contact lenses applied to the eye, or as drug-releasing coatings on mucosal, skin or open wound surfaces. They have also been applied as non-fouling coatings on implants and devices that may contact blood, such as catheters. More recently they are being developed as scaffolds for tissue engineering implants.

BIOMEDICAL APPLICATIONS OF HYDROGELS

Contact Lenses

One of the earliest biomedical applications of hydrogels was the use of PHEMA hydrogels in contact lenses (Wichterle and Lim, 1960). Hydrogels are particularly useful as contact lenses because of their relatively good mechanical stability and favorable refractive index (see also Tighe 1976; Peppas and Yang, 1981; Michalek et al., 2010). More recently, extended wear contact lenses have been fabricated from an IPN composed of PNVP chains entrapped within a silicone hydrogel network. In this system silicone monomers and cross-linkers are polymerized in a solution containing PNVP, and an IPN hydrogel is formed. The PNVP acts to lubricate the surface of the lens against the cornea, and the silicone hydrogel provides high oxygen transport to the cornea, as well as enhanced permeability of small nutrient molecules and ions (McCabe et al., 2003).

Blood-Contacting Hydrogels

Hydrogels also exhibit properties that make them desirable candidates for blood-contacting biomaterials (Merrill et al., 1987). Nonionic hydrogels have been prepared from poly(vinyl alcohol), polyacrylamides, PNVP, PHEMA, and poly(ethylene oxide), (PEO, sometimes also referred to as PEG) (Peppas et al., 1999). Heparinized polymer hydrogels (Sefton, 1987) and heparin-based hydrogels (Tae et al., 2007) also show promise as materials for blood-contacting applications.

Drug Delivery from Hydrogels

Applications of hydrogels in controlled drug delivery systems (DDS) have become very popular in recent years. They include equilibrium-swollen hydrogels, i.e., matrices that have a drug incorporated in them and are swollen to equilibrium, releasing the drug. This category of *solvent-activated*, matrix-type, controlled-release devices comprises two important types of systems: *(1) rapidly swelling*, *diffusion-controlled devices*; and *(2) slowly swelling*, *swelling-controlled devices*. In general, a drug-loaded hydrogel may be prepared by swelling the hydrogel to equilibrium in a drug solution, and carefully drying it. In the dry state it becomes a glassy polymer that can be swollen when brought in contact with water or simulated biological fluids. This swelling process may or may not be the controlling mechanism for diffusional release, depending on the relative rates of the macromolecular relaxation of the polymer and drug diffusion from the gel.

In swelling-controlled release systems, the bioactive agent is dispersed into the polymer to form nonporous films, disks, or spheres. Upon contact with an aqueous dissolution medium, a distinct front (interface) is observed that corresponds to the water penetration front into the polymer and separates the glassy from the rubbery (gel-like) state of the material. Under these conditions, the macromolecular relaxation of the polymer influences the diffusion mechanism of the drug through the rubbery state. This water uptake can lead to considerable swelling of the polymer, with a thickness that depends on time. The swelling process proceeds toward equilibrium at a rate determined by the water activity in the system and the structure of the polymer. If the polymer is cross-linked, or if it is of sufficiently high molecular weight (so that chain entanglements can maintain structural integrity), the equilibrium state is a water-swollen gel. The equilibrium water content of such hydrogels can vary from ~30% to over 90%. If the dry hydrogel contains a water-soluble drug, the drug is essentially immobile in the glassy matrix, but begins to diffuse out as the polymer swells with water. Drug release thus depends on the simultaneous rate processes of water migration into the device, polymer chain hydration and relaxation, followed by drug dissolution and diffusion outward through the swollen gel. An initial burst effect is frequently observed in matrix devices, especially if the drying process brings a higher concentration of drug to the surface. The continued swelling of the matrix causes the drug to diffuse increasingly easily, mitigating the slow tailing off of the release curve. The net effect of the swelling process is to prolong and "linearize" the release curve. Details of the process of drug delivery from hydrogels have been presented by Korsmeyer and Peppas (1981) for poly(vinyl alcohol) systems, and by Reinhart et al. (1981) for PHEMA systems and their copolymers. One of numerous examples of such swelling-controlled systems was reported by Franson and Peppas (1983) who prepared cross-linked copolymer gels of poly(HEMA–co–MAA) of varying compositions. Theophylline release was studied and it was found that near zero-order release could be achieved using copolymers containing 90% PHEMA.

Targeted Drug Delivery from Hydrogels

Promising new methods for the delivery of chemotherapeutic agents using hydrogels have been recently

reported. Novel biorecognizable sugar-containing copolymers have been investigated for use in targeted delivery of anti-cancer drugs. Peterson et al. (1996) have used poly(N-2-hydroxypropyl methacrylamide) carriers for the treatment of ovarian cancer.

Tissue Engineering Scaffolds from Hydrogels

This is an application area that continues to expand. It is driven by the same attractive properties that drive the use of hydrogels for drug delivery applications: high water content gels that may be synthesized with degradable backbone polymers, with an added advantage of being able to attach cell adhesion ligands to the network polymer chains. There are a number of natural polymer-based hydrogel scaffolds that have been studied (e.g., collagen, gelatin, alginates, hyaluronic acid, chitosan, etc.) and the reader is referred to two chapters in this text (see Chapters I.2.7 and II.6.3) and some excellent review articles (Lee and Mooney, 2001; Lutolf and Hubbell, 2005; Jin and Dijkstra, 2010).

One very interesting observation with hydrogels that has recently been reported is that they may stimulate stem cell differentiation; that is, when stem cells are deposited on some hydrogel surfaces, depending on the composition and/or mechanical stiffness of the surface, differentiation of the stem cells into certain phenotypes may occur (e.g., Liu et al., 2010; Nguyen et al., 2011).

Miscellaneous Biomedical Applications of Hydrogels

Other potential applications of hydrogels mentioned in the literature include artificial tendon materials, wound-healing bioadhesives, artificial kidney membranes, articular cartilage, artificial skin, maxillofacial and sexual organ reconstruction materials, and vocal cord replacement materials (Byrne et al., 2002a,b).

INTRODUCTION

Clinical circumstances often require the application of implants that must serve a temporary rather than a permanent purpose (Table I.2.6.1). In these situations degradable polymers are of interest because the implants fabricated from these materials do not need to be surgically removed. The surgical removal of an implant with a temporary purpose is undesirable, as the process creates another wound with the possibility of surgical complication and infection. Additionally, the use of degradable implants can sometimes circumvent problems related to the long-term safety of permanent implants, such as long-term immune rejection, chronic inflammation at the implant–tissue interface, and failure of the device. However, degradable implants are not without their own safety concerns, such as the toxicity of their degradation products, and the degradation-related, premature failure of the implant. Therefore, designing a degradable implant requires careful testing for potential toxicity of its degradation products and careful consideration of the implant's mechanical integrity during the required service life of the implant. To facilitate a better understanding of the complex decisions that have to be made during the design of a degradable implant, this chapter covers basic definitions relating to the process of degradation and/or erosion, the most prominent types of *synthetic*, degradable polymers available today, a classification of degradable medical implants, and considerations specific for the design and use of degradable medical polymers.

DEFINITIONS RELATING TO THE PROCESSES OF DEGRADATION VERSUS BIODEGRADATION, AND EROSION VERSUS BIOEROSION

The term "degradation" refers to a chemical process resulting in the cleavage of covalent bonds. Hydrolysis is the most common chemical process by which polymers degrade, but degradation can also occur via oxidative, photodegradative, and enzymatic mechanisms. In contrast, the term "erosion" refers to physical changes in size, shape or mass of a device, which could be the consequence of degradation, dissolution, ablation or mechanical wear. Thus, it is important to realize that erosion can occur in the absence of degradation, and degradation can occur in the absence of erosion. For example, erosion without degradation occurs when a sugar cube is placed in water: the sugar cube loses its mass through dissolution, e.g., it erodes, but the sugar does not degrade as its chemical structure remains unchanged. Degradation without erosion is observed when an implant made of poly(lactic acid) (PLA) is first placed into the body of a patient: PLA clearly starts to degrade, as evidenced by the reduction of its molecular weight, but the initial degradation of the polymer is not associated with erosion, as evidenced by the lack of mass loss of the implant. Only when the degradation of PLA is well advanced do the first signs of implant erosion become evident.

> It is important to distinguish between the many different terms that describe the conversion of a solid biomaterial into a solution of the biomaterial or its molecular fragments. The list of terms includes *degradation*, *biodegradation*, *bioabsorption*, *bioresorption*, *erosion*, *bioerosion*, *surface erosion*, and *bulk erosion*. These terms are often used in an inconsistent fashion in the biomaterials literature; the reader is encouraged to read this section carefully and also the Glossary of Key Terms at the end of the chapter.

All polymers undergo some degree of degradation. Therefore, the practice of designating certain polymers as "degradable" and others as "non-degradable" represents a certain amount of arbitrariness. For the purposes

TABLE I.2.6.1	Some "Short Term" Medical Applications of Degradable Polymeric Biomaterials
Application	**Comments**
Sutures	The earliest successful application of synthetic, degradable polymers in human medicine
Drug delivery devices	One of the most widely investigated medical applications for degradable polymers. Commonly used in clinical devices for the delivery of chemotherapeutics for the treatment of cancer
Orthopedic fixation devices	Requires polymers of exceptionally high mechanical strength and stiffness
Adhesion prevention	Requires polymers that can form soft membranes or films
Temporary vascular grafts and stents made of degradable polymers	Only investigational devices are presently available. Blood compatibility and fouling, as well as device fragmentation upon degradation, are major concerns
Tissue engineering or guided tissue regeneration scaffold	Attempts to recreate or improve native tissue function using degradable scaffolds. Cells may be seeded with the scaffolds before implantation. Bioactives (e.g., growth factors, short selective peptide sequences, etc.) are sometimes included in the scaffolds to modulate cellular responses

of this chapter, we will use the criteria as described by Göpferich that "degradable polymers" are those that degrade within the time scales of their expected service life or shortly thereafter (Göpferich, 1996). Conversely, "non-degradable" polymers have degradation times that are substantially longer than their service life.

Currently, at least four different terms (biodegradation, bioerosion, bioabsorption, and bioresorption) are used to indicate that a given material or device will eventually disappear after having been introduced into a living organism. However, within the literature, no consistent distinctions in the meaning of these four terms are evident. Likewise, the meaning of the prefix "bio" is not well established, often leading to the interchangeable use of the terms "degradation" and "biodegradation", or "erosion" and "bioerosion." Although efforts have been made to establish generally applicable and widely accepted definitions for all aspects of biomaterials research (Williams, 1987), there is still confusion even among experienced researchers in the field as to the correct terminology of various degradation processes.

In the context of this chapter, we follow the usage suggested by the Consensus Conference of the European Society for Biomaterials (Williams, 1987), and refer to "biodegradation" when we wish to emphasize that a biological agent (enzyme, cell or microorganism) is causing the chemical breakdown of the implanted device. After extensive discussion in the literature, it is now widely believed that the chemical degradation of the polymeric backbone of poly(lactic acid) (PLA) is predominantly controlled by simple hydrolysis and occurs independently of any biological agent (Li, 1999). Consequently, in these instances, the degradation of PLA to lactic acid should not be described as "biodegradation" but rather as "degradation." (Only under rare conditions may the enzyme proteinase K catalyze the hydrolytic degradation of PLA (Williams, 1981; Tsuji and Miyauchi, 2001); that situation is so rare that we will not consider it further here.)

In agreement with Heller's suggestion (Heller, 1987), we define a "bioerodible polymer" as a water-insoluble polymer that is converted under physiological conditions into water-soluble material(s) without regard to the specific mechanism involved in the erosion process.

"Bioerosion" includes, therefore, both physical processes (such as dissolution) and chemical processes (such as backbone cleavage). Here the prefix "bio" indicates that the erosion occurs under physiological conditions, as opposed to other erosion processes caused, for example, by high temperature, strong acids or bases, UV light, mechanical stresses or weather conditions. The terms "bioresorption" and "bioabsorption" are used interchangeably and often imply that the polymer or its degradation products are removed by cellular activity (e.g., phagocytosis) in a biological environment. While commonly found within the literature, these terms have not been consistently defined.

An understanding of the distinct definitions of degradation and bioerosion are necessary to facilitate the subsequent discussion of degradable polymers and devices. The mechanisms and of degradation and bioerosion are discussed more thoroughly on pages 189–190: The Process of Bioerosion, Mechanisms of Chemical Degradation, and Factors that Influence the Rate of Bioerosion.

OVERVIEW OF CURRENTLY AVAILABLE DEGRADABLE POLYMERS

The development of highly stable materials has always been a major research challenge. Today, many polymers are available for clinical purposes that are virtually non-destructible in biological systems, e.g., Teflon™ (poly(tetrafluoroethylene)), Kevlar™ (poly(paraphenylene terephthalamide)), poly(ether-ether-ketone) (PEEK), or poly(ethylene terephthalate) (PET). On the other hand, the development of degradable biomaterials is a relatively new area of research. The variety of available, degradable biomaterials is still too limited to cover a wide enough range of diverse material properties. Thus, the design and synthesis of new, degradable biomaterials is currently an important research challenge. Within the context of tissue engineering, new biomaterials that provide predetermined and controlled cellular responses are a critically needed component of most practical applications (Anderson et al., 2004).

Degradable materials must fulfill more stringent requirements, in terms of their biocompatibility, than

non-degradable materials. In addition to the potential problem of toxic contaminants leaching from the implant (residual monomers, stabilizers, polymerization initiators, emulsifiers, sterilization byproducts), one must also consider the potential toxicity of the degradation products and subsequent metabolites. The practical consequence of this consideration is that only a limited number of non-toxic, monomeric starting materials have been successfully applied to the preparation of degradable biomaterials.

Over the last decade a number of hydrolytically unstable polymers have been suggested as degradable biomaterials. However, in most cases, no attempts have been made to develop these new materials for specific medical applications. Thus, detailed toxicological studies *in vivo*, investigations of degradation rate and mechanism, and careful evaluations of the physico-mechanical properties have so far been published for only a small fraction of those polymers. An even smaller number of synthetic, degradable polymers have so far been used in medical implants and devices that have gained approval by the Food and Drug Administration (FDA) for use in patients. The FDA does not approve polymers or materials *per se*, but only specific medical devices and drug delivery formulations. As of 2006, only seven distinct synthetic, degradable polymer classes have been approved for use in a narrow range of clinical applications (Kohn et al., 2007). These polymers are polyesters containing lactic acid, polyesters containing glycolic acid, polyesters containing dioxanone, polyesters containing caprolactone, poly(trimethylene carbonate)s, polyanhydrides containing sebacic acid, and tyrosine-derived polyarylates. Various other synthetic, degradable biomaterials currently in clinical use are blends or copolymers of these base materials, such as a wide range of copolymers of lactic and glycolic acid. This listing does not include polymers derived from animal sources such as collagen, gelatin or hyaluronic acid.

> It is important to note that no polymer will degrade or erode by either hydrolytic or enzymatic processes unless water molecules can reach and "interact with" the molecular groups of the polymer chains. Thus, the "degree of hydrophobicity," the presence of crystallites, and the resultant absorption of water by the polymer are critical factors for all degradation/resorption processes.

Recent research has led to several well-established investigational polymers that may find practical applications as degradable implants within the next decade. This chapter will concern itself mostly with *synthetic* degradable polymers, since *natural* polymers (e.g., polymers derived from animal or plant sources) are described elsewhere in this book. Furthermore, the chapter on Hydrogels (Chapter I.2.5) contains a section on degradable hydrogels, and therefore, that subject won't be covered in this chapter.

Table I.2.6.2 provides an overview of some representative degradable polymers. For completeness, some of the natural polymers have also been included here. Structural formulas of commonly investigated synthetic degradable polymers are provided in Figure I.2.6.1. A large proportion of the currently investigated, *synthetic*, degradable polymers are polyesters. It remains to be seen whether some of the alternative backbone structures such as polyanhydrides, polyphosphazenes, polyphosphonates, polyphosphoesters, polyamides, or polycarbonates will be able to challenge the predominant position of the polyesters in the future.

Poly(glycolic acid) and poly(lactic acid) and their copolymers are currently the most widely investigated, and most commonly used, synthetic, bioerodible polymers. In view of their importance in the field of biomaterials, their properties and applications will be described in more detail.

Poly(glycolic acid) (PGA) is the simplest linear, aliphatic polyester (Figure I.2.6.1). Since PGA is highly crystalline, it has a high melting point and low solubility in organic solvents. PGA was used in the development of the first totally synthetic, absorbable suture (Herrmann et al., 1970). PGA sutures have been commercially available under the trade name "Dexon™" since 1970. A practical limitation of Dexon™ sutures is that they tend to lose their mechanical strength rapidly, typically over a period of two to four weeks after implantation. PGA has also been used in the design of internal bone fixation devices (bone pins). These pins have become commercially available under the trade name "Biofix™."

To adapt the material properties of PGA to a wider range of possible applications, copolymers of glycolic acid with the more hydrophobic lactic acid were intensively investigated (Gilding and Reed, 1979). The hydrophobicity of lactic acid limits the water uptake of poly(lactic acid) (PLA) thin films to about 2%, and reduces the rate of backbone hydrolysis as compared to PGA. Sutures composed of copolymers of lactic acid and glycolic acid, poly(lactide-co-glycolide) (PLGA), were developed as an alternative to PGA sutures. The suture and the 90:10 PLGA copolymer it is composed of are distributed under the trade names "Vicryl™" and "Polyglactin 910™."

It is noteworthy that there is no linear relationship between the ratio of glycolic acid to lactic acid and the physico-mechanical properties of the corresponding copolymers. Whereas PGA is highly crystalline, crystallinity is rapidly lost in copolymers of glycolic acid and lactic acid. These morphological changes lead to an increase in the rates of hydration and hydrolysis. Thus, 50:50 PLGA copolymers degrade more rapidly than either PGA or PLA.

Since lactic acid is a chiral molecule, it exists in two stereoisomeric forms which give rise to four morphologically distinct polymers: the two-stereoregular polymers, D-PLA and L-PLA; and the racemic form D,L-PLA. A fourth morphological form, meso-PLA, can be obtained from D,L lactide but is rarely used in practice.

TABLE I.2.6.2	Degradable Polymers and Applications Under Investigation
Synthetic Degradable Polyesters	**Current Major Research Applications**
Poly(glycolic acid) (PGA), poly(lactic acid) (PLA) and copolymers	Barrier membranes, drug delivery, hormone delivery, guided tissue regeneration (in dental applications), orthopedic applications, vascular/urological stents, staples, sutures, injectable fillers, dura mater substitutes, skin replacement materials, tissue engineering
Poly(hydroxybutyrate) (PHB), poly(hydroxyvalerate) (PHV), and copolymers thereof	Long-term drug delivery, orthopedic applications, stents, artificial skin, surgical patching materials for congenital heart defects, sutures
Polycaprolactone (PCL)	Long-term drug delivery, implantable contraceptive drug devices, orthopedic applications, staples, stents
Polydioxanone (PDS)	Fracture fixation in non-load-bearing bones, sutures, wound clips
Other Synthetic Degradable Polymers	
Polyanhydrides	Drug delivery
Polycyanoacrylates	Adhesives, drug delivery
Poly(amino acid)s and "pseudo"-poly(amino acid)s	Drug delivery, tissue engineering, orthopedic applications, stents, anti-adhesion barriers
Poly(ortho ester) (POE)	Drug delivery, and stents
Polyphosphazenes	Blood contacting devices, drug delivery, skeletal reconstruction, vaccine adjuvants
Poly(propylene fumarate) (PPF)	Orthopedic applications
Poly(trimethylene carbonate) (PTMC)	Sutures, orthopedic applications
Some Natural Resorbable Polymers	
Collagen	Drug delivery, gene delivery, artificial skin, coatings to improve cellular adhesion, guided tissue regeneration in dental applications, spinal dural repair, orthopedic applications, soft tissue augmentation, tissue engineering, scaffold for reconstruction of blood vessels, wound closure, hemostatic agents
Fibrinogen and fibrin	Tissue sealant, cell delivery
Elastin-like peptides (ELP)	Drug delivery, coating of vascular grafts
Gelatin	Capsule coating for oral drug delivery, hemorrhage arrester
Hyaluronic acid	Wound dressing applications, drug delivery, tissue engineering, synthetic bone grafts, synovial fluid substitutes
Cellulose	Adhesion barrier, hemostat
Various polysaccharides such as chitosan, alginate	Drug/vaccine delivery, encapsulation of cells, sutures, wound dressings/healing
Starch and amylose	Oral drug delivery

The polymers derived from the optically active D and L monomers are semicrystalline materials, while the optically inactive D,L-PLA is always amorphous. Generally, L-PLA is more frequently employed than D-PLA, since the hydrolysis of L-PLA yields L(+) lactic acid, which is the naturally occurring stereoisomer of lactic acid.

The differences in the crystallinity of D,L-PLA and L-PLA have important practical ramifications. Since D,L-PLA is an amorphous polymer, it is usually considered for applications such as drug delivery, where it is important to have a homogeneous dispersion of the active species within the carrier matrix. On the other hand, the semicrystalline L-PLA is preferred in applications where high mechanical strength and toughness are required, such as sutures and orthopedic devices.

PLA and PGA and their co-polymers have been investigated for more applications than any other degradable polymer. The high interest in these materials is not based on their superior material's properties, but mostly on the fact that these polymers have already been used successfully in a number of approved medical implants and are considered safe, non-toxic, and biocompatible by regulatory agencies in virtually all developed countries. Therefore, implantable devices prepared from PLA, PGA or their copolymers can be brought to market in less time and for a lower cost than similar devices prepared from novel polymers whose biocompatibility is still unproven.

Currently available and approved products include: sutures; suture reinforcements; GTR membranes for dentistry; orthopedic fixation devices; injectable fillers for restoration of facial volume; skin replacement materials; dura mater substitutes; hormone delivery systems; and implantable drug delivery systems. The polymers are also being widely investigated in the design of vascular and urological stents, and as scaffolds for tissue engineering and tissue reconstruction. In many of these applications, PLA, PGA and their copolymers have performed with moderate to high degrees of success. However, there are still unresolved issues: first, in tissue culture experiments, most cells do not attach to PLA or PGA surfaces and do
FIGURE I.2.6.1 Chemical structures of widely investigated degradable polymers.

not grow as vigorously as on the surface of other materials, indicating that these polymers are actually poor substrates for cell growth *in vitro*. Second, the degradation products of PLA and PGA are relatively strong acids (lactic acid and glycolic acid). When these degradation products accumulate at the implant site, a delayed inflammatory response is often observed months to years after implantation (Bergsma et al., 1995; Ignatius and Claes, 1996; Törmälä et al., 1998).

Poly(ethylene glycol) (PEG) has been used to initate lactide and/or glycolide ring opening, producing A–B–A triblock copolymers, which are degradable, producing LA, GA, and PEG as byproducts. They have been made into a variety of PEG-based hydrogels and used in drug delivery, and as tissue engineering scaffolds. They are discussed in detail in the chapter on Hydrogels (Chapter I.2.5).

Polydioxanone (PDS) is a poly(ether-ester) made by a ring opening polymerization of p-dioxanone monomer. PDS was first introduced in the early 1980s and has gained increasing interest in the medical and pharmaceutical fields due to the low toxicity of its degradation products *in vivo*. The degradation time of PDS *in vivo* is approximately 60 days, with complete mass loss within 9 to 12 months (Maurus and Kaeding, 2004). This degradation time is comparable to PGA. PDS has a lower modulus and glass transition temperature than PLA or PGA. PDS became the first degradable polymer to be used to make a monofilament suture (Ray et al., 1981). PDS has also been introduced to the market as a suture clip, a degradable ligating device, as well as a bone pin marketed under the name OrthoSorb® in the USA and Ethipin® in Europe.

Poly(hydroxybutyrate) (PHB), poly(hydroxyvalerate) (PHV), and their copolymers represent examples of resorbable polyesters that are derived from microorganisms. PHB and PHV are intracellular storage polymers providing a reserve of carbon and energy to microorganisms similar to the role of starch in plant metabolism. Therefore, although these classes of polymers are examples of *natural* materials (as opposed to *synthetic* materials), they are included here because they have similar properties and similar areas of

application as the widely investigated poly(lactic acid). The polymers can be degraded by soil bacteria (Senior et al., 1972), but are relatively stable under physiological conditions (pH 7.4, 37°C). PHB is currently available as either poly(3-hydroxybutyrate) (P3HB) or poly(4-hydroxybutyrate) (P4HB). P3HB and its copolymers with up to 30% of 3-hydroxyvaleric acid are commercially available under the trade name "Biopol®" (Miller and Williams, 1987). P4HB is likewise available for clinical applications under the trade name "PHA4400." Within a relatively narrow window, the rate of degradation can be modified slightly by varying the copolymer composition between PHB and PHV. Members of the P3HB family of polymers require several years for complete resorption *in vivo*, while P4HB members require 8–52 weeks. *In vivo*, P3HB and P4HB degrade to D-3-hydroxybutyric acid and D-4-hydroxybutyric acid, respectively, which are natural metabolites present in the brain, heart, lung, liver, kidney, and muscle (Nelson et al., 1981). The low toxicity of PHBs may at least in part be due to this fact.

The mechanical properties of PHBs are dependent on the morphology considered. P3HB homopolymer is a highly crystalline and brittle material, while the copolymers of PHB with hydroxyvaleric acid are less crystalline, more flexible, and more readily processible (Barham et al., 1984). In contrast, P4HB is a strong, pliable thermoplastic material that is more flexible than PLA and PGA with an elongation break around 1000% (Martin and Williams, 2003). These polymers have been considered in several biomedical applications, such as: controlled drug release devices; sutures; artificial skin; surgical patching materials for congenital cardiovascular defects; heart valves; vascular grafts; and also in industrial applications such as medical disposables (Martin and Williams, 2003). P3HB is especially attractive for orthopedic applications due its slow degradation time. The polymer typically retains 80% of its original stiffness over 500 days upon *in vivo* degradation (Knowles, 1993).

Polycaprolactone (PCL) was first synthesized via ring-opening polymerization in the 1930s (Van Natta et al., 1934). However, its degradability was identified in the 1970s and it became available commercially following efforts at Union Carbide to identify synthetic polymers that could be degraded by microorganisms (Huang, 1985). Based on a large number of tests, ε-caprolactone and polycaprolactone are currently regarded as non-toxic and tissue-compatible materials. It is a semicrystalline polymer having a low glass transition temperature. The high solubility of polycaprolactone, its low melting point (59–64°C), and exceptional ability to form blends has stimulated research on its application as a biomaterial. Polycaprolactone degrades at a slower rate than PLA and has a high permeability to many drugs, therefore prompting its use in drug delivery devices that remain active for over one year (Sinha et al., 2004). The release characteristics of polycaprolactone have been investigated in detail by Pitt and his co-workers (Pitt et al.,

1979). The Capronor™ system, a one-year implantable contraceptive device, has been commercially available in Europe and the USA. The toxicology of polycaprolactone has been extensively studied as part of the evaluation of Capronor™. In Europe, polycaprolactone is already in clinical use as a degradable staple (for wound closure). A monofilament suture derived from copolymers of polycaprolactone and PGA is widely used clinically and is available under the brand name Monocryl™ (Bezwada et al., 1995). Caprolactones have also been used in block copolymers with glycolide, lactide, and poly(ethylene glycol) for a commercially available drug delivery device under the brand name SynBiosys™.

Polyanhydrides were explored as possible substitutes for polyesters in textile applications, but failed due to their pronounced hydrolytic instability. It was this property that prompted Langer and his co-workers to explore polyanhydrides as degradable implant materials (Tamada and Langer, 1993). The main advantages of polyanhydrides are that: their production requires a single-step synthesis scheme with inexpensive reagents; they have controllable molecular weights and predictable degradation/drug release profiles; they are easily processable; and they are relatively non-toxic upon degradation (Kumar et al., 2002).

The polyanhydride library includes a large number of synthetic materials that all contain degradable anhydride bonds within the backbone of the polymer chain. To date, polyanhydrides have been synthesized with aliphatic monomers, unsaturated monomers, aromatic monomers, and linear fatty acid monomers (Nair and Laurencin, 2007). Aliphatic polyanhydrides degrade within days, whereas some aromatic polyanhydrides degrade over several years. Thus, aliphatic–aromatic copolymers are usually employed to achieve intermediate rates of degradation which are dependant on the monomer composition (Göpferich and Tessmar, 2002).

Polyanhydrides are among the most reactive and hydrolytically unstable polymers currently used as biomaterials. The high chemical reactivity is both an advantage and a limitation of polyanhydrides. Many polyanhydrides degrade by surface erosion without the need to incorporate various catalysts or excipients into the device formulation. While this property makes them good candidates for drug delivery applications, their hydrolytic instability limits shelf life. To maintain their integrity, polyanhydride materials must be stored under anhydrous and low temperature conditions. Additionally, polyanhydrides can react with drugs containing free amino groups or other nucleophilic functional groups, especially during high temperature processing (Leong et al., 1986). The potential reactivity of the polymer matrix toward nucleophiles limits the type of drugs that can be successfully incorporated into a polyanhydride matrix by melt processing techniques.

A comprehensive evaluation of the toxicity of polyanhydrides, as reviewed by Katti et al. demonstrates that, in general, the polyanhydrides possess excellent *in vivo*

biocompatibility (Katti et al., 2002). The most immediate applications for polyanhydrides have been in the field of drug delivery. Drug loaded devices made of polyanhydrides can be prepared by compression, injection or melt molding, solvent casting or microencapsulation (Kumar et al., 2002). Depending on the monomer composition, polyanhydrides are able to release drugs with zero order kinetics over time periods ranging from days to years (Nair and Laurencin, 2007). A wide variety of drugs and proteins including insulin, bovine growth factors, angiogenesis inhibitors (e.g., heparin and cortisone), enzymes (e.g., alkaline phosphatase and β-galactosidase), and anesthetics have been incorporated into polyanhydride matrices with their *in vitro* and *in vivo* release characteristics evaluated (Katti et al., 2002; Kumar et al., 2002). The first polyanhydride-based drug delivery system to enter clinical use was for the delivery of chemotherapeutic agents. An example of this application is the delivery of BCNU (bis-chloroethylnitrosourea) to the brain for the treatment of glioblastoma multiforme, a highly fatal brain cancer (Brem et al., 1993). For this application, BCNU-loaded implants made of the polyanhydride derived from bis-p-carboxyphenoxypropane and sebacic acid received FDA regulatory approval in the fall of 1996 and are currently being marketed under the name Gliadel™. Septacin™, a drug delivery vehicle for gentamicin sulfate has been developed for the treatment of osteomyelitis (Li et al., 2002).

Poly(ortho ester)s (POE) are a family of synthetic, degradable polymers that have been under development for a number of years (Heller and Gurny, 1999). Currently, there are four major types of poly(ortho ester)s: first generation (POE I); second generation (POE II); third generation (POE III); and fourth generation (POE IV) (Heller et al., 2002). (See also the chapter on Drug Delivery, Chapter II.5.16.)

POE I were first prepared by Choi and Heller via the transesterification of 2,2′-dimethoxyfuran with a diol (Heller and Gurny, 1999). Unfortunately, the hydrolysis of POE I is an acid-sensitive process that itself results in the release of acidic degradation products. This leads to autocatalysis of the polymer, limiting its utility for clinical applications. The second generation of poly(ortho ester)s (POE II) were based on an acid catalyzed addition reaction of diols with diketeneacetals (Heller, 1990). Unlike POE I, the degradation products of this polymer are neutral in pH, therefore preventing the autocatalysis of the polymer. The mechanical properties of the POE II can be controlled to a large extent by the choice of the diols used in the synthesis. Materials ranging from stiff materials to those that are quite soft at room temperature can be achieved. Since the ortho ester linkage in POE I and II is far more stable in base than in acid, Heller and his co-workers controlled the rate of polymer degradation by incorporating acidic or basic excipients into the polymer matrix. The third generation of poly(ortho ester)s (POE III) were very soft and were even viscous liquids at room temperature (Merkli et al., 1993). POE III can be used in the formulation of drug delivery systems that are injected rather than implanted into the body. Release profiles of the chemotherapeutic agent 5-fluorouracil demonstrated zero order kinetics and were investigated for ocular implants (Heller, 2005). Unfortunately, difficulties in synthesis and reproducibility limited the practical applications of this material, and currently it is no longer under development. The final generation of poly(ortho ester)s (POE IV) was synthesized by Heller and his co-workers to address the need for excipients in POE I and II (Ng et al., 1997). This polymer achieves consistent degradation profiles via the incorporation of glycolic or lactic acid to the polymer backbone. Upon degradation, the acid segments are released, therefore catalyzing the hydrolysis of the ortho ester linkages.

POE IV is naturally "surface eroding", while POE I and II can erode by "surface erosion" if appropriate excipients are incorporated into the polymeric matrix. One concern about the "surface erodability" of poly(ortho ester)s is that the incorporation of highly water-soluble drugs into the polymeric matrix can result in swelling of the polymer matrix. The increased amount of water imbibed into the matrix can then cause the polymeric device to exhibit "bulk erosion" instead of "surface erosion" (see the section The Process of Bioerosion, pp. 189–190, for a more detailed explanation of these erosion mechanisms) (Okada and Toguchi, 1995). Since surface eroding, slab-like devices tend to release drugs embedded within the polymer at a constant rate, poly(ortho ester)s appear to be particularly suited for controlled release drug delivery applications. For example, poly(ortho ester)s have been studied for the controlled delivery of cyclobenzaprine and steroids, and a significant number of publications describe the use of poly(ortho ester)s for various drug delivery applications (Heller and Gurny, 1999) (see Chapter II.5.16).

Poly(amino acid)s and "pseudo"-poly(amino acid)s: since proteins are composed of amino acids, researchers explored the possible use of poly(amino acid)s in biomedical applications (Anderson et al., 1985). Poly(amino acid)s were regarded as promising candidates since the amino acid side chains offer sites for the attachment of drugs, cross-linking agents, or pendent groups that can be used to modify the physico-mechanical properties of the polymer. Additionally, they initially held potential as degradable polymer materials because they possessed long range order, defined conformations in solution, and their amino acid-derived building blocks lacked toxicity (Kohn, 1993). Poly(amino acid)s have been investigated for use as suture materials (Williams, 1982), as artificial skin substitutes (Spira et al., 1969), and as drug delivery systems (Matsumura, 2008). Various drugs have been attached to the side chains of poly(amino acid)s, usually via a spacer unit that distances the drug from the backbone. Poly(amino acid)–drug combinations investigated for chemotherapy include poly(L-lysine) with methotrexate and pepstatin

(Campbell et al., 1980), poly(glutamic acid) with adriamycin and cisplatin (Van Heeswijk et al., 1985), and PEG-polyaspartate with paclitaxel (Matsumura, 2008).

Despite their apparent potential as biomaterials, poly(amino acid)s have actually found few practical applications due to several synthetic disadvantages: the expense of production; insolubility in common organic solvents; and thermal degradation upon melting limiting processibility. Poly(amino acid)s have a pronounced tendency to swell in aqueous media, therefore making the prediction of drug release rates difficult. Furthermore, the antigenicity of polymers containing three or more amino acids limits their use in biomedical applications (Kohn, 1993). Due to these difficulties, only a few poly(amino acid)s have been investigated for clinical uses. While some poly(amino acid) derivatives of poly(glutamic acid) carrying various pendent chains at the γ-carboxylic acid group have been investigated as implant materials (Lescure et al., 1989), the majority of their clinical success has been in the drug delivery of chemotherapeutics. As of 2008, PEG-poly(glutamic acid) nanocarrier formulations are in Phase 1 clinical trials for the delivery of paclitaxel and camptothecin, while Phase 2 trials are underway for cisplatin delivery against stomach cancer (Matsumura, 2008). So far, no implantable devices made of a poly(amino acid) have been approved for clinical use in the USA.

In an attempt to circumvent the problems associated with conventional poly(amino acid)s, backbone-modified "pseudo"-poly(amino acid)s were introduced in 1984 (Kohn and Langer, 1984, 1987). The first "pseudo"-poly(amino acid)s investigated were a polyester from N-protected trans-4-hydroxy-L-proline, and a polyiminocarbonate derived from tyrosine dipeptide. The tyrosine-derived "pseudo"-poly(amino acid)s are processable by solvent or heat methods and exhibit a high degree of biocompatibility.

The reason for the improved physico-mechanical properties of "pseudo"-poly(amino acid)s relative to conventional poly(amino acid)s can be traced to the reduction in the number of interchain hydrogen bonds. In conventional poly(amino acid)s, individual amino acids are polymerized via repeated amide bonds, leading to strong interchain hydrogen bonding. In natural peptides, hydrogen bonding is one of the interactions leading to the spontaneous formation of secondary structures such as α-helices or β-pleated sheets. Strong hydrogen bonding also results in high processing temperatures and low solubility in organic solvents, which tends to lead to intractable polymers with limited applications. In "pseudo"-poly(amino acid)s, half of the amide bonds are replaced by other linkages (such as, for example, carbonate, ester, or iminocarbonate bonds) which have a much lower tendency to form interchain hydrogen bonds, leading to better processibility and, generally, a loss of crystallinity.

For example, tyrosine-derived polycarbonates (Pulapura and Kohn, 1992; Bourke and Kohn, 2003) are high strength materials that may be useful in the formulation of degradable orthopedic implants. One of the tyrosine-derived pseudo-poly(amino acid)s, poly(DTE carbonate) exhibits a high degree of bone conductivity (e.g., bone tissue will grow directly along the polymeric implant) (Choueka et al., 1996; James et al., 1999; Asikainen et al., 2006). As of 2012, tyrosine derived "pseudo"-poly(amino acid)s have been used in two FDA approved devices (a hernia repair device and an antimicrobial pacemaker pouch from TyRx Pharma, Inc.) and a third is in clinical trials (a resorbable cardiovascular stent from REVA Medical, Inc.).

Polycyanoacrylates are used as bioadhesives and have been investigated for drug delivery. These adhesives are known for their high rates of curing, high adhesive strength, and good adhesion to both tissue and inorganic materials. Cyanoacrylates undergo spontaneous polymerization at room temperature in the presence of water. Their toxicity and erosion rate after polymerization differs with the length of their alkyl chain (Vezin and Florence, 1980). Methyl cyanoacrylates are more commonly used as general-purpose glues and are commercially available as "Crazy Glue." Methyl cyanoacrylate was used during the Vietnam War as an emergency tissue adhesive, but is no longer used today. Butyl cyanoacrylate is a slowly degrading polymer approved for use in Canada and Europe as a dental adhesive. n-Butyl-cyanoacrylate is used in veterinary glues, while 2-octyl cyanoacrylate (Dermabond™) is used in liquid bandages. Polycyanoacrylates have several limiting properties: first, the monomers (cyanoacrylates) are very reactive compounds that often have significant toxicity; second, upon degradation polycyanoacrylates release formaldehyde resulting in intense inflammation in the surrounding tissue. In spite of these inherent limitations, polycyanoacrylates have been investigated as potential drug delivery matrices, have been suggested for use in ocular drug delivery (Deshpande et al., 1998) and the delivery of nucleic acids (Fattal and Couvreur, 2004), and are in late stage clinical trials for cancer therapy (Vauthier et al., 2003).

Polyphosphazenes are polymers whose backbone consists of nitrogen–phosphorous bonds. These polymers are at the interface between inorganic and organic polymers, and have unusual material properties. Polyphosphazenes have found industrial applications, mainly because of their high thermal stability. They have also been used in investigations for the formulation of controlled drug delivery systems (Allcock, 1990). Polyphosphazenes are interesting biomaterials in many respects. Most polyphosphazenes are not degradable, but the incorporation of certain chemical groups into the polymer structure may render these materials degradable (Allcock, 1999). They have been claimed to be biocompatible, and their chemical structure provides a readily accessible "pendent chain" to which various drugs, peptides or other biological compounds can be attached and later released via hydrolysis. Polyphosphazenes have been examined for

use in skeletal tissue regeneration and have been shown to be osteocompatible (Qiu and Zhu, 2000; Nair et al., 2006). Another novel use of polyphosphazenes is in vaccine design, where these materials were used as immunological adjuvants (Andrianov et al., 1998).

Poly(propylene fumarate)s (PPF) and Poly(trimethylene carbonate) (PTMC) are polyester based materials, like PGA and PLA. PPF is most commonly synthesized using a two-step process (Shung et al., 2002) that results in the formation of either a viscous liquid or a yellow solid. The formation of the liquid or the solid depends on the molecular weight of the synthesized polymer, with high molecular weights yielding the solid, and low molecular weights yielding the liquid. PPF, unlike PGA and PLA, is an unsaturated polyester. Since a double bond is present within the backbone, various chemical modifications, including cross-linking, can be used to alter the physico-mechanical properties of the material. Cross-linking of the liquid polymer allows the material to be processed and molded into any number of shapes both pre-implantation and *in situ*. The ability to harden the materials *in situ* via thermal or photo initiated processes coupled with their osteoconductivity *in vitro* (Yaszemski et al., 1995) and *in vivo* (Lewandrowski et al., 2000; Fisher et al., 2002) has prompted exploration of these materials as cements and scaffolding materials for bone. PFF is degraded via hydrolytic cleavage of its ester bonds yielding propylene glycol and fumarate upon complete degradation. Both propylene glycol and fumarate are non-toxic *in vivo*. PPF, like PGA and PLA, releases acidic products upon degradation. However, PPF seems to lack susceptibility to autocatalyzed degradation as cross-linking density governs degradation rates to a far greater extent than local pH (Timmer et al., 2003).

PTMC is an elastomeric polyester with high flexibility but poor mechanical properties. It is synthesized via the ring opening polymerization of trimethyl carbonate and has a degradation rate that is 20 times slower than poly(ε-caprolactone) in phosphate buffered saline *in vitro* (Zhu et al., 1991). Interestingly, the *in vivo* degradation time of PTMC is significantly faster than its *in vitro* degradation, thus strongly suggesting a role for enzymatic degradation (Zhu et al., 1991; Zhang et al., 2006). This makes PTMC a polymer that truly undergoes "biodegradation." Copolymers of trimethylene carbonate and glycolide have been used as sutures and orthopedic fixation devices under the brand names Maxon™ and Acufex™ respectively. Additionally, a terpolymer of trimethylene carbonate, glycolide, and dioxane has been used to create a degradable suture under the brand name of BioSyn™ (Suzuki and Ikada, 2005).

Polyurethanes represent a class of elastomeric materials that have been used in the fabrication of a number of medical devices. While considered to be resistant to hydrolysis, polyurethane pacemaker leads were found to degrade through oxidative, enzymatic, and cellular mechanisms (Mcmillin, 1991). Recent work has focused on the incorporation of degradable linkages to impart predictable degradation kinetics. Linkages based on chemicals such as lysine diisocyanate have allowed the creation of degradable polyurethanes that are non-toxic. Polyurethanes are of particular interest in implantables because they have robust mechanical properties and good biocompatibility (Gunatillake and Adhikari, 2003). Non-degradable polyurethanes are currently used in a number of clinical devices, but have gained particular interest as vascular grafts. This stems from the observation that protein adsorption, and therefore clotting, is less pronounced on polyurethanes as compared to other materials. Degradable polyurethanes have also been investigated as artificial skin (Bruin et al., 1990), orthopedic injectables, and tissue engineering scaffolds (Degrapol™) (Saad et al., 1997; Zhang et al., 2000).

APPLICATIONS OF SYNTHETIC, DEGRADABLE POLYMERS AS BIOMATERIALS

Classification of Degradable Medical Implants

Some typical short-term applications of biodegradable polymers are listed in Table I.2.6.1. From a practical perspective, it is convenient to distinguish between five main types of degradable implants: the temporary support device; the temporary barrier; the drug delivery device; the tissue-engineering scaffold; and the multi-functional implant.

A temporary support device is used in those circumstances in which the natural tissue bed has been weakened by disease, injury or surgery, and requires some artificial support. A healing wound, a broken bone or a damaged blood vessel are examples of such situations. Sutures, bone fixation devices (e.g., bone nails, screws or plates), and vascular grafts would be examples of the corresponding support devices. In all of these instances, the degradable implant would provide temporary, mechanical support until the natural tissue heals and regains its strength. In order for a temporary support device to work properly, a gradual stress transfer should occur: as the natural tissue heals, the degradable implant should gradually weaken. The need to adjust the degradation rate of the temporary support device to the healing of the surrounding tissue represents one of the major challenges in the design of such devices.

A successful example of a temporary support device, the first synthetic, degradable sutures were made of PGA and became available under the trade name "Dexon™" in 1970. This represented the first routine use of a degradable polymer in a major clinical application (Frazza and Schmitt, 1971). Later, copolymers of lactic acid and glycolic acid were developed. The widely used "Vicryl™" suture, for example, is a 90:10 copolymer of lactic and glycolic acid, introduced into the market in 1974. Sutures

made of polydioxanone (PDS) became available in the USA in 1981. Sutures of ε-caprolactone and trimethylene carbonate with glycolide have been developed under the names "MonoCryl™" and "Maxon™," respectively. "Biosyn™" is a terpolymer suture composed of trimethylene carbonate, glycolide, and dioxane. In spite of extensive research efforts in many laboratories, no other degradable polymers are currently used to any significant extent in the formulation of degradable sutures.

A temporary barrier has its major medical use in the prevention of postsurgical adhesions. During surgical closure, barrier devices are interposed between tissues that must remain separate following surgery. Adhesions are formed between two tissue sections by clotting of blood in the extravascular tissue space, followed by inflammation and fibrosis. If this natural healing process occurs between surfaces that were not meant to bond together, the resulting adhesion can cause pain, functional impairment, and problems during subsequent surgery. Surgical adhesions are a significant cause of morbidity, and represent one of the most significant complications of a wide range of surgical procedures such as abdominal, cardiac, spinal, and tendon surgery. A temporary barrier could take the form of a thin polymeric film or a mesh-like device that would be placed between adhesion-prone tissues at the time of surgery. To be useful, such a temporary barrier would have to prevent the formation of scar tissue connecting adjacent tissue sections, followed by the slow resorption of the barrier material. This sort of barrier has also been investigated for sealing of breaches of the lung tissue that cause air leakage.

Another important example of a temporary barrier is in the field of skin reconstruction. Several products have become available that are generally referred to as "artificial skin." The first such product consists of an artificial, degradable collagen/glycosaminoglycan matrix that is placed on top of the skin lesion to stimulate the regrowth of a functional dermis. Another product consists of a degradable collagen matrix with pre-seeded human fibroblasts. Synthetic degradable polymers have also been used to create "artificial skin." Dermagraft™ is an artificial skin product that uses a PLGA-based mesh scaffold to provide structural support. Again, the goal is to stimulate the regrowth of a functional dermis. These products are used in the treatment of burns and other deep skin lesions, and represent an important application for temporary barrier type devices.

Implantable drug delivery devices and **injectable polymer-drug depot delivery systems** are capable of delivering drugs to specific locations over an extended period of time. They are, by necessity, temporary devices, for the drug reservoir will eventually be depleted or the need for delivery of a specific drug will be eliminated once the disease is adequately treated. The development of implantable drug delivery systems is probably the most widely investigated application of degradable polymers (Nair and Laurencin, 2007). One can expect that the future

acceptance of implantable and injectable drug delivery devices by physicians and patients alike will depend on the availability of degradable systems that do not have to be surgically explanted.

Since PLA and PGA have an extensive safety profile based on their use as sutures, these polymers have been very widely investigated in the formulation of implantable controlled release devices. Several implantable, controlled release formulations based on copolymers of lactic and glycolic acid have already become available. However, a wide range of other degradable polymers has also been investigated. Particularly noteworthy is the use of a new type of polyanhydride in the formulation of an intracranial, implantable device for the administration of BCNU (a chemotherapeutic agent) to patients suffering from glioblastoma multiforme, a usually lethal form of brain cancer (Gliadel™). A clinical trial by Westphal et al. in 2003 demonstrated a 29% reduction in the risk of death in patients treated with Gliadel™ versus those who were not (Westphal et al., 2003). The topic of drug delivery systems is discussed in more detail in Chapter II.5.16.

The term **tissue engineering scaffold** will be used in this chapter to describe a degradable implant that is designed to act as an artificial extracellular matrix by providing space for cells to grow into and reorganize into functional tissue (Hutmacher, 2001).

It has become increasingly obvious that man-made implantable prostheses do not function as well as the native tissue, or maintain the functionality of native tissue over long periods of time. Therefore, tissue engineering has emerged as an interdisciplinary field that utilizes degradable polymers, among other substrates and biologics, to develop treatments that enhance the body's potential to heal itself without the need for permanently implanted, artificial prosthetic devices. In the ideal case, a tissue engineering scaffold is implanted to restore lost tissue function, maintain tissue function or enhance existing tissue function (Langer and Vacanti, 1993). These scaffolds can take the form of a felt-like material obtained from knitted or woven fibers or from fiber meshes. Alternatively, various processing techniques can be used to obtain foams or sponges. For all tissue engineering scaffolds, pore volume and pore interconnectivity are key properties, as cells need to be able to migrate and grow throughout the entire scaffold. Thus, industrial foaming techniques used, for example, in the fabrication of furniture cushions, are not applicable to the fabrication of tissue engineering scaffolds, as these industrial foams are designed to contain "closed pores," while tissue engineering scaffolds require an "open pore" structure to attain the requisite interconnectivity. Tissue engineering scaffolds may be pre-seeded with cells *in vitro* prior to implantation. Alternatively, tissue-engineering scaffolds may consist of a cell-free structure that is either invaded and "colonized" by cells after implantation, or a surgeon may seed the scaffold with autologous cells intraoperatively (e.g., combining bone marrow aspirate

with demineralized bone matrix to treat bone defects). In either case, the tissue engineering scaffold must allow the formation of functional tissue *in vivo*, followed by the safe resorption of the scaffold material.

There has been some debate in the literature as to the exact definition of the related term "guided tissue regeneration" (GTR). Guided tissue regeneration is a term traditionally used in dentistry. This term sometimes implies that the scaffold encourages the growth of specific types of tissue. For example, in the treatment of periodontal disease, periodontists use the term "guided tissue regeneration" when using implants that favor new bone growth in the periodontal pocket over soft tissue ingrowth (scar formation) (Asikainen et al., 2006).

One of the major challenges in the design of tissue engineering scaffolds is the need to adjust the rate of scaffold degradation to the rate of tissue healing. Depending upon the application of the scaffold, the polymer may need to maintain integrity in the order of days to months. Scaffolds intended for the reconstruction of bone illustrate this point: in most applications, the scaffold must maintain some mechanical strength to support the bone structure while new bone is formed. Premature degradation of the scaffold material can be as detrimental to the healing process as a scaffold that remains intact for excessive periods of time. The future use of tissue engineering scaffolds has the potential to revolutionize the way aging, trauma, and disease related loss of tissue function could be treated.

Multifunctional devices, as the name implies, combine several of the above-mentioned functions within a single device. Over the last few years, there has been a trend toward increasingly sophisticated applications for degradable biomaterials. Usually, these applications envision the combination of several functions within the same device and require the design of custom-made materials with a narrow range of predetermined material properties. For example, the availability of biodegradable bone nails and bone screws made of ultra high strength poly(lactic acid) opens the possibility of combining the "mechanical support" function of the device with a "site-specific drug delivery" function: a biodegradable bone nail that holds the fractured bone in place and can simultaneously stimulate the growth of new bone tissue at the fracture site by slowly releasing bone growth factors (e.g., bone morphogenetic protein or transforming growth factor β) throughout its degradation process.

Likewise, biodegradable stents for implantation into coronary arteries are currently being investigated (Ramcharitar and Serruys, 2008). The stents are designed to mechanically prevent the collapse and restenosis (reblocking) of arteries that have been opened by balloon angioplasty. Ultimately, the stents could deliver an anti-inflammatory or anti-thrombogenic agent directly to the site of vascular injury. Again, it would potentially be possible to combine a mechanical support function with site-specific drug delivery.

Various functional combinations involve the tissue engineering scaffold. Perhaps the most important multi-functional device for future applications is a tissue engineering scaffold that also serves as a drug delivery system for cytokines, growth hormones or other agents that directly affect cells and tissue in the vicinity of the implanted scaffold.

The Process of Bioerosion

One of the most important prerequisites for the successful use of a degradable polymer for any medical application is a thorough understanding of the way the device will degrade/erode and ultimately resorb from the implant site. Within the context of this chapter, we are limiting our discussion to the case of a solid, polymeric implant. The transformation of such an implant into water-soluble material(s) is best described by the term "bioerosion." The bioerosion process of a solid, polymeric implant is associated with macroscopic changes in the appearance of the device, changes in its physico-mechanical properties and in physical processes such as swelling, deformation or structural disintegration, weight loss and the eventual depletion of drug or loss-of-function. It is important to note that the bioerosion of a solid device is not necessarily due to the chemical cleavage of the polymer backbone, cross-links or side chains. Rather, simple solubilization of the intact polymer chains, for instance, due to changes in pH, may also lead to the erosion of a solid device.

Two distinct modes of bioerosion have been described in the literature: bulk erosion and surface erosion. In bulk erosion, the rate of water penetration into the solid device exceeds the rate at which the polymer is transformed into water-soluble material(s). Consequently, an erosion process that occurs throughout the entire volume of the solid device follows the uptake of water. Due to the rapid penetration of water into the matrix of the polymer, most of the currently available polymers will give rise to bulk eroding devices. In a typical bulk erosion process, cracks and crevices will form throughout the device, which may crumble into pieces. A good illustration for a typical bulk erosion process is the disintegration of an aspirin tablet that has been placed into water. Depending on the specific application, the uncontrollable tendency of bulk eroding devices to crumble into little pieces can be a disadvantage.

Alternatively, in surface erosion, the bioerosion process is limited to the surface of the device. Therefore, the device will become thinner with time, while maintaining its structural integrity throughout much of the erosion process. In surface erosion, the polymer must impede the rapid transport of water into the interior of the device. In addition, the rate at which the polymer is transformed into water-soluble material(s) has to be fast relative to the rate of water penetration into the device. Under these conditions, scanning electron microscopic evaluation of

surface eroding devices has sometimes shown a sharp border between the eroding surface layer and the intact polymer in the core of the device (Mathiowitz et al., 1990).

The determination of whether a material is surface eroding or bulk eroding is dependent on several factors. Since the transport of water into the interior of a device is necessary for erosion, polymer hydrophobicity plays an important role. However, polymer chemistry is not the sole mediator of whether a material undergoes surface or bulk erosion. Von Burkersroda et al. have proposed that the physical architecture of the device may determine if it is surface or bulk eroding (Von Burkersroda et al., 2002). In this publication, a critical thickness is calculated for a selection of polymeric materials. Above this critical thickness, a material is surface eroding, while below this critical thickness it is bulk eroding. This critical thickness is so large for some polymer classes (in the order of meters) that with regard to implantable devices they cannot practically be surface eroding. Therefore, surface eroding devices have so far been obtained only from a small number of hydrophobic polymers containing hydrolytically highly reactive linkages in the backbone. Currently, polyanhydrides, and poly(ortho ester)s are the best-known examples of polymers that can be fabricated into surface eroding devices.

A possible exception to this general rule is enzymatic surface erosion. The inability of enzymes to penetrate into the interior of a solid, polymeric device may result in an enzyme-mediated surface erosion mechanism. In the case of enzymatic surface erosion, the term biodegradation may be correctly applied, for enzymatic degradation of the polymer backbone dominates the rate of hydrolysis under physiological conditions. It is possible for a polymeric device to be classified as bulk eroding and biodegrading if the polymer imbibes sufficient water to allow enzymes to penetrate the swollen network of polymer chains.

Mechanisms of Chemical Degradation

Although bioerosion can be caused by the solubilization of an intact polymer, chemical degradation of the polymer is usually the underlying cause for the bioerosion of a solid, polymeric device. Several distinct types of chemical degradation mechanisms have been identified (Figure I.2.6.2) (Rosen et al., 1988). Chemical reactions can lead to cleavage of cross-links between water-soluble polymer chains (Mechanism I), to cleavage of polymer side chains resulting in the formation of polar or charged groups (Mechanism II), or to cleavage of the polymer backbone (Mechanism III). Obviously, combinations of these mechanisms are possible: for instance, a cross-linked polymer may first be partially solubilized by the cleavage of cross-links (Mechanism I), followed by the cleavage of the backbone itself (Mechanism III). It should be noted that water is key to all of these degradation schemes. Even enzymatic degradation occurs in an aqueous environment.

Since the chemical cleavage reactions described above can be mediated by water or by biological agents, such as enzymes and microorganisms, it is possible to distinguish between hydrolytic degradation and biodegradation. It has often been stated that the availability of water is virtually constant in all soft tissues and varies little from person to person. On the other hand, the levels of enzymatic activity may vary widely not only from person to person, but also between different tissue sites in the same person. Thus polymers that undergo hydrolytic cleavage tend to have more predictable *in vivo* erosion rates than polymers whose degradation is mediated predominantly by enzymes. The latter polymers tend to be generally less useful as degradable medical implants.

## Factors that Influence the Rate of Bioerosion

Although the solubilization of intact polymer, as well as several distinct mechanisms of chemical degradation have been recognized as possible causes for the observed bioerosion of a solid, polymeric implant, virtually all currently available implant materials erode due to the hydrolytic cleavage of the polymer backbone (Mechanism III in Figure I.2.6.2). We therefore limit the following discussion to solid devices that bioerode in this manner.

The main factors that determine the overall rate of the erosion process are the chemical stability of the hydrolytically-susceptible groups in the polymer backbone, the hydrophilic–hydrophobic character of the repeat units, the morphology of the polymer, the initial molecular weight and molecular weight distribution of the polymer, the fabrication process used to prepare the device, the presence of catalysts, additives or plasticizers, and the geometry (specifically the surface area to volume ratio) of the implanted device.

The susceptibility of the polymer backbone to hydrolytic cleavage is probably the most fundamental parameter. Anhydride bonds are the most susceptible to hydrolysis, followed by carbonate, ester, urethane, ortho ester, and amide bonds (Figure I.2.6.3) (Gombotz and Pettit, 1995). Thus, polyanhydrides will tend to degrade faster than polyesters, which in turn will have a higher tendency to bioerode than polyamides. Based on the known susceptibility of the polymer backbone structure to hydrolysis, it is possible to make predictions about the bioerosion of a given polymer.

However, the actual erosion rate of a solid polymer cannot be predicted on the basis of the polymer backbone structure alone. The observed erosion rate is strongly dependent on the ability of water molecules to penetrate into the polymeric matrix. The hydrophilic versus hydrophobic character of the polymer, which is a function of the structure of the monomeric starting materials, can therefore have an overwhelming influence on the observed bioerosion rate. For instance, the erosion rate of polyanhydrides can be slowed by about three orders of magnitude when the less hydrophobic sebacic acid is
FIGURE I.2.6.2 Mechanisms of chemical degradation, adapted from Gombotz and Pettit (1995). Mechanism I involves the cleavage of degradable cross-links between water-soluble polymer chains. Mechanism II involves the cleavage or chemical transformation of hydrophobic polymer side chains, resulting in the formation of charged or polar groups. The presence of charged or polar groups leads then to the solubilization of the intact polymer chain. Mechanism III involves the cleavage of unstable linkages in the polymer backbone, followed by solubilization of the low molecular weight fragments.
FIGURE I.2.6.3 Relative hydrolytic susceptibility of degradable bonds at physiologic pH, adapted from Gombotz and Pettit (1995). In general, polymers with high rates of main chain bond hydrolysis will degrade more quickly than polymers with low rates of main chain bond hydrolysis, but many other factors, such as pH and autocatalysis at low pHs, copolymer composition and structure, percent crystallinity, and related equilibrium water content, and geometry of the degradable polymer, will influence the polymer/device degradation rate. For example, at acidic pHs, the order in this table would change, because poly(ortho ester)s will have a higher rate of hydrolysis, perhaps somewhere between polyanhydrides and polycarbonates. In a related example, with thicker samples of polyesters such as PLGA, the acidic byproducts (lactic acid and glycolic acid) may accumulate within the bulk, lowering the internal bulk pH and leading to more rapid degradation within the bulk of the sample than at the surface.

replaced by the more hydrophobic bis(carboxy phenoxy) propane as the monomeric starting material (Tamada and Langer, 1993). Likewise, devices made of PGA erode faster than identical devices made of the more hydrophobic PLA, although the ester bonds have about the same chemical reactivity toward water in both polymers.

The observed bioerosion rate is further influenced by the morphology of the polymer. Polymers can be classified as either semicrystalline or amorphous. At body temperature (37°C) amorphous polymers with Tg (glass transition temperature) above 37°C will be in a glassy state, and polymers with a Tg below 37°C will be in a rubbery state. In this discussion it is therefore necessary to consider three distinct morphological states: semicrystalline; amorphous-glassy; and amorphous-rubbery.

In the crystalline state, the polymer chains are densely packed and organized into crystalline domains that resist the penetration of water. Consequently, backbone hydrolysis tends to occur in the amorphous regions of a semicrystalline polymer and at the surface of the crystalline regions. This phenomenon is of particular importance to the erosion of devices made of poly(L-lactic acid) and poly(glycolic acid), which tend to have high degrees of crystallinity, around 50%.

Another good illustration of the influence of the polymer morphology on the rate of bioerosion is provided by a comparison of poly(L-lactic acid) and poly(D,L-lactic acid); although these two polymers have chemically identical backbone structures and an identical degree of hydrophobicity, devices made of poly(L-lactic acid) tend to degrade much more slowly than identical devices made of poly(D,L-lactic acid). The slower rate of bioerosion of poly(L-lactic acid) is due to the fact that this stereoregular polymer is semicrystalline, while the racemic poly(D,L-lactic acid) is an amorphous polymer.

Likewise, a polymer in its glassy state is less permeable to water than the same polymer when it is in its rubbery state. This observation could be of importance in cases where an amorphous polymer has a glass transition temperature that is not far above body temperature (37°C). In this situation, water absorption into the polymer could lower its Tg below 37°C, resulting in abrupt changes in the bioerosion rate.

The manufacturing process may also have a significant effect on the erosion profile. For example, Mathiowitz and co-workers (Mathiowitz et al., 1990) showed that polyanhydride microspheres produced by melt encapsulation were very dense and eroded slowly, whereas when the same polymers were formed into microspheres by solvent evaporation, the microspheres were very porous (and therefore more water permeable) and eroded more rapidly.

The above examples illustrate an important technological principle in the design of bioeroding devices; the bioerosion rate of a given polymer is not an unchangeable property, but depends to a very large degree on readily controllable factors such as the presence of plasticizers or additives, the manufacturing process, the initial molecular weight of the polymer, and the geometry of the device.

Storage Stability, Sterilization, and Packaging

It is important to minimize premature polymer degradation during fabrication and storage. Traces of moisture can seriously degrade even relatively stable polymers, such as poly(bisphenol A carbonate), during injection molding or extrusion. Degradable polymers are particularly sensitive to hydrolytic degradation during high temperature processing. The industrial production of degradable implants therefore often requires the construction of facilities with controlled atmospheres where the moisture content of the polymer and the ambient humidity can be strictly controlled.

After fabrication, γ-irradiation or exposure to ethylene oxide may be used for the sterilization of degradable implants. Both methods have disadvantages, and as a general rule the choice is between the lesser of two evils. γ-Irradiation at a dose of 2 to 3 Mrad can result in significant backbone degradation. Since the aliphatic polyesters PLA, PGA, and PDS are particularly sensitive to radiation damage, these materials are usually sterilized by exposure to ethylene oxide, and not by γ-irradiation. Unfortunately, the use of the highly dangerous ethylene oxide gas represents a serious safety hazard by potentially leaving residual traces in the polymeric device. Polymers sterilized with ethylene oxide must be degassed for extended periods of time.

Additionally, for applications in tissue engineering, biodegradable scaffolds may be pre-seeded with viable cells or may be impregnated with growth factors or other biologics. There is currently no method that could be used to sterilize scaffolds that contain viable cells without damaging the cells. Therefore, such products must be manufactured under sterile conditions, and must be used within a very short time after manufacture. Currently, a small number of products containing pre-seeded, living cells are in clinical use. These products are expensive, are shipped in special containers, and have a short shelf life.

Likewise, it has been shown that sterilization of scaffolds containing osteoinductive or chondroinductive agents leads to significant losses in bioactivity, depending on the sterilization method used (Athanasiou et al., 1998). The challenge of producing tissue engineering scaffolds that are pre-seeded with viable cells or that contain sensitive biological agents has not yet been fully solved.

After sterilization, degradable implants are usually packaged in air-tight aluminum-backed plastic-foil pouches. In some cases, refrigeration may also be required to prevent backbone degradation during storage.

Evaluating Toxicity of Bioerodible Materials

A polymeric medical device is not completely pure. Device toxicity could originate from many sources, such as those listed below:

Polymer impurities: Initiators, residual monomers and oligomers, byproducts.
Solvents: Contamination from solvents used in synthesis, to clean equipment or in fabrication (e.g., solvent casting processes to produce films, microspheres or fibers).
Additives: Stabilizers, emulsifiers, antioxidants, plasticizers.

Processing byproducts: Byproducts of high-temperature processing and sterilization.
Degradation products: Products of hydrolytic or enzymatic degradation and their subsequent metabolites.

Testing for potential toxicity is governed by ISO 10993 and the FDA G95-1 Memorandum. Cytotoxicity, sensitization, irritation, carcinogenicity, genotoxicity, hemocompatibility, and systemic toxicity are evaluated using cell culture methods and animal testing:

Mammalian cell culture: Indirect (agar overlay) or direct sample contact or exposure to device extract.
Animal testing: Mouse, rat, guinea pig, and dog models are typically used with evaluation by histopathology, gross observation of redness or swelling, lymph node extraction, micronucleous assay, and blood thrombogenicity, lysis, and complement activation.

GLOSSARY OF KEY TERMS

Degradation: A chemical process by which covalent bonds are cleaved.
Erosion: A process that results in physical changes to the size, shape, or mass of a material.
Biodegradation: Degradation as a consequence of a biological agent, such as an enzyme, cell, or microorganism.
Bioerosion: Conversion of a water-insoluble material into a water-soluble material(s) under physiological conditions, regardless of the mechanism of conversion.
Surface erosion: A process of polymer erosion where the rate of conversion to water-soluble material(s) exceeds the rate of water infiltration into the interior of the device. As a consequence, material erodes from the surface of the device, while the core remains structurally consistent.
Bulk erosion: A process of polymer erosion where the rate of water penetration into the interior of the device exceeds the rate of conversion into water-soluble material(s). As a consequence, material erosion is equally likely to happen throughout the bulk of the device.

CHAPTER I.2.7 ENGINEERED NATURAL MATERIALS

Glenn D. Prestwich[1] and Sarah Atzet[2]

[1]Department of Medicinal Chemistry and The Center for Therapeutic Biomaterials, The University of Utah, Salt Lake City, Utah, USA

[2]Glycosan BioSystems, Inc., Salt Lake City, Utah, USA

INTRODUCTION TO COMMONLY USED NATURAL MATERIALS

Naturally occurring materials offer several advantages, since the surrounding biological environment can recognize and metabolically process implanted substances through established pathways. However, natural materials have historically been plagued with several drawbacks, including immunogenicity, lot-to-lot variability, structural complexity, and inadequate biomechanical properties. Recent developments in the field have led to a reduction of these unfavorable properties, and a substantial number of successful biomaterials and biomaterial applications based on the unique properties of naturally occurring polymers and their chemically-modified derivatives have been developed (Shin et al., 2003; Khademhosseini et al., 2009).

A unique advantage of naturally derived materials is that through either enzymatic or hydrolytic degradation the host can successfully clear and metabolize the implanted substance. While this may not be desirable in permanent and long-term implants such as hip replacements, it is extremely advantageous when timed biological resorption is desired, i.e., in delivery vehicles for drugs or therapeutic cells. Natural materials can be chemically modified and cross-linked to match the degradation rate to a particular biological application (Augst et al., 2006; Badylak and Gilbert, 2008).

One frequent concern about natural materials is the immunogenic response that can occur following implantation. This response results from the fact that the implanted materials, although similar to the endogenous

| TABLE I.2.7.1	General Properties and Sources of Select Natural Materials		
Alginate	Algae (Kelp)	Anionic polysaccharide, limited degradation unless modified, forms hydrogels	Wound dressing (Phytacare™) (see ref. FDA PhytaCare)
Chitosan	Crustacean exoskeletons	Positively charged, enzymatic degradation, can form hydrogels	Hemostats/wound dressings (HemCon™) (see ref. FDA HemCon)
Silk	Synthesized by arthropods (spider or silk worm)	Physiologic function is as a protective cocoon, strong and can be woven, slow or minimal degradation, reported biocompatibility issues	Sutures (Ethicon) (see ref. Ethicon Silk Sutures)
Elastin	Animal tissues	Structural ECM protein found in connective tissues, low solubility, reversible deformation, soluable precursor is tropoelastin	Surgical Mesh (Bard) (see ref. FDA Collamend)
Elastin-Like Peptides	Synthetically produced	Synthetic mimic of elastin based on highly repetitive amino acid motifs, reversible thermal phase transition	N/A
Collagen	Animal tissues/ cell culture/ bacterial fermentation	Abundant ECM protein, triple helix structure, provide cell attachment sites, well documented	Dermal filler (CosmoDerm™) (see ref. FDA CosmoDerm)
Gelatin	Denatured collagen	Inexpensive form of collagen, used for cell attachment in culture	Gelfoam™ Sterile Sponge (see ref. FDA GelFoam)
Fibrin/ Fibrinogen	Animal tissues or plasma	Fibrin results from polymerization of fibrinogen with thrombin, crucial component for clot formation	Fibrin Sealent (Evicel™) (see ref. FDA Evicel)
Hyaluronic Acid	Animal tissues/ bacterial fermentation	Lubricating polymer only non-sulfated GAG, negatively charged, can form hydrogels	Dermal fillers (Restylane™) / Wound dressings (see ref. FDA Restylane)
Heparin	Animal tissues/plasma	Strongly negatively charged GAG, binds to numerous GFs, anti-coagulant activity, used for coating stents	Stent and catheter coatings (see ref. FDA TyCo)
Chondroitin Sulfate	Animal tissues (commonly shark cartilage)	Negatively charged GAG, major component of cartilage	Nutritional supplements/ Wound Dressings (gels) (Applied Nutritionals) (see ref. FDA Applied Nutritionals)
Decellularized Tissue	Animal tissue	Complex mixture of proteins/GAGs that retains tissue's ECM composition and structure, residual cellular components can cause immune reactions	Decellularized pulmonary artery patch (Allograft™) (see ref. FDA Allograft)

host extracellular matrix component, may not be identical, and thus contain antigenic determinants. This issue is more common among protein-based materials, but is typically significantly lower among polysaccharides including glycosaminoglycans. Additionally, this immunogenic effect can be reduced by either chemical modification or through sourcing of the natural material (Badylak and Gilbert, 2008). Chemical modification and cross-linking are common methods for altering mechanical properties such as elasticity and tensile strength of natural materials that are often not appropriate for dynamic physiologic environments (i.e., the beating myocardium). However, the complex structures of natural materials can complicate technical modifications that are simple to perform in synthetic polymers. Nonetheless, numerous research studies have demonstrated the successful modification and purification of natural-based materials. Another common issue arising with natural materials is the lot-to-lot variability in molecular structure that occurs due to animal sourcing. Variability arises not only due to species-to-species variation, but also from tissue-to-tissue variation. This can complicate processing and quantification of the materials. Recently bacterial recombinant techniques have been use to produce several natural materials including hyaluronic acid (HA) and collagen.

This production technique reduces both the variability and immunogenicity issues with natural materials. The following section will discuss common types of natural based biomaterials, their origins, and uses. Table I.2.7.1 details several of these natural materials, their common sources, characteristics, and notable FDA approved products. Figure I.2.7.1 illustrates the structures of natural polymers commonly used in biomaterials and medical devises. The remainder of this chapter will focus on biomaterials engineered from one specific biopolymer, HA.

Alginate

Alginates constitute a family of linear anionic polysaccharides isolated from coastal brown algae species (commonly known as kelp) such as *Laminaria hyperborean* (Augst et al., 2006). Alginates are composed of (1,4)-linked β-D-mannuronic acid (M) and α-L-guluronic acid (G) residues in homopolymer blocks of either similar or strictly alternating sections (i.e., MMMMM, GGGGG, MGMGMG) (Rowley et al., 1999). The relative amounts of the blocks are dependent on the origin of the alginate. Due to axial links, G blocks are stiffer than M blocks and alternating sequences in turn increase the solubility of the alginate. The molecular weight of alginates
FIGURE I.2.7.1 Structures of natural polymers found in biomaterials and medical devices.

can vary between 50 kDa and 100,000 kDa. Hydrogels can be formed by various cross-linking methods. A common technique is to use a divalent cation (Ca^{2+} or Ba^{2+}) to form ionic bonds between the carboxylic groups of neighboring strands, thereby inducing chain–chain associations. Alginate can also be cross-linked by partial oxidation of the poly(guluronate), followed by reaction with adipic dihydrazide to form covalent cross-links. A third cross-linking strategy uses polyethylene glycol diamines to covalently link alginate chains. Gel stiffness and elasticity vary with composition and cross-linking method. The stiffness of divalent cation cross-linked alginate increases with the following trends in composition: MG < MM < GG, whereas elasticity increases following GG < MM < MG. Thus the M:G ratio, cross-linking method, and molecular weight can all be used to tune mechanical properties of alginate gels.

Because alginate is foreign to mammalian cells, alginate materials are not naturally broken down enzymatically *in vivo*, and as a result have poorly controlled degradation *in vivo*. When the divalent cations are exchanged with Na^+ ions, ionically cross-linked alginate typically undergoes slow uncontrolled dissolution at neutral pH (i.e., greater than three months) (Mi et al., 2002a; FDA PhytaCare 510(k), 2010; FDA HemCon 510(k), 2010). Degradation kinetics of covalently cross-linked alginate generally depends on the type and density of cross-linker (Mi et al., 2002a). However, there are strategies to adjust degradation kinetics by modifying polymer molecular weight, composition (M:G), and by partial oxidation.

Another unique property of alginate is that it is relatively biologically inert. Cells do not naturally adhere to alginate, which has fostered investigations in the attachment of extracellular matrix (ECM) proteins and peptide sequences to hydrogels. Adhesion proteins such as laminin, fibronectin, and collagen have all been coupled to alginate, as well as the integrin-binding,

fibronectin-derived, cell adhesive peptide arginine–glycine–aspartic acid (RGD) and its derivatives (FDA PhytaCare 510(k), 2010; FDA Collamend 510(k), 2010). These modifications have led to significant changes in cellular attachment to alginate materials.

Specifically tailored alginate hydrogels have numerous proposed uses, including as bulking agents, drug delivery vehicles, and scaffolds for regenerative medicine. Alginate hydrogels have been clinically investigated as a carrier for transplanted chondrocytes to treat intrinsic sphincter disease, and as a delivery vehicle for mineralization promoting proteins. Alginate-based biomaterials have been approved by the FDA for topical use in wound healing. The PhytaCare™ Alginate Hydrogel and the Silverlon™ Calcium Alginate Dressing products both have 510(k) clearance as barrier wound dressings that provide a microbial barrier for partial to full thickness wounds including ulcers, graft sites, surgical wounds, and burns.

Chitosan

Chitosan is a polycationic copolymer of *N*-acetyl-glucosamine and *N*-glucosamine, and is generally obtained by alkaline deacetylation of chitin, a linear homopolymer of *N*-acetyl-glucosamine. Chitin is structurally related to glycosaminoglycans, but lacks the uronic acid groups. It is the primary component in fungi cell walls, and the exoskeleton of crustaceans such as shrimp, crab, and lobster (Khor and Lim, 2003). When the degree of deacetylation (DD) (conversion to *N*-glucosamine) is greater than 50%, the biopolymer is termed chitosan. The biopolymer is soluble in dilute acidic solutions, such as acetic acid or hydrochloric acid, and as a result the amino groups become protonated (Jiang et al., 2008). Chitosan hydrogels can be formed by entangled networks, ionic cross-links/polyelectrolyte complexes or by covalent cross-linking (Mi et al., 2002b; Berger et al., 2004). Once dissolved, entangled networks

of chitosan can gel by increasing the pH or extruding the solution into a nonsolvent. Entangled networks have limited use due to a lack of mechanical strength and a tendency to dissolve. Due to the cationic nature of chitosan, combination with a negatively charged polymer, such as chondroitin sulfate or hyaluronan, will result in an ionic bound network. Covalently cross-linked hydrogels can be prepared by reaction with various di-functional molecules such as glutaraldehyde, poly(ethylene glycol) dialdehyde diethyl acetal, or genipin (Dal Pozzo et al., 2000). Chitosan has been shown to be metabolized by human enzymes such as lysozyme, and thus is considered biodegradable. Degradation rates depend on the type of hydrogel network, and specifically for covalent networks, the type and density of cross-linker (Freier et al., 2005a). As with alginate, much research has explored the conjugation of biomolecules to chitosan, either by ionic, adsorption, or covalent modification of ECM proteins and peptide sequences to modify cellular response (Suh and Matthew, 2000; Ho et al., 2005). Chitosan provides multiple hydroxyl and amino functional sites for chemical modification opportunities (Berger et al., 2005). Chitosan-based hydrogels have been researched and developed for applications in drug and growth factor delivery, tissue regenerative scaffolds, and wound dressings (Rao and Sharma, 1997; Mi et al., 2002c; VandeVord et al., 2002; Mi et al., 2003; Freier et al., 2005b). Currently, chitosan based biomaterials have been approved by the FDA for topical use in wound healing and as hemostats. Scion Cardio-Vascular, Inc. developed and markets a soft absorbent pad called the Clo-Sur P.A.D™ as a noninvasive topical approach to hemostasis based on chitosan and its absorbent properties. This product has been cleared as a Class III medical device by the FDA. Other devices with FDA 510(k) clearance are Aquanova's super absorbent dressing for wounds such as ulcers, and Celox's granulated chitosan for hemostasis.

Collagen

Collagen is the most prevalent protein in the connective tissue of animals, and constitutes approximately 25% of total body protein in vertebrates. The molecular subunit of collagen, called tropocollagen, is a rigid rod with a molecular weight ~300 kDa (Ratner and Hoffman, 2004). Tropocollagen self assembles into larger structural units called fibrils or fibers. While there are several types of collagen, these larger units, or fibers, all share the characteristic triple helical structure, but have variations in the length of the non-helical and helical sections, and variations in the number of carbohydrates attached to the helical fraction (Stenzel et al., 1974). There are four commonly used types of collagen, and here we will follow the nomenclature proposed by Kauzmann (Kauzmann, 1959). Type I collagen is the type commonly found in skin, bone, and tendons, while type II is common in cartilage. Type III collagen is prevalent in the vasculature structures (i.e., blood vessel walls), and can also be found

in small amounts in skin. Type IV collagen is unique in that it is largely non-helical and does not form fibrils. Collagen Type IV is found in the basement membrane that separates epithelial and mesodermal tissues (Kauzmann, 1959; Kuntz and Kauzmann, 1974). Gelatin is an irreversibly denatured, hydrolyzed form of collagen that is commonly used in pharmaceuticals, cosmetics, and foodstuffs. Most medical-grade collagen and gelatin are obtained from closely regulated bovine and porcine tissue. However, human collagen can be obtained by recombinant methodology, isolation from tissues such as lung and placenta, or from human cell culture (Lee et al., 2001).

Collagen is used as a biomaterial because of its widespread abundance in nature and ease of modification (Stenzel et al., 1974; Stone et al., 1997; Friess, 1998). Collagen is composed of some 20 amino acids, each providing pendant side groups available for chemical modification (White et al., 1973; Lin et al., 2003). The prevalence of hydroxyl, amine, and carboxylic acid groups allows simple cross-linking between and within collagen units. Cross-linking collagen can decelerate the degradation of implanted materials, and is thought to reduce immunogenicity in xenografted collagen materials (Nimni et al., 1987). Self-cross-linking of collagen via interchain peptide bonds can be induced by dehydration when exposed to high temperatures (i.e., >105°C). Dialdehydes are also commonly used to cross-link collagen, and have long been used in the leather industry as tanning agents. Exposure to glutaraldehyde produces collagen with firm covalent cross-links and elastic behavior. Numerous commercial products have been developed from collagen and collagen-based technologies; a few examples are dermal fillers CosmoDerm™ and Zyderm™ (Allergan), and the sponge-like Gelfoam™ (Pfizer). CosmoDerm™ is a human collagen-based implant generated and purified from human fibroblast cell culture. Type I collagen is the major component of this material while Type III provides minor contributions, as determined by Western blot analysis. Alternatively, Zyderm™ is based on bovine-derived Type I collagen, although both products are chemically cross-linked by treatment with glutaraldehyde. Gelfoam™ is an absorbable, sterile compressed sponge produced from denatured collagen I from porcine skin. It is water-soluble, non-elastic and porous, and is used for compression, and in combination with human thrombin as a hemostat.

Fibrin

Fibrin is a naturally occurring biodegradable matrix that can be produced via polymerization of fibrinogen and thrombin to form a mesh network (Ahmed et al., 2008). Fibrinogen is a glycoprotein synthesized by the liver and soluble in the bloodstream (Linnes et al., 2007). Thrombin, also produced in the liver and found in the bloodstream, initiates end-to-end polymerization of the soluble fibrinogen to form long strands which precipitate to form a fibrin mesh. This polymerization occurs naturally at a

wound site and contributes, in conjunction with plate-lets, to form a clot. *In vivo*, fibrin gels are degraded by the proteolytic enzyme plasmin. Fibrin gels often do not possess the required mechanical strength for some physi-cally dynamic environments. To overcome this, research-ers have combined various natural or synthetic polymers, such as collagen or polyglactin, to provide stronger gels (Eyrich et al., 2007; Dare et al., 2009). Commercially available fibrin sealants are used to control bleeding and speed wound healing. Fibrinogen can be isolated from animal plasma, including human plasma. Thus, autolo-gous scaffolds for tissue engineering applications can be generated from a patient's own blood.

Elastin and Elastin-Like-Peptides

Elastin is an extracellular matrix protein that pro-vides elasticity to tissues and organs. It is abundant in blood vessels, ligament, lung tissue, and skin; all organs that commonly stretch and relax (Geutjes et al., 2006; Daamen et al., 2007). Tropoelastin, the soluble protein precursor to elastin, can align and form intermolecular cross-links resulting in extremely stable insoluble elastin. As a biomaterial, elastin can have various forms. Insolu-ble elastin can be used in autografts or allografts, it can be hydrolyzed to be used in soluble elastin preparations, or tropoelastin can provide components of biomaterials. Elastin-like peptides (ELPs) have been synthetically pro-duced (Urry et al., 2002; McHale et al., 2005). These polypeptides are composed of the highly repetitive amino acid sequences found in elastin. Physical properties of the ELPs can be manipulated based on amino acid sequence and resulting hydrophobicity. The polypeptides can coacervate and then be cross-linked by gamma irradia-tion. Researchers have produced non-woven fabrics and fibers by electrospinning ELPs (Huang et al., 2000).

Decellularized Tissues

Tissues are composed of both cellular material and extra-cellular matrix proteins in various densities. Decellular-ized tissues are natural materials, usually from an animal or human source, that have been purified in such a way as to remove all cellular components and debris but maintain the three-dimensional structural and functional proteins of the ECM (Gilbert et al., 2006). The tissue site, species of origin, decellularization process methods, and end point sterilization techniques can vary greatly for these materials. It is necessary to remove the cellular components and antigens as they are recognized by host tissue as foreign and irrevocably induce an inflammatory response or immune-mediated rejection of the decellular-ized tissue (Badylak et al., 1995). On the other hand, the structure of ECM components is generally well-conserved between species, and typically well-tolerated by host recipients. Ideally, a decellularization protocol, which often includes multiple stages of physical, chemical, and

enzymatic treatments, should gently remove all cellular and nuclear components while minimizing effects on the ECM. Reported batch-to-batch variations are large due to tissue source, composition, and density, even when decellularization protocols are predominately similar (Daamen et al., 2007). A number of ECM-based devices have received regulatory approval, including porcine heart valves (Synergraft™, CryoLife™), porcine small intestinal submucosa (SurgiSIS™, Cook Biotech), and a pulmonary artery patch (Allograft™).

Glycosaminoglycans

Glycosaminoglycans (GAGs) are a family of linear polysac-charides that can generally be described as an alternating copolymer, and are found in all animal tissues. The repeat units of GAGs consist of a hexamine unit (glucosamine or galactosamine) and a sugar (galactose, glucuronic acid, or iduronic acid). GAGs are found on cell surfaces in the extracellular matrix and are well-preserved among spe-cies (Hildebrandt, 2002; Prestwich 2008a; Prestwich and Kuo, 2008). When GAGs are bound to a protein core the resulting macromolecule is termed a proteoglycan and is often described as having a "bottlebrush-like" configu-ration. The molecular weights of GAGs generally range from 5 to 5000 kDa. There are several specific GAGs used as biomaterials including heparin, heparan sulfate, keratan sulfate, dermatan sulfate, chondroitin sulfate, and HA. GAGs are naturally degraded by enzymes such as hyaluronidase, chondroitinase, and heparanase.

Heparin is a highly sulfated GAG and is widely used as an anticoagulant (Breckwoldt et al., 1991; van der Giessen et al., 1998; Hildebrandt, 2002). Due to the sul-fation levels it is very strongly negatively charged. Phar-maceutical heparin is commonly derived from bovine or porcine mucosal tissues. Heparin is chemically related to heparan sulfate and is composed of variably sulfated disaccharides. The predominant saccharide units are D-glucosamine and uronic acid (either D-glucuronic acid or L-iduronic acid) with sulfation of some hydroxyl groups. Due to the strong negative charge, heparin has been found to bind to growth factors, such as vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF), and stabilize them *in vivo*, thus regulating their release (Peattie et al., 2008). Growth fac-tor release is dependent on the strength of association with heparin, and can vary depending on the growth factor and environment from days to weeks. Heparin was one of the first biological molecules to be covalently immobilized to biomaterials (Hoffman et al., 1972; Schmer, 1972; Basmadjian and Sefton, 1983), and has since been used extensively for coating in catheters, stents, and other medical devices (Breckwoldt et al., 1991; van der Giessen et al., 1998; Cauda et al., 2008; Jiang et al., 2009; FDA TyCo, 2010).

Chondroitin sulfate (CS) is also a negatively charged GAG, but it is composed of repeating glucuronic acid and
FIGURE I.2.7.2 The non-sulfated glycosaminoglycan hyaluronan (HA) forms viscoelastic solutions that are important in human biology.

FIGURE I.2.7.3 Chemically-modified HA can occur in monolithic or living forms, and this table summarizes the principal differences with examples of specific products.

N-acetylgalactosamine units. Most disaccharide units contain a single sulfate at C-4 or C-6 hydroxyl groups, as well as a carboxyl group that can be chemically modified (Yuan et al., 2008; Baldwin and Kiick, 2010). CS is a major component of cartilage tissue, and being capable of readily absorbing water is credited for the compressive strength of that tissue. It is generally found attached to proteoglycans as a structural protein or on cell surfaces or basement membranes where it functions as a receptor. Commercial chondroitin sulfate is often sourced and purified from shark or whale cartilage, or from bovine or porcine tissues (Baldwin and Kiick, 2010).

Hyaluronic acid (HA) is the only non-sulfated glycosaminoglycan, and consists of repeating disaccharide units of N-acetylglucosamine and glucuronic acid (Figure I.2.7.2). In addition to being unsulfated, HA is unique among GAGs in that it exists in much higher molecular weights (50–5000 kDa), is secreted by cells, and (with a few exceptions) does not occur as a proteoglycan, that is, bound to a protein core (Prestwich and Kuo, 2008). HA has been extensively studied as a biomaterial, in part due to these and other unique properties (Shu et al., 2002, 2004, 2006). The remainder of this chapter will now focus on HA as a unique glycosaminoglycan, and discuss its chemistry, biology, and its future as the basis of clinical products for reparative and regenerative medicine.

HA IN MEDICINE: THE OLD AND THE NEW

The molecular weight can vary from over 6000 kDa in umbilical cords and rooster combs, to 100 kDa and below in serum. HA is found in the ECM of all tissues of the body, and is particularly abundant in umbilical cords, embryonic hearts, the eye, synovial fluid, and cartilage (Laurent, 1989). HA occurs primarily as the sodium salt under physiological conditions; collectively, HA, sodium HA, and other HA salts are often referred to as hyaluronan. The two major commercial sources of HA are rooster combs for >2000 kDa HA and bacterial fermentation for 50–100 kDa HA, and these are polydisperse. Recently, a third option, unique to Hyalose,

is HA and labeled HA oligosaccharides produced enzymatically to give monodisperse polymers ranging from only a few disaccharide units up to 20 kDa (DeAngelis et al., 2003). HA forms lubricious and viscoelastic solutions that can protect eye tissues during ophthalmic surgeries, provide viscosupplementation in joints, reduce post surgical adhesions, and deliver drugs (Kuo, 2006). However, the short residence time *in vivo* of HA and its poor mechanical properties led to many chemical modifications of HA (Shu and Prestwich, 2004; Allison and Grande-Allen, 2006). In the last two decades, HA-based medical devices and coatings have addressed clinical needs with different levels of success.

Chemically-modified HA derivatives can be grouped into two types: monolithic and living (Figure I.2.7.3) (Prestwich and Kuo, 2008). The chemistry and biology of HA is exhaustively reviewed on the Glycoforum website (http://glycoforum.gr.jp/science/hyaluronan/). Monolithic derivatives arise when the chemical modification gives a final form that cannot form new chemical bonds in the presence of cells or tissues, and can only be physically fabricated into different forms. In contrast, living derivatives contain modifications that permit the formation of new covalent bonds in the presence of cells or tissues, enabling a change in physical form during *in vivo* or *in vitro* biological use. For example, an *in situ* cross-linkable material for adhesion prevention or cell encapsulation would be a living modification.

The Old: Monolithic Ha Derivatives

Carbodiimide-mediated reaction products. In water at pH <5, the carboxylic acid groups of HA can react with an ethyl dimethylaminopropylcarbodiimide (EDCI) to form an intermediate *O*-acylurea that can be trapped or rearranged to the more stable *N*-acylurea adduct (Pouyani et al., 1994). Interaction of the cationic aminopropyl moiety with remaining carboxylates can lead to physical gelation. Seprafilm™ (Genzyme) is the product of EDCI plus HA and carboxymethylcelluose, yielding a bioabsorbable material that is used to prevent post-surgical adhesions in abdominal and gynecological indications. Seprafilm™ is brittle when dry, and sticky when moist, and is therefore difficult for surgeons to handle. The use of biscarbodiimides affords chemically cross-linked HA

(Kuo et al., 1991), a technology found in the post-surgical adhesion product Incert™ (Anika Therapeutics).

Divinylsulfone cross-linking. Hylans™ (Biomatrix, Genzyme) are HA derivatives that are cross-linked through the hydroxyl groups, leaving the majority of the carboxylic acids unmodified (Band, 1998). Hylan A™ develops HA–protein cross-links with formaldehyde, giving HA products with increased molecular weight. In contrast, Hylan B™ is a highly swollen gel with an infinite network of divinylsulfone cross-links. Hylans™ are more viscoelastic than HA and have longer half-lives *in vivo*. Hylans™ are used as injectable materials (Synvisc) to treat osteoarthritic joints (Arrich et al., 2005), as dermal fillers (Beasley et al., 2009) to treat facial wrinkles (Hylaform™), and as space-occupying stents in nasal/sinus surgery (Hylasine™, Sepragel Sinus) (Kuo, 2006).

Esterification. HA esters are prepared by the reaction of the quaternary ammonium salt of HA with an alcohol that imparts hydrophobicity, using a non-aqueous solvent such as dimethylformamide for the reaction (Campoccia et al., 1998). For example, the benzyl ester HYAFF-11 (Fidia Advanced Biopolymers) is less susceptible to enzymatic degradation than native HA. HYAFF-11 scaffolds are cell adhesive and are stable in aqueous solution for over three weeks. A three-dimensional HYAFF scaffold supports proliferation of keratinocytes, fibroblasts, chondrocytes, and mesenchymal stem cells. The dermal replacement (Hyalograft 3D™) consists of HYAFF-11 with autologous fibroblasts combined with an epidermal replacement (Laserskin) made of a microperforated HYAFF-11 membrane containing autologous keratinocytes. A clinical study showed 59% of treated pressure ulcers reached complete closure in less than four months with this product. Hyalograft C™, which consists of autologous chondrocytes grown on a HYAFF-11 scaffold, is used to treat cartilage defects of the knee, and patients improved continuously up to three years.

HA carboxyl groups can be activated with 2-chloro-1-methylpyridinium iodide (CMPI) to form internal ester bonds. The so-called autocross-linked polymer (ACP; Fidia) which can be used as a gel (Hyalobarrier™, Hyaloglide™) was effective in the prevention of adhesions in gynecological and joint surgeries in preclinical model studies (Acunzo et al., 2003; Brunelli et al., 2005).

Bis-epoxide cross-linked HA. HA that can be cross-linked with a diglycidyl ether under strongly alkaline conditions to give a biocompatible material with *in vivo* residence times up to 4 weeks (Beasley et al., 2009). For example, Restylane™ (Q-Med) and Juvederm™ (Allergan) are used as cosmetic dermal fillers. HA can also be cross-linked twice with the same bis-epoxide, first under basic conditions and then under acidic conditions. Double cross-linking reduced hyaluronidase degradation compared to the single cross-linked intermediate. Puragen™ (Mentor) is a doubly cross-linked HA gel, and is used as dermal filler in the same manner as Restylane™ and Juvederm™.

The New: Living HA Derivatives

Reversible cross-linking using carbodiimide-mediated hydrazide chemistry. As described above, HA-derived *O*-acylureas can undergo further coupling reactions with compounds that are nucleophilic at pH 4–6, e.g., N-hydroxysuccinimide, aminooxy compounds, and hydrazides (Shu and Prestwich, 2004). When hydrazides containing disulfide bonds are used, living HA derivatives can be produced (Shu et al., 2002). The resulting thiol-modified HA can be cross-linked to itself or to other synthetic and natural polymers bearing thiol groups. Moreover, a variety of physical properties and rates of biodegradation can be obtained by controlling several parameters for the biocompatible HA hydrogels, including: (1) molecular weight of starting HA employed; (2) percentage thiol modification; (3) concentration of thiol-modified HA; (4) choice of chemistry for polyfunctional cross-linker; (5) molecular weight of polyfunctional cross-linker; and (6) ratio of thiols to electrophiles (Prestwich, 2008b).

The cross-linked hydrogel can act as a barrier to cell infiltration and migration. Such a material promotes scar-free wound healing and prevents post-operative adhesion formation. This formulation has been employed for scar-free mucosal healing following endoscopic sinus surgery (Proctor et al., 2006), for prevention of post-surgical abdominal adhesions (Liu et al., 2007a), and to minimize subglottic stenosis in airway stents (Sondrup et al., 2006). Veterinary products from Sentrx Animal Care have been successfully employed for equine and small animal wound care (Figure I.2.7.4).

Electrophilic HA. HA derivatives equipped with thiol-reactive electrophilic esters can react with thiol-modified macromolecules to give "cross-linker-free" hydrogels. HA was converted to the bromoacetate and iodoacetate derivatives (Serban and Prestwich, 2007). Cross-linker-free semi-synthetic ECM (sECM) hydrogels were prepared by combining the polyfunctional electrophilic HA haloacetates with thiol-modified HA (CMHA-S). The resulting hydrogel was cytocompatible, but did not support the attachment of primary fibroblasts. Thus, the HA haloacetates offer an alternative living macromonomer for producing cross-linker-free sECM biomaterials that can function as anti-adhesive barriers or for culture of non-adherent cell types.

Photo-cross-linked HA. Methacrylation of HA by modification of the hydroxyl groups produces macromonomers that can be seeded with cells and photocrosslinked into hydrogels with either UV or visible light plus an initiator (Ifkovits and Burdick, 2007). Potential uses for *in situ* photopolymerized HA hydrogels include prevention of adhesions and tissue regeneration. For example, chondrocytes encapsulated in photocross-linkable HA methacrylate retained the chondrocytic phenotype and synthesized cartilage matrix *in vitro*, and accelerated healing in an osteochondral defect model *in vivo* (Chung

and Burdick, 2009). Importantly, photocross-linked HA methacrylates have been used for self-renewal of human embryonic stem cells without differentiation (Gerecht et al., 2007).

Summary

The first generation of chemically-modified HA derivatives were "monolithic" materials that could be injection molded, shaped, spun, or woven for a variety of clinical uses. While these monolithic materials continue to enjoy commercial and clinical success, an important second generation of "living" HA derivatives have emerged. The living polymers offer many opportunities for three-dimensional cell culture, injectable tissue engineering, wound repair, scar-free healing, drug delivery, and toxicology testing. The applications of the living HA derivatives to produce a synthetic ECM, and the use of sECMs to produce clinical biomaterials, will be described below.

RECREATING THE EXTRACELLULAR MATRIX

Design Criteria

What is the problem to be solved? The native ECM is a heterogeneous network of soluble and fibrous proteins and glycosaminoglycans, which is maintained by both covalent and non-covalent interactions (Figure I.2.7.5). Recapitulating the composition and structure of the ECM is a daunting yet irresistible challenge to engineers and chemists.

Scientific Criteria

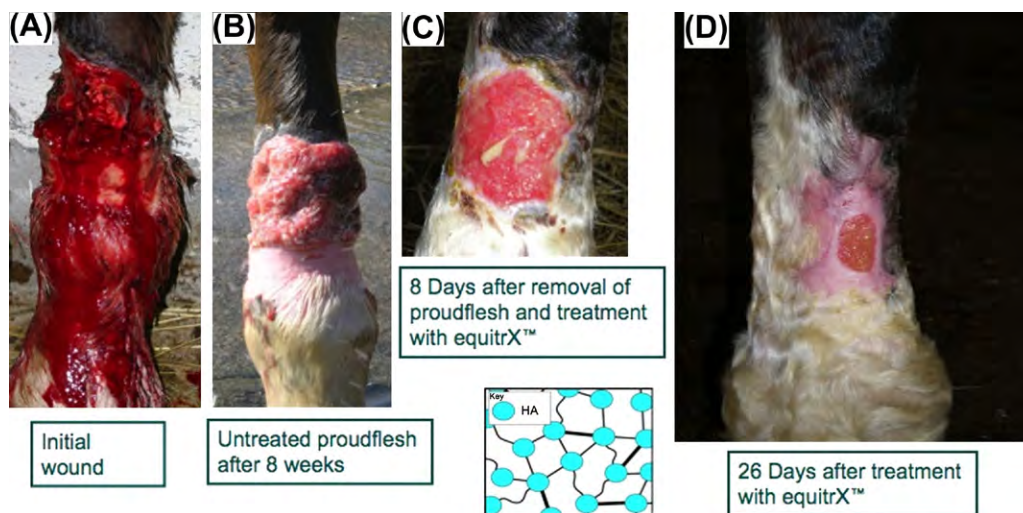
A biomaterial ECM-mimetic needs to recapitulate the principal functions of the natural ECM in orchestrating cell proliferation, migration, differentiation, angiogenesis, and invasion. Several objective design criteria


FIGURE I.2.7.4 The initial injury to this horse's leg (A) went untreated for two months, resulting in the formation of exuberant granulation tissue, or proud flesh (B). The wound was then debrided by a veterinarian, treated with the cross-linked HA product equitrX™. After eight days, the proud flesh had not recurred (C) and 26 days after an additional equitrX™ treatment, the wound was over 80% healed. Courtesy of Sentrx Animal Care (www.sentrxanimalcare.com).
FIGURE I.2.7.5 The native ECM is a heterogeneous network of glycosaminoglycans, proteoglycans, and proteins that consists of both covalent and non-covalent interactions.

must be met to recreate the intertwined biochemical and mechanical cues in the cellular microenvironment, and allow experimental versatility in fabrication (Prestwich, 2007). These performance criteria should include: (1) experimental control over composition; (2) experimental control over compliance; (3) controllable biodegradability *in vitro* and *in vivo*; (4) moldable *in situ* cross-linking during cell encapsulation and fabrication; (5) batch-to-batch consistency; (6) ease of use at physiological temperature and pH; (7) transparency for ease of visualization; and (8) seamless translation from lab to clinic. Modularized sECMs that meet these criteria would allow end users to add soluble factors, attachment peptides, matricellular proteins, cross-linkers, and macromomers to customize them for research or treatment.

Market Criteria

The needs of the end-user must also be included as design criteria (Prestwich, 2008a), whether for cell therapy or for drug evaluation and research tools. These additional design criteria (see Box 1) are derived from the realization that commercialization is *sine qua non* for translating technology from the academic lab to the private sector. This requires significant financial commitment to developing the technology and to recruiting a team capable of reducing the technology to practice. Investor interest is highest for products for which a large market can be readily penetrated. Specifically, for biomaterials to be used in regenerative medicine, several key parameters must be satisfied.

Building a Semi-synthetic ECM

The solution: A modular sECM. We selected the thiol-modified HA described in the section The Old: Monolithic HA Derivatives as the starting point to make an *in situ* cross-linkable synthetic mimic of the extracellular matrix (sECM). We deconstructed the ECM into modular units containing one, two, or several chemically

modified macromonomers that could be covalently cross-linked into a hydrogel network (Figure I.2.7.6) (Serban and Prestwich, 2007). The resulting sECM offers user-controllable composition and compliance, to which a variety of growth factors or matricellular proteins may be added. Moreover, the elastic moduli of hydrogels could be tailored to match the cell type to achieve optimal regeneration of a new tissue. Importantly, it is also easy to use and meets all of the scientific criteria in the section on Divinylsulfone cross-linking (Figure I.2.7.7).

BOX 1   Commercial Constraints for a Clinical Biomaterial

It's all about the difference between sales and marketing. In developing a technology, we sell our concepts and results to review committees, journals, students, and our peers. Converting a technology to a product is different. Creating a product requires identifying and meeting the needs of your customers, the end-users. While technological advances are driven by curiosity, asking questions, and conducting experiments with many variables, products must be simple, consistent, robust, reproducible, and must meet a need. Consciously including these real-world design criteria is crucial for developing high-cost biomaterials for use in a competitive and highly-regulated environment.

Design Criteria for a Clinical Biomaterial

- Meet needs of end-users: patients & physicians
- Simple, effective composition
- Simple to use
- Easy to manufacture under GMP
- Clear path to regulatory approval
- Reimbursable by health care payers

Interest by investors and industry partners

Clinically useful product

The sECMs may be cross-linked *in situ* in the presence of cells to provide an injectable cell-seeded hydrogel for tissue repair or without cells for the controlled, localized delivery of drugs or growth factors. Thiol-modified glycosaminoglycans and proteins are also living macro-monomers that can be cross-linked with biocompatible polyvalent electrophiles to form biocompatible, bioerodable hydrogels and porous sponges. This new technology offers a powerful set of new tools for culturing primary cells in three dimensions (3-D). Indeed, the applications of this technology include *in vitro* and *in vivo* growth of 3-D cellularized, vascularized tissues using films, sponges, and hydrogels.

The thiol modified carboxymethylated HA known as CMHA-S was readily cross-linkable and yielded biocompatible hydrogels that did not support cell attachment and proliferation. Cross-linking was accomplished slowly via disulfide bond formation in air, or with better control of cross-linking time and hydrogel stiffness using cytocompatible bivalent cross-linkers such as polyethylene glycol diacrylate (PEGDA) or other PEG-based bielectrophiles (Vanderhooft et al., 2007). As indicated above in the section The Old: Monolithic HA Derivatives, the one-component gel has proven utility in scar-free wound healing, post-surgical adhesion prevention, and stem cell expansion.

Incorporation of attachment factors provides an sECM that supports cell attachment, growth, and proliferation in 3-D. By co-cross-linking thiol-modified gelatin and CMHA-S, we obtained materials to which cells readily attached and spread. Gelatin can be replaced by an RGD peptide or selected domains of fibronectin (Ghosh et al., 2006). These two-component sECMs have been employed in repair of osteochondral defects (Liu and Prestwich, 2006), centrifugal casting of endothelial cells (Mironov et al., 2005), repair of vocal fold defects (Duflo et al., 2006), growth of tumor xenografts (Liu et al., 2007b), and *ex vivo* culture of cells in 2-D and 3-D (Shu et al., 2006). Both *in vivo* and *in vitro*, cells invade the compliant hydrogel, remodel it with matrix metalloproteinases, and secrete a new tissue-like cell-specific ECM. The fundamental role of the sECM hydrogel is to enhance the natural biological repair processes mediated by endogenous cells.

Engineered tissues require a blood supply to survive, and developing an internal vasculature in the neotissue and connecting that network to the host are formidable challenges to overcome. Thiol-modified heparin (HP-DTPH) and chondroitin sulfate (CS-DTPH) macromonomers provide the biomimetic equivalents of heparan sulfate (HS) and CS proteoglycans (Cai et al., 2005). Other heparin–HA bioconjugates have also been produced for controlled growth factor release (Liu et al., 2002). These hydrogels provided spatiotemporal control of growth factor release over a time course of weeks to months. In addition, they allowed dual growth factor release, and simultaneously enhanced the rate of neovascularization *in vivo* (Pike et al., 2006). These materials can also be used to deliver bFGF to accelerate excisional wound repair in diabetic mice (Liu et al., 2007c).

MEETING THE TRANSLATIONAL CHALLENGE

No technology will reach patients and physicians unless it is commercialized. The translational challenge implicit in this statement is three-fold. First, the inventors and origin of the technology must be willing and effective in identifying licensing or start-up options and following through on their intentions. Second, the technology must be robust and fulfill a market need. Third, the investors and management team must identify key funding and market opportunities, and then guide the company unerringly to the successful fulfillment of the plan.

Too often, scientists have underestimated the importance of the financial, production, and regulatory constraints during the development of a biomaterial for reparative or regenerative medicine. In contrast, a marketing approach driven by the needs of the end-users places these crucial and limiting pragmatic factors as part of the initial design criteria.

The native ECM evolved to co-optimize biological and structural features. Rather than rebuilding the entire biological complexity *de novo*, the modular sECM approach uses the minimum number of components necessary to enable cells to rebuild tissues. Biology is best at doing the "heavy lifting" of tissue engineering.

The message of the translational imperative is summarized in Figure I.2.7.8 (Prestwich, 2008a). As scientists, we must **embrace the complexity** of biology, but we cannot let this complexity dominate the design of a clinical material. Since no one formulation can fulfill every need, we should **engineer flexibility/versatility** into our products, so that a single suite of approvable materials can be exploited in a variety of clinical niches. Finally, for regenerative medicine to succeed as a reality, we must **deliver simplicity**. The penetration of new technology into any market is not determined only by improvement in patient outcome. The true limiting factors are cost, familiarity, and ease of use. The living sECM technology addresses a balance between the physiological and the practical requirements, and is currently used in clinical and veterinary medicine, and for translational laboratory research.

The Translational Imperative

1. Embrace complexity
2. Engineer versatility
3. **Deliver simplicity**

FIGURE I.2.7.8 The translational imperative.

GLOSSARY OF ACRONYMS

bFGF: Basic fibroblast growth factor
CMHA-S: Carboxymethylated hyaluronic acid
CMPI: 2-chloro-1-methylpyridinium iodide
CS: Chondroitin sulfate
CS-DTPH: Thiol-modified chondroitin sulfate
CTB: Center for Therapeutic Biomaterials
DD: Degree of deacetylation
ECM: Extracellular matrix
EDCI: Ethyl dimethylaminopropylcarbodiimide
ELP: Elastin-like peptide
ENT: Ear-nose-throat
G: a-L-guluronic acid
GAG: Glycosaminoglycan
GMP: Good manufacturing practice
HA: Hyaluronic acid
HP-DTPH: Thiol-modified heparin

HS: Heparan sulfate
IP: Intellectual property
M: b-D-mannuronic acid
PEG: Poly (ethylene glycol)
PEGDA: Poly (ethylene glycol) diacrylate
RGD: Arginine-glycine-aspartic acid peptide sequence
SBIR: Small business innovative research
sECM: Semi-synthetic extracellular matrix
VC: Venture capital
VEGF: Vascular endothelial growth factor

DISCLOSURE STATEMENT

Glenn Prestwich holds equity in Glycosan, Sentrx Animal Care, and Carbylan Biosurgery which uses the sECM technology. Sarah Atzet is an employee of Glycosan.

Case Study	Fields of Use

How Sentrx Surgical became three separate companies
Figure I.2.7.9 shows how a university-based technology can be effectively commercialized. The original discovery of the chemical modification of HA to give monolithic and later living polymers occurred over 15 years with industry, state, and federal support. As inventions were reduced to practice, patent applications were filed to protect the intellectual property (IP), and papers were published on the chemical and biological results. Technology transfer offices at two universities assisted with the patenting process and with interactions with potential licensees. In the end, negotiations reached a standstill. However, at this juncture, the State of Utah provided financial support to create a Center of Excellence, the Center for Therapeutic Biomaterials (CTB), to facilitate commercialization of technologies in this area. The CTB then spun out Sentrx Surgical, so named because two of the co-founders were otolargynologists (ear, nose, and throat (ENT) surgeons). The name incorporated our mission – ENT plus Rx – biomaterials for ENT treatments. Sentrx applied for, and received, four SBIR grants, using

non-dilutive federal funding as well as state funding to the CTB, to develop its IP portfolio and compelling preclinical results to show to potential investors.

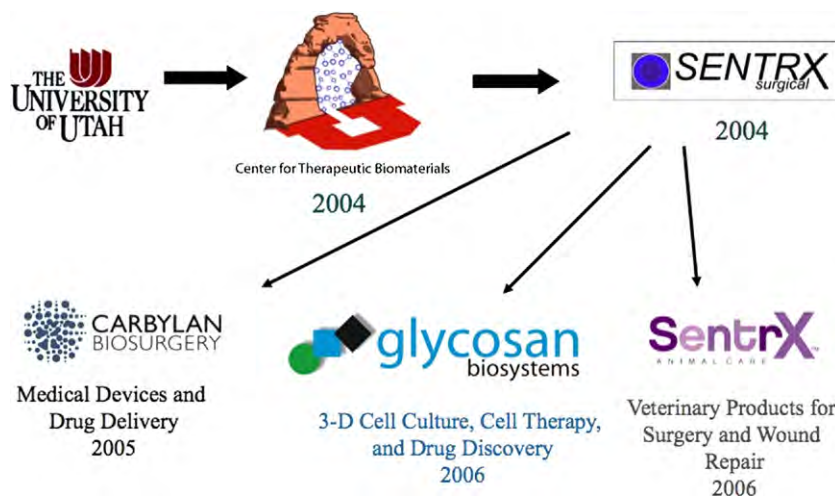
During the "road shows" to raise money, a Utah venture capital (VC) group offered to lead the investment if we could raise additional funding to match their terms. In identifying additional investors, a VC firm expressed interest, but only wanted exclusive control human medical device and drug device combination uses of the technology, and also wanted the university to have less equity. This was accomplished by removing other fields from the license to Carbylan Biosurgery, with the exception of non-exclusive rights for cell therapy uses. Within two months, we started two additional companies: Glycosan Biosystems, with an exclusive license for research uses and a co-exclusive for cell therapy, and Sentrx Animal Care, with exclusive rights to veterinary uses. All three companies use the same original IP, which they each customize for use in their respective market segments.


FIGURE I.2.7.9 Paradigm for commercialization of a university technology with state and federal support followed by venture investments and division into distinct product-oriented fields of use.

CHAPTER I.2.8 PYROLYTIC CARBON FOR LONG-TERM MEDICAL IMPLANTS

Robert B. More,[1] Axel D. Haubold,[2] and Jack C. Bokros[3]
[1]Integra Life Sciences, Austin, TX, USA
[2]Bed Rock Ranch, Decatur, TX, USA
[3]On-X Life Technologies, Inc, Austin, TX, USA

INTRODUCTION

Carbon materials are ubiquitous and of great interest because the majority of substances that make up living organisms are carbon compounds. Although many engineering materials and biomaterials are based on carbon or contain carbon in some form, elemental carbon itself is also an important and very successful biomaterial. Furthermore, there exists enough diversity in their structure and properties for elemental carbons to be considered as a unique class of materials beyond the traditional molecular carbon focus of organic chemistry, polymer chemistry, and biochemistry. Through a serendipitous interaction between researchers during the late 1960s the outstanding blood compatibility of a special form of elemental pyrolytic carbon deposited at high temperature in a fluidized bed was discovered. The material was found to have not only remarkable blood compatibility, but also the structural properties needed for long-term use in artificial heart valves (LaGrange et al., 1969). The blood compatibility of pyrolytic carbon was recognized empirically using the Gott vena cava ring test. This test involved implanting a small tube made of a candidate material in a canine vena cava and observing the development of thrombosis within the tube in time. Prior to pyrolytic carbon, only surfaces coated with graphite, benzylalkonium chloride, and heparin would resist thrombus formation when exposed to blood for long periods. The incorporation of pyrolytic carbon in mechanical heart valve implants was declared "an exceptional event" (Sadeghi, 1987) because it added the durability and stability needed for heart valve prostheses to endure for a patient's lifetime. The objective of this chapter is to present the elemental pyrolytic carbon materials currently used in the fabrication of medical devices, and to describe their manufacture, characterization, and properties.

ELEMENTAL CARBON

Elemental carbon is found in nature as two crystalline allotrophic forms: graphite and diamond. Elemental carbon also occurs as a spectrum of imperfect, turbostratic crystalline forms that range in degree of crystallinity from amorphous to the perfectly crystalline allotropes. Recently a third crystalline form of elemental carbon, the fullerene structure, has been discovered. The crystalline polymorphs of elemental carbon are shown in Figure I.2.8.1.

The properties of the elemental carbon crystalline forms vary widely according to their structure. Diamond with its tetrahedral sp[3] covalent bonding is one of the hardest materials known. In the diamond crystal structure, covalent bonds of length 1.54 Å connect each carbon atom with its four nearest neighbors. This tetrahedral symmetry repeats in three dimensions throughout

Diamond   Graphite

Fullerene
Bucky Ball
FIGURE I.2.8.1 Allotropic crystalline forms of carbon: diamond, graphite, and fullerene.

the crystal (Pauling, 1964). In effect, the crystal is a giant isotropic covalently-bonded molecule; therefore, diamond is very hard.

Graphite, with its anisotropic layered in-plane hexagonal covalent bonding and interplane van der Waals bonding structure, is a soft material. Within each planar layer, each carbon atom forms two single bonds and one double bond with its three nearest neighbors. This bonding repeats in-plane to form a giant molecular (graphene) sheet. The in-plane atomic bond length is 1.42 Å, which is a resonant intermediate (Pauling, 1964) between the single bond length of 1.54 Å and the double bond length of 1.33 Å. The planer layers are held together by relatively weak van der Waals bonding at a distance of 3.4 Å, which is more than twice the 1.42 Å bond length (Pauling, 1964). Graphite has low hardness and a lubricating property because the giant molecular sheets can readily slip past one another against the van der Waals bonding. Nevertheless, although large-crystallite-size natural graphite is used as a lubricant, some artificially produced graphites can be very abrasive if the crystallite sizes are small and randomly oriented.

Fullerenes have yet to be produced in bulk, but their properties on a microscale are entirely different from those of their crystalline counterparts. Fullerenes and nanotubes consist of a graphene layer that is rolled up or folded (Sattler, 1995) to form a tube or ball. These large molecules, C_{60} and C_{70} fullerenes and (C_{60} + 18j) nanotubes, are often mentioned in the literature (Sattler, 1995) along with more complex multilayer "onion skin" structures.

There exist many possible forms of elemental carbon that are intermediate in structure and properties between those of the allotropes diamond and graphite. Such "turbostratic" carbons occur as a spectrum of amorphous, through mixed amorphous, graphite-like and diamond-like, to the perfectly crystalline allotropes (Bokros, 1969). Because of the dependence of properties upon structure, there can be considerable variability in properties for the turbostratic carbons. Glassy carbons and pyrolytic carbons, for example, are two turbostratic carbons with considerable differences in structure and properties. Consequently, it is not surprising that carbon materials are often misunderstood through oversimplification. Properties found in one type of carbon structure can be totally different in another type of structure. Therefore, it is very important to specify the exact nature and structure when discussing carbon.

PYROLYTIC CARBON (PyC)

The biomaterial known as pyrolytic carbon is not found in nature; it is manmade. The successful pyrolytic carbon biomaterial was developed at General Atomic during the late 1960s using a fluidized-bed reactor (Bokros, 1969). In the original terminology, this material was considered a low-temperature isotropic carbon (LTI carbon). Since the initial clinical implant of a pyrolytic carbon component in the DeBakey–Surgitool mechanical valve in 1968, 95% of the mechanical heart valves implanted worldwide have at least one structural component made of pyrolytic carbon. On an annual basis this translates into approximately 500,000 components (Haubold, 1994). Pyrolytic carbon components have been used in more than 25 different prosthetic heart valve designs since the late 1960s, and have accumulated a clinical experience in the order of 16 million patient-years. Clearly, pyrolytic carbon is one of the most successful, critical biomaterials both in function and application. Among the materials available for mechanical heart valve prostheses, pyrolytic carbon has the best combination of blood compatibility, physical and mechanical properties, and durability. However, the blood compatibility of pyrolytic carbon in heart valve applications is not perfect; chronic anticoagulant therapy is needed for patients with mechanical heart valves. Whether the need for anticoagulant therapy arises from the biocompatible properties of the material itself or from the particular hydrodynamic interaction of a given device and the blood remains to be resolved.

The term "pyrolytic" is derived from "pyrolysis," which is thermal decomposition. Pyrolytic carbon is formed from the thermal decomposition of hydrocarbons such as propane, propylene, acetylene, and methane, in the absence of oxygen. Without oxygen the typical decomposition of the hydrocarbon to carbon dioxide and water cannot take place; instead a more complex cascade of decomposition products occurs that ultimately results in a "polymerization" of the individual carbon atoms into large macroatomic arrays.
FIGURE I.2.8.2 Fluidized-bed reactor schematic.

Pyrolysis of the hydrocarbon is normally carried out in a fluidized-bed reactor such as the one shown in Figure I.2.8.2. A fluidized-bed reactor typically consists of a vertical tube furnace that may be induction or resistance heated to temperatures of 1000 to 2000°C (Bokros, 1969). Reactor diameters ranging from 2 cm to 25 cm have been used; however, the most common size used for medical devices has a diameter of about 10 cm. These high-temperature reactors are expensive to operate, and the reactor size limits the size of device components able to be produced.

Small refractory ceramic particles are placed into the vertical tube furnace. When a gas is introduced into the bottom of the tube furnace, the gas causes the particle bed to expand. Interparticle spacing increases to allow for the flow of the gas. Particle mixing occurs and the bed of particles begins to "flow" like a fluid. Hence the term "fluidized bed." Depending upon the gas flow rate and volume, this expansion and mixing can be varied from a gentle bubbling bed to a violent spouting bed. An oxygen-free, inert gas, such as nitrogen or helium, is used to fluidize the bed, and the source hydrocarbon is added to the gas stream when needed.

At a sufficiently high temperature, pyrolysis or thermal decomposition of the hydrocarbon can take place. Pyrolysis products range from free carbon and gaseous hydrogen to a mixture of $C_x H_y$ decomposition species. The pyrolysis reaction is complex and is affected by the gas flow rate, composition, temperature, and bed surface area. Decomposition products, under the appropriate conditions, can form gas-phase nucleated droplets of carbon/hydrogen, which condense and deposit on the surfaces of the wall and bed particles within the reactor (Bokros, 1969). Indeed, the fluidized-bed process was

originally developed to coat small (200–500 micrometer) diameter spherical particles of uranium/thorium carbide or oxide with pyrolytic carbon. These coated particles were used as the fuel in the high temperature gas-cooled nuclear reactor (Bokros, 1969).

Pyrolytic carbon coatings produced in vertical tube reactors can have a variety of structures, such as laminar or isotropic, granular or columnar (Bokros, 1969). The structure of the coating is controlled by the gas flow rate (residence time in the bed), hydrocarbon species, temperature, and bed surface area. For example, an inadequately fluidized or static bed will produce a highly anisotropic, laminar pyrolytic carbon (Bokros, 1969).

Control of the first three parameters (gas flow rate, hydrocarbon species, and temperature) is relatively easy. However, until recently, it was not possible to measure the bed surface area while the reactions were taking place. As carbon deposits on the particles in the fluidized bed, the diameter of the particles increases. Hence the surface area of the bed changes, which in turn influences the subsequent rate of carbon deposition. As surface area increases, the coating rate decreases, since a larger surface area now has to be coated with the same amount of carbon available. Thus, the process is not in equilibrium. The static-bed process was adequate to coat nuclear fuel particles without attempting to control the bed surface area because such thin coatings (25–50 μm thick) did not appreciably affect the bed surface area.

It was later found that larger objects could be suspended within the fluidized bed of small ceramic particles and also become uniformly coated with carbon. This finding led to the demand for thicker, structural coatings, an order of magnitude thicker (250–500 μm). Bed surface area control and stabilization became an important factor (Akins and Bokros, 1974) in achieving the goal of thicker, structural coatings. In particular, with the discovery of the blood-compatible properties of pyrolytic carbon (LaGrange et al., 1969), thicker structural coatings with consistent and uniform mechanical properties were needed to realize the application to mechanical heart valve components. Quasi-steady-state conditions as needed to prolong the coating reaction were achieved empirically by removing coated particles and adding uncoated particles to the bed while the pyrolysis reaction was taking place (Akins and Bokros, 1974). However, the rates of particle addition and removal were based upon little more than good guesses.

Three of the four parameters that control carbon deposition could be accurately measured and controlled, but a method to measure and control bed surface area was lacking. Thus, the quasi-steady-state process was more of an art than a science. If too many coated particles were removed, the bed became too small to support the larger components within it and the bed collapsed. If too few particles were removed, the rate of deposition decreased, and the desired amount of coating was not achieved in the anticipated time. Furthermore, there

were considerable variations in the mechanical properties of the coating from batch to batch. It was found that in order to consistently achieve the hardness needed for wear resistance in prosthetic heart valve applications, it was necessary to add a small amount of β-silicon carbide to the carbon coating. The dispersed silicon carbide particles within the pyrolytic carbon matrix added sufficient hardness to compensate for potential variations in the properties of the pyrolytic carbon matrix. The β-silicon carbide was obtained from the pyrolysis of methyl-trichlorosilane, CH_3SiCl_3. For each mole of silicon carbide produced, the pyrolysis of methyltrichlorosilane also produces three moles of hydrogen chloride gas. Handling and neutralization of this corrosive gas added substantial complexity and cost to an already complex process. Nevertheless, this process allowed consistency for the successful production of several million components for use in mechanical heart valves.

A process has been developed and patented that allows precise measurement and control of the bed surface area. A description of this process is given in the patent literature and elsewhere (Emken et al., 1993, 1994; Ely et al., 1998). With precise control of the bed surface area, it is no longer necessary to include the silicon carbide. Elimination of the silicon carbide has produced a stronger, tougher, and more deformable pure pyrolytic carbon. Historically, pure carbon was the original

objective of the development program because of the potential for superior biocompatibility (LaGrange et al., 1969). Furthermore, the enhanced mechanical and physical properties of the pure pyrolytic carbon now possible with the improved process control allow prosthesis design improvements in the hemodynamic contribution to thromboresistance (Ely et al., 1998).

Structure of Pyrolytic Carbons

X-ray diffraction patterns of the biomedical-grade fluidized-bed pyrolytic carbons are broad and diffuse because of the small crystallite size and imperfections. In silicon-alloyed pyrolytic carbon, a diffraction pattern characteristic of the β form of silicon carbide also appears in the diffraction pattern along with the carbon bands. The carbon diffraction pattern indicates a turbostratic structure (Kaae and Wall, 1996) in which there is order within carbon layer planes, as in graphite; but, unlike graphite, there is no order between planes. This type of turbostratic structure is shown in Figure I.2.8.3 compared to that of graphite. In the disordered crystalline structure, there may be lattice vacancies and the layer planes are curved or kinked. The ability of the graphite layer planes to slip is inhibited, which greatly increases the strength and hardness of the pyrolytic carbon relative to that of graphite. From the Bragg
(A)

(B)

(C)
FIGURE I.2.8.3 Structures of: (A) diamond; (B) graphite; and (C) turbostratic pyrolytic carbon.

equation, the pyrolytic carbon layer spacing is reported to be 3.48 Å, which is larger than the 3.35 Å graphite layer spacing (Kaae and Wall, 1996). The increase in layer spacing relative to graphite is due to both the layer distortion and the small crystallite size, and is a common feature for turbostratic carbons. From the Scherrer equation the crystallite size is typically 25–40 Å (Kaae and Wall, 1996).

During the coating reaction, gas-phase nucleated droplets of carbon/hydrogen form that condense and deposit on the surfaces of the reactor wall and bed particles within the reactor. These droplets aggregate, grow, and form the coating. When viewed with high-resolution transmission electron microscopy, a multitude of near-spherical polycrystalline growth features are evident, as shown in Figure I.2.8.4 (Kaae and Wall, 1996). These growth features are considered to be the basic building blocks of the material, and the shape and size are related to the deposition mechanism. In the silicon-alloyed carbon, small silicon carbide particles are present within the growth features, as shown in Figure I.2.8.5. Based on a crystallite size of 33 Å, each growth feature contains about 3×10^9 crystallites. Although the material is quasi-crystalline on a fine level, the crystallites are very small and randomly oriented in the fluidized bed pyrolytic carbons so that overall the material exhibits isotropic behavior.
Glassy carbon, also known as vitreous carbon or polymeric carbon, is another turbostratic carbon form that has been proposed for use in long-term implants. However, its strength is low and the wear resistance is poor. Glassy carbons are quasi-crystalline in structure, and are named "glassy" because the fracture surfaces closely resemble those of glass (Haubold et al., 1981).

Vapor-deposited carbons are also used in heart valve applications. Typically, the coatings are thin (<1 μm) and may be applied to a variety of materials in order to confer the biochemical characteristics of turbostratic carbon. Some examples are vapor-deposited carbon coatings on heart valve sewing cuffs and metallic orifice components (Haubold et al., 1981).

Mechanical Properties

Mechanical properties of pure pyrolytic carbon, silicon-alloyed pyrolytic carbons, and glassy carbon are given in Table I.2.8.1. Pyrolytic carbon flexural strength is

FIGURE I.2.8.4 Electron micrograph of pure pyrolytic carbon microstructure showing near-spherical polycrystalline growth features formed during deposition (Kaae and Wall, 1996).

FIGURE I.2.8.5 Electron micrograph of silicon-alloyed pyrolytic carbon microstructure showing near-spherical polycrystalline growth features formed during deposition (Kaae and Wall, 1996). Small silicon carbide particles are shown in concentric rings in the growth features.

TABLE I.2.8.1	Mechanical Properties of Biomedical Carbons		
Property	**Pure PyC**	**Typical Si-alloyed PyC**	**Typical Glassy Carbon**
Flexural strength (MPa)	493.7 ± 12	407.7 ± 14.1	175
Young's modulus (GPa)	29.4 ± 0.4	30.5 ± 0.65	21
Strain-to-failure (%)	1.58 ± 0.03	1.28 ± 0.03	-
Fracture toughness (MPa √m)	1.68 ± 0.05	1.17 ± 0.17	0.5–0.7
Hardness (DPH, 500 g load)	235.9 ± 3.3	287 ± 10	150

Wear resistance	Excellent	Excellent	Poor

high enough to provide the necessary structural stability for a variety of implant applications, and the density is low enough to allow for components to move easily under the applied forces of circulating blood. With respect to orthopedic applications, Young's modulus is in the range reported for bone (Reilly and Burstein, 1974; Reilly et al., 1974), which allows for compliance matching. Relative to metals and polymers, the pyrolytic carbon strain-to-failure rate is low; it is a nearly ideal linear elastic material and requires consideration of brittle material principles in component design. Strength levels vary with the effective stressed volume or stressed area, as predicted by classical Weibull statistics (De Salvo, 1970). The flexural strengths cited in Table I.2.8.1 are for specimens tested in four-point bending, third-point loading (More et al., 1993) with effective stressed volumes of 1.93 mm^3. The pyrolytic carbon material Weibull modulus is approximately 10 (More et al., 1993).

Fracture toughness levels reflect the brittle nature of the material, but the fluidized-bed isotropic pyrolytic carbons are remarkably fatigue resistant. Recent fatigue studies indicate the existence of a fatigue threshold that is very nearly the single-cycle fracture strength (Gilpin et al., 1993; Ma and Sines, 1996, 1999, 2000). Fatigue-crack propagation studies indicate very high Paris-law fatigue exponents, on the order of 80, and display clear evidence of a fatigue-crack propagation threshold (Ritchie et al., 1990; Beavan et al., 1993; Cao, 1996).

Crystallographic mechanisms for fatigue-crack initiation, as occur in metals, do not exist in the pyrolytic carbons (Haubold et al., 1981). In properly designed and manufactured components, and in the absence of externally induced damage, fatigue does not occur in pyrolytic-carbon mechanical heart valve components. In the 30 years of clinical experience, there have been no clear instances of fatigue failure. Few pyrolytic carbon component fractures have occurred, less than 60 out of more than four million implanted components (Haubold, 1994), and most are attributable to induced damage from handling or cavitation (Kelpetko et al., 1989; Kafesjian et al., 1994; Richard and Cao, 1996).

Wear resistance of the fluidized-bed pyrolytic carbons is excellent. The strength, stability, and durability of pyrolytic carbon are responsible for the extension of mechanical valve lifetimes from less than 20 years to more than the recipient's expected lifetime (Schoen et al., 1982; Schoen, 1983; More and Silver, 1990; Wieting, 1996).

Pyrolytic carbon in heart valve prostheses is often used in contact with metals, either as a carbon disk in a metallic valve orifice or as a carbon orifice stiffened with a metallic ring. Carbon falls with the noble metals in the galvanic series (Haubold et al., 1981), the sequence being silver, titanium, graphite, gold, and platinum. Carbon can accelerate corrosion when coupled to less noble metals *in vivo*. However, testing using mixed potential corrosion theory and potentiostatic polarization has determined that no detrimental effects occur when carbon is coupled with titanium or cobalt–chrome alloys (Thompson et al., 1979; Griffin et al., 1983). Carbon couples with stainless steel alloys are not recommended.

STEPS IN THE FABRICATION OF PYROLYTIC CARBON COMPONENTS

To convert a gaseous hydrocarbon into a shiny, polished black component for use in the biological environment is not a trivial undertaking. Furthermore, because of the critical importance of long-term implants to a recipient's health, all manufacturing operations are performed to stringent levels of quality assurance under the auspices of US Food and Drug Administration Good Manufacturing Practices and International Standards Organization ISO-9000 regulations. As in the case of fabrication of metallic implants, numerous steps are involved. Pyrolytic carbon is not machined from a block of material, as is the case with most metallic implants, nor is it injection or reactive molded, as are many polymeric devices. An overview of the processing steps leading to a finished pyrolytic carbon coated component for use in a medical device is shown in Figure I.2.8.6, and is further described in the following sections.

Substrate Material

Since pyrolytic carbon is a coating, it must be deposited on an appropriately shaped, preformed substrate (preform). Because the pyrolysis process takes place at high temperatures, the choice of substrates is severely

**FIGURE I.2.8.6** Schematic of manufacturing processing steps.

limited. Only a few of the refractory materials, such as tantalum or molybdenum/rhenium alloys and graphite, can withstand the conditions at which the pyrolytic carbon coating is produced. Some refractory metals have been used in heart valve components; for example, Mo/Re preforms were coated to make the struts for the Beall–Surgitool mitral valve. It is important for the thermal expansion characteristics of the substrate to closely match those of the applied coating. Otherwise, upon cooling of the coated part to room temperature the coating will be highly stressed and can spontaneously crack. For contemporary heart valve applications, fine-grained isotropic graphite is the most commonly used substrate. This substrate graphite can be doped with tungsten in order to provide radioopacity for X-ray visualizations of the implants. The graphite substrate does not impart structural strength. Rather, it provides a dimensionally stable platform for the pyrolytic carbon coating, both at the reaction temperature and at room temperature.

Preform

Once the appropriate substrate material has been selected and prior to making a preform, it must be inspected to ensure that the material meets the desired specifications. Typically, the strength and density of the starting material are measured. Thermal expansion is ordinarily validated and monitored through process control. The preform, which is an undersized replica of the finished component, is normally machined using conventional machining methods. Because the fine-grained isotropic graphite is very abrasive, standard machine tools have given way to diamond-plated or single-point diamond tools. In the case of heart valves, numerical control machining methods are often required to maintain critical component dimensional tolerances. After the preform is completed, it is inspected to ensure that its dimensions fall within the specified tolerances and that it contains no visible flaws or voids.

Coating

Generally numerous preforms are coated in one furnace run. A batch to be coated is made up of substrates from a single lot of preforms. Such batch processing by lot is required in order to maintain "forward and backward" traceability. In other words, ultimately it is necessary to know all of the components that were prepared using a specific material lot, given either the starting material lot number (forward) or given the specific component serial number (backward). The number of parts that can be coated in one furnace run is dictated by the size of the furnace and the size and weight of the parts to be coated. The batch of substrates is placed within the fluidized bed in the vertical tube furnace and is coated to the desired thickness. Coating times are generally on the order of
FIGURE I.2.8.7 Metallographic mount cross-section of heat valve component. The light-colored pyrolytic carbon layer is coated over the interior, darker-colored granular-appearing graphite substrate.

a few hours, but the entire cycle (heat-up, coating, and cool-down) may take as long as a full day.

A statistical sample from each coating lot is taken for analysis. At this point, typical measurements include coating thickness, microhardness, and microstructure. The microhardness and microstructure are determined from a metallographically prepared cross-section of the coated component taken perpendicular to the plane of deposition. Thus, this test is destructive. An example of a metallographically prepared cross-section of a pyrolytic carbon component is shown in Figure I.2.8.7.

Machine to Size

The components used to manufacture medical devices have strict dimensional requirements. Because of the inability, until recently, to precisely measure and control bed size, and indirectly coating thickness, the preforms were generally coated more thickly than necessary to ensure adequate pyrolytic carbon coating thickness on the finished part. The strict dimensional requirements were then achieved through precision grinding or other machining operations. Because pyrolytic carbon is very hard, conventional machine tools again cannot be used. Diamond-plated grinding wheels and other diamond tooling are required. The dimensions of final machined parts are again verified.

Polish

The surface of as-deposited, machined, and polished components is shown in Figure I.2.8.8. It was found early on in experiments (LaGrange et al., 1969; Sawyer et al., 1975; Haubold et al., 1981) that clean polished pyrolytic carbon surfaces of tubes when placed within the vasculature of experimental animals accumulated minimal if any thrombus; and certainly less than
**FIGURE I.2.8.8** Scanning electron microscope micrographs of: (A) as-coated; and (B) as-polished surfaces.

TABLE I.2.8.2	Surface Finish (R_a, Average, and R_q, Root Mean Square) of Pyrolytic Carbon Heat Valve Components[a]		
Specimen	R_a (nm)	R_q (nm)	Comments
Glass microscope slide	17.14	26.80

As-coated slab	389.07	503.72	

[a]Components/prepared by: On-X/Medical Carbon Research Institute, Austin, TX, USA; Sorin/Sorin Biomedica, Saluggia, Italy; SJM/Saint Jude Medical, Saint Paul, MN, USA; CMI (SJM)/CarboMedics, Austin, TX, USA; DeBakey-S/CarboMedics, San Diego, USA (circa 1968). "Clinical" was from as-packaged valve; "nonclinical" lacks component traceability.

FIGURE I.2.8.9 Components for On-X bileaflet heart valve.

pyrolytic carbon tubes with the as-deposited surface. Consequently, the surfaces of pyrolytic carbon have historically been polished, either manually or mechanically, using fine diamond or aluminum oxide pastes and slurries. The surface finish achieved has roughness measured on the scale of nanometers. As can be seen from Table I.2.8.2 (More and Haubold, 1996), the surfaces of polished pyrolytic carbon (30–50 nm) are an order of magnitude smoother than the as-deposited surfaces (300–500 nm).

Once the desired surface quality is achieved, components are again inspected. The final component inspection may include measurement of dimensions, X-ray inspection in two orientations to verify coating thickness, and visual inspection for surface quality and flaws. In many cases, automated inspection methods with computer-controlled coordinate measurement machines are used. X-ray inspection can be used to ensure that minimum coating thickness requirements are met. Two orthogonal views ensure that machining and grinding of the coating was achieved uniformly, and that the coating is symmetrical. The machining and grinding operation after coating is not without the risk of inducing cracks or flaws in the coating, which may subsequently affect the service life of the component. Such surface flaws are detected visually or with the aid of dye-penetrant techniques. Components may also be proof-tested to detect and eliminate components with subsurface flaws. With the advent of bed size control, which allows coating to exact final dimensions, the concerns about flaws introduced during the machining and grinding operation have been eliminated.

The polished and inspected components, thus prepared, are now ready for assembly into devices, or are packaged and sterilized in the case of standalone devices. Shown in Figure I.2.8.9 are the three pyrolytic carbon components for a bileaflet mechanical heart valve. The components were selected and matched for assembly using the data generated from the final dimensional inspection to achieve the dimensional requirements specified in the device design. In Figure I.2.8.10, the pyrolytic carbon components for a

FIGURE I.2.8.10 Replacement metacarpophalangeal total joint prosthesis components, Ascension Orthopedics, Austin TX, USA.

replacement metacarpophalangeal total joint prosthesis are shown.

Assembly

The multiple components of a mechanical heart must be assembled. The brittleness of pyrolytic carbon poses a significant assembly problem. Because the strain-to-failure is on the order of 1.28% to 1.58%, there is a limited range of deformation that can be applied in order to achieve a proper fit. Relative fit between the components defines the capture and the range of motion for components that move to actuate valve opening and closing. Furthermore, component obstructive bulk and tolerance gaps are critical to hemodynamic performance.

In designs that use a metallic orifice, the metallic components are typically deformed in order to insert the pyrolytic carbon occluder disk. For the all-carbon bileaflet designs, the carbon orifice must be deflected in order to insert the leaflets. As the valve diameter decreases, and as the section modulus of the orifice design increases, the orifice stiffness increases. The possibility of damage or fracture during assembly was a limiting factor in early orifice design. For this reason, the orifices in valve designs using silicon-alloyed pyrolytic carbon were simple cylindrical geometries, and the smallest sizes were limited to the equivalent of a 19 mm diameter tissue annulus. The simple cylindrical orifice designs are often reinforced with a metallic stiffening ring that is shrunk on after assembly. The stiffening ring ensures that physiological loading will not produce deflections that can inhibit valve action or result in leaflet escape.

The increased strain-to-failure of pure pyrolytic carbon, relative to the silicon-alloyed carbon, allows designs with more complex orifice section moduli. This allows designers to utilize hydrodynamically efficient shapes such as flared inlets and to incorporate external stiffening bands that eliminate the need for a metallic stiffening ring. The increased strain-to-failure of On-X carbon has been used to advantage in the On-X mechanical heart valve design (Ely et al., 1998).

Cleaning and Surface Chemistry

Pyrolytic carbon surface chemistry is important because the manufacturing and cleaning operations to which a component is subjected can change and redefine the surface that is presented to the blood. Oxidation of carbon surfaces can produce surface contamination that detracts from blood compatibility (LaGrange et al., 1969; Bokros et al., 1969). Historically, the initial examinations of pyrolytic carbon biocompatibility assumed *de facto* that the surface needed to be treated with a thromboresistant agent such as heparin (Bokros et al., 1969). It was found, however, that the non-heparin-coated surface was actually more blood compatible than the treated surface. Hence, the efforts toward surface coating with heparin were abandoned.

In general it is desired to minimize the surface oxygen and any other non-carbon surface contaminants. From X-ray photoelectron spectroscopy (XPS) analyses, a typical heart valve component surface has 76–86% C, 12–21% O, 0–2% Si, and 1–2% Al (King et al., 1981; Smith and Black, 1984; More and Haubold, 1996). Polishing compounds tend to contain alumina, and some alumina particles may become imbedded in the carbon surface. Other contaminants that may be introduced at low levels (<2% each) are Na, B, Cl, S, Mg, Ca, Zn, and N. The XPS carbon 1s peak when scanned at high resolution can be deconvoluted to determine carbon oxidation states. The carbon 1s peak will typically consist primarily of hydrocarbon-like carbon (60–81%), ether alcohol/ester-like carbon (10–24%), ketone-like carbon (0–6%), and ester/acid-like carbon (1–12%) (More and Haubold, 1996). Each manufacturing, cleaning, and sterilizing operation potentially redefines the surface. The effect of modified surface chemistry on blood compatibility is not well characterized, so this adds a level of uncontrolled variability when considering the blood compatibility of pyrolytic-carbon heart valve materials from different manufacturing sources and different investigators. In general, the presence of oxygen and surface contaminants should be eliminated.

BIOCOMPATIBILITY OF PYROLYTIC CARBON

The suitability of a material for use in an implant is a complex issue. Biocompatibility testing is the focus of other chapters. In the case of pyrolytic carbon, its successful history interfacing with blood in mechanical heart valves attests to its suitability for this application. A note of caution, however, is in order. Until about a decade ago, the pyrolytic carbon used so successfully in mechanical heart valves was produced by a single manufacturer; the material, many applications in the biological environment, and the processes for producing the material, were all patented. Since the expiration of the last of these patents in 1989, other sources for pyrolytic carbon have

appeared that are copies of the original General Atomic material. When considering alternative carbon materials, it is important to recognize that the proper combination of physical, mechanical, and blood-compatible properties is required for the success of the implant application. Furthermore, because there are a number of different possible pyrolysis processes, it should be recognized that each can result in different microstructures with different properties. Just because a material is carbon, a turbostratic carbon or a pyrolytic carbon does not qualify its use in a long-term human implant (Haubold and Ely, 1995). For example, pyrolytic carbons prepared by chemical vapor deposition processes, other than the fluidized-bed process, are known to exhibit anisotropy, nonhomogeneity, and considerable variability in mechanical properties (Agafonov et al., 1999). Although these materials may exhibit biocompatibility, the potential for variability in structural stability and durability may lead to valve dysfunction.

The original General Atomic-type fluidized-bed pyrolytic carbons all demonstrate negligible reactions in the standard Tripartite and ISO 10993-1 type biocompatibility tests. Results from such tests are given in Table I.2.8.3 (Ely et al., 1998). Pure pyrolytic carbon is so non-reactive that it can serve as a negative control for these tests.

It is believed that pyrolytic carbon owes its demonstrated blood compatibility to its inertness and to its ability to quickly absorb proteins from blood without triggering a protein denaturing reaction. Ultimately, the blood compatibility is thought to be a result of the protein layer formed upon the carbon surface. Baier observed that pyrolytic carbon surfaces have a relatively high critical surface tension of 50 dyn/cm, which immediately drops to 28–30 dyn/cm following exposure to blood (Baier et al., 1970). The quantity of sorbed protein was thought to be an important factor for blood compatibility. Lee and Kim (1974) quantified the amount of radiolabeled proteins sorbed from solutions of mixture proteins (albumin, fibrinogen, and gamma-globulin). While pyrolytic carbon does adsorb albumin, it also adsorbs a considerable quantity of fibrinogen, as shown in Figure I.2.8.11. As can be seen in Figure I.2.8.11, the amount of fibrinogen adsorbed on pyrolytic carbon surfaces is far greater than the amount of albumin on these surfaces, and is comparable to the amount of fibrinogen that is sorbed on silicone rubber. The mode of albumin adsorption, however, appears to be drastically different for these two materials. Albumin sorbs immediately on the pyrolytic carbon surfaces, whereas the build-up of fibrinogen is much slower. In the case of silicone rubber, both proteins sorb at a much slower rate. It appears that

| TABLE I.2.8.3	Biological Testing of Pure PyC	
Test Description	**Protocol**	**Results**
Klingman maximization	ISO/CD 10993–10	Grade 1; not significant
Rabbit pyrogen	ISO/DIS 10993–11	Nonpyrogenic
Intracutaneous injection	ISO 10993–10	Negligible irritant
Systemic injection	ANSI/AAMI/ISO 10993–11	Negative – same as controls
Salmonella typhimurium reverse mutation assay	ISO 10993–3	Nonmutagenic
Physico-chemical	USP XXIII, 1995	Exceeds standards
Hemolysis – rabbit blood	ISO 10993–4/NIH 77–1294	Nonhemolytic
Elution test (L929 mammalian cell culture)	ISO 10993–5, USP XXIII, 1995	Noncytotoxic
FIGURE I.2.8.11 Fibrinogen and albumin adsorption on pyrolytic carbon (PyC) and Silastic silicone rubber.

the mode of protein adsorption is important, and not the total amount sorbed.

Nyilas and Chiu (1978) studied the interaction of plasma proteins with foreign surfaces by measuring directly the heats of adsorption of selected proteins onto such surfaces using microcalorimetric techniques. They found that the heats of adsorption of fibrinogen, up to the completion of first monolayer coverage, are a factor of eight smaller on pyrolytic carbon surfaces than on the known thrombogenic control (glass) surface, as shown in Figure I.2.8.12. Furthermore, the measured net heats of adsorption of gamma globulin on pyrolytic carbon were about 15 times smaller than those on glass. They concluded that low heats of adsorption onto a foreign surface imply small interaction forces with no conformational changes of the proteins that might trigger the clotting cascade. It appears that a layer of continuously exchanging blood proteins in their unaltered state "masks" the pyrolytic carbon surfaces from appearing as a foreign body.

There is further evidence that the minimally altered sorbed protein layers on pyrolytic carbon condition blood compatibility. Salzman et al. (1977), for example, observed a significant difference in platelet reaction with pyrolytic carbon beads in packed columns prior to and after pretreatment with albumin. With no albumin preconditioning treatment, platelet retention by the columns was high, but the release of platelet constituents was low. However, with albumin pretreatment, platelet retention and the release of constituents was minimal.
The foregoing observations led to the view that pyrolytic carbon owes its demonstrated blood compatibility to its inertness, and to its ability to quickly adsorb proteins from blood without triggering a protein-denaturing reaction (Nyilas and Chiu, 1978; Haubold et al., 1981). However, the assertion that pyrolytic carbon is an inert material and induces minimal conformational changes in adsorbed protein was re-examined by Feng and Andrade (1994). Using differential scanning calorimetry and a variety of proteins and buffers, they found that pyrolytic carbon surfaces denatured all of the proteins studied. They concluded that whether or not a surface denatures protein cannot be the sole criteria for blood compatibility. Their suggestion was that the specific proteins and the sequence in which they are denatured may be important. For example, it was suggested that pyrolytic carbon may first adsorb and denature albumin, which forms a layer that subsequently passivates the surface and inhibits thrombosis.

Chinn et al. (1994) re-examined the adsorption of albumin and fibrinogen on pyrolytic carbon surfaces and noted that relatively large amounts of fibrinogen were adsorbed, and speculated that the adsorbed fibrinogen was rapidly converted to a non-elutable form. If the elutable form is more reactive to platelets than the non-elutable form, then the non-elutable protein layer may contribute to the passivating effect.

Work on visualizing the carbon surface and platelet adhesion done by Goodman et al. (1995) using low accelerating-voltage scanning electron microscopy, along with critical-point drying techniques, has discovered that the platelet spreading on pyrolytic carbon surfaces is more extensive than previously observed (Haubold et al., 1981). However, platelet loading was in a static flow situation that does not model the physiological flow that a heart valve is subjected to. Hence, this approach cannot resolve kinetic effects on platelet adhesion. However, Okazaki, Tweden, and co-workers observed adherent platelets on valves following implantation in sheep that were not treated with anticoagulants (Okazaki et al., 1997). There were no instances of valve thrombosis, even though platelets were present on some of the valve surfaces. But the relevance of this observation to clinical valve thromboses is not clear, because human patients with mechanical heart valves undergo chronic anticoagulant therapy (Edmunds, 1987), and have a hemostatic system different from that of sheep.

A more contemporary version of the mechanism of pyrolytic carbon blood compatibility might be to reject the assumption that the surface is inert, as it is now thought by some that no material is totally inert in the body (Williams, 1998), and to accept that the blood–material interaction is preceded by a complex, interdependent, and time-dependent series of interactions between the plasma proteins and the surface (Hanson, 1998) that is as yet poorly understood. To add to the confusion, it must also be recognized that much of the

FIGURE I.2.8.12 Integral heat of sorption for fibrinogen on glass and fibrinogen on PyC at two different temperatures (Nyilas and Chiu, 1978).

aforementioned conjecture depends on the assumption that all of the carbon surfaces studied were in fact pure and comparable to one another.

CLINICAL APPLICATIONS

Widespread clinical use of pyrolytic carbon components for heart valve replacement began in October of 1968 when Dr. Michael DeBakey implanted an aortic valve with a hollow Pyrolite® carbon ball occluder. Following this first implant, several million PyC mechanical valve prostheses have been implanted worldwide, generating an experience on the order of 20 million patient-years. Use of PyC to replace polymers in valve prostheses was declared an "exceptional event" (Sadeghi, 1987) because the superior durability, stability, and biocompatibility of PyC enabled valves to endure for the patient's lifetime.

However, patients with mechanical valve prostheses require chronic anticoagulation therapy because of the risk of valve-related hemostatic complications. In efforts to reduce the risk of hemostatic complications and the need for chronic anticoagulation, it was hypothesized that valve-related hemostatic complications were in part due to flow-induced mechanical trauma to the blood, and to the presence of PyC itself because of the potential thrombogenicity of the silicon-carbide alloy constituent (LaGrange et al., 1969).

In 1992, advances in pyrolytic carbon manufacturing technology enabled precise control of processing parameters (Bokros et al., 1994). With this precise control it was possible to produce pure isotropic pyrolytic carbons having significantly improved properties relative to silicon-alloyed PyC, thus eliminating the need for the silicon-carbide alloy (see Table I.2.8.1). Precise process control also enabled a coat-to-size capability needed to eliminate surface blemishes caused by post-coating machining processes such as grinding.

The On-X valve shown in Figure I.2.9 was specifically designed to exploit the improved pure PyC which enables features to reduce flow-induced trauma (Bokros et al., 1994, 1997, 1998, 2003), and introduced into clinical practice (FDA, 2001, 2002). The success of the On-X valve in general clinical experience, particularly in noncompliant anticoagulant therapy patient populations (Williams and van Riet, 2006) and animal studies (Flameng and Meuris, 2002) strongly indicated improvements in mechanical valve-related hemostatic complications. Data from this experience was used to justify the first and only FDA approved non-warfarin and reduced warfarin prospective randomized trial for a mechanical heart valve. This trail for the On-X Prosthetic Heart Value, with the objective to reduce anticoagulation bleeding risk, was initiated at Emory Crawford Long Hospital, Atlanta in 2006. The trial is currently ongoing at 40 institutions to include 1200 patients. The high risk aortic group has been fully enrolled, with more than 500 pt-yr experience, maintained with a reduced dose of Coumadin (INR of 1.5 to 2.0) and aspirin (81 mg/dy). The low risk aortic group is maintained with platelet inhibitors, (75 mg/dy plavix) and aspirin. The mitral group enrollment was extended to 2012; this group is maintained at an INR of 2.0 to 2.5 and aspirin (81 mg/dy). A successful outcome for this trial would offer further improvements in quality of life for a significant number of On-X mechanical heart valve recipients.

During the past 28 years PyC has also been used as a loadbearing material for small orthopedic joint replacement implants. Such prostheses relieve pain, correct deformity, and improve the appearance of joints damaged by disease such as rheumatoid arthritis, osteoarthritis, and post-traumatic conditions. However, all PyC joint replacements require careful patient selection for good quality bone and soft tissue. As is true with all implants, prosthesis sizing, alignment, and interactions with soft tissue are critical considerations during implantation surgery and rehabilitation.

Successful applications for upper limb total joint prostheses include the metacarpophalangeal (MCP) joint (Figure I.2.8.10) and the proximal interphalangeal (PIP) joint (Cook et al., 1999; Bravo et al., 2007). Pure isotropic PyC is a nearly ideal material for orthopedic application, with demonstrated advantages over traditional materials such as polymers, ceramics, and metals (Stanley et al., 2008) which include:

- Elimination of wear-related failures
- Absence of osteolytic adverse tissue reactions
- Excellent fatigue resistance
- Non-cemented fixation via bone apposition
- Minimization of stress shielding effects and bone resorption
- Excellent compatibility with joint cartilage and bone tissues.

This excellent compatibility with cartilage and bone tissue enables a number of hemiarthroplasty applications, in which only one component of the joint is replaced leaving the PyC device bearing and articulating against native synovial surfaces. Successful devices for hemiarthroplasty include the MCP and PIP joints, carpometacarpal (CMC) joints, radial head, lunate, and inter-positional articulating surface spacers for use in the CMC joint. Currently, approximately 18,000 PyC small joint and hemiarthroplasty devices have been implanted worldwide.

Given the clinical success of the small joint implants, enhanced compatibility with joint tissue, superior durability, and potential significantly extended device lifetimes, efforts are currently underway to use PyC as a platform for larger joint implants such as the shoulder, knee, and hip. In the larger loadbearing joints, a viable strategy is to use PyC as the bearing surface in conservative resurfacing devices and in total joint modular devices. The mechanical valve experience has demonstrated excellent PyC compatibility with traditional

implant material metals, ceramics, and polymers. This PyC materials compatibility lends great versatility in design for modular devices. We fully expect that PyC devices will prove more functional, aesthetic, durable, and complication free than implants with traditional materials only.

CONCLUSION

Because the blood compatibility of pyrolytic carbon in mechanical heart valves is not perfect, anticoagulant therapy is required for mechanical heart valve patients. However, pyrolytic carbon has been the most successful material in heart valve applications because it offers excellent blood and tissue compatibility which, combined with the appropriate set of physical and mechanical properties and durability, allows for practical implant device design and manufacture. Improvements in biocompatibility are desired, of course, because when heart valves and other implants are used, a deadly or disabling disease is often treated by replacing it with a less pathological, more manageable chronic condition. Ideally, an implant should not lead to a chronic condition.

It is important to recognize that the mechanism for the blood compatibility of pyrolytic carbons is not fully understood, nor is the interplay between the biomaterial itself, design-related hemodynamic stresses, and the ultimate biological reaction. The elucidation of the mechanism for blood and tissue compatibility of pyrolytic carbon remains a challenge.

It is also worth restating that the suitability of carbon materials from new sources for long-term implants is not assured simply because the material is carbon. Elemental carbon encompasses a broad spectrum of possible structures and mechanical properties. Each new candidate carbon material requires a specific assessment of biocompatibility based on its own merits, and not by reference to the historically successful General Atomic-type pyrolytic carbons.

CHAPTER I.2.9 COMPOSITES

Claudio Migliaresi
Department of Materials Engineering and Industrial Technologies and
BioTech Research Center, University of Trento, Trento, Italy

INTRODUCTION

The word *composite* means "consisting of two or more distinct parts." At the atomic level, materials such as metal alloys and polymeric materials could be called composite materials in that they consist of different and distinct atomic groupings. At the microstructural level (about 1 to 10 microns), a metal alloy such as a plain carbon steel containing ferrite and pearlite could be called a composite material since the ferrite and pearlite are distinctly visible constituents as observed in the optical microscope.

In engineering, a composite material usually refers to a material consisting of constituents in the nano- to micro- to macrosize range, each having a distinct interface separating them. Such composites usually consist of one or more discontinuous phases embedded within a continuous phase. The discontinuous phase is usually harder and stronger than the continuous phase, and is called the *reinforcement* or *reinforcing material*, whereas the continuous phase is termed the *matrix*. In some cases, tough fillers, e.g., rubber particles, are combined with brittle matrices in order to produce higher toughness materials with better impact strength. In other cases, the "reinforcement" could be aimed at achieving specific functional properties, such as bioactivity in the case of biomedical composites. Many body tissues are composites, such as extracellular matrix (ECM), tendons, ligaments, skin, bone, and so on, with an additional complexity due to their hierarchical structure.

The addition to a matrix of harder, stronger or tougher fillers may improve to different extents the resulting material stiffness, strength or toughness, depending on the filler type, content, and filler–matrix adhesion. Properties of composites are strongly influenced by the properties of their constituent materials, their distribution and content, and the interface and interphase interactions between them. The interface is particularly important for short fiber- or particle-reinforced composites. External applied stresses are in fact transferred from the matrix to the filler through the interface, and properties of composites with the same constituents but strong or weak interfaces can be better or worse than those of the pure matrix.

The composite properties may be the volume fraction sum of the properties of the constituents, or the constituents may interact in a synergistic way (e.g., due to geometrical orientation) so as to provide properties in the composite that are not accounted for by a simple volume fraction sum. Thus, in describing a composite material, besides specifying the constituent materials and their properties, one needs to specify the geometry of the reinforcement, their concentration, distribution, and orientation. At increasing filler surface-to-volume ratio, i.e., at decreasing filler dimensions, the role of interface/interphase becomes more and more important, and, for this reason, properties of nanocomposites (matrices loaded with fillers of nanometric sizes) are difficult to predict.

Most composite materials are fabricated to provide desired mechanical properties such as strength, stiffness, toughness, and fatigue resistance. Therefore, it is natural to study together the composites that have a common strengthening mechanism. The strengthening mechanism strongly depends upon the geometry of the reinforcement. This approach leads to a classification of composites on the basis of the geometry of a representative unit of reinforcement more than on the type of matrix, e.g., composites with long fibers, short fibers or particles (see Figure I.2.9.1). A fiber is characterized as having a length that is much greater than its cross-sectional dimensions. Particle-reinforced composites are sometimes referred to as *particulate composites*. Short or long fiber-reinforced composites are, understandably, called *fibrous composites*. Matrices loaded with nanofibers or nanoparticles are referred as *nanocomposites*. *Laminates* are composite structures made by stacking laminae of oriented fiber composites. Such composites are characterized by the number and orientation of the laminae.

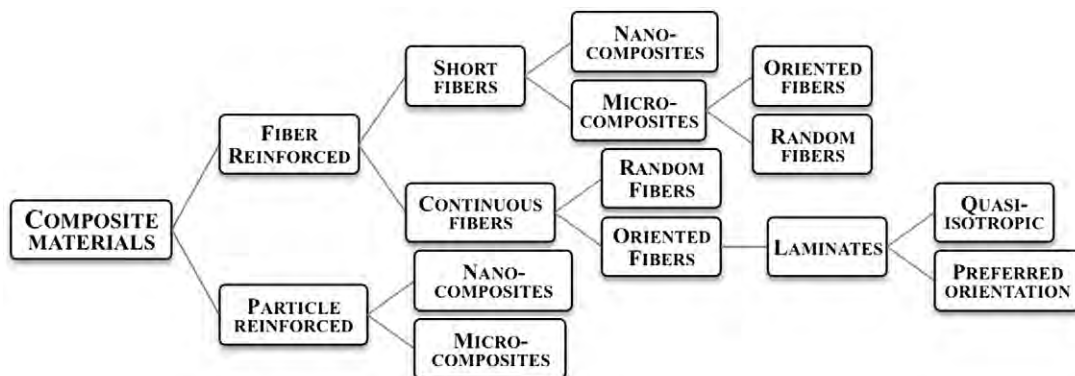

FIGURE I.2.9.1 Classification of composite materials.

Fibers are much more mechanically effective than particles, and polymer–fiber composites can reach stiffness and strengths per unit area that are comparable to metals and even higher. Moreover, while particle-reinforced composites are isotropic, fiber-reinforced composites are anisotropic. Properties in different directions can, in most cases, be designed to match specific requirements. The ability to design anisotropic properties into a composite material is without doubt one of the most important advantages offered by composites with respect to more traditional monolithic materials. Most of the composite body tissues have anisotropic properties, and the match between the properties of the prosthesis and the properties of the substituted tissues is, when possible, the first design criterion.

Failure of a composite material implant can expose fibers or particles to the surrounding biological environment. In many cases failure in composites is preceded by the failure of the interface between filler and matrix, this being due to hydrothermal aging or stresses exceeding the interface strength (Pegoretti and Migliaresi, 2002). Sterilization methods and conditions can play an important role, due to the potential sensitivity of the matrix, and sometimes the filler and its interface, to temperature, humidity or radiation (Godara et al., 2007).

Proper arrangement of fibers in a soft polymer matrix can generate materials mimicking structure and mechanical properties of soft tissues, such as tendons, ligaments, arteries, and so on. These advantages can be used to construct arterial prostheses (Gershon et al., 1990, 1992), or intervertebral discs mimicking the natural structure (Ambrosio et al., 1996; Gloria et al., 2007), or fixation plates and nails with controlled stiffness (Veerabagu et al., 2003), or composite scaffolds for cartilage tissue engineering (Moutos and Guilak, 2008). The addition of hydroxyapatite particles into a stiff biodegradable polymer may improve the compression properties of the matrix while enhancing osteoblast proliferation and improving bone mineralization (Wahl and Czernuszka, 2006). For some applications, moreover, radiolucency is considered to be a further potential advantage. An example is when external or internal fracture fixation devices do not shield the bone fracture site in the X-ray radiograph (Migliaresi et al., 2004).

Design flexibility, strength, and lightweight properties have helped to make carbon fiber-reinforced materials into ideal materials for orthotic aids that can return walking and even athletic abilities to impaired people (Dawson, 2000). Composite material prostheses can be tailored to meet the specific requirements for amputee athletes aiming to compete. Recently, C-shaped carbon fiber composite blades that simulated the spring action of a normal foot allowed a South African double-amputee sprinter, Oscar Pistorius, to run and to compete with the strongest unimpaired world-class athletes. Examples of composite prosthetics for athletes can be found in McCarvill (2005) and Nolan (2008).

As with all biomaterials, the question of biocompatibility (tissue response to the material) is paramount. Being composed of two or more materials, composites may have enhanced probability of causing adverse tissue reactions. Also, the fact that one constituent (the reinforcement) usually has dimensions on or even below the cellular scale always leaves open the question of the effect of cellular ingestion of the particulate which can result in either the expression and secretion of tissue-lysing enzymes by the cell, or transport into the lymph system.

REINFORCING SYSTEMS

The main reinforcing materials that have been used in biomedical composites are carbon fibers, polymer fibers, ceramic particles, and glass fibers and particles. Depending upon the application, the reinforcements have either been inert or absorbable. Several nanocomposites have also been studied in the last few years that contain carbon nanotubes, nanoclays, silica, and hydroxyapatite nanoparticles.

Carbon Fiber

Carbon fiber is a lightweight, flexible, high strength, and high tensile modulus material produced by the pyrolysis of organic precursor fibers, such as rayon, polyacrylonitrile (PAN), and pitch in an inert environment (Matsumoto, 1985).

The term carbon is often indifferently interchanged with the term graphite, but carbon and graphite fibers differ in the temperature of fabrication, thermal treatment, and the content of carbon (93–95% for carbon fibers; more than 99% for graphite fibers). Due to their low density (depending on the precursor, density ranges from 1.7 to 2.1 g/cm^3) and high mechanical properties (elastic moduli up to 900 GPa and strengths up to 4.5 GPa, depending on the precursor and on the fabrication process – hence they can be much stiffer and stronger than steel!) these fibers are used in composites in a variety of applications that demand light weight and high mechanical properties. Their disadvantage is that carbon fibers have poor shear strength and can be brittle.

In medicine, several products have used carbon fibers. Some of them reached the market, some others clinical studies in humans. Examples of carbon fiber composites that are already in the market are the Zimmer BAK® Vista® interbody fusion implants poly(ether-ether-ketone) (PEEK) and carbon fibers), the OCELOT™ Stackable Cage System made by DePuy (PEEK and carbon fibers), the QUANTUM™ Humeral Composite Nailing System produced by Invibio (PEEK and carbon fibers), and the different prosthetics (spine, limb, knee, foot, etc.) produced by Ossur (UK).

Studies on the use of carbon fiber composites for biomedical applications date back to 1990 (Kwarteng, 1990). Examples are spine cages (Brooke et al., 1997) or hip prosthesis stems with tailored rigidity where long

carbon fibers have been coupled with epoxy resins, poly-sulfone or poly(ether-ether-ketone) (PEEK). A follow-up of 51 carbon fiber/epoxy resin composite hip joint stem prostheses implanted in humans did show failure at the bone–implant interface without osteointegration, but never showed failure or wear of the composites (Adam et al., 2002). Some early devices, however, have experienced severe negative effects and have been recalled from the market. Two examples are:

- Short carbon fiber-reinforced ultra-high molecular weight polyethylene (UHMWPE) was developed for orthopedic applications. The assumption was that increase of strength and decrease of creep would increase the longevity of the articular surfaces of the hip implant. The favorable indications of reduced wear in laboratory tests contrasted with the *in vivo* results, where many patients were presented with osteolysis and failure of the tibial inserts (Kurtz et al., 1999).
- In the 1980s carbon fibers were used to develop a scaffolding device to induce tendon or ligament repair. The low shear strength of fibers caused fiber breakage and the formation of harmful debris. A resorbable polymeric coating was somewhat successful in preventing carbon fiber breakage and localizing debris. However, due to poor performance and permanent wear debris in the joint, the carbon fiber device was not approved by the US Food and Drug Administration (FDA) for anterior cruciate ligament (ACL) reconstruction (Dunn, 1998).

In spite of these early failures, however, carbon fibers display unique properties for the fabrication of loadbearing medical devices. Most successful applications are for prosthetics where carbon fiber composites exhibit unique properties in term of lightness, stiffness, and strength.

Polymer Fibers

Polymer fibers are not comparable to carbon fibers in strength or stiffness when used to reinforce other polymers, with the possible exceptions of aramid fibers or UHMWPE fibers. For biomedical applications, biocompatibility, of course, and high strength and fatigue resistance are compulsory, while stiffness is a design parameter to be adapted to the specific conditions. This is why poly(ethylene terephthalate) (PET) fibers have been used for some applications. In addition, thanks to their absorbability, not to their mechanical superiority, certain absorbable fibers have been employed (see below).

- *Aramid* is the generic name for aromatic polyamide fibers. The most well-known aramids are Kevlar™ and Nomex™ (DuPont trademarks), and Twaron™ (made by Teijin/Twaron of Japan). Kevlar is produced by spinning a sulfuric acid/poly(p-phenylene terephthalamide) solution through an air layer into a coagulating water bath. Aramid fibers are relatively

light (density = 1.44 g/cm^3), stiff (the modulus can go up to 190 GPa), and strong (tensile strength about 3.6 GPa). Moreover, they resist impact and abrasion damage, due to the high energy dissipation mechanism involved in their failure (they break into microfibrils). In particular, aramide fibers are less stiff and strong than carbon, but being lighter, they possess comparable specific strength (i.e., strength-to-weight ratio). A negative point, that can be relevant for biomedical applications, is that aramid fibers absorb moisture, and worth noting is their poor compressive strength, about 1/8 of the tensile strength. Aramid fiber composites are used commercially where high tensile strength and stiffness, resistance to impact damage, and resistance to fatigue and stress rupture are important. In medicine, these composites have not seen extensive use, due perhaps to some concerns about their biocompatibility or long-term fate. Main applications have been in dentistry and for ligament prostheses (Wening et al., 1994). The use of partially degradable Kevlar-reinforced composites for bone fracture fixation plates has also been proposed (Jayabalan, 2009). In this paper the author refers to publications assessing the *in vivo* biocompatibility of Kevlar; these papers, while assessing the absence of short-term negative reaction to a PMMA–Kevlar composite and to Kevlar bundles implanted subcutaneously in rats, did not fully elucidate the long-term reaction to free Kevlar fibers in the body (Henderson et al., 1987; Wening et al., 1989).

- Commercially available high-strength, high-modulus polyethylene fibers include Spectra® from Honeywell Performance Fibers (Colonial Heights, VA), Dyneema® from DSM (Heerlen, The Netherlands), and Toyobo fibers from Toyobo (Shiga, Japan). Ultra-high molecular weight polyethylene (UHMWPE) fibers are produced by a gel-spinning technique starting from an approximately 2–8 weight percent solution of the ultra-high molecular weight polymer (Mw > 10^6) in a common solvent, such as decalin. Spinning at 130–140°C and hot drawing at very high draw ratios produces fibers with the highest specific strength of all commercial fibers available to date. UHMWPE fibers possess high modulus and strength, besides displaying light weight (density about 0.97 g/cm^3) and high-energy dissipation ability, compared to other fibers. In addition, polyethylene fibers resist abrasion and do not absorb water. However, the chemical properties of UHMWPE fibers are such that few resins bond well to the fiber surfaces, and so the structural properties expected from the fiber properties are often not fully realized in a composite. The low melting point of the fibers (about 147°C) impedes high temperature fabrication. Bulk UHMWPE has extensive applications in medicine for the fabrication of bearings for joint prostheses, displaying excellent biocompatibility, but with lifetime restricted by its wear resistance. Bulk UHMW polyethylene demonstrates excellent biocompatibility.

Polyethylene fibers have been used to reinforce acrylic resins for application in dentistry or to make inter-verterbral disc prostheses (Kotani et al., 2002). They have also been used for the fabrication of ligament augmentation devices (Guidoin et al., 2000).

• Dacron™ is the DuPont trade name commonly used for poly(ethylene terephthalate) (PET) fibers. These fibers have several biomedical uses, mostly in cardiovascular surgery for arterial grafts or as fabrics for implant fixation, as sewing rings on artificial heart valves. PET fibers have also been proposed in orthopedics for the fabrication of artificial tendons or ligaments (Kolarik et al., 1981) and ligament augmentation devices, as fibers or fabrics alone or as a reinforcing fabric embedded in a polymer matrix, such as in the casing for ventricles in the total artificial heart. Other proposed applications include soft tissue prostheses, intervertebral discs (Ambrosio et al., 1996), and plastic surgery applications.

• Poly(lactic acid) (PLA), poly(glycolic acid) (PGA) and their copolymers (poly(lactic-co-glycolic acid), PLGA) are the principal biodegradable polymers used for the fabrication of biodegradable fibers. These fibers have been used for a number of years in absorbable sutures. Properties of these fibers depend upon several factors, such as LA/GA ratio, water absorption, degree of crystallinity, molecular weight, purity, etc. (Migliaresi and Fambri, 1997). Fibers and tissues of these polymers have been proposed for ligament reconstruction or as scaffolds for tissue engineering applications (Lu and Mikos, 1996; Guarino et al., 2008). PLA and PGA fibers have been employed in composites, e.g., in combination with PLA biodegradable matrices. Examples are the intramedullary biodegradable pins and plates (Middleton and Tipton, 2000), and biodegradable scaffolds for bone regeneration. Electrospun nonwoven nets of PLA and PGA have been recently used in combination with several natural and synthetic polymer matrices to construct degradable scaffolds for tissue engineering applications.

• Polycaprolactone (PCL) is a relatively hydrophobic, slowly degrading, semicrystalline polymer used as a homopolymer or as a component of copolymers with PLA and PGA in implant applications for drug release systems, adhesion barrier film, plastic surgery, and, more recently, for the fabrication of tissue engineering scaffolds. PCL fibers for biomedical applications have been produced by electrospinning, loaded by hydroxyapatite powders (Erisken et al., 2008; Gupta et al., 2009) or used as reinforcement for natural or synthetic polymer matrices.

Ceramics

A number of different ceramic materials have been used to reinforce biomedical composites. Since most biocompatible ceramics, when loaded in tension or shear, are relatively weak and brittle materials compared to metals, the preferred form for this reinforcement has usually been particulate. These reinforcements have included various calcium phosphates, aluminum- and zinc-based phosphates, glass and glass–ceramics, and bone mineral. Minerals in bone are numerous. In the past, bone has been defatted, ground, and calcined or heated to yield a relatively pure mix of the naturally occurring bone minerals. It was recognized early that this mixture of natural bone mineral was poorly defined and extremely variable. Consequently, its use as an implant material was limited.

Tricalcium phosphates and hydroxyapatite are commonly referred as bioceramics, i.e., bioactive ceramics. The definition refers to their ability to elicit a specific biological response that results in the formation of a bond between the tissues and material (Hench et al., 1971).

The calcium phosphate ceramic systems have been the most intensely studied ceramic systems. Of particular interest are the calcium phosphates having calcium to phosphorous ratios of 1.5–1.67. Tricalcium phosphate and hydroxyapatite form the boundaries of this compositional range. At present, these two materials are used clinically for dental and orthopedic applications. Tricalcium phosphate has a nominal composition of $Ca_3(PO_4)_2$. The common mineral name for this material is *whitlockite*. It exists in two crystographic forms, α- and β-whitlockite. In general, it has been used in the β-form. Moreau and Xu (2009) investigated the properties of calcium phosphate–chitosan composites to be used as injectable bone repair materials. The ceramic hydroxyapatite has received a great deal of attention. Hydroxyapatite is, of course, the major mineral component of bone. The nominal composition of this material is $Ca_{10}(PO_4)_6(OH)_2$.

Hydroxyapatite (HA) ceramic and tricalcium phosphates are used in orthopedics and dentistry, alone or in combination with other substances or also as coating of metal implants. The rationale behind the use of bioceramics in combination with polymeric matrices for composites is in their potential ability to enhance the integration in bone, while improving the device mechanical properties. One example is the HA–Polyethylene composite developed by Bonfield (Bonfield, 1988; Bonfield et al., 1998), and today commercialized with the name of HAPEX (Smith & Nephew ENT, Memphis, TN, USA).

Many papers have been published on HA-reinforced polymers. A recent example is the use of HA to reinforce PLGA for the fabrication of nanofibrous scaffolds for tissue engineering applications (Jose et al., 2009).

Glasses

Glass fibers, namely C glasses and S glasses, are used to reinforce plastic matrices to form structural composites and molding compounds. Commercial glass fiber plastic composite materials have the following favorable characteristics: high strength-to-weight ratio; good dimensional stability; good resistance to heat, cold, moisture,

and corrosion; good electrical insulation properties; ease of fabrication; and relatively low cost. The following are examples of glass composites:

- De Santis et al. (2000) have stacked glass and carbon/PEI (poly(ether-imide)) laminae to manufacture a hip prosthesis with constant tensile modulus, but with bending modulus increasing in the tip-head direction.
- An isoelastic intramedullary nail made of PEEK and chopped glass fibers has been evaluated by Lin et al. (1997). Zhao et al. (2009) compared properties and *in vivo* behavior of intramedullary nails that were implanted in rabbits; the nails were either made of titanium or a Bis-GMA–TEGDMA/E-glass fiber composite that was HA-coated. They observed that the composite materials implants induced proper healing of the fixed femurs with no signs of adverse tissue reactions or implant failure.

> The term isoelastic has often been improperly used. It means "having the same elastic modulus as." For bone fracture fixation plates, the fact that the plate has an elastic modulus similar to bone (i.e., isoelastic) has been claimed to be a major requirement. The concept is misleading, because the deformation of a plate would not only depend on the elastic modulus of the material that it is composed of, but also on the size and shape of the plate (for loading mode other than tension or compression). For example, a toothpick and the tree from which it was made are isoelastic, but no one could imagine supporting a tree with a toothpick!

Glass fibers have also been used to increase the mechanical properties of acrylic resins for applications in dentistry (Chen et al., 2001). Zimmerman et al. (1991) and Lin (1986) introduced an absorbable polymer composite reinforced with an absorbable calcium phosphate glass fiber. This allowed for the fabrication of a completely absorbable composite implant material. Commercial glass fiber produced from a lime–aluminum–borosilicate glass typically has a tensile strength of about 3 GPa and a modulus of elasticity of 72 GPa. Lin (1986) estimates the absorbable glass fiber to have a modulus of 48 GPa, comparing favorably with the commercial fiber. The tensile strength, however, was significantly lower, approximately 500 MPa.

Nanoparticles and Nanofibers: "Nanofillers"

In recent years, polymers filled with nanoparticles or nanofibers have been proposed for several applications in medicine. Due to the huge amount of interface or interphase being created between fillers and matrix by nanofillers, small amounts of such fillers can cause large modifications in both mechanical and functional properties of the matrix. The list of nano-reinforcements that have been investigated for biomedical use includes silica nanoparticles, nanoclays,

carbon nanotubes, and POSS (polyhedral oligomeric silsesquioxane, silicon and oxygen atoms linked together in a cubic form, with silicon atoms occupying the corners). Here are some examples of nanocomposites:

- Nanoclays, such as montomorillonite, have been used as reinforcement in poly(L-lactic acid) polymer (PLLA) electrospun fibers (Lee et al., 2005).
- A recent work suggested the use of poly(carbonate)–urethane–POSS nanocomposites for blood contacting applications (Sarkar et al., 2009). These materials were found to be thrombo-resistant, biostable, and more compliant than PTFE vascular grafts *in vitro*.
- Carbon nanotubes are geometrically nanofibers, having diameters of the order of 10 nm (multi-walled nanotubes) or 1 nm (single-walled nanotubes), and lengths equal to 1000–2000 times their diameter. Their exceptionally high mechanical properties (Elastic modulus = 1 TeraPascal; Strength (calculated) = 50 GPa) have stimulated numerous researchers to study their application for composites, also for biomedical applications. For instance, carbon nanotubes have been used to produce electrospun silk fibroin nanocomposites for potential tissue engineering applications (Gandhi et al., 2009). However, carbon nanotubes can be cytotoxic (Tian et al., 2006), and this should be clearly kept in mind when investigating their use for biomedical composites.

> The use of nanoparticles to reinforce polymer matrices has brought novelty and excitement to the field of composites, and as often occurs, this trend has also become very popular for biomedical applications. However, the biomaterials scientist should be aware of the fact that different sized objects of the same material can induce very different biological responses, especially in this case, where the size scale of at least one dimension of a nanoparticle or "nanorod" (e.g., nanofiber or nanotube) is much smaller than a cell.

MATRIX SYSTEMS

Ceramic matrix or metal matrix composites have important technological applications, but their use is mostly in non-biomedical applications (e.g., cutting tools, power generation equipment, process industries, aerospace), with just a few examples for biomedical applications (e.g., calcium phosphate bone cements). Most biomedical composites have polymeric matrices, mostly thermoplastic, that can be bioabsorbable or not.

The most common matrices in biomedical products are synthetic non-absorbable polymers, such as polysulfone, poly(ether-ether-ketone) (PEEK), ultra-high molecular weight polyethylene (UHMWPE), polytetrafluoroethylene (PTFE) and poly(methylmethacrylate)

(PMMA). These matrices may be reinforced with carbon fibers, polyethylene fibers, and ceramic particles. They have been used as components of prosthetic hip stems, fracture fixation devices, artificial joint bearing surfaces, artificial tooth roots, and bone cements. A comprehensive review on PEEK biomaterials in medicine is found in Kurtz and Devine (2007). Epoxy composite materials have also been used. However, due to concerns about the toxicity of monomers (Morrison et al., 1995) the research activity on epoxy composites for implantable devices gradually decreased. Hydrogel matrix composites have been also studied for soft tissue applications (Ambrosio et al., 1996; Kolarik et al., 1981).

The materials used and some proposed applications are reported in Table I.2.9.1. Not all the proposed

systems have undergone clinical trials, and only some of them are commercialized today. A review on biomedical applications of composites is found in Ramakrishna et al. (2001).

Absorbable composite implants can be produced from absorbable α-polyester materials such as poly(lactic acid) (PLA) and poly(glycolic acid) (PGA) polymers. Previous work has demonstrated that, for most applications, it is necessary to reinforce these polymers to obtain adequate mechanical strength. PGA was the first biodegradable polymer synthesized (Frazza and Schmitt, 1971). It was followed by PLA and copolymers of the two (Gilding and Reed, 1979). These α-polyesters have been investigated for use as sutures, and as implant materials for the repair of a variety of

osseous and soft tissues. Other biodegradable polymers that have been developed include poly(ortho esters), synthesized by Heller and co-workers (Heller et al., 1980), and a class of bioerodable dimethyl-trimethylene carbonates (DMTMCs) (Tang et al., 1990). A review of absorbable polymers by Nair and Laurencin (2007) included PGA, PLA, PLGA polydioxanone, polycaprolactone (PCL), poly(trimethylenecarbonate), bacterial polyesters, polyurethanes, poly(esteramide), poly(orthoesters), polyanhydrides, poly(anhydride-co-imide), cross-linked polyanhydrides, poly(propylene fumarate), poly(pseudo amino acids), poly(alkyl cyanoacrylates), polyphosphazenes, and polyphosphoesters. Another review by Middleton and Tipton (2000) focused on biodegradable polymers suited for orthopedic applications, mainly PGA, PLA, and PLGA. The authors examined the chemistry, fabrication, degradation mechanisms, and biocompatibility of different polymers and their devices. Degradable polymers are also discussed in other chapters of this text.

In addition to synthetic biodegradable polymers, natural polymers have been also investigated as matrices for biomedical composites (see also Chapter I.2.7). Examples are collagen (Wahl and Czernuszka, 2006), silk fibroin (Wang et al., 2010), and chitosan (Kong et al., 2005). Reis et al. (1998) have studied blends of starch with various thermoplastic polymers. They were proposed for a large range of applications such as temporary hard tissue replacement, bone fracture fixation, drug delivery devices or tissue engineering scaffolds.

FABRICATION OF COMPOSITES

Composite materials can be fabricated with different technologies. Some of them are particular for the type of filler (particle, short or long fiber) and matrix (thermoplastic or thermosetting). Some methods, such as compression molding, extrusion or injection molding, are the same that are used for polymers. Some make use of solvents that are unacceptable, even in trace amounts, and are therefore not suitable for the fabrication of biomedical composites. Some biomedical composites, moreover, are fabricated *in situ*. This is the case for composite bone cements.

The selection of the most appropriate manufacturing technology is also influenced by the relatively low volumes of the materials used in the product compared to other applications, and by the relatively low importance of the manufacturing cost compared to the overall cost of the device.

Properties of composites mainly depend on the properties and geometry of the constituents, their volume fraction, and their interfacial interactions with the matrix. For example, properties such as strength for particulate or short fiber composites and stiffness/strength for off-axis loaded fiber composites are influenced by the filler–matrix adhesion. Poor adhesion between reinforcing

filler and matrix can be also responsible for undesirable hydrolytic breakdown of composites in the body environment (Pegoretti and Migliaresi, 2002). Hydrolytic instability of the fillers can also lead to degradation of composites in the body (Brown et al., 2005). In order to improve the strength of the interface, fillers can be surface treated in different ways to increase their surface energy, i.e., wettability or by binding to the filler surface molecules that will react with the matrix (e.g., silanes for glassy fillers).

Fabrication of Particle-Reinforced Composites

Injection molding, compression molding, and extrusion are the most common fabrication technologies for biomedical particulate composites. In some applications composites are manufactured *in situ*. This is the case of dental restorative composites and particle-reinforced bone cements.

Fabrication of Fiber-Reinforced Composites

Hand Lay-Up. This technique is mostly used for the preparation of thermosetting matrix, long fiber composite laminates, with relatively high fiber content (i.e., 50–60% by volume) and well-controlled in-plane mechanical properties. The basic structure is a thin sheet of matrix embedded with uniaxially or 0–90° oriented reinforcing fibers named lamina. Unidirectional or 0–90° oriented fiber sheets are cut in the desired shape and deposited with different orientation on a mold, then impregnated with the proper amount of resin. Impregnation can be performed after the deposition of each layer or previously resin-impregnated laminae ("prepregs") may be used. After lamination, the system is usually enclosed in a plastic vacuum bag, vacuum is applied to extract air (which can inhibit free radical curing processes) and compact the laminae, and finally the assembly will undergo a thermal program ("cure") to achieve resin cross-linking. For better quality composites, cure is often made in an autoclave at pressures of 6–8 atmospheres. (Composite materials produced by this method are currently used in aircraft and aerospace applications.) The conditions for curing vary depending upon the material. After being removed from the autoclave, the composite part is stripped from its tooling and is ready for further finishing operations.

The stacking sequence of the laminae and their number will determine the mechanical properties of the resulting composite (see Appendix). Composites with the same number and type of laminae but with different stacking sequences will have the same tensile modulus but different bending moduli.

The hand lay-up processing technique is potentially useful for the production of fracture fixation devices and total hip stems. The technique has been applied to the

fabrication of various types of biomedical prostheses, such as hip prostheses or intervertebral discs.

Filament-Winding Process. The filament-winding process is an open-mold process used to produce high-strength hollow cylinders. In this process, the fiber reinforcement is fed through a resin bath and then wound on a suitable mandrel. When sufficient layers have been applied, the fiber–polymer wound mandrel is cured. The molded part is then stripped from the mandrel. The high degree of fiber orientation and high fiber loading with this method can produce extremely high tensile strengths. Biomedical applications for this process include intramedullary rods for fracture fixation, prosthetic hip stems, ligament prostheses, and interverterbral discs.

Other Processes. There are many closed-mold methods used for producing fiber-reinforced plastic materials. The methods of most importance to biomedical composites are compression and injection molding, and continuous "pultrusion."

In compression molding, the previously-fabricated prepregs are arranged in a two-piece mold that is then heated under pressure to produce the laminated part. This method is particularly useful for use with thermoplastic matrices.

In injection molding the fiber–matrix mix is injected into a mold at elevated temperature and pressure. The finished part is removed after cooling. This is an extremely fast and inexpensive technique that has application to chopped fiber-reinforced thermoplastic composites. It offers the possibility of producing composite devices, such as bone plates and screws, at much lower costs than comparable metallic devices. In resin transfer molding (RTM), the resin is injected in a closed mold that contains the fiber mat or fabric already deposited in the desired geometrical sequence. This procedure has been used for the production of composite hip prostheses.

Continuous pultrusion is a process used for the manufacture of fiber-reinforced plastics of constant cross-section, such as structural shapes, beams, channels, pipe, and tubing. In this process, continuous-strand fibers are impregnated in a resin bath and then are drawn through a heated die, which determines the shape of the finished stock. Highly oriented parts cut from this stock can then be used in other structures or they can be used alone in such applications as intramedullary rods or pin fixation of bone fragments.

ABSORBABLE MATRIX COMPOSITES

Absorbable matrix composites have been used in situations where absorption of the matrix is desired. Matrix absorption may be desired to expose surfaces to tissue or to release admixed materials such as antibiotics or growth factors (drug release) (Yasko et al., 1992). However, the most common reasons for the use of this class of matrices for composites has been to accomplish time-varying mechanical properties and ensure complete

dissolution of the implant, eliminating long-term biocompatibility concerns. This type of composite would contain an absorbable matrix as well as absorbable reinforcing fillers. A typical clinical example is fracture fixation (Daniels et al., 1990; Tormala, 1992).

Fracture Fixation

Rigid internal fixation of fractures has conventionally been accomplished with metallic plates, screws, and rods. During the early stages of fracture healing, rigid internal fixation maintains alignment and promotes primary osseous union by stabilization and compression. Unfortunately, as healing progresses, or after healing is complete, rigid fixation may cause bone to undergo stress protection atrophy. This can result in significant loss of bone mass and osteoporosis. Additionally, there may be a basic mechanical incompatibility between the metal implants and bone. The elastic modulus of cortical bone ranges from 17 to 24 GPa, depending upon the age and location of the specimen, while the commonly used alloys have moduli ranging from 110 GPa (titanium alloys) to 210 GPa (316L steel). This large difference in stiffness can result in disproportionate load sharing, which can lead to relative motion between the implant and bone upon loading, as well as to high stress concentrations at bone–implant junctions.

Another potential problem is that the metal alloys currently used for plates corrode to some degree. Metal ions are released and they have been reported to cause adverse local tissue reactions, which in turn raises questions of adverse effects on bone mineralization, as well as adverse systemic responses such as local tumor formation (Bauer et al., 1987). Consequently, it is usually recommended that a second operation be performed to remove the metal hardware after healing.

The advantages of absorbable devices are thus twofold. First, the devices degrade mechanically with time, reducing stress protection and the accompanying osteoporosis. Second, there is no need for secondary surgical procedures to remove absorbable devices. The state of stress at the fracture site gradually returns to normal, allowing normal bone remodeling.

Absorbable fracture fixation devices have been produced from poly(L-lactic acid) polymer (PLLA), PGA polymer, and polydioxanone. An excellent review of the mechanical properties of biodegradable polymers was prepared by Daniels and co-workers (Daniels et al., 1990). Their review revealed that unreinforced biodegradable polymers are initially 36% as strong in tension as annealed stainless steel, and 54% in bending, but only 3% as stiff in either test mode. With fiber reinforcement, highest initial strengths exceeded those of stainless steel. Stiffness reached 62% of stainless steel with nondegradable carbon fibers, 15% with degradable inorganic fibers, but only 5% with degradable polymeric fibers.

Most previous work on absorbable composite fracture fixation has been performed with PLLA polymer. PLLA possesses three major characteristics that make it a potentially attractive biomaterial:

- It degrades in the body. The degradation rate depends on the polymer purity, crystallinity, and molecular weight.
- The degradation product of PLLA is mainly lactic acid, which is nontoxic, biocompatible, easily absorbed into and eliminated from the body. Lactic acid enters the lactic acid cycle of metabolites within cells. Ultimately it is metabolized to carbon dioxide and water.
- The PLLA rate of degradation can be controlled by copolymerizing lactic acid with glycolic acid to form PLGA or blending it with PGA or PLGA.

Poly(L-lactic acid) polymer reinforced with randomly oriented chopped carbon fiber was used to produce partially degradable bone plates (Corcoran et al., 1981). It was demonstrated that the plates, by virtue of the fiber reinforcement, exhibited mechanical properties superior to those of pure polymer plates. *In vivo*, the matrix degraded and the plates lost rigidity, gradually transferring load to the healing bone. However, the mechanical properties of such chopped fiber plates were relatively low; consequently, the plates were only adequate for low-load situations. Zimmerman et al. (1987) used composite theory to determine an optimum fiber lay-up for a long fiber composite bone plate. Composite analysis predicted the mechanical superiority of a 0°/±45° laminae lay-up. Although the 0°/±45° carbon/poly(lactic acid) composite possessed adequate initial mechanical properties, water absorption and subsequent delamination degraded the properties rapidly in an aqueous environment. The fibers did not chemically bond to the matrix.

In an attempt to develop a totally absorbable composite material, a calcium–phosphate-based glass fiber has been used to reinforce poly(lactic acid). Experiments were pursued to determine the biocompatibility and *in vitro* degradation properties of the composite (Zimmerman et al., 1991). These studies showed that the glass fiber–PLA composite was biocompatible, but its degradation rate was too high for use as an orthopedic implant.

Shikinami and Okuno (2001) have used compression molding to produce miniplates, rods, and screws made of PLLA containing 30% and 40% by weight of hydroxyapatite particles. These composites were suggested for indications such as repair of bone fracture in osteosynthesis, and fixation of bony fragments in bone grafting and osteotomy, exhibiting total resorbability and osteological bioactivity while retaining sufficiently high stiffness for a long period of time to achieve bony union. Furukawa et al. (2000a,b) have investigated the *in vivo* biodegradation behavior of hydroxyapatite/poly (L-lactide) composite rods implanted subcutaneously and in the intramedullary cavities of rabbits, showing that after 25 weeks of implantation, rods maintained a bending strength higher than 200 MPa. Their conclusion was that such strength was sufficient for application of the rods for the fixation of human bone fractures. In another *in vivo* study, Hasegawa et al. (2006) marked the excellent biodegradability and osteoconductivity of the HA/PLLA composites with no apparent late aseptic reactions after over seven years of implantation. HA/PLLA composite plates have been commercialized with the name of Fixsorb-MX and are presently commercialized in the USA and Europe with the name of OSTEOTRANS™ for several bone fixation applications.

By using a sintering technique, Tormala et al. (1988) produced self-reinforced PGA rods that have been used in the treatment of fractures and osteotomies. Afterwards, by using the same technique, self-reinforced PLLA pins and screws have been produced. The self-reinforced PLGA had higher initial mechanical properties, but degraded faster with respect to the parent PLLA material, which is reabsorbed in 12–16 months. These products are commercially available.

NON-ABSORBABLE MATRIX COMPOSITES

Non-absorbable matrix composites are generally used to provide specific mechanical properties unattainable with homogeneous materials. Particulate and chopped-fiber reinforcement have been used in bone cements and bearing surfaces to stiffen and strengthen these structures. Because the matrices and fillers are non-absorbable, they are used for "lifelong" implants such as orthopedic appliances and total joint replacements.

Reduced-stiffness carbon fiber-reinforced epoxy bone plates have been studied for fracture fixation with the aim of reducing "stress protection," which can cause osteoporosis. Many authors have demonstrated the negative stress protecting effect exerted by high rigidity fixation plates. Composites can offer unique advantages, since it is possible to produce plates equal in size, shape, and materials, but with different mechanical properties, such as with different ratios of tensile stiffness to bending or torsion stiffness (e.g., this is achieved by changing fiber orientation or fiber orientation sequence within the plate thickness).

Fujihara et al. (2003) investigated the influence of braiding angles and plate thickness on the bending performance of braided carbon/PEEK composite bone plates compared to metal plates. Different braiding angles produced composite plates with different stiffnesses (see Figure I.2.9.2) that could be adapted better than metals to different bone fixation and stiffness requirements.

Epoxy/carbon fiber fracture plates, produced by Orthodynamics Ltd, UK, are currently commercially available. As reported by the company, these plates have been implanted in more than 1000 cases since 1981,

showing significant advantages over the more rigid metal plates (Pemberton et al., 1994).

Total Joint Replacement

By far the most studied, and potentially the most valuable, use of non-absorbable composites has been in total joint replacement. Bone resorption in the femur leading to aseptic loosening is an all-too-common occurrence associated with the implantation of metallic femoral hip replacement components. Several publications have shown that a relationship exists between bone remodeling and the state of stress and strain of the cortical femur, and that bone loss can occur after total hip replacement (Rosenthall et al., 2000).

It has long been recognized that bone adapts to functional stress by remodeling to re-establish a stable mechanical environment. When applied to the phenomenon of bone loss around implants, one can postulate that the relative stiffness of the metallic component is depriving bone of its accustomed load. Clinical and experimental results have shown the significant role that implant elastic characteristics play in allowing the femur to attain a physiologically acceptable stress state. Femoral stem stiffness has been indicated as an important determinant of cortical bone remodeling (Cheal et al., 1992). Composite materials technology offers the ability to alter the elastic characteristics of an implant and provide a better mechanical match with the host bone, potentially leading to a more favorable bone remodeling response (Bougherara et al., 2007).

Using different polymer matrices reinforced with carbon fiber, a large range of mechanical properties is possible. Campbell et al. (2008) have recently proposed carbon fibers/polyamide 12 (CF/PA12) composites for the fabrication of isoelastic stems of hip protheses. In their process, overlaid braided sleeves of CF/PA12 were

placed around an inflatable bladder, compressed against a mold, and cured at temperature higher than the melting temperature of the matrix (see Figure I.2.9.3).

St. John (1983) reported properties for ±15° laminated test specimens) with moduli ranging from 18 to 76 GPa. However, the best reported study involved a press-fit device constructed of carbon fiber/polysulfone composite implanted in dogs (Magee et al., 1988). The femoral component was designed to have strength and elastic properties that matched well with the proximal canine femur. The component contained a core of unidirectional carbon/polysulfone composite enveloped with a bidirectional-braided layer composed of carbon/polysulfone composite covering the core. These regions were encased in an outer coating of pure polysulfone. Finite-element stress analysis predicted that this construction would cause minimal disruption of the normal stresses in the intact cortical bone. Canine animal studies carried out over four years showed a favorable bone remodeling response. The authors proposed that implants fabricated from carbon/polysulfone composites should have the potential for use in loadbearing applications. An implant with appropriate elastic properties provides the opportunity for the natural bone remodeling response to enhance implant stability.

Poly(ether-ether-ketone) (PEEK) matrix has been one of the most studied matrices for bone interfacing prosthesis. An *in vitro* study of Scotchford et al. (2003) showed a similar osteoblast attachment and proliferation on a PEEK/carbon fiber stem component as referred to Ti6Al4V stems. A reduced stiffness acetabular cup prosthesis made by a ceramic bearing cup mounted on a PEEK/carbon fiber composite back that was investigated by Mathias and Tabeshfar (2006) surpassed five million cycles in a fatigue test at a load three times higher than the one specified by ISO standards for femoral stems.

According to information available from the manufacturer (Orthodynamics Ltd, Dorset, UK), a hip protheses with a stem made with metal coated with PEEK/carbon

fiber composite was implanted in 65 patients between 1992 and 1998, with favorable early clinical results.

This concept was also pursued by Simoes and Marques (2005), who developed a prosthetic stem made with a Cr–Co core and an external, controlled stiffness layer of a hybrid braided carbon/glass fiber composite. The stems were produced by a molding technology (see Figure I.2.9.4) that could be easily applied to the manufacture of other long and short fiber composite prostheses. The technology is an example of a manufacturing process that can be applied to the fabrication of laminated composites with or without an internal core.

Adam et al. (2002) reported on the revision of 51 press-fit hip prostheses implanted in humans that were made of epoxy resin/carbon fiber composites. Their results showed that within six years 92% of the prostheses displayed aseptic loosening, i.e., did not induce bone ingrowth. Authors attributed the failure to the smoothness of the stem surface. No osteolysis or wear or inflammatory reactions were, however, observed.
FIGURE I.2.9.4 Fabrication of a composite hip prosthesis. (Reprinted from *Materials & Design*, Vol. 26, Simões and Marques Design of a composite hip femoral prothesis, 391-401, (2005) with permission from Elsevier.)

Different fiber matrices and fabrication technologies have been proposed for the fabrication of hip prostheses. A review of materials and methods is found in the papers of Ramakrishna et al. (2001) and de Oliveira, Simões and Marques (2001).

The EPOCH® hip prosthesis developed by Zimmer was approved by the FDA to begin clinical trials in 2002. The stem of the prosthesis is made by an inner core of Cr–Co, an intermediate layer of PEEK (the configuration was modified in 2006), and an outer layer of titanium fibers. This is not a composite, as strictly defined, but nevertheless is a composite structure where different materials make a stem less stiff with respect to the more traditional metal stems.

Tissue Engineering Scaffolds

Composites have been widely proposed as tissue engineering (TE) scaffolds. The aim of the addition of fillers to a biodegradable polymer matrix is not only to reinforce the matrix, but also to impart to the scaffold specific bioactive properties, such as drug delivery. The role of the scaffold is to provide a support to the newly forming tissue through a favorable interaction with cells, but also fulfilling specific requirements of the implant site (Hollister, 2005; Agrawal et al., 2006).

Sometimes, polymeric particles have been added to polymeric matrices to promote sustained release of specific molecules. For instance, gelatin microparticles have been added to injectable cross-linked oligo(ethylene glycol fumarate) matrices to release drugs or growth factors for regenerating tissue in an osteochondral defect (Guo et al., 2009).

In a similar type of study, the addition of PLGA particles to silk fibroin porous sponges (Wenk et al., 2009), or PLGA particles to a poly(propylene fumarate) matrix (Kempen et al., 2006) was investigated. A three-dimensional PGA structure impregnated with gels of agarose and fibroin showed mechanical properties similar to the native articular cartilage; it was also seeded with chondrocytes (Moutos et al., 2007).

The reader should also refer to Section II.6 on tissue engineering in this volume.

SUMMARY

Biomedical composites have demanding properties that allow few, if any, "off-the-shelf" materials to be used. Few biomedical composites are yet in general clinical use. In many cases, those that have been developed to date have not been designed for a specific clinical use. They are simple laminates, or chopped fiber- or particulate-reinforced systems, sometimes without attempts made to react or bond the phases together. Such bonding may be accomplished by altering the surface chemistry, surface texture of the filler or by the introduction of coupling agents, i.e., molecules that can react with both filler and matrix. However, concerns about the biocompatibility of coupling agents and the high development costs of surface texture alteration procedures have curtailed major developments in this area. It is also possible to provide three-dimensional reinforcement with complex fiber weaving and impregnation procedures that are now regularly used in high-performance aerospace composites. Unfortunately, the high development costs associated with these techniques have restricted their application in biomedical composites.

Biomedical composites, because of their unique requirements, are probably the first general class of materials developed exclusively for implantation purposes. In recent years, nano-composite prostheses and composite scaffolds for tissue engineering applications have been proposed. In both cases, specific functional properties were provided by the filler addition. For nano-composites, often the proposed solutions did not consider the biocompatibility implications behind the use of nanoparticles that are so small they can easily cross the cell membrane.

APPENDIX 1: MECHANICAL AND PHYSICAL PROPERTIES OF COMPOSITES

CONTINUOUS FIBER COMPOSITES

Laminated continuous fiber-reinforced composites are described from either a micro- or macro-mechanical point of view. Micromechanics is the study of composite material behavior wherein the interaction of the constituent materials is examined on a local basis. Macro-mechanics is the study of composite material behavior wherein the material is presumed homogeneous and the effects of the constituent materials are detected only as averaged apparent properties of the composite.

Micro-mechanics

There are two basic approaches to understanding the micro-mechanics of composite materials: the "mechanics-of-materials" approach and the elasticity approach. The mechanics-of-materials approach embodies the concept of simplifying assumptions regarding the hypothesized behavior of the mechanical system. It is the simpler of the two and the traditional choice for micro-mechanical evaluation.

The most prominent assumption made in the mechanics-of-materials approach is that strains in the fiber direction of a unidirectional fibrous composite are the same in the fibers and the matrix. This assumption allows the planes to remain parallel to the fiber direction. It also allows the longitudinal normal strain to vary linearly throughout the member with the distance from the neutral axis. Accordingly, the stress will also have a linear distribution.

Some other important assumptions are as follows:

1. The lamina is macroscopically homogeneous, linearly elastic, orthotropic, and initially stress-free.
2. The fibers are homogeneous, linearly elastic, isotropic, regularly spaced, and perfectly aligned.
3. The matrix is homogeneous, linearly elastic, and isotropic.

In addition, no voids are modeled in the fibers, the matrix or between them.

The mechanical properties of a lamina are determined by fiber orientation. The most often used laminate coordinate system has the length of the laminate in the x direction and the width in the y direction. The principal fiber direction is the 1 direction, and the 2 direction is normal to that. The angle between the x and 1 directions is Φ. A counterclockwise rotation of the 1-2 system yields a positive Φ.

The mechanical properties of the lamina are dependent on the material properties and the volume content of the constituent materials. The equations for the mechanical properties of a lamina in the 1-2 directions are:

$$E_1 = E_f V_f + E_m V_m \tag{1}$$

$$E_2 = E_m \frac{1 + \xi \eta V_f}{1 - \eta V_f} \tag{2}$$

$$G_{12} = G_m \frac{1 + \xi \eta V_f}{1 - \eta V_f} \tag{3}$$

$$v_{12} = V_m v_m + V_f v_f \tag{4}$$

$$v_{21} E_1 = v_{12} E_2 \tag{5}$$

where E = modulus, G = shear modulus, V = volume fraction, v = Poisson's ratio, and subscripts f and m = fiber and matrix properties, respectively. The equations 2 and 3 are known as the Halpin-Tsai equation. This equation can be used to predict the stiffness of the lamina in the direction orthogonal to the fibers, but also the lamina shear modulus or the stiffness of short fibers laminae, or other properties, by adjusting the numerical parameter ξ. The factor η depends on ξ and on the fibers/matrix properties.

Macromechanics of a Lamina

The generalized Hooke's law relating stresses to strains is

$$\sigma_i = C_{ij} \varepsilon_j \qquad ij = 1, 2, \ldots, 6 \tag{6}$$

where σ_i = stress components, C_{ij} = stiffness matrix, ε_j = strain components. An alternative form of the stress-strain relationship is

$$\varepsilon_j = S_{ij} \sigma_i \qquad ij = 1, 2, \ldots, 6 \tag{7}$$

where S_{ij} = compliance matrix.

Given that $C_{ij} = C_{ji}$, the stiffness matrix is symmetric, thus reducing its population of 36 elements to 21 independent constants. We can further reduce the matrix size by assuming the laminae are orthotropic. There are 9 independent constants for orthotropic laminae. In order to reduce this three-dimensional situation to a two-dimensional situation for plane stress, we have

$$\tau_3 = 0 = \sigma_{23} = \sigma_{13} \tag{8}$$

thus reducing the stress-strain relationship to

$$\begin{vmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \gamma_{12} \end{vmatrix} = \begin{vmatrix} S_{11} & S_{12} & 0 \\ S_{21} & S_{22} & 0 \\ 0 & 0 & S_{66} \end{vmatrix} \begin{vmatrix} \sigma_1 \\ \sigma_2 \\ \tau_{12} \end{vmatrix} \tag{9}$$

The stress-strain relation can be inverted to obtain

$$\begin{vmatrix} \sigma_1 \\ \sigma_2 \\ \tau_{12} \end{vmatrix} = \begin{vmatrix} Q_{11} & Q_{12} & 0 \\ Q_{21} & Q_{22} & 0 \\ 0 & 0 & Q_{66} \end{vmatrix} \begin{vmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \gamma_{12} \end{vmatrix} \tag{10}$$

where Q_{ij} are the reduced stiffnesses. The equations for these stiffnesses are

$$Q_{11} = \frac{E_1}{1 - v_{21} v_{12}} \tag{11}$$

$$Q_{12} = \frac{v_{12} E_2}{1 - v_{12} v_{21}} = \frac{v_{21} E_1}{1 - v_{12} v_{21}} = Q_{21} \tag{12}$$

$$Q_{22} = \frac{E_2}{1 - v_{12} v_{21}} \tag{13}$$

$$Q_{66} = G_{12} \tag{14}$$

The material directions of the lamina may not coincide with the body coordinates. The equations for the transformation of stresses in the 1-2 direction to the x-y direction are

$$\begin{vmatrix} \sigma_x \\ \sigma_y \\ \tau_{xy} \end{vmatrix} = \begin{vmatrix} T^{-1} \end{vmatrix} \begin{vmatrix} \sigma_1 \\ \sigma_2 \\ \tau_{12} \end{vmatrix} \tag{15}$$

where $[T^{-1}]$ is

$$\begin{vmatrix} T^{-1} \end{vmatrix} = \begin{vmatrix} \cos^2\varphi & \sin^2\varphi & -2\sin\varphi\cos\varphi \\ \sin^2\varphi & \cos^2\varphi & 2\sin\varphi\cos\varphi \\ \sin\varphi\cos\varphi & \sin\varphi\cos\varphi & \cos^2\varphi - \sin^2\varphi \end{vmatrix} \tag{16}$$

The x and 1 axes form angle φ. This matrix is also valid for the transformation of strains,

$$\begin{vmatrix} \varepsilon_x \\ \varepsilon_y \\ \gamma_{xy} \end{vmatrix} = \begin{vmatrix} T^{-1} \end{vmatrix} \begin{vmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \gamma_{12} \end{vmatrix} \tag{17}$$

Finally, it can be demonstrated that

$$\begin{vmatrix} \sigma_x \\ \sigma_y \\ \tau_{xy} \end{vmatrix} = \begin{vmatrix} \overline{Q}_{ij} \end{vmatrix} \begin{vmatrix} \varepsilon_x \\ \varepsilon_y \\ \gamma_{xy} \end{vmatrix} \tag{18}$$

where $[\overline{Q}_{ij}]$ is the transformed reduced stiffness. The transformed reduced stiffness matrix is

$$[\overline{Q}_{ij}] = \begin{vmatrix} \overline{Q}_{11} & \overline{Q}_{12} & \overline{Q}_{16} \\ \overline{Q}_{21} & \overline{Q}_{22} & \overline{Q}_{26} \\ \overline{Q}_{16} & \overline{Q}_{26} & \overline{Q}_{66} \end{vmatrix} \tag{19}$$

where

$$\overline{Q}_{11} = Q_{11}\cos^4 \Phi + Q_{22}\operatorname{sen}^4 \Phi + 2(Q_{12} + 2Q_{66})\operatorname{sen}^2 \Phi \cos^2 \Phi$$

$$\overline{Q}_{22} = Q_{11}\operatorname{sen}^4 \Phi + Q_{22}\cos^4 \Phi + 2(Q_{12} + 2Q_{66})\operatorname{sen}^2 \Phi \cos^2 \Phi$$

$$\overline{Q}_{12} = (Q_{11} + Q_{22} - 4Q_{66})\operatorname{sen}^2 \Phi \cos^2 \Phi + Q_{12}(\cos^4 + \operatorname{sen}^4 \Phi)$$

$$\overline{Q}_{66} = (Q_{11} + Q_{22} - 2Q_{12} - 2Q_{66})\operatorname{sen}^2 \Phi \cos^2 \theta$$
$$\qquad + Q_{66}(\cos^4 \Phi + \operatorname{sen}^4 \Phi)$$

$$\overline{Q}_{16} = (Q_{11} - Q_{12} - 2Q_{66})\cos^3 \Phi \operatorname{sen} \Phi$$
$$\qquad - (Q_{22} - Q_{12} - 2Q_{66})\cos \Phi \operatorname{sen}^3 \Phi$$

$$\overline{Q}_{26} = (Q_{11} - Q_{12} - 2Q_{66})\cos \Phi \operatorname{sen}^3 \Phi$$
$$\qquad - (Q_{22} - Q_{12} - 2Q_{66})\cos^3 \Phi \operatorname{sen} \Phi \tag{20}$$

The transformation matrix $[T^{-1}]$ and the transformed reduced stiffness matrix $[\overline{Q}_{ij}]$ are very important matrices in the macromechanical analysis of both laminae and laminates. These matrices play a key role in determining the effective in-plane and bending properties and how a laminate will perform when subjected to different combinations of forces and moments.

Macromechanics of a Laminate

The stiffness matrices of the laminate can be calculated through the following equations, where the $\overline{Q}_{ij}$ coefficients of the laminae have been defined before.

$$\left|A_{ij}\right| = \sum_{k=1}^{n}\left(\overline{Q}_{ij}\right)(h_k - h_{k-1})$$

$$\left|B_{ij}\right| = \frac{1}{2}\sum_{k=1}^{n}\left(\overline{Q}_{ij}\right)(h_k^2 - h_{k-1}^2)$$

$$\left|D_{ij}\right| = \frac{1}{3}\sum_{k=1}^{n}\left(\overline{Q}_{ij}\right)(h_k^3 - h_{k-1}^3) \tag{21}$$

The matrix [A] is called the *extensional stiffness matrix* because it relates the resultant forces to the midplaine strains, while matrix [D] is called the *bending stiffness matrix* because it relates the resultant moments to the laminate curvature. The so called *coupling stiffness matrix*, [B], accounts for coupling between bending and extension, which means that normal and shear forces acting at the laminate midplane are causing laminate curvature or that bending and twisting moments are accompanied by midplane strain.

The letter k denotes the number of laminae in the laminate with a maximum number (N). The letter h represents the distances from the neutral axis to the edges (k and k-1) of the respective laminae. A standard procedure for numbering laminae is used where the 0 lamina is at the bottom of a plate and the Kth lamina is at the top.

It is possible to demonstrate that the deformation in each point of the laminate at a distance z from the midplane can be correlated to the deformation, ε, and the curvature, k, of the midplane.

The integration of eq. 18 to the thickness of the laminate results in the calculation of the components of the forces and of the momentum per unit of width acting on the laminate:

$$\begin{vmatrix} N_x \\ N_y \\ N_{xy} \end{vmatrix} = \begin{vmatrix} A \end{vmatrix}\begin{vmatrix} \varepsilon_x \\ \varepsilon_y \\ \gamma_{xy} \end{vmatrix} + \begin{vmatrix} B \end{vmatrix}\begin{vmatrix} k_x \\ k_y \\ k_{xy} \end{vmatrix} \tag{22}$$

$$\begin{vmatrix} M_x \\ M_y \\ M_{xy} \end{vmatrix} = \begin{vmatrix} B \end{vmatrix}\begin{vmatrix} \varepsilon_x \\ \varepsilon_y \\ \gamma_{xy} \end{vmatrix} + \begin{vmatrix} D \end{vmatrix}\begin{vmatrix} k_x \\ k_y \\ k_{xy} \end{vmatrix} \tag{23}$$

As told, the above equations, which hold for generic laminates, couple extensional forces with curvatures and momentum with warping. In other words, if extensional forces and momentum are applied to a generic laminate, it bends and warps.

The coupling between bending and extension can be eliminated if the coefficient of the B_{ij} matrix are equal to zero, that means if the laminate is fabricated symmetric with respect to its midplane.

$$\begin{vmatrix} N_x \\ N_y \\ N_{xy} \end{vmatrix} = \begin{vmatrix} A \end{vmatrix}\begin{vmatrix} \varepsilon_x \\ \varepsilon_y \\ \gamma_{xy} \end{vmatrix} \tag{24}$$

In a generic laminate, normal stresses N_x and/or N_y (or thermal stresses or liquid sorption) will cause deformations in the directions x and/or y, but also shear strains, unless A16 and A26 of the extensional stiffness matrix are equal to 0. These coefficient become 0 if the laminate is balanced, i.e. has the same number of laminae oriented at Φ and -Φ. Once the laminate strains are determined, the stresses in the *xy* direction for each lamina can be calculated. The most useful information gained from the *ABD* matrices involves the determination of generalized in-plane and bending properties of the laminate.

The equivalent elastic constants (E_x, E_y, G_{xy}, v_{xy}) of a symmetric and balanced laminate can be easily evaluated from the A_{ij} coefficients (Barbero, 1998)

$$E_x = \frac{1}{h}\frac{A_{11}A_{22} - A_{12}^2}{A_{22}} \tag{25}$$

$$E_y = \frac{1}{h}\frac{A_{11}A_{22} - A_{12}^2}{A_{11}} \tag{26}$$

$$G_{xy} = \frac{1}{h}A_{66} \tag{27}$$

$$v_{xy} = \frac{A_{12}}{A_{22}} \tag{28}$$

SHORT-FIBER COMPOSITES

A distinguishing feature of the unidirectional laminated composites discussed above is that they have higher strength and modulus in the fiber direction, and thus their properties are amenable to alteration to produce specialized laminates. However, in some applications,

unidirectional multiple-ply laminates may not be required. It may be advantageous to have isotropic lamina. An effective way of producing an isotropic lamina is to use randomly oriented short fibers as the reinforcement. Of course, molding compounds consisting of short fibers that can be easily molded by injection or compression molding may be used to produce generally isotropic composites. The theory of stress transfer between fibers and matrix in short-fiber composites goes beyond this text; it is covered in detail by Agarwal and Broutman (1980). However, from the theory, the longitudinal and transverse moduli (E_L and E_T, respectively) for an aligned shortfiber lamina can be found from

$$\frac{E_L}{E_m} = \frac{1 + (2l/d)\eta V_f}{1 - \eta_L V_f} \tag{29}$$

$$\frac{E_T}{E_m} = \frac{1 + 2\eta_T V_f}{1 - \eta_T V_f} \tag{30}$$

$$\eta_L = \frac{E_f/E_m - 1}{E_f/E_m + 2(l/d)} \qquad \eta_r = \frac{E_f/E_m - 1}{E_f/E_m + 2} \tag{31}$$

The problem of predicting properties of *randomly oriented* short-fiber composites is more complex. The following empirical equation can be used to predict the modulus of composites containing fibers that are randomly oriented in a plane:

$$E_{random} = \frac{3}{8}E_L + \frac{5}{8}E_T \tag{32}$$

where E_L and E_T are respectively the longitudinal and transverse moduli of an aligned short-fiber composite having the same fiber aspect ratio and fiber volume fraction as the composite under consideration. Moduli E_L and E_T can either be determined experimentally or calculated using Eqs. 34 and 35.

PARTICULATE COMPOSITES

The reinforcing effect of particles on polymers was first recognized for rubbery matrices while studying the effect of carbon black on the properties of natural rubber.

Several models have been introduced to predict the effect of the addition of particles to a polymeric matrix, starting from the equation developed by Einstein in 1956 to predict the viscosity of suspensions of rigid spherical inclusions. The paper by Ahmed and Jones, 1990, well reviews theories developed to predict strength and modulus of particulate composites.

One of the most versatile equations predicting the shear modulus of composites of polymers and spherical fillers is due to Kerner, 1956:

$$G_c = G_m \left(1 + \frac{V_f 15(1+v_m)}{V_m(8-10v_m)} \right) \tag{33}$$

Nielsen developed a more generalized form,

$$M = M_m \frac{1 + ABV_f}{1 - B\delta V_f} \tag{34}$$

where the function $B\delta$ depends on the particle packing fraction and M is the shear, elastic or bulk modulus.

By using a finite element analysis method Guild and Bonfield, 1993, predicted the elastic modulus of hydroxyapatitepolyethylene reinforced composites for various filler content. Their result, indicated a good agreement between theoretical and experimental data, except at higher hydroxyapatite volume fraction.

While elastic modulus of a particulate composites increases with the filler content, strength decreases in tension and increases in compression. Size and shape of the inclusion play an important role, with a higher stress concentration cause by non-regularly shaped inclusions. For spherical particles, the tensile strength σ_{cu} of the particulate composite can be correlated to the one of the matrix, σ_{mu}, through the equation (Nicolais and Narkis, 1971):

$$\sigma_{cu} = \sigma_{mu}(1 - 1.21 V_f^{2/3}) \tag{35}$$

GLOSSARY OF TERMS

Bis-GMA: Bis-glycidyl dimethacrylate
CF: carbon fibers
CP: calcium phosphate
DMTMC: dimethyl-trimethylene carbonate
GF: glass fibers
HA: hydroxyapatite
KF: Kevlar fibers
PA12: polyamide 12
PBT: poly(butylene terephthalate)
PCL: polycaprolactone
PDLA: poly(D-lactic acid)
PDLLA: poly(D,L-lactic acid)
P(DLLA-CL): poly(D,L-lactide/-caprolactone)
PE: polyethylene
PEEK: poly(ether-ether-ketone)
PEG: poly(ethyleneglycol)
PEI: poly(ether-imide)
PELA: poly(ethylene oxide)-b-poly(lactic acid) block copolymer
PET: poly(ethylene terephthalate)
PGA: poly(glycolic acid)
PLA: poly(lactic acid)
PLGA: poly(lactic-co-glycolic acid)
PLLA: poly(L-lactic acid)
PMMA: poly(methylmethacrylate)
POSS: Polyhedral Oligometric Silsequioxane
PP: polypropylene
PSU: polysulfone
PTFE: polytetrafluoroethylene
PU: polyurethane
TCP: tricalciumphosphate
TEGDMA: Tetraethyleneglycol Dimethacrylate
UHMWPE: ultra-high molecular weight polyethylene

[2]Professor of Bioengineering and Chemical Engineering, UWEB Investigator, University of Washington, Seattle, WA, USA

INTRODUCTION

"Non-fouling" surfaces (NFSs) refer to surfaces that resist the adsorption of proteins and/or adhesion of cells. They are also loosely referred to as protein-resistant surfaces and "stealth" surfaces. It is generally acknowledged that surfaces that strongly adsorb proteins will generally bind cells, and that surfaces that resist protein adsorption will also resist cell adhesion. It is also generally recognized that hydrogel surfaces are more likely to resist protein adsorption, and that hydrophobic surfaces will usually adsorb a monolayer of tightly adsorbed protein. Exceptions to these generalizations exist but, overall, they are accurate statements. Further details on protein adsorption can be found in Chapter II.1.2.

Given that proteins have a strong tendency to adsorb to almost all surfaces, how might NFSs work to inhibit such adsorption? Although there are many potential mechanisms for action, most non-fouling surfaces seem to have strong interactions with water. This water–polymer interaction highly hydrates and expands surface hydrophilic polymer chains. Also, the NFSs bind water tightly, and this water shield separates the proteins from the material of the surface. These mechanisms will be elaborated on below.

An important area for NFSs focuses on bacterial biofilms (see Chapter II.2.8). Bacteria are believed to adhere to surfaces via a "conditioning film" of organic molecules that adsorbs first to the surface. The bacteria stick to this conditioning film and begin to exude a gelatinous slime layer (the biofilm) that aids in their protection from external agents (for example, antibiotics). Such layers are particularly troublesome in devices such as urinary catheters and endotracheal tubes. However, they also form on vascular grafts, hip joint prostheses, heart valves, and other long-term implants, where they can stimulate significant inflammatory reaction to the infected device. If the conditioning film can be inhibited, bacterial adhesion and biofilm formation can also be reduced. NFSs offer this possibility.

> Non-fouling surfaces are important in medical devices where they may inhibit bacterial colonization and blood cell adhesion. They are also valuable for microfluidic devices, surface-based diagnostic assays, preventing marine organism build-up on ships, and reducing biofilm formation on heat exchangers.

NFSs have medical and biotechnology uses as blood-compatible materials (where they may resist fibrinogen adsorption and platelet attachment), implanted devices (where they reduce the foreign-body reaction; simplify device removal), urinary catheters, biosensors, affinity separation processes, microchannel flow devices, intravenous syringes and tubing, and non-medical uses as biofouling-resistant heat exchangers and ship hulls. It is important to note that many of these applications involve *in vivo* implants or extra-corporeal devices, and others involve *in vitro* diagnostic assays, sensors, and affinity separation processes. As well as having considerable medical and economic importance, they offer significant experimental and theoretical insights into an important phenomenon in biomaterials science: protein adsorption. Hence, NFSs have been the subject of many investigations. Aspects of non-fouling surfaces are addressed in many other chapters of this textbook, including the chapters on water at interfaces (Chapter I.1.6), surface modification (Chapter I.2.12), and protein adsorption (Chapter II.1.2).

The significant portion of the literature on non-fouling surfaces focuses on surfaces containing the relatively simple polymer, poly(ethylene glycol) or PEG:

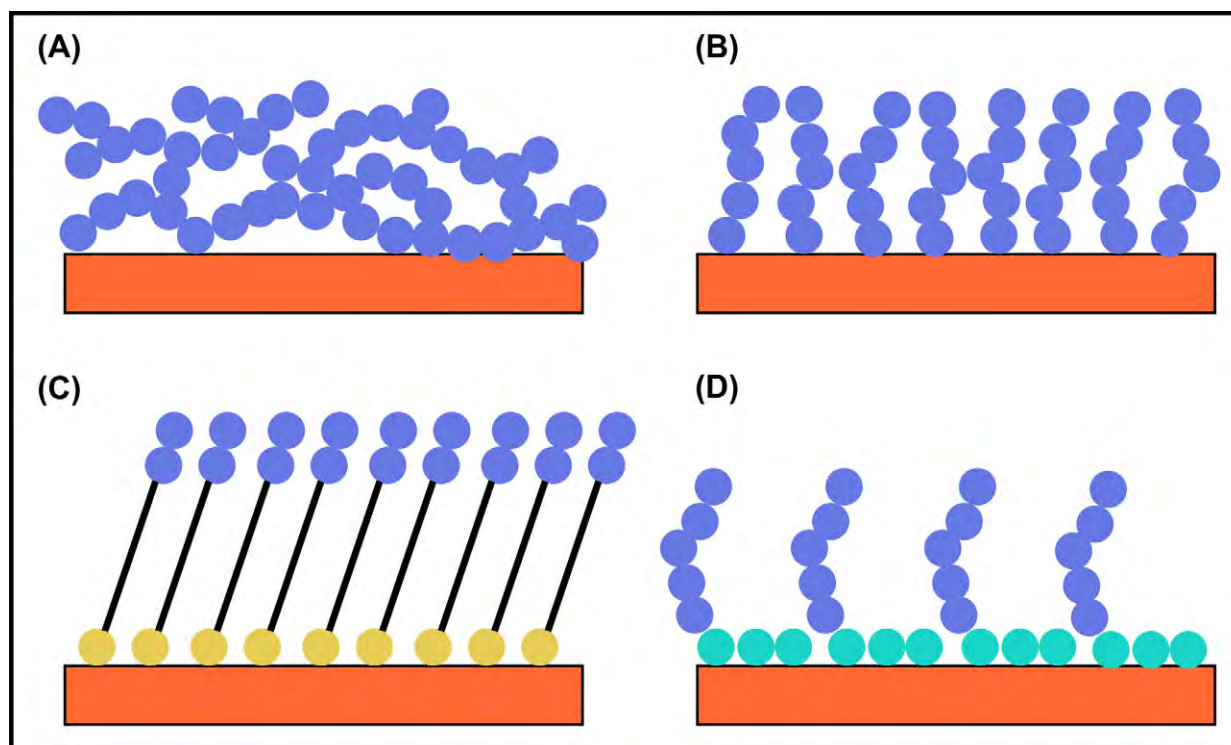
$$HO(-CH_2CH_2O-)_n\ H$$
When n is in the range of 15–3500 (molecular weights of approximately 400–100,000), the PEG designation is used. Where molecular weights are greater than 100,000, the molecule is commonly referred to as poly(ethylene oxide) (PEO). Where n is in the range of 2–15, the term oligo(ethylene glycol) (OEG) is often used. Other natural and synthetic polymers besides PEG show non-fouling behavior, and they will also be discussed in this chapter. Figure I.2.10.1 schematically illustrates types of surfaces that show non-fouling properties.


FIGURE I.2.10.1 Four surfaces that can show non-fouling behavior. The blue dot represents a non-fouling chemical moiety such as $(CH_2CH_2O)_n$. (A) Cross-linked network of long, polymeric chains; (B) polymer brush grown off the surface; (C) oligo-non-fouling headgroups on a self-assembled monolayer (the yellow dot is the anchor group such as a thiol); (D) surfactant adsorbed to the surface. The hydrophobic tails are represented by turquoise dots.

BACKGROUND

The published literature on protein and cell interactions with biomaterial surfaces has grown significantly in the past 40 years, and the following concepts have emerged:

- It is well-established that hydrophobic surfaces have a strong tendency to adsorb proteins, often irreversibly (Hoffman, 1986; Horbett and Brash, 1987, 1995). The driving force for this action is most likely the unfolding of the protein on the surface, accompanied by release of many bound water molecules from the solid surface at the interface (see Chapter I.1.6), leading to a large entropy gain for the system (Hoffman, 1999). Note that adsorbed proteins can be displaced (or "exchanged") from the surface by solution phase proteins (Brash et al., 1974).

- It is also well-known that, at low ionic strengths, cationic proteins bind to anionic surfaces and anionic proteins bind to cationic surfaces (Horbett and Hoffman, 1975; Bohnert et al., 1988; Hoffman, 1999). The major thermodynamic driving force for these actions is a combination of ion–ion coulombic interactions, accompanied by an entropy gain due to the release of counter-ions along with their waters of hydration. However, these interactions are diminished at physiologic conditions by shielding of the protein ionic groups at 0.15 N ionic strength (Horbett and Hoffman, 1975). Still, lysozyme, a highly charged

cationic protein at physiologic pH, strongly binds to hydrogel contact lenses containing anionic monomers (see Bohnert et al., 1988, and Chapter II.5.9A).

- It has been a common observation that proteins tend to adsorb in monolayers, i.e., proteins do not adsorb non-specifically onto their own monolayers (Horbett, 1993). This is probably due to retention of hydration water by the adsorbed protein molecules, preventing close interactions of the protein molecules in solution with the adsorbed protein molecules. In fact, adsorbed protein films are, in themselves, reasonable non-fouling surfaces with regard to other proteins (but not necessarily to cells).

- Early studies were carried out on surfaces coated with physically- or chemically-immobilized PEG, and a conclusion was reached that a minimum PEG molecular weight (MW) was needed in order to provide good protein repulsion (Mori et al., 1983; Gombotz et al., 1991; Merrill, 1992). This seemed to be the case whether PEG was chemically bound: (1) as a side-chain of a polymer that was grafted to the surface (Mori et al., 1983); (2) by one end to the surface (Gombotz et al., 1991; Merrill, 1992); or was incorporated (3) as segments in a cross-linked network (Merrill, 1992). The minimum MW to achieve an NFS with these low molecular weight polymeric PEGs was found to be ca. 500–2000, depending on packing density (Mori et al., 1983; Gombotz et al., 1991; Merrill, 1992).

- The mechanism of protein resistance by the polymeric PEG surfaces may be due to a combination of factors, including the resistance of the polymer coil to compression due to its desire to retain the more expanded volume of a random coil (called "entropic repulsion" or "elastic network" resistance) plus the resistance of the PEG molecule to release both bound and free water from within the hydrated coil (called "osmotic repulsion") (Gombotz et al., 1991; Antonsen and Hoffman, 1992; Heuberger et al., 2005). It is interesting, as noted above, that the non-fouling character of PEG surfaces begins when the MWs of PEG reach around 500–2000. As that size is reached, Gombotz et al. postulated that the chain segments will begin to form random coils, which could retain water more efficiently between the chain segments. The retention of water by shorter chains would not be as efficient as by the higher MW coils, especially at relatively low surface OEG/PEG densities. The size of the adsorbing protein and its resistance to unfolding may also be important factors determining the extent of adsorption on any surface (Lim and Herron, 1992).

The thermodynamic principles governing the adsorption of proteins onto surfaces involve a number of enthalpic and entropic terms favoring or resisting adsorption. These terms are summarized in Table I.2.10.1. The major factors favoring adsorption will be the entropic gain of released water and the enthalpy loss due to cation–anion attractive interactions between ionic protein groups and surface groups. The major factors favoring resistance to protein adsorption will be the retention of bound water plus, in the case of an immobilized hydrophilic polymer, entropic and osmotic repulsion of the polymer coils.

Although evidence was discussed above for a PEG molecular weight effect, excellent protein resistance can be achieved with very short chain PEGs (OEGs) and PEG-like surfaces (Lopez et al., 1992; Prime and Whitesides, 1993; Sheu et al., 1993). When these surfaces with only short OEG units have sufficiently high (CH_2CH_2O) unit molar densities, they exhibit excellent non-fouling behavior under conditions of low protein concentration. For example, Prime and Whitesides (1993) have noted that non-fouling behavior begins when around 50–60% of the surface groups in their self-assembled monolayer (SAM) are conjugated with OEGs having six EG units. This may be due to formation of a "contiguous" surface film of bound water that is extensive in area and a nanometer or so thick. Another way to view this phenomenon is that, if the OEG units are spaced isotropically on the surface, the remaining "bare" or exposed surface areas on average are less than the diameter of a typical globular protein. (Note: At higher protein solution concentrations, these oligo surfaces foul with adsorbed protein. This solution concentration effect will be discussed shortly.)

Observations on self-assembled monolayers (SAMs) of lipid-oligoEG molecules have been particularly important in the understanding of NFSs (SAMs are described in Chapter I.2.12). SAMs prepared to explore NFSs were formed on gold with a set of molecules based on this alkyl thiol structure: $HS(CH_2)_{11}(OCH_2CH_2)_nOH$. The oligo(ethylene glycol) chain length, n, was 0, 1, 2, 4, 6 or 17. OEGs with larger n (more EG units) were more protein-resistant. The surface concentration of these OEG-thiol units needed to achieve non-fouling behavior decreased with increasing n (Prime and Whitesides, 1993). Note that when $n = 17$, the OEG chain has a molecular weight over 700. Thus, the excellent non-fouling behavior of this surface can be attributed to both chain entropy arguments, and the ability of EG units to interact with water. Thus, protein resistance by OEG-coated surfaces may be related to a "cooperativity" between the hydrated, short OEG chains in the "plane of the surface," wherein the OEG chains interact together to bind water to the surface in a manner analogous to the hydrated coil and its osmotic repulsion, as described above. It was observed that a minimum of three EG units are needed for highly effective protein repulsion (Harder et al., 1998), although Prime and Whitesides (1993) demonstrated that good protein resistance could be achieved with $n = 2$, if the surface density was high enough. Based on all of these observations, one may describe the mechanism as being related to the conformation of the individual oligoEG chains, along with their packing density in the SAM. It has been proposed that helical or amorphous OEG conformations lead to stronger water–OEG interactions than an all-trans OEG conformation (Harder et al., 1998).

Packing density of the non-fouling groups on the surface is clearly an important factor in preparing non-fouling surfaces. Nevertheless, one may conclude that the one common factor connecting all NFSs is their resistance to release of bound water molecules from

TABLE I.2.10.1	Thermodynamics of Protein Adsorption
Favoring Adsorption	
ΔH_{ads}	- van der Waals interactions (short range)

	- protein hydrophobic exposure
	- chain compression (PEO)
	- osmotic repulsion (PEO)
FIGURE I.2.10.2 A surface plasmon resonance (SPR) study of protein adsorption to plasma-deposited triglyme and tetraglyme surfaces. The SPR response (y axis) is proportional to protein concentration. At minute 7, bovine serum albumin (BSA) solution (1 mg/mL) is introduced into the buffer flow over the surfaces being examined. A gold surface adsorbs significant levels of BSA. Both the triglyme and the tetraglyme surfaces show much lower SPR responses. At 17 minutes, the protein flow is switched to a buffer flow. No protein desorbs from the gold. Essentially all the protein on the triglyme and tetraglyme surfaces desorbs, bringing the SPR signal for those surfaces back to baseline. This experiment is described in Mar et al., 1999.

the surface. This argument is supported by neutron reflectivity measurements by Skoda et al. (2009), where they found a depletion of protein concentration around 4–5 nm above an OEG surface that might be attributable to a tightly-bound water layer interfering with the protein approach to the actual surface. Also, direct measurements by D_2O exchange and sum frequency generation (SFG, see Chapter I.1.5) of water organization at the interface of non-fouling and fouling SAMs demonstrate that NFSs lead to a more bound, organized water (Stein et al., 2009). Interfacial water may be reorganized both by hydrophobic groups and by hydrophilic (primarily via hydrogen bonds) interactions. In the latter case, the water may be H-bonded to neutral polar groups, such as hydroxyl (-OH) or ether (-C-O-C-) groups, or it may be polarized by ionic groups, such as $-COO^-$ or $-NH_3^+$. The more profound molecular reorganizations of water seen in NFSs are associated with certain hydrophilic surfaces. The overall conclusion from all of the above observations is that resistance to protein adsorption at biomaterial interfaces is directly related to retention by interfacial groups of their bound waters of hydration.

> Resistance to protein adsorption at biomaterial interfaces is directly related to resistance of interfacial groups to the release of their bound waters of hydration.

Based on these conclusions, it is obvious why the most common approaches to reducing protein and cell binding to biomaterial surfaces have been to form surfaces that strongly interact with water. This has been accomplished by a variety of strategies:

- Chemical immobilization of a hydrophilic polymer (e.g., PEG or OEG) on the biomaterial surface using: (1) UV or ionizing radiation to graft copolymerize a hydrophilic monomer onto surface groups; (2) deposition of such a polymer from the vapor of a precursor monomer in a gas discharge process; (3) covalent immobilization of a pre-formed hydrophilic polymer or surfactant to the surface using radiation, gas discharge or wet-chemical coupling processes; or (4) growth of a non-fouling polymer brush off the surface by controlled radical polymerization methods.

Examples of some of these strategies follow.

- Gas discharge has been used to covalently bind non-fouling surfactants such as Pluronic® polyols to polymer surfaces (Sheu et al., 1993), and it has also been used to deposit an "oligoEG-like" coating from vapors of triglyme or tetraglyme (Lopez et al., 1992; Mar et al., 1999) (Figure I.2.10.2). Highly fouling-resistant brushes of PEG chains have been grown from surfaces using atom transfer radical polymerization (ATRP) methods (Ma et al., 2004).
- Chemical derivitization of surface groups with neutral groups, such as hydroxyls, or with negatively-charged groups (especially since most proteins and cells are negatively charged) such as carboxylic acids or their salts, or sulfonates.
- Physical adsorption of surfactants or other surface-active molecules that are coupled to non-fouling moieties. Examples include: adsorption of poly(ethylene

gycol-propylene glycol) block copolymers (Lee et al., 1989); surface attachment of biomimetic analogs of muscle adhesive peptides coupled to PEG chains (Dalsin et al., 2003); and immobilization of PEG brushes to metal oxides through interaction with a positively charged polylysine backbone (Kenausis et al., 2000).

- Hydrophilic polymers containing zwitterionic groups along their backbones have been extensively studied for their non-fouling properties. Examples include: poly[2-(methacryloyloxy)ethyl phosphorylcholine] (Ishihara et al., 1998; Iwasaki et al., 1999; Ishihara and Takai, 2009); sulfbetaines (Stein et al., 2009); and carboxybetaines (Zhang et al., 2008).

- Coatings of many hydrogels, including poly(2-hydroxyethyl methacrylate) and polyacrylamide, show reasonable non-fouling behavior (Lopez et al., 1993).

A number of naturally-occurring biomolecules such as albumin, casein, hyaluronic acid, and mucin have been coated on surfaces and exhibited resistance to non-specific adsorption of proteins (Vogt et al., 1987; Van Beek et al., 2008). Albumin and non-fat milk solids (mainly containing casein) are often used as "blocking" agents to prevent non-specific protein adsorption in ELISA assays. Naturally-occurring ganglioside lipid surfactants having saccharide head groups have been used to make "stealth" liposomes (Lasic and Needham, 1995). One paper even suggested that the protein resistance of PEGylated surfaces is related to the "partitioning" of albumin into the PEG layers, causing those surfaces to "look like native albumin" (Vert and Domurado, 2000).

SAMs presenting an interesting series of head group molecules that can act as H-bond acceptors, but not as H-bond donors, have been shown to yield surfaces with unexpected protein resistance (Chapman et al., 2000; Ostuni et al., 2001; Kane et al., 2003). Interestingly, PEG fits in this category of H-bond acceptors but not donors; Merrill first noted this in 1983 (Merrill and Salzman, 1983). However, this generalization does not explain all non-fouling surfaces; consider that mannitol groups with H-bond donor -OH groups were found to be non-fouling (Luk et al., 2000). Also, adsorbed protein films are non-fouling, and these have H-bond donor and acceptor groups. Another hypothesis proposes that the functional groups that impart a non-fouling property are kosmotropes, order-inducing molecules (Kane et al., 2003). Perhaps because of the ordered water surrounding these molecules, they cannot penetrate the ordered water shell surrounding proteins, therefore strong intermolecular interactions between surface group and protein cannot occur. An interesting kosmotrope molecule with good non-fouling ability described in this paper is taurine $H_3N^+(CH_2)2SO^3$. Table I.2.10.2 summarizes some of the different compositions that have been applied as non-fouling surfaces.

It is worthwhile mentioning computational papers (supported by some experiments) that offer new insights

TABLE I.2.10.2	"Non-Fouling" Surface Compositions

Synthetic Hydrophilic Surfaces
- PEG polymers and surfactants
- Neutral polymers
  poly(2-hydroxyethyl methacrylate)
  polyacrylamide and poly(N-methyl acrylamide)
  poly(N-vinyl 2-pyrrolidone)
  poly(N-isopropyl acrylamide) (below 31°C)
- Anionic polymers
- Phosphoryl choline polymers
- Sulfobetaines, carboxybetaines, taurine-functionalized materials
- Poly(2-methyl-2-oxazoline)
- Gas discharge-deposited coatings (especially from PEG-like monomers)
- Self-assembled n-alkyl molecules with oligo-PEG headgroups

Natural Hydrophilic Surfaces
- Passivating proteins (e.g., albumin and casein)
- Polysaccharides (e.g., hyaluronic acid)
- Liposaccharides
- Phospholipid bilayers
- Glycoproteins (e.g., mucin)

Other Molecules (see Ostuni et al., 2001).

and ideas on NFSs (Lim and Herron, 1992; Pertsin and Grunze, 2000; Pertsin et al., 2002; Xu et al., 2011). Also, many new experimental methods have been applied to study the mechanism of non-fouling surfaces, including neutron reflectivity to measure the water density in the interfacial region (Schwendel et al., 2003; Skoda et al., 2009), scanning force microscopy (Feldman et al., 1999; Heuberger et al., 2005), and sum frequency generation (Zolk et al., 2000; Stein et al., 2009).

The significance of protein solution concentration for surface protein resistance requires further discussion. In relatively dilute protein solutions, such as are used in diagnostic assays and sometimes in cell culture, all of the surfaces described so far will demonstrate non-fouling behavior. However, at protein concentrations similar to that in the bloodstream or in body fluids, many of these surfaces no longer appear non-fouling. The surfaces that exhibit non-fouling behavior at higher protein concentration are comprised of longer hydrophilic chains with high conformational freedom (Ma et al., 2004; Zhang et al., 2008). Surfaces comprised of short oligo units of non-fouling chemistries (Figure I.2.10.1C or the glyme surfaces described in Figure I.2.10.2) probably function by tightly binding water. It may be that at high solution protein content, the protein molecules compete for the bound surface water, and the non-fouling effect vanishes. On the other hand, when longer, flexible chains are present, the entropic repulsion effect described earlier permits these surfaces to remain free of adsorbed protein, as long as the hydrophilic polymer surface density is high enough.

Finally, it should be noted that bacteria tend to adhere and colonize almost any type of surface, perhaps even

many protein-resistant NFSs. However, the best NFSs can provide acute resistance to bacteria and biofilm build-up better than most surfaces (Johnston et al., 1997). Resistance to bacterial adhesion remains an unsolved problem in surface science. Also, it has been pointed out that susceptibility of PEGs to oxidative damage may reduce their utility as non-fouling surfaces in real-world situations (Kane et al., 2003).

CONCLUSIONS AND PERSPECTIVES

It is remarkable how many different surface compositions appear to be non-fouling (although the majority of surfaces used in medicine and biology adsorb protein). Although the unifying mechanisms are not fully clarified, it appears that the major factor favoring resistance to protein adsorption will be the retention of bound water by the surface molecules, plus, in the case of an immobilized hydrophilic polymer, entropic and osmotic repulsion of the polymer coils. Little is known about how long a nonfouling surface will remain non-fouling *in vivo*. Longevity and stability for non-fouling biomaterials remains an uncharted frontier. Defects (e.g., pits, uncoated areas) in NFSs may provide "footholds" for bacteria and cells to begin colonization. Enhanced understanding of how to optimize the surface density and composition of NFSs will lead to improvements in quality and fewer micro-defects. Finally, it is important to note that a clean, "non-fouled" surface may not always be desirable. In the case of cardiovascular implants or devices, emboli may be shed when such a surface is exposed to flowing blood (Hoffman et al., 1982). This can lead to undesirable consequences, even though (or perhaps especially because) the surface is an effective, non-fouling surface. In the case of contact lenses, a protein-free lens may seem desirable, but there are concerns that such a lens will not be comfortable (mucin adsorption, for example, may contribute to comfort). Although biomaterials scientists can presently create surfaces that are non-fouling for a period of time, applying such surfaces must take into account the specific application, the biological environment, and the intended service life.

CHAPTER I.2.11 APPLICATIONS OF "SMART POLYMERS" AS BIOMATERIALS

Allan S. Hoffman
Professor of Bioengineering and Chemical Engineering, UWEB
Investigator, University of Washington, Seattle, WA, USA

INTRODUCTION

Stimulus-responsive, "intelligent" polymers are polymers that respond to small changes in physical or chemical conditions near a critical condition with sharp and relatively large phase or property changes. They are also known as "smart," stimuli-responsive or "environmentally-sensitive"

polymers. These polymers can take many forms; for example, they may be dissolved in aqueous solutions, adsorbed or grafted on aqueous–solid interfaces, or cross-linked in the form of hydrogels. They may also be combined chemically or physically with other molecules, especially a variety of bioactive molecules. A number of reviews over the past 20–25 years have highlighted applications of smart polymers in the biomedical field (Hoffman, 1987, 1995, 1997; Hoffman et al., 2000; Okano et al., 2000; Roy and Gupta, 2003; Roy et al., 2010).

Many different stimuli-responsive polymers have been investigated, and the various stimuli that researchers have used are listed in Table I.2.11.1. Typically, when the polymer's smart response is stimulated, the resultant behavior will depend on the initial state of the polymer

(Figure I.2.11.1). Three examples of this are described below:

- When a smart polymer is dissolved in an aqueous solution, it will exhibit a sudden onset of turbidity as it phase separates, and if its concentration is high enough it may convert from a viscous solution to a gel.
- When a smart polymer is chemically grafted to an aqueous–solid interface and is stimulated to phase separate, it will collapse, converting that interface

Note that all systems are reversible when the stimulus is reversed. (Hoffman et al., (2000) *Journal of Biomedical Materials Research* (JBMR): Reproduced with permission of *JBMR*, J. Wiley, Publisher.)

from a hydrophilic to a hydrophobic interface. If the smart polymer is dissolved in solution and is stimulated to phase separate in the presence of a solid–aqueous interface, it may physically adsorb at the interface, especially when the surface composition has a balance of hydrophobic and polar groups similar to the phase-separating smart polymer.
- A smart polymer may be chemically cross-linked into a network. When it is swollen in an aqueous solution below its critical condition, it may be called a "smart hydrogel." When the polymer network chains are stimulated to phase separate at their critical condition, the hydrogel will collapse and release much of its swelling solution as a burst.

These phenomena all reverse when the stimulus is reversed. The phase separation of a water-solvated smart polymer chain is driven by the release of the hydrophobically bound water molecules on the polymer backbone, which creates a large gain in entropy in the system. Often the rate of reversion back to the hydrated state is slower than the collapse, because in the reverse process the hydrophobic groups of the polymer have to be rehydrated, and that process is thermodynamically opposed by the resultant decline in entropy of the system (the reswelling process is favored by the exothermic hydration and expansion of the polymer chains). The rate of collapse of smart polymer systems and its reversal can also depend on the dimensions of the smart polymer system. Rates will be more rapid for systems with smaller dimensions, e.g., nanoscale versus microscale dimensions.

> The rate of collapse of smart polymer systems and its reversal can depend on the dimensions of the smart polymer system. Rates will be more rapid for systems with smaller dimensions, e.g., nanoscale versus microscale dimensions.

Smart polymers may be physically mixed with, complexed with, or chemically conjugated to biomolecules to yield a large and diverse family of polymer–biomolecule "biohybrid" systems that can respond to biological, as well as to physical and chemical, stimuli. Sometimes such biohybrids are called "doubly smart." Biomolecules that may be combined with smart polymer systems include proteins and peptides, sugars and polysaccharides, single and double-stranded oligonucleotides, RNA and DNA, simple lipids and phospholipids, and a wide spectrum of recognition ligands and synthetic drug molecules. In addition, polyethylene glycol (PEG) may be conjugated to the smart polymer backbone to provide it with "stealth" properties (Figure I.2.11.2 schematically shows many different molecules, one or several together, which may be conjugated to a single smart polymer chain). The reader is referred to recent reviews of the synthesis and applications of smart polymer-protein conjugates (e.g.,

Hoffman, et al., 2000; Heredia and Maynard, 2007; Hoffman and Stayton, 2010; Grover and Maynard, 2010; Broyer et al., 2011).

Among the most studied of these smart polymer–biomolecule systems are conjugates of the smart polymer with drugs, enzymes, and antibodies (see below). Such smart bioconjugates may be utilized as free conjugates in solution, or they may be physically adsorbed or chemically immobilized at solid interfaces. A free enzyme, antibody or drug may also be physically or chemically entrapped within smart hydrogels or smart polymer phase-separated masses (phase-separated polymer–drug masses *in vivo* are known as "depot" drug delivery systems). There have been a number of successful applications in both medicine and biotechnology for such smart polymer–biomolecule systems and, as such, they represent an important and exciting extension of polymeric biomaterials beyond their well-known uses in implants, medical devices, and drug delivery (see Chapter II.5.16 on Drug Delivery Systems for more details).

> Smart polymer–biomolecule conjugates in solution, on surfaces, and within hydrogels represent an important and exciting extension of polymeric biomaterials beyond their well-known uses in implants, medical devices, and drug delivery.

SMART POLYMERS IN SOLUTION

There are many polymers that exhibit thermally-induced precipitation out of aqueous solutions (Table I.2.11.2), and the polymer that has been the most extensively studied is poly(*N*-isopropyl acrylamide), or PNIPAAm. This polymer is soluble in water below 32°C, and it precipitates sharply as temperature is raised above 32°C (Heskins and Guillet, 1968; Schild, 1992). The precipitation temperature is called the lower critical solution temperature, or LCST. If the solution contains buffer and salts the LCST may be reduced several degrees. If NIPAAm monomer is copolymerized with more hydrophilic monomers, such as acrylamide, the LCST will increase and may even disappear. If NIPAAm monomer is copolymerized with more hydrophobic monomers, such as *n*-butyl-acrylamide, the LCST decreases (Figure I.2.11.3) (Priest et al., 1987). NIPAAm may also be copolymerized with pH-sensitive monomers, leading to random copolymers with both temperature- and pH-responsive behavior (Murthy, et al., 1999; Zareie et al., 2000; Murthy et al., 2003a,b; Yin, et al., 2006). Tirrell, and more recently, Stayton, Hoffman, and co-workers have studied the behavior of pH-sensitive alpha-alkylacrylic acid polymers

FIGURE I.2.11.2 Schematic illustration showing the variety of natural or synthetic biomolecules that may be conjugated to a smart polymer. In some cases, only one molecule may be conjugated, such as a recognition protein, which may be linked to the protein at a reactive terminal group of the polymer, or it may be linked at a reactive pendant group along the polymer backbone. In other cases more than one molecule may be conjugated along the polymer backbone, such as a targeting ligand along with many drug molecules. (Hoffman et al., (2000) *Journal of Biomedical Materials Research* (JBMR): Reproduced with permission of *JBMR*, J. Wiley, Publisher.)

Labels in figure:
- Biocompatible polymer backbone (may also be biodegradable or stimuli-responsive to pH, T, E)
- Biofunctional molecule (linked by biodegradable spacer arm) — B
- Ligand (for cell receptor, mucin, E.C.M. component, plasma protien, …)
- Signal group (for imaging) — X
- Liphophilic group (for insertion in cell membrane, liposome, micelle, nanoparticle)
- Plasmid vector (for insertion into cell nucleus)
- Non-fouling group (to repel IgGs)

Effect of copolymerization
on LCST of poly (NIPAAm)
FIGURE I.2.11.3 Copolymerization of a thermally sensitive polymer, PNIPAAm, with a more hydrophilic comonomer, AAm, raises the LCST of the copolymer, whereas copolymerization with a more hydrophobic comonomer, N-tBAAm, lowers the LCST. (Hoffman et al., (2000) *Journal of Biomedical Materials Research* (JBMR): Reproduced with permission of *JBMR*, J. Wiley, Publisher.)

in solution (Tirrell, 1987; Lackey et al., 1999; Murthy et al., 1999; Stayton et al., 2000; Murthy et al., 2003a,b; Yin et al., 2006; Stayton and Hoffman, 2008). As pH is lowered, these polymers become increasingly protonated and hydrophobic, and eventually phase separate; this transition can be sharp, resembling the phase transition at the LCST. If a polymer such as poly(ethylacrylic acid) (PEAA) or poly(propylacrylic acid) (PPAA) is in the vicinity of a lipid bilayer membrane as pH is lowered, the polymer will interact with the membrane and disrupt it. These polymers have been applied by Stayton and Hoffman and co-workers to stimulate endosomal escape of the drug (with or without its nanocarrier) to the cytosol. This action is a consequence of the drop in pH in the endosome, which causes PPAA to become hydrophobic and disrupt the endosomal membrane (e.g., Stayton and Hoffman, 2008; also see detailed discussion and referencing of this work in Chapter II.5.16 on Drug Delivery Systems). Bae and co-workers have also developed interesting temperature- and pH-sensitive polymers for endosomal release of drug formulations (e.g., Na et al., 2006; Kang and Bae, 2007).

NIPAAm has been copolymerized with pH-responsive macromonomers of acrylic acid (AAc), which yielded graft copolymers that independently exhibit two distinct stimuli responses, one for the backbone PNIPAAm and one for the side chain PAAc (Chen and Hoffman, 1995). Block copolymers of two such smart polymers also exhibit two distinct stimuli responses if the two individual blocks are each long enough.

A family of thermally gelling and biodegradable triblock copolymers has been developed by Sung Wan Kim and co-workers for injectable formulations that form degradable, drug depot masses at body conditions (Vernon et al., 2000; Lee et al., 2001; Jeong et al., 2002).

The formulation is a medium viscosity, injectable solution at room temperature, and a phase-separated hydrogel mass at 37°C. These polymers are based on blocks of hydrophobic, degradable polyesters combined with blocks of PEO. The copolymers are triblocks with varying MW segments of PLGA and PEO. Typical compositions are PEO–PLGA–PEO and PLGA–PEO–PLGA. They are discussed further in Chapter II.5.16 on Drug Delivery Systems.

Doo Sung Lee, You Han Bae, and co-workers have developed similar biocompatible and degradable A–B–A triblock copolymers having both pH and temperature sensitivity; they are based on two blocks of poly-(caprolactone-co-lactic acid) copolymers (PCLA), combined with a central PEG block. The pH sensitivity is derived from short blocks containing the sulfonamide group (OSM) that are attached at each end of the triblock. Typical formulae of the copolymers are PCLA–PEG–PCLA and, when modified with oligomers containing the sulfonamide group at each end, OSM–PCLA–PEG–PCLA–OSM (Shim et al., 2005, 2006).

SMART POLYMER–PROTEIN BIOCONJUGATES IN SOLUTION

Smart polymers may be conjugated randomly to proteins by binding the reactive end of the polymer or reactive pendant groups along the polymer backbone to reactive sites on the protein. One may utilize functionalized free radical initiator or chain transfer agents to synthesize oligomers with one functional end group, which can then be derivatized to form a reactive group that can be conjugated to the protein. For example, NIPAAm has been copolymerized with reactive monomers such as N-hydroxysuccinimide acrylate (NHS acrylate) to yield a random copolymer with pendant NHS groups, which have then been conjugated to the protein. (These synthesis methods are described in Cole et al., 1987; Monji and Hoffman, 1987; Chen et al., 1990; Chen and Hoffman, 1990; Yang et al., 1990; Takei et al., 1993a; Chen and Hoffman, 1994; Ding et al., 1996, 1998.) Vinyl monomer groups may also be conjugated to proteins to provide "comonomer" vinyl groups for copolymerization with free monomers such as NIPAAm (Shoemaker et al., 1987).

Normally the lysine amino groups are the most reactive protein sites for random polymer conjugation to proteins, and N-hydroxysuccinimide (NHS) attachment chemistry is often utilized. Other possible sites include –COOH groups of aspartic or glutamic acid residues, –OH groups of serine or tyrosine residues, –SH groups of cysteine residues, and terminal amino groups. The most likely attachment site will be determined by the reactive group on the polymer and the reaction conditions, especially the pH. Because these conjugations are generally carried out in a nonspecific way, the conjugated polymer can interfere sterically with the protein's active site or
FIGURE I.2.11.4 Various methods for synthesizing polymer–protein bioconjugates.

modify its microenvironment, typically reducing the bio-activity of the protein. Although PEG is not a smart polymer like PNIPAAm, in the special case of PEGylation of the new recombinant protein drugs, it is critical to attach the PEG molecule in a way so as to minimize such steric hindrance. In this situation, the pH may be lowered to favor conjugation of PEG–NHS to the terminal amino group, rather than to randomly located lysine amino groups. On rare occasions the conjugation of a polymer may increase the activity of the protein (e.g., Ding et al., 1998). Figure I.2.11.4 shows various ways that polymers may be directly conjugated to proteins or formed by growth from the protein (Hoffman and Stayton, 2010).

Random conjugation of temperature-sensitive (mainly) and pH-sensitive (occasionally) polymers to proteins has been extensively investigated, and applications of these conjugates have been focused on immunoassays, affinity separations, enzyme recovery, and drug delivery. One of the earliest applications of a smart polymer–biomolecule conjugate was an immunoassay developed by Hoffman, along with co-workers at a Seattle company called Genetic Systems Corp. They conjugated PNIPAAm to an antibody and used it to capture an antigen, then added a second, labeled antibody to the antigen, and warmed to phase separate the labeled immune complex sandwich. The assay was similar to an ELISA assay, but was much faster and was as accurate as ELISA. This concept was first presented by Hoffman at a PIMS meeting in 1986 (Hoffman et al., 1986), published in 1987 (Monji and Hoffman, 1987), and patented in 1988 (Monji et al.,

1988). Other interesting work on soluble–insoluble polymer–biomolecule conjugates can be found in the following references: Schneider et al., 1981; Okamura et al., 1984; Nguyen and Luong, 1989; Taniguchi et al., 1989; Chen and Hoffman, 1990; Monji et al., 1990; Pecs et al., 1991; Taniguchi et al., 1992; Takei et al., 1993b; Galaev and Mattiasson, 1993; Takei et al., 1994a; Fong et al., 1999; Anastase-Ravion et al., 2001.

In some cases the "smart" polymer may be a poly-ligand, such as polybiotin or poly(glycosyl methacrylate), which is used to phase separate target molecules by complexation to multiple binding sites on target proteins, such as streptavidin and Concanavalin A, respectively (Larsson and Mosbach, 1979; Morris et al., 1993; Nakamae et al., 1994).

Wu et al. have synthesized PNIPAAm–phospholipid conjugates for use in drug delivery formulations as components of thermally sensitive composites and liposomes (Wu et al., 1992, 1993).

There has been some concern about the toxicity of PNIPAAm, related to the toxic nature of the acrylamide monomer which is similar to NIPAAm. If any NIPAAm monomer residues are present in the polymer product, it is most likely they can be washed out. Although there are no significant reports of PNIPAAm toxicity, this issue has not been adequately investigated to date.

> Although there are no significant reports of PNIPAAm toxicity, that issue has not been adequately investigated to date.

SMART POLYMERS AND THEIR BIOMOLECULE CONJUGATES ON SURFACES

Smart polymers, especially PNIPAAm, have been coated on various surfaces by physical adsorption, chemical conjugation, affinity complexation, radiation-induced polymerization, direct or chain-transfer initiated polymerization from the surface, and plasma discharge deposition. These methods and various applications of them are discussed in this section.

> Smart polymers, especially PNIPAAm, have been coated on various surfaces by physical adsorption, chemical conjugation, affinity complexation, radiation-induced polymerization, direct or chain-transfer initiated polymerization from the surface, and plasma discharge deposition.

One may covalently graft PNIPAAm to a surface by exposing the surface to ionizing radiation in the presence of the monomer (and in the absence of air) or by pre-irradiating the polymer surface in air, and later contacting the surface with the monomer solution and heating in the absence of air to expose trapped radicals. These surfaces exhibit stimulus-responsive changes in wettability (e.g., Uenoyama and Hoffman, 1988; Takei et al., 1994b; Kidoaki et al., 2001). Okano and Yamato and co-workers have been pioneers in the area of smart polymer cell culture surfaces. They applied the radiation grafting technique to form surfaces having a surface layer of grafted PNIPAAm (Yamato and Okano, 2001; Shimizu et al., 2003). They cultured cells to confluent sheets on these surfaces at 37°C, which is above the LCST of the polymer. When the PNIPAAm collapses, the interface becomes hydrophobic and leads to physical adsorption of cell adhesion proteins from the culture medium, enhancing the cell culture process. Then, when the temperature is lowered, the interface becomes hydrophilic as the PNIPAAm chains rehydrate, and the cell sheets are released from the surface along with the cell adhesion proteins, which remain bound to the cell surfaces. The cell sheet can be recovered and used in tissue engineering, e.g., for artificial corneas and heart patches, and in peri-odontal applications. These exciting new applications of smart surface cell sheets are being pursued in the clinic. Patterned PNIPAAm surfaces have also been prepared for cell culture (Yamato et al., 2001).

Ratner and co-workers have used a gas plasma discharge technique to deposit temperature-responsive coatings from a NIPAAm monomer vapor phase plasma discharge. When cells are cultured on these surfaces, they also form reversible cell sheets in a manner similar to Okano and Yamato's PNIPAAm-grafted surfaces (Pan et al., 2001).

Smart polymers may also be grafted to surfaces by polymerizing the monomer directly from the surface. This may be done by first attaching to the surface either a radical initiator, such as an azo or peroxide initiator, or a chain transfer agent (CTA) for controlled radical polymerizations such as reversible addition-fragmentation chain transfer polymerization (RAFT) (e.g., Chiefari et al., 1998; McCormick and Lowe, 2004; Moad et al., 2008) or atom transfer radical polymerization (ATRP) (e.g., Wang and Matyjaszewski, 1995; Matyjaszewski and Xia, 2001; Matyjaszewski and Tsarevsky, 2009). (The ATRP of the smart polymer from a biomolecule such as a protein to form the bioconjugate directly was discussed above in this chapter.) Then the polymerization is initiated at the surface or in the surrounding solution, and the result is a smart polymer grafted to the surface. In the case of RAFT or ATRP controlled radical polymerizations, the molecular weights of the grafted polymer can be controlled to a narrow range. In a recent example, Golden and co-workers conjugated a RAFT CTA to the surface of a microporous, hydroxyl-ated nylon membrane, and graft polymerized NIPAAm directly from the surface, forming a graft polymer of around 9000 MW (Golden et al., 2010). Then this surface was heated, and the collapsed PNIPAAm-coated porous membrane was used in a microfluidic channel to sequester dilute PNIPAAm-antibody conjugates that had earlier captured a biomarker antigen in a blood test sample. In this way, the captured biomarker was concentrated on the membrane surface and later released by cooling to provide a concentrated pulse flowing downstream in the channel for this smart polymer microfluidic immunoassay.

The research team of Stayton and Hoffman, and co-workers have also developed a variety of nanoparticles (nps) coated with PNIPAAm for various applications in diagnostic immunoassays. They include polystyrene latex nanoparticles, magnetic nanoparticles, and gold nanoparticles. In the case of the latex nps, Malmstadt and co-workers functionalized aminated polystyrene latex nps with PNIPAAm by conjugating an NHS-terminated PNIPAAm chain to the surface amino groups. The aminated beads were also functionalized with an NHS–PEG–biotin polymer, and streptavidin was bound to the biotin groups. The beads were localized in a microfluidic channel by raising the temperature in one section of the channel. The PNIPAAm- and antibody-functionalized beads were then used to capture labeled, biotinylated antigens in a test sample, to produce a smart polymer competition immunoassay carried out in a microfluidic device (Malmstadt et al., 2003a,b, 2004).

The research team of Lai and Nash and co-workers developed PNIPAAm and PNIPAAm-antibody coatings on magnetic and gold nps, which were used to capture dilute antigen biomarkers in a test sample, then later were captured on the PNIPAAm-grafted porous membrane surface described above (Golden et al., 2010). After that they were released by cooling, forming a concentrated pulse of labeled nps for assay downstream in a microfluidic device. PNIPAAm-coated magnetic and

gold nps were also applied in lateral flow, "dipstick" assay by the Stayton–Hoffman group.

In a process for coating magnetic nps with PNIPAAm, Lai and co-workers formed magnetic nps in the presence of a dodecyl-terminated PNIPAAm. The dodecyl-terminated PNIPAAm polymer formed micelles that concentrated the pentacarbonyl iron precursor of magnetic iron oxides in the dodecyl core of the micelle before it was converted at high temperature to magnetic iron oxide (Lai et al., 2007, 2009). To coat the gold nps, Nash bound RAFT-polymerized PNIPAAm chains to the gold surface via sulfur's affinity to gold, utilizing the sulfur-containing groups in the dithioester or trithio carbonate terminal groups from the original CTA of the RAFT polymer chain (Nash et al., 2010a,b,c). The coated magnetic particles were mainly used for separating and concentrating the captured antigen, and the coated gold particles were mainly used as color (red) labels to indicate the approximate concentration of the captured antigen.

PNIPAAm may also be physically adsorbed to surfaces. Work by Miura and Hoffman and co-workers established the importance of matching the smart polymer composition with the surface composition in order to enhance the stimulus-driven adsorption of the smart polymer on the surface (Miura et al., 1994).

Smart polymers may also be grafted in gradients to surfaces to provide surfaces of gradually varying hydrophilicity and hydrophobicity as a function of the polymer composition and conditions. This phenomenon has been applied by Okano, Kikuchi, and co-workers to prepare chromatographic column packing for use in eluate-free ("green") chromatographic separations (Kobayashi et al., 2001; Kikuchi and Okano, 2002). Ishihara et al. (1982, 1984) developed photo-responsive coatings and membranes that reversibly change surface wettability or swelling due to the photo-induced isomerization of an azobenzene-containing polymer.

SITE-SPECIFIC SMART POLYMER BIOCONJUGATES

Conjugation of a responsive polymer to a specific site near the "activity" pocket of a genetically engineered protein is a powerful new concept initially demonstrated by Chilkoti et al. (1994) (see also later work by Stayton and Hoffman et al., 2000). Such site-specific protein–smart polymer conjugates can permit sensitive environmental control of the protein's recognition process, which controls all living systems. They conjugated the smart polymer to a reactive –SH thiol group from a cysteine that had been inserted by site-specific mutagenesis at a site nearby the active site of the protein (Figure I.2.11.5). To do this, they first used cassette mutagenesis to insert a site-specific mutation into the DNA sequence of the protein, and then cloned the mutant in cell culture. This method is applicable only to proteins whose complete peptide sequence is known. The preparation of the reactive smart polymer is similar to methods described above, but in this case, the reactive end or pendant groups and the reaction conditions were specifically designed to
FIGURE I.2.11.5 Schematic illustration of various processes for preparing a site-specific conjugate of a polymer with a genetically-engineered, mutant protein.

favor conjugation to –SH groups rather than to –NH$_2$ groups. Typical SH-reactive polymer end groups include maleimide and vinyl sulfone groups.

The specific site for polymer conjugation can also be located far away from the active site (Chilkoti et al., 1994), in order to avoid interference with the biological functioning of the protein, or nearby or even within the active site, in order to control the ligand–protein recognition process, and the resulting biological activity of the protein (Figure I.2.11.5), (see also Hoffman and Stayton, 2010). Temperature-, pH-, and light-sensitive smart polymers have been used to form such novel, "really smart" bioconjugates (Ding et al., 1999; Bulmus et al., 1999; Stayton et al., 2000; Ding et al., 2001; Shimoboji et al., 2001, 2002a,b, 2003). Since the objective is to control the activity of the protein, and not to phase separate it, in practice these smart polymer-engineered protein bioconjugates would be immobilized on the surfaces of microarray chips, microbeads or nanobeads.

Site-specific conjugates of PNIPAAm to protein mutants of streptavidin and the enzyme endocellulase have been extensively studied by the Stayton–Hoffman group. Site-specific bioconjugates of PNIPAAm with streptavidin have been used to control access of biotin to its binding site on streptavidin (Stayton et al., 1995), and have enabled separation of biotinylated proteins according to the size of the protein (Ding et al., 2001). Ding, Stayton, and Hoffman et al. (1999) also found that raising the temperature to induce the collapse of the PNIPAAm chain "triggered" the release of the bound biotin molecules (perhaps due to a reduced biotin "off" rate compared to the "on" rate) (Ding et al., 1999). For the site-specific enzyme conjugates, a combined temperature- and light-sensitive polymer was conjugated to specific sites on endocellulase, which provided "on-off" control of the enzyme activity with either light or temperature (Shimoboji et al., 2001, 2002a,b, 2003). Bulmus et al. (1999) conjugated a pH- and temperature-responsive PNIPAAm copolymer to a specific site on streptavidin.

Triggered release of bound ligands by the smart polymer-engineered protein bioconjugates could be used to release therapeutics, such as for topical drug delivery to the skin or mucosal surfaces of the body, and also for localized delivery of drugs within the body by stimulated release at pretargeted sites using noninvasive, focused stimuli such as ultrasound or delivery of light stimuli from catheters. Triggered release could also be used to release and recover affinity-bound ligands from chromatographic and other supports in eluate-free conditions, including capture and release of specific cell populations to be used in stem cell and bone marrow transplantation. These processes could involve two different stimuli-responsive polymers with sensitivities to the same or different stimuli. For delicate target ligands such as peptides and proteins, recovery could be affected without the need for time-consuming and harsh elution conditions. Triggered release could also be used to remove inhibitors, toxins or fouling agents from the recognition sites of enzymes and affinity molecules, such as those used in biosensors, diagnostic assays or affinity separations. This could be used to "regenerate" such recognition proteins for extended process use. Light-controlled binding and release of site-specific protein conjugates may be utilized as a molecular switch for various applications in biotechnology, medicine, and bioelectronics, including hand-held diagnostic devices, biochips, and lab-on-a-chip devices.

Fong, Stayton, and Hoffman (Fong et al., 1999) have developed an interesting construct to control the distance of the PNIPAAm from the active site. For this purpose, they conjugated one sequence of complementary nucleotides to a specific site near the binding pocket of streptavidin, and a second sequence to the end of a PNIPAAm chain. Then, by controlling the location and length of the complementary sequence, the self-assembly via hybridization of the two single-chain DNA sequences could be used to control the distance of the polymer from the streptavidin binding site.

SMART POLYMER HYDROGELS

When a smart polymer is cross-linked to form a gel, it will collapse and reswell in water as a stimulus raises or lowers it through its critical condition. PNIPAAm hydrogels have been extensively studied, starting with the pioneering work of Toyoichi Tanaka in 1981 (Tanaka, 1981). In the mid- to late-1980s, Hoffman and co-workers were among the first to recognize the potential of PNIPAAm hydrogels as biomaterials; they showed that smart gels could be used to entrap enzymes and cells, and then by inducing cyclic collapse and swelling of the gel, the enzymes (or enzymes within the cells) could be turned "on" and "off." Park and Hoffman also showed enhanced enzyme efficiency for an entrapped enzyme in a packed bed, hydrogel bead reactor, since the collapse delivered product faster than it could diffuse out, and the reswelling imbibed substrate faster than it could diffuse in. They also could deliver drugs or remove toxic biomolecules, by stimulus-induced collapse or swelling. Dong and Hoffman developed an interesting pH- and temperature-responsive gel that swelled linearly at 37°C and pH 7.4, at rates depending on the AAc monomer content in the gel. This work with PNIPAAm gels in drug delivery systems (DDS) is discussed in detail in Chapter II.5.16 on Drug Delivery Systems (Dong and Hoffman, 1986, 1987, 1990, 1991; Park and Hoffman, 1988, 1990a,b,c, 1994) (Figure I.2.11.6).

The research team of Kim, Okano, Bae, and their co-workers were also actively studying smart hydrogels in the late 1980s and 1990s. For example, they investigated smart gels containing entrapped cells that could be used as artificial organs (Vernon et al., 2000). Their drug delivery work with smart hydrogels is discussed in detail in Chapter II.5.16 on Drug Delivery Systems.
FIGURE I.2.11.6 Schematic illustration showing three ways that smart gel formulations may be stimulated to release bioactive agents: (A) thermally-induced collapse, which is relevant to skin or mucosal drug delivery; (B) pH-induced swelling, which is relevant to oral drug delivery, where the swelling is induced by the increase in pH in going from the gastric to enteric regions; and (C) sol-to-gel formation, which is relevant to injectable or topical formulations of a triblock copolymer solution that are thermally gelled at body temperature. For *in vivo* uses, the block copolymer is designed to be degradable. The first two apply to cross-linked gels applied topically or orally, and the third is relevant to thermally-induced formation of gels from polymer solutions that are delivered topically or by injection. (See also Chapter II.5.16 Drug Delivery Systems.)

Since then, the properties of PNIPAAm hydrogels have been widely investigated in the form of beads, slabs or discs, and multilamellar laminates (Park and Hoffman, 1992a,b; Hu et al., 1995, 1998; Mitsumata et al., 2001; Gao and Hu, 2002; Kaneko et al., 2002).

Okano and co-workers designed and synthesized PNIPAAm gels that collapse much more rapidly than PNIPAAm gels that are simply cross-linked with a divinyl comonomer. Yoshida, Okano, and co-workers copolymerized NIPAAm monomer with a PNIPAAm macromer and a cross-linker, which yielded a gel with PNIPAAm chains grafted to the PNIPAAm network. The grafted chains collapsed first at the LCST, enhancing the rate of collapse of the network, along with the related rate of expulsion of water from the gel (Yoshida et al., 1995; Masahiko et al., 2003).

Peppas and co-workers (e.g., Peppas et al., 2000; Robinson and Peppas, 2002) have extensively studied pH-sensitive acrylic acid-acrylate copolymer smart gels. This work is discussed in more detail in Chapter I.2.5 on Hydrogels (see also Peppas, 1997, 2001; Peppas et al., 1999, 2000).

Smart hydrogel compositions have been developed that are both thermally gelling and biodegradable (Zhong et al., 2002; Yoshida et al., 2003). These sol–gel systems have been used to deliver drugs by *in vivo* injections, and are discussed in the section on Smart Polymers in Solution (see also Chapter I.2.5 on Hydrogels, and Chapter II.5.16 on Drug Delivery Systems).

Matsuda and co-workers incorporated PNIPAAm into physical mixtures with natural polymers such as hyaluronic acid and gelatin, for use as tissue engineering scaffolds (Ohya et al., 2001a,b). Park and Hoffman developed a unique process for synthesizing mm-size spherical beads of PNIPAAm (Park and Hoffman, 1992c).

Nakamae, Hoffman, and co-workers developed novel compositions of smart gels containing phosphate groups that were used to bind cationic proteins as model drugs, and then to release them by a combination of thermal stimuli and ion exchange (Nakamae et al., 1992, 1997; Miyata et al., 1994).

A number of smart hydrogel drug delivery systems have been designed to respond to biologic signals in a feedback manner. Many of these gels contain an immobilized enzyme. They are discussed in detail in the Chapter II.5.16 on Drug Delivery Systems.

CONCLUSIONS

Smart polymers in solution, on surfaces, and as hydrogels have been utilized in many interesting ways, especially in combination with biomolecules such as proteins and drugs. Important applications include affinity separations, enzyme processes, immunoassays, drug delivery, and toxin removal. These smart polymer–biomolecule systems represent an important extension of polymeric biomaterials beyond their well-known uses in implants and medical devices.

Investigator, University of Washington, Seattle, WA, USA

INTRODUCTION

Much effort goes into the design, synthesis, and fabrication of biomaterials and devices to ensure that they have the appropriate mechanical properties, durability, and functionality. To cite a few examples, a hip joint should withstand the high stresses associated with walking and running, a hemodialyzer should have the requisite permeability characteristics, and the pumping bladder in an artificial heart should flex for millions of cycles without failure. The bulk composition and organization of materials govern these properties.

The biological response to biomaterials and devices, on the other hand, is controlled largely by their surface chemistry and structure (see Chapters I.1.5, II.1.3, and II.1.4). The rationale for the surface modification of biomaterials is therefore straightforward: to retain the key physical properties of a biomaterial while modifying only the outermost surface to influence the biointeraction. If such surface modification is properly effected, the mechanical properties and functionality of the device will be unaffected, but the bioresponse related to the tissue–device interface will be improved or modulated.

Materials can be surface modified by using biological, mechanical or physicochemical methods. Many biological surface modification schemes are covered in Chapter I.2.17. Surface modification for creating non-fouling surfaces is reviewed in Chapter I.2.12. Generalized examples of physicochemical surface modifications, the focus of this chapter, are illustrated schematically in Figure I.2.12.1. Surface modification with Langmuir–Blodgett (LB) films has elements of both biological modification and physicochemical modification. LB films will be discussed later in this chapter. Some applications for surface modified biomaterials are listed in Table I.2.12.1. Physical and chemical surface modification methods, and the types of materials to which they can be applied, are listed in Table I.2.12.2. Methods to modify or create surface texture or roughness will not be explicitly covered here (see Chapter I.2.15).

GENERAL PRINCIPLES

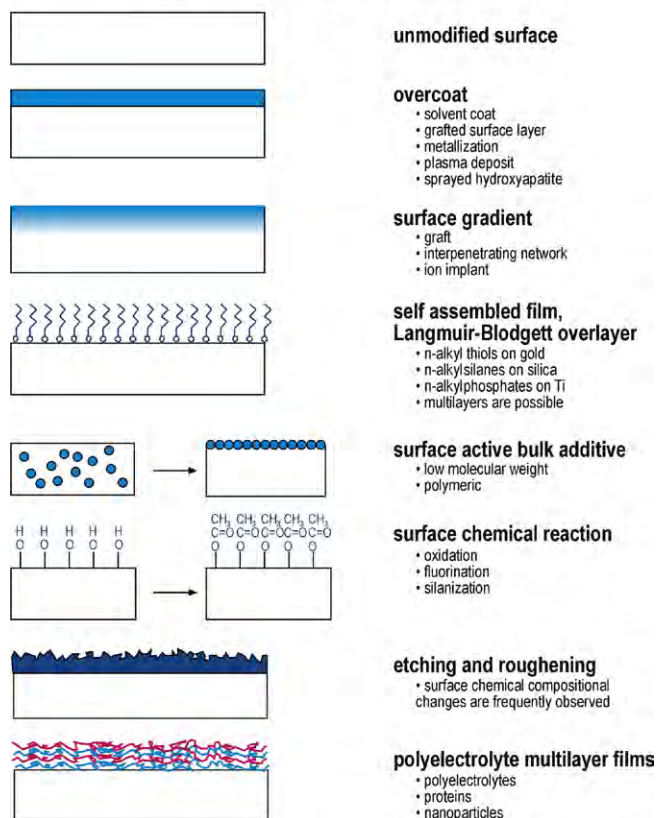
Surface modifications fall into three categories: (1) chemically or physically altering the atoms, compounds or molecules in the existing surface (chemical modification, etching, mechanical roughening); (2) overcoating the existing surface


FIGURE I.2.12.1 Schematic representations of methods to modify surfaces.

with a material having a different composition (coating, grafting, thin film deposition); (3) creating surface textures or patterns (Figure I.2.12.1). A few general principles provide guidance when undertaking surface modifications.

Thin Surface Modifications

Thin surface modifications are desirable. Modified surface layers that are too thick can change the mechanical and functional properties of the material. Thick coatings are also more subject to delamination and cracking. How thin should a surface modification be? Ideally, alteration of only the outermost few molecular layers (3–10 nm) should be sufficient. In practice, thicker films than this will be necessary, since it is difficult to ensure that the original surface is uniformly covered when coatings and treatments are molecularly thin. This is because of intrinsic non-uniformities in many coating processes, and also because of surface roughness that exists on almost all surfaces at the nanometer scale. Also, extremely thin layers may be more subject to surface reversal (see below) and mechanical erosion. Some coatings intrinsically have a specific thickness. For example, the thickness of LB films is related to the length of the amphiphilic molecules that comprise them (2–5 nm). Other coatings, such as poly(ethylene glycol) (PEG) protein-resistant layers, may require a minimum thickness (a dimension

TABLE I.2.12.1	Examples of Surface Modified Biomaterials by Physicochemical Methods

To Modify Blood Compatibility

Octadecyl group attachment to surfaces (albumin affinity)
Silicone-containing block copolymer additive
Plasma fluoropolymer deposition
Plasma siloxane polymer deposition
Grafted poly(ethylene glycol) (PEG) or PEG-containing polymers
Chemically-modified polystyrene for heparin-like activity

To Modulate Cell Adhesion and Growth

Oxidized polystyrene surface
Ammonia plasma-treated surface
Plasma-deposited acetone or methanol film
Plasma fluoropolymer deposition (reduce corneal endothelial adhesion and modify blood interactions)
Varying surface modulus
Anti-bacterial treatments?

To Control Protein Adsorption

Surface with immobilized poly(ethylene glycol) (reduce adsorption)
Treated ELISA dish surface (increase adsorption)
Affinity chromatography column
Surface cross-linked contact lens (reduce adsorption)

To Improve Lubricity

Plasma treatment?
Radiation grafting (hydrogels)
Interpenetrating polymeric networks

To Improve Wear Resistance and Corrosion Resistance

Ion implantation
Diamond deposition
Anodization

To Alter Transport Properties

Polyelectrolyte grafting
Surface self-assembled film barrier
Plasma-deposited barrier layer

To Modify Electrical Characteristics

Polyelectrolyte grafting
Magnetron sputtering of titanium
Surface fluoropolymer insulation

related to the molecular weight of chains) to function (see Chapter I.2.10). In general, surface modifications should be the minimum thickness needed for uniformity, durability, and functionality, but no thicker. This is often experimentally defined for each system.

Delamination Resistance

The surface modified layer should be resistant to delamination and cracking. Resistance to delamination is achieved by covalently bonding the modified region to the substrate, intermixing the components of the substrate and the surface film at an interfacial zone (for example, an interpenetrating network or IPN), applying a compatibilizing ("primer") layer at the interface or incorporating appropriate functional groups for strong intermolecular adhesion between a substrate and an

overlayer (Wu, 1982). Where the mechanical properties of the substrate and overlayer are significantly mismatched, delamination becomes increasingly of concern.

Surface Rearrangement

Surface rearrangement can readily occur. It is driven by a thermodynamic minimization of interfacial energy and enhanced by molecular mobility. Surface chemistries and structures can "switch" due to diffusion or translation of surface atoms or molecules in response to the external environment (see Chapter I.1.5 and Figure I.1.5.2 in that chapter). A newly formed surface chemistry can migrate from the surface into the bulk or molecules from the bulk can diffuse to cover the surface. Such reversals occur in metallic and other inorganic systems, as well as in polymeric systems. Terms such as "reconstruction," "relaxation," and "surface segregation" are often used to describe mobility-related alterations in surface structure and chemistry (Ratner and Yoon, 1988; Garbassi et al., 1989; Somorjai, 1990, 1991; Cometa et al., 2010). The driving force for these surface changes is a minimization of the interfacial energy. However, sufficient atomic or molecular mobility must exist for the surface changes to occur in reasonable periods of time. For a modified surface to remain as intended, surface reversal must be prevented or inhibited. This can be done by cross-linking, by sterically blocking the ability of surface structures to move, by incorporating a rigid, impermeable layer between the substrate material and the surface modification or by reducing the hydrophilic character of the modified surface, which will reduce water uptake and the mobility of surface atoms.

Surface Analysis

Surface modification and surface analysis are complementary and sequential technologies. The surface modified region is usually thin, and consists of only minute amounts of material. Undesirable contamination can readily be introduced during modification reactions. The potential for surface reversal to occur during surface modification is also high. The surface reaction should be monitored to ensure that the intended surface is indeed being formed. Since conventional analytical methods are often insufficiently sensitive to detect surface modifications, special surface analytical tools are called for (Chapter I.1.5).

Commercializability

The end products of biomaterials research are devices and materials that are manufactured to exacting specifications for use in humans. A surface modification that is too complex will be challenging and expensive to reproducibly manufacture and commercialize. It is best to minimize the number of steps in a surface modification process, and to design each step to be relatively insensitive to small changes in reaction conditions.

METHODS FOR MODIFYING THE SURFACES OF MATERIALS

General methods to modify the surfaces of materials are illustrated in Figure I.2.12.1, with many examples listed in Table I.2.12.2. A few of the more widely used of these methods will be briefly described. Some of the conceptually simpler methods, such as solution coating of a polymer onto a substrate or metallization by sputtering or thermal evaporation, will not be elaborated upon here.

Chemical Reaction

There are hundreds of chemical reactions that can be used to modify the chemistry of a surface. Chemical reactions, in the context of this article, are those performed with reagents that react with atoms or molecules at the surface, but do not overcoat those atoms or molecules with a new layer. Chemical reactions can be classified as nonspecific and specific.

Nonspecific reactions leave a distribution of different functional groups at the surface. An example of a nonspecific surface chemical modification is the chromic acid oxidation of polyethylene surfaces leading to numerous surface oxygen species including carboxylic acid, carbonyl, hydroxyl, etc. Other examples include the corona discharge modification of materials in air; radio frequency glow discharge (RFGD) (plasma) treatment of materials in oxygen, argon, nitrogen, carbon dioxide, fluorinated gases or water vapor; and the oxidation of metal surfaces to a mixture of metallic suboxides.

Specific chemical surface reactions change only one functional group into another with a high yield and few side reactions. A few examples of specific chemical surface modifications for polymers are presented in Figure I.2.12.2. Certain specific reactions can be used for inorganic (silicon) surfaces as well as polymeric surfaces (Filler and Bent, 2003). Still another example (expanded upon in the section, below, titled "Specific Chemical Reactions for Forming Surface Grafts") uses atomic transfer radical polymerization (ATRP) chain growth on surfaces (Hucknall et al., 2009). Others have also used radical addition chain transfer polymerization (RAFT) to graft polymer chains to a surface with high precision.

(a)
Alkylation of poly(chlorotrifluoroethylene)

(b)
Trifluoroacetic anhydride reaction of a hydroxylated surface

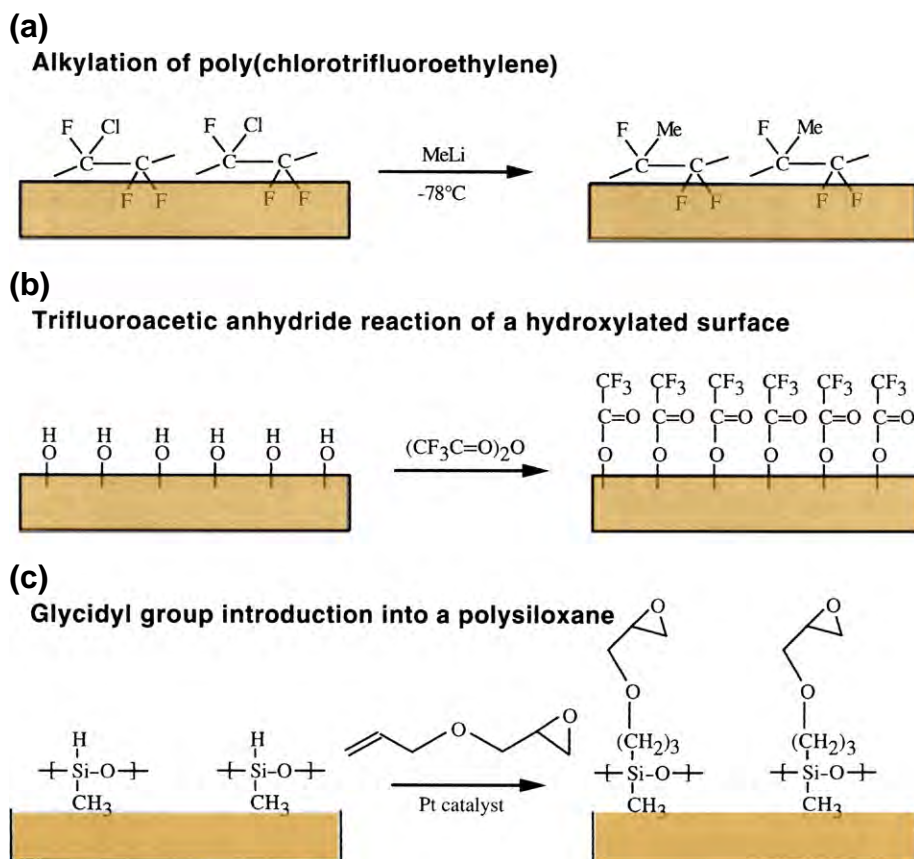
(c)
Glycidyl group introduction into a polysiloxane


FIGURE I.2.12.2 Some specific chemical reactions to modify surfaces.

This may be done by conjugating the chain transfer agent (CTA) to the surface and then initiating graft polymerization of a monomer to the CTA using a typical free radical initiator (Boyer et al., 2009; Golden et al., 2010).

Protein immobilization is typically (although not always) a surface modification reaction performed with high chemical specificity. Detailed chemistries for biomolecule immobilization are described in Chapter I.2.17.

Surface Grafting: Radiation Grafting, Photografting, and Newer Methods

Surface grafting methods have been widely applied for the surface modification of biomaterials since the early days of the field (Hoffman et al., 1972). Comprehensive review articles are available (Ratner, 1980; Hoffman, 1981; Hoffman et al., 1983; Stannett, 1990; Safrany, 1997; Ma et al., 2007). Surface grafting methods can be divided into two general categories: (1) using energetic or highly reactive species to activate chemically inert surface permitting the attachment of desired surface species; and (2) taking advantage of well-defined, reactive surface chemical groups to covalently attach the surface modifying species (a polymer, a low molecular weight compound, a drug, a protein, etc.). These category (2) specific reactions for forming surface grafts will be addressed in a separate section below.

The earliest biomedical surface modification studies focused on attaching chemically reactable groups (-OH, -COOH, $-NH_2$, etc.) to the surfaces of relatively inert hydrophobic polymers using methods from category (1), above. Four types of reactions can be distinguished in category (1): grafting using ionizing radiation sources (most commonly, a cobalt 60 or cesium 137 gamma radiation source) (Dargaville et al., 2003); grafting using UV radiation (photografting) (Matsuda and Inoue, 1990; Dunkirk et al., 1991; Swanson, 1996; Sebra et al., 2007); grafting using high-energy electron beams (Singh and Silverman, 1992); and grafting using a reactive, surface-activating species such as ozone (Chiang et al., 2009). In all cases, similar processes occur. The radiation or reactive chemical breaks chemical bonds in the material to be grafted, forming free radicals, peroxides or other reactive species. These reactive surface groups are then exposed to a monomer. The monomer reacts with the free radicals at the surface and propagates as a free radical chain reaction incorporating other monomers into a surface grafted polymer. Electron beams and gamma radiation sources are also used for biomedical device sterilization (see Chapter III.1.2). Note that glow discharge plasma reactions to surfaces also have similarities to these non-specific surface modification approaches. Plasma reaction will be discussed in its own section, below.

High energy surface modification technologies are strongly dependent on the source energy, the radiation dose rate, and the amount of the dose absorbed. The energy of the radiation produced by gamma sources is roughly 1 MeV (1 eV = 23.06 kcal/mol; for comparison, a carbon–carbon bond has a strength of approximately 85 kcal/mol). Typical energies for electron beam processing are in the range 5–10 MeV. UV radiation sources are of much lower energy (<6 eV). Radiation dose rates are low for UV and gamma, and very high for electron beams. The amount of energy absorbed is measured in units of Grays (Gy), where 1 kiloGray (Kgy) = 1000 joules/kilogram. Units of megarads (MR) are often used for gamma sources, 1 MR = 1×10^6 ergs/gram.

Three distinct reaction modes can be described: (1) in the mutual irradiation method, the substrate material is immersed in an oxygen-free solution (monomer ± solvent) that is then exposed to the radiation source; (2) the substrate materials can also be exposed to the radiation under an inert atmosphere or at low temperatures (to stabilize free radicals) (in this case, the materials are later contacted with a monomer solution to initiate the graft process); (3) finally, the exposure to the radiation can take place in air or oxygen, leading to the formation of peroxide groups on the surface. Heating the material to be grafted in the presence of monomer or addition of a redox reactant (e.g., Fe^{++}) which will decompose the peroxide groups to form free radicals can initiate the graft polymerization (in O_2-free conditions).

Graft layers formed by energetic irradiation of the substrate are often relatively thick (>1 μm) and are comprised of high molecular weight polymer chains. However, they are typically well-bonded to the substrate material, and thus resist delamination. Since many polymerizable monomers are available, a wide range of surface chemistries can be created. Mixtures of monomers can form unique graft copolymers (Ratner and Hoffman, 1980). For example, the hydrophilic/hydrophobic ratio of surfaces can be controlled by varying the ratio of a hydrophilic and a hydrophobic monomer in the grafting mixture (Ratner et al., 1979; Ratner and Hoffman, 1980).

Photoinitiated grafting (usually with visible or UV light) represents a unique subcategory of surface modifications for which there is growing interest (Deng et al., 2009; Park et al., 2009). There are many approaches to effect this photoinitiated covalent coupling. For example, a phenyl azide group can be converted to a highly reactive nitrene upon UV exposure. This nitrene will quickly react with many organic groups. If a synthetic polymer is prepared with phenyl azide side groups, and this polymer is exposed simultaneously to UV light and a substrate polymer or polymeric medical device, the polymer containing the phenyl azide side groups will be immobilized to the substrate (Matsuda and Inoue, 1990). Another method involves the coupling of a benzophenone molecule to a hydrophilic polymer (Dunkirk et al., 1991). In the presence of UV irradiation, the benzophenone is excited to a reactive triplet state that can covalently couple with many polymers. As still another example, a dithiocarbamate-functionalized polyurethane was used to photo-pattern an extracellular-matrix-like coating (Sebra et al., 2007).

Radiation, electron beam, and photografting have frequently been used to bond hydrogels to the surfaces of hydrophobic polymers (Matsuda and Inoue, 1990; Dunkirk et al., 1991; Sebra et al., 2007). Electron beam grafting of N-isopropyl acrylamide to polystyrene has been used to create a new class of temperature-dependent surfaces for cell growth (Kwon et al., 2000) (also see Chapter I.2.17). The protein interactions (Horbett and Hoffman, 1975), cell interactions (Ratner et al., 1975; Matsuda and Inoue, 1990), blood compatibility (Chapiro, 1983; Hoffman et al., 1983), and tissue reactions (Greer et al., 1979) of hydrogel graft surfaces have been investigated.

RFGD Plasma Deposition and Other Plasma Gas Processes

RFGD plasmas, as used for surface modification, are low-pressure ionized gas environments typically at ambient (or slightly above ambient) temperature. They are also referred to as glow discharge or gas discharge depositions or treatments. Plasmas can be used to modify existing surfaces by ablation or etching reactions or, in a deposition mode, to overcoat surfaces (Figure I.2.12.1). Good review articles on plasma deposition and its application to biomaterials are available (Yasuda and Gazicki, 1982; Hoffman, 1988; Ratner et al., 1990; Chu et al., 2002; Kitching et al., 2003; Desmet et al., 2009). Some biomedical applications of plasma-modified biomaterials are listed in Table I.2.12.3.

RFGD plasma surface modifications are widely used in biomaterials research and development. Because such coatings and treatments are now used in commercialized biomaterials products and have special promise for improved biomaterials, they will be emphasized in this chapter. The specific advantages of plasma-deposited films (and to some extent, plasma-treated surfaces) for biomedical applications are:

1. They are conformal. Because of the penetrating nature of a low-pressure gaseous environment in which mass transport is governed by both molecular (line-of-sight) diffusion and convective diffusion, complex geometric shapes can be treated.
2. They are free of voids and pinholes. This continuous barrier structure is suggested by transport studies and electrical property studies (Charlson et al., 1984).
3. Plasma-deposited films can coat almost any clean solid, including polymers, metals, ceramics, and semiconductors. Other surface grafting or surface modification technologies are highly dependent upon the chemical nature of the substrate.

TABLE I.2.12.3	Biomedical Applications of Glow Discharge Plasma-Induced Surface Modification Processes

A. Plasma Treatment (Etching)
   1. Clean
   2. Sterilize
   3. Cross-link surface molecules

B. Plasma Treatment (Etching) and Plasma Deposition
   1. Form barrier films
      a. Protective coating
      b. Electrically insulating coating
      c. Reduce absorption of material from the environment
      d. Inhibit release of leachables
      e. Control drug delivery rate
   2. Modify cell and protein reactions
      a. Modulate biointeractions
      b. Promote selective protein adsorption
      c. Enhance cell adhesion
      d. Improve cell growth
      e. Form nonfouling surfaces
      f. Increase lubricity

Anti-Bacterial Properties?
   3. Provide reactive sites
      a. For grafting or polymerizing polymers
      b. For immobilizing biomolecules

4. They exhibit good adhesion to the substrate. The energetic nature of the gas phase species in the plasma reaction environment can induce mixing, implantation, penetration, and reaction between the overlayer film and the substrate.

5. Unique film chemistries can be produced. The chemical structure of the polymeric overlayer films generated from the plasma environment usually cannot be synthesized by conventional chemical methods.

6. They can serve as excellent barrier films because of their pinhole-free and dense, cross-linked nature.

7. Plasma-deposited layers generally show low levels of leachables. Due to their highly cross-linked nature, plasma-deposited films contain negligible amounts of low molecular weight components that might lead to an adverse biological reaction. They can also inhibit leaching of low molecular weight material from the substrate and, in the case of drug delivery implants or inserts, they can reduce the rate of drug diffusion out of the device (Hendricks et al., 2000).

8. These films are easily prepared. Once the apparatus is set up and optimized for a specific deposition, treatment of additional substrates is rapid and simple.

9. Plasma deposition is a mature technology. The microelectronics industry has made extensive use of inorganic plasma-deposited films for many years (Sawin and Reif, 1983; Nguyen, 1986).

10. Plasma surface modifications, although chemically complex, can be characterized by infrared (IR) (Inagaki et al., 1983; Haque and Ratner, 1988; Krishnamurthy et al., 1989), nuclear magnetic resonance (NMR) (Kaplan and Dilks, 1981), electron spectroscopy for chemical analysis (ESCA) (Chilkoti et al., 1991a), chemical derivatization methods (Everhart and Reilley, 1981; Gombotz and Hoffman, 1988; Griesser and Chatelier, 1990; Chilkoti et al., 1991a), and static secondary ion mass spectrometry (SIMS) (Chilkoti et al., 1991b, 1992; Johnston and Ratner, 1996).

11. Plasma-treated surfaces are sterile when removed from the reactor, offering an additional advantage for cost-efficient production of medical devices.

12. New developments in the generation of atmospheric pressure plasmas may permit plasma processing without the need for a vacuum environment (Pappas, 2011).

Although plasma treatments have many advantages, there are concerns with plasma surface modification that should be discussed. First, the chemistry produced on a surface is often ill-defined. For example, if tetrafluoroethylene gas is introduced into the reactor, polytetrafluoroethylene (PTFE) will not be deposited on the surface. Rather, a complex, branched fluorocarbon polymer will be produced with a stoichiometry different from PTFE. This scrambling of monomer structure has been addressed in studies dealing with retention of monomer structure in the final film (Lopez and Ratner, 1991; Lopez et al., 1993; Panchalingam et al., 1993). Second, the apparatus used to produce plasma depositions can be expensive. A good laboratory-scale reactor will cost $10,000–$30,000, and a production reactor can cost $100,000 or more. Third, uniform reaction within tubes and narrow pores can be difficult to achieve. Finally, contamination can be a problem, and care must be exercised to prevent extraneous gases and pump oils from entering the reaction zone. However, the advantages of plasma reactions outweigh these potential disadvantages for many types of modifications that cannot be accomplished by other methods.

The Nature of the Plasma Environment

Plasmas are atomically and molecularly dissociated gaseous environments. A plasma environment contains positive ions, negative ions, free radicals, electrons, atoms, molecules, and photons (visible and near UV). Typical conditions within the plasma include an electron energy of 1–10 eV, a gas temperature of 25–60°C, an electron density of 10^{-9} to 10^{-12}/cm^2, and an operating pressure of 0.025–1.0 torr.

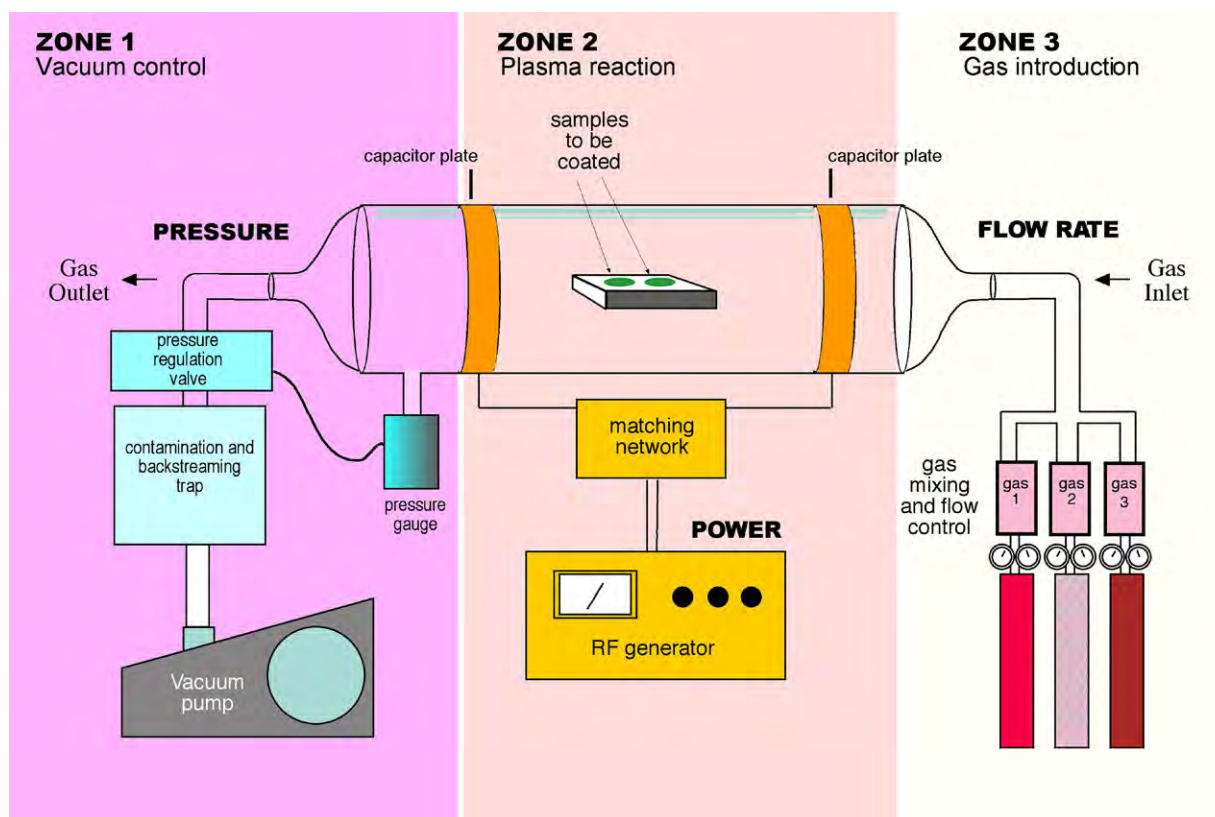
Many processes can occur on the substrate surface that lead to the observed surface modification or deposition. First, a competition takes place between deposition and etching by the high-energy gaseous species (ablation) (Yasuda, 1979). When ablation is more rapid than deposition, no deposition will be observed. Because of its energetic nature, the ablation or etching process can


FIGURE I.2.12.3 A capacitively-coupled RF plasma reactor. Redish colors indicate gas storage and mixing. Yellow colors are components that power the reactor. Zone 1: Vacuum system (pressure measurement and control); Zone 2: Plasma generation and sample placement; Zone 3: Gas introduction and flow control.

result in substantial chemical and morphological changes to the substrate.

A number of mechanisms have been postulated for the deposition process. The reactive gaseous environment may create free radical and other reactive species on the substrate surface that react with and polymerize molecules from the gas phase. Alternatively, reactive small molecules in the gas phase could combine to form higher molecular weight units or particulates that may settle or precipitate onto the surface. Most likely, the depositions observed are formed by some combination of these two processes.

The Apparatus to Generate Plasmas for Surface Modification

Many experimental variables relating both to reaction conditions and to the substrate onto which the deposition is placed affect the final outcome of the plasma deposition process. A diagram of a typical capacitively-coupled radio frequency plasma reactor is presented in Figure I.2.12.3. The major subsystems that comprise this apparatus are a gas introduction system (control of gas mixing, flow rate, and mass of gas entering the reactor), a vacuum system (measurement and control of reactor pressure and inhibition of backstreaming of molecules from the pumps), an energizing system to efficiently

couple energy into the gas phase within the reactor, and a reactor zone in which the samples are treated. Radio frequency, acoustic or microwave energy can be coupled to the gas phase. Devices for monitoring the molecular weight of the gas phase species (mass spectrometers), the optical emission from the glowing plasma (spectro-photometers), and the deposited film thickness (ellipsometers, vibrating quartz crystal microbalances) are also commonly found on plasma reactors. Technology has been developed permitting atmospheric pressure plasma deposition (Klages et al., 2000; Massines et al., 2000; Pappas, 2011). Another important development is "reel-to-reel" (continuous) plasma processing opening the way to low cost, high-throughput treatment of films, fibers, and tubes. Finally, methods have been developed to assist in the retention of polymer chemical structure during plasma deposition. These methods include using pulsed plasmas (Panchalingam et al., 1993), condensing vapors on a cold stage during the plasma process (Lopez and Ratner, 1991), and using very low plasma powers (Pan et al., 2001). Such controlled chemistry plasma deposition might be thought of as at some intermediate location on a continuum between the scrambled surface chemistries achieved with conventional plasma deposition of polymers, and the precise graft structures described in the section below titled "Specific Chemical Reactions for Forming Surface Grafts."

RFGD Plasmas for the Immobilization of Molecules

Plasmas have often been used to introduce reactive organic functional groups (e.g., amine, hydroxyl) on a surface that can be activated to attach biomolecules (see Chapter I.2.17). Certain reactive gas environments can also be used for directly immobilizing organic molecules such as surfactants. For example, a poly(ethylene glycol)-n-alkyl surfactant will adsorb to polyethylene (PE) via the hydrophobic alkyl block. If the polyethylene surface with the adsorbed surfactant is briefly exposed to an argon plasma, the n-alkyl chains will cross-link to surface atoms of PE, thereby leading to the covalent attachment of pendant poly(ethylene glycol) chains (Sheu et al., 1992).

High Temperature and High-Energy Plasma Treatments

The plasma environments described above are of relatively low energy and low temperature. Consequently, they can be used to deposit organic layers on polymeric or inorganic substrates. Under higher energy conditions, plasmas can effect unique and important inorganic surface modifications on inorganic substrates. For example, flame-spray deposition involves injecting a high-purity, relatively finely divided (~100 mesh) metal powder into a high-velocity plasma or flame. The melted or partially melted particles impact the surface and rapidly solidify (see Chapter I.2.3). Examples of plasma thermal spray coating on titanium are seen in Gruner (2001), and Vidigal et al. (2009).

Specific Chemical Reactions for Forming Surface Grafts

Techniques such as radiation grafting and plasma deposition create polymer surface grafts, although the polymeric species are generally highly cross-linked, chemically rearranged, and difficult to characterize. A new generation of polymer reactions permits surface grafts with precision in chain length, control of chain architectures (for example, diblock and triblock units), and minimization of unwanted branching and other side reactions. These polymer reactions applied to surface grafting include ATRP (Hucknall et al., 2009), reversible addition-fragmentation chain transfer (RAFT) polymerization (Boyer et al., 2009; Golden et al., 2010), and CLICK chemistry (Fleischmann et al., 2008).

Silanization

Silane treatments of surfaces involve a liquid phase or vapor phase chemical reaction, and are straightforward to perform and of low cost. A typical silane surface modification reaction is illustrated in Figure I.2.12.4 (although some details of this reaction have been questioned, see Schlecht and Maurer, 2011). Silane reactions are most often used to modify hydroxylated surfaces. Since glass, silicon, alumina, titania, and quartz surfaces, as well as other metal oxide surfaces, are rich in hydroxyl groups, silanes are particularly useful for modifying these materials. Numerous silane compounds are commercially available, permitting a broad range of chemical functionalities to be incorporated on surfaces (Table I.2.12.4). The advantages of silane reactions are their simplicity and stability, attributed to their covalent, cross-linked structure. However, the linkage between a silane and a hydroxyl group is also subject to hydrolysis, and film breakdown under some conditions must be considered (Wasserman et al., 1989).

Silanes can form two types of surface film structures. If only surface reaction occurs (perhaps catalyzed by traces of adsorbed surface water), a structure similar to that shown in Figure I.2.12.4 can be formed. However, if more water is present, a thicker silane layer can be formed consisting of both Si–O groups bonded to the surface, and silane units participating in a "bulk," three-dimensional, polymerized network. The initial stages in the formation of a thicker silane film are suggested by the further reaction of the group at the right side of Figure I.2.12.4(d) with solution phase silane molecules. Without careful control of silane liquid purity, water, and reaction conditions, thicker silane films can form and be rough and inhomogeneous.

A new class of silane-modified surfaces based upon monolayer silane films and yielding self-assembled, highly ordered structures is of particular interest in the precision engineering of surfaces (Pomerantz et al., 1985; Maoz et al., 1988; Heid et al., 1996; Haensch et al., 2010). These self-assembled monolayers are described in more detail later in this chapter.

Many general reviews and basic science studies on surface silanization are available (Arkles, 1977; Plueddemann, 1980; Rye et al., 1997). Applications for silanized surface modified bomaterials are on the increase, and include cell attachment (Hickman and Stenger, 1994; Matsuzawa et al., 1997), biomolecule and polymer immobilization (Mao et al., 1997; Xiao et al., 1997), non-fouling surfaces (Lee and Laibinis, 1998), surfaces for DNA studies (Hu et al., 1996), biomineralization (Archibald et al., 1996), and model surfaces for biointeraction studies (Jenney and Anderson, 1999).

Ion Beam Implantation

The ion beam method injects accelerated ions with energies ranging from 10^1 to 10^6 eV (1 eV = 1.6×10^{-19} joules) into the surface zone of a material to alter its properties. It is largely, but not exclusively, used with metals and other inorganics such as ceramics, glasses, and semiconductors. Ions formed from most of the atoms in the periodic table can be implanted, but not all provide useful modifications to the surface properties. Important potential applications for biomaterial surfaces include
FIGURE I.2.12.4 The chemistry of a typical silane surface modification reaction: (a) a hydroxylated surface is immersed in a solution containing n-propyl trimethoxysilane (nPTMS); (b) one of the methoxy groups of the nPTMS couples with a hydroxyl group releasing methanol; (c) two of the methoxy groups on another molecule of the nPTMS have reacted, one with a hydroxyl group and the other with a methoxy group from the first nPTMS molecule; (d) a third nPTMS molecule has reacted only with a methoxy group. This molecule is tied into the silane film network, but is not directly bound to the surface.

modification of hardness (wear), lubricity, toughness, corrosion, conductivity, and bioreactivity.

If an ion with kinetic energy greater than a few electron volts impacts a surface, the probability that it will enter the surface is high. The impact transfers much energy to a localized surface zone in a very short time interval. Some considerations for the ion implantation process are illustrated in Figure I.2.12.5. These surface changes must be understood quantitatively for engineering of modified

surface characteristics. Many review articles and books are available on ion implantation processes and their application for tailoring surface properties (Picraux and Pope, 1984; Colligon, 1986; Sioshansi, 1987; Nastasi et al., 1996; Rautray et al., 2010).

Specific examples of biomaterials that have been surface altered by ion implantation processes are plentiful. Iridium was ion implanted in a Ti-6Al-4V alloy to improve corrosion resistance (Buchanan et al., 1990). Nitrogen implanted into titanium greatly reduces wear (Sioshansi, 1987). The ion implantation of boron and carbon into type 316L stainless steel improves the high cycle fatigue life of these alloys (Sioshansi, 1987). Silver ions implanted into polystyrene permit cell attachment (Tsuji et al., 1998).

Langmuir–Blodgett Deposition

The Langmuir–Blodgett (LB) deposition method overcoats a surface with one or more highly ordered layers of surfactant molecules. Each of the molecules that assemble into this layer contains a polar "head" group and a nonpolar "tail" group. The deposition of an LB film using an LB trough is illustrated schematically in Figure I.2.12.6. By withdrawing the vertical plate out of the aqueous phase and through the air–water interface (keeping the surface film at the air–water interface compressed at all times,
FIGURE I.2.12.5 Ion impact and implantation considerations with a 50 KeV cesium ion accelerated into a surface.

as illustrated in Figure I.2.12.6), an assembled structure coats the glass with the hydrophilic tail group contacting the hydrophilic glass surface. By next pushing the plate back down through the air–water interface, another layer can be deposited, this time with the hydrophobic tails of the two layers in contact; dipping in and out with the film at the water surface always compressed permits multilayer structures to be created. Some compounds that form organized LB layers are shown in Figure I.2.12.7. Other techniques to create such ordered lipd structures at surfaces include Langmuir–Schaefer transfer and vesicle fusion (Li et al., 2008). The advantages of films deposited on surfaces by this method are their high degree of order and uniformity, and also their resemblance to the lipid bilayer membranes surrounding living cells. Also, since a wide range of chemical structures can form LB films, there are many options for incorporating new chemistries at surfaces. The stability of LB films can be improved by cross-linking or internally polymerizing the molecules after film formation, often through double bonds in the alkyl portion of the chains (Meller et al., 1989). A number of research groups have investigated LB films for biomedical applications (Hayward and Chapman, 1984; Bird et al., 1989; Cho et al., 1990; Heens et al., 1991; Knoll et al., 2008). A cross between silane thin films and LB layers has been developed for biomedical surface modification (Takahara et al., 2000). Many general reviews on these surface structures are available (Knobler, 1990; Ulman, 1991; Park and Advincula, 2011).

Self-Assembled Monolayers

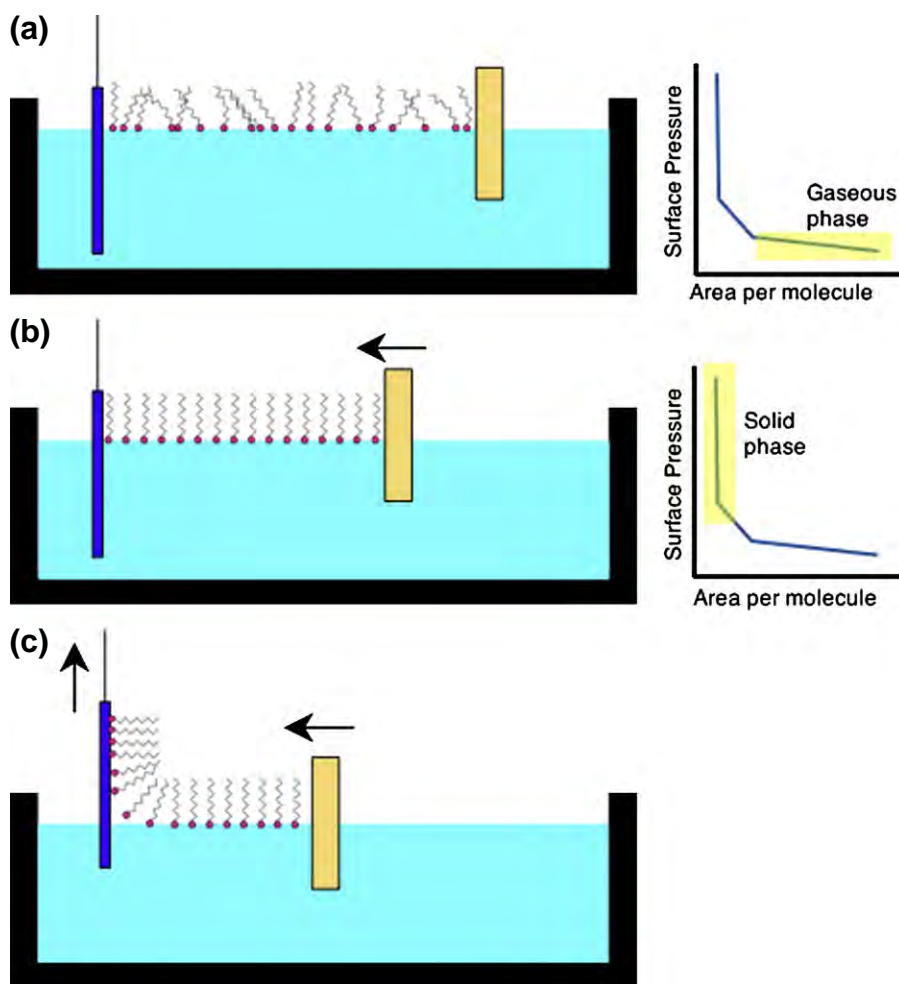
Self-assembled monolayers (SAMs) are surface films that spontaneously form as highly ordered structures (two-dimensional crystals) on specific substrates (Maoz et al., 1988; Ulman, 1990, 1991; Whitesides et al., 1991; Knoll, 1996; Raynor et al., 2009). In some ways SAMs resemble LB films, but there are important differences, in particular their ease of formation. Examples of SAM films include n-alkyl silanes on hydroxylated surfaces (silica, glass, alumina), alkane thiols (e.g., $CH_3(CH_2)_nSH$) and disulfides on coinage metals (gold, silver, copper), amines and alcohols on platinum, carboxylic acids on aluminum oxide, and silver and phosphates (phosphoric acid or phosphonate groups) on titanium or tantalum surfaces. Silane SAMs and thiols on gold are the most commonly used types. Most molecules that form SAMs have the general characteristics illustrated in Figure I.2.12.8. Two processes are particularly important for the formation of SAMs (Ulman, 1991): a moderate-to-strong adsorption of an anchoring chemical group to the surface (typically 30–100 kcal/mol), and van der Waals interaction of the alkyl chains. The bonding to the substrate (chemisorption) provides a driving force to fill every site on the surface, and to displace contaminants from the surface. This process is analogous to the compression to the LB film by the movable barrier in the trough. Once adsorption sites are filled on the surface, the chains will be in sufficiently close proximity so that the weaker van der Waals interactive forces between


FIGURE I.2.12.6 Deposition of a lipid film onto a glass slide by the Langmuir–Blodgett method: (a) the lipid film is floated on the aqueous layer; (b) the lipid film is compressed by a moveable barrier; (c) the vertical glass slide is withdrawn while pressure is maintained on the floating lipid film with the moveable barrier.

chains can exert their influence and lead to a crystallization of the alkyl groups. Too few CH_2 groups do not provide sufficient interactive force to stabilize the two-dimensional quasi-crystal and are difficult to assemble. More than 24 CH_2 groups have too many options for defects in the crystal, and are also difficult to assemble. Molecules with lengths between 9 and 24 methylene groups will assemble well. Molecular mobility is an important consideration in this surface crystal formation process, so that: (1) the molecules have sufficient time to maneuver into position for tight packing of the binding end groups at the surface; and (2) the chains can enter the quasi-crystal.

The advantages of SAMs are their ease of formation, their chemical stability (often considerably higher than chemically-related LB films), and the many options for changing the outermost group that interfaces with the external environment. Many biomaterials applications have already been suggested for SAMs (Lewandowska et al., 1989; Mrksich and Whitesides, 1996; Ferretti et al., 2000; Raynor et al., 2009). Useful SAMs for creating molecularly-engineered functional surfaces include headgroups of ethylene glycol oligomers, biotin, free-radical

initiators, N-hydroxysuccinimide esters, ATRP or RAFT chain transfer agents, anhydrides, perfluoro groups, and amines, just to list a small sample of the many possibilities. Although most SAMs are based on n-alkyl chain assembly, SAMs can form from other classes of molecules including peptides, proteins (Sara and Sleytr, 1996), porphyrins, nucleotide bases, and aromatic ring hydrocarbons.

LAYER-BY-LAYER DEPOSITION AND MULTILAYER POLYELECTROLYTE DEPOSITION

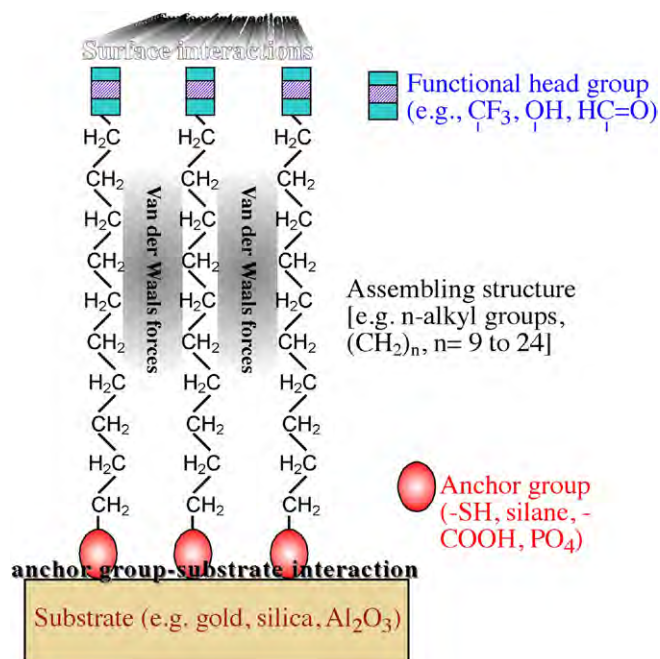
Layer-by-layer (L-b-L) deposition of thin films, and the most common variant of this method, multilayer polyelectrolyte adsorption, has become an important strategy for the surface modification of biomaterials (Decher, 1996; Ariga et al., 2007). For L-b-L surface treatment, a molecule (or polymer or protein) is chosen that adsorbs strong to the substrate (adsorbate 1). Then the substrate is rinsed (retaining adsorbate 1), and dipped in a solution of a molecule that interacts strongly with adsorbate 1
FIGURE I.2.12.7 Three examples of molecules that form organized Langmuir–Blodgett Films.


FIGURE I.2.12.8 General characteristics of molecules that form self-assembled monolayers.

FIGURE I.2.12.9 Layer by layer deposition of a multilayer surface coating. A series of adsorption-rinse steps lead to a multilayer surface deposition: (1) the "blue" compound is adsorbed to the substrate; (2) the adsorbed layer is rinsed in solvent (frequently water) to remove weakly adherent material; (3) the "pink" compound is adsorbed to the blue layer on the substrate; (4) the adsorbed layer is rinsed in solvent to remove weakly adherent material; (5) the "blue" compound is adsorbed to the "pink" adsorbed layer; (6) the adsorbed layer is rinsed in solvent to remove weakly adherent material; (7) the "pink" compound is adsorbed to the blue layer; (8) this process continues to build as many layers as desired.

(adsorbate 2). After rinsing, the surface layer is again dipped in a solution of adsorbate 1. Absorbate 1, adsorbate 2, and the rinsing step are alternated until the coating has the desired multilayer thickness (Figure I.2.12.9). Commonly, the substrate has a fixed positive or negative charge, permitting multilayers of polyanions and polycations. The rinse step is important for the removal of any unadsorbed polyions, as well as for removal of the counter-ions released upon formation of each layer of the polyion complex. Some surfaces are intrinsically charged (for example, mica), others can be modified with

methods already described in this chapter. Once a thin layer of a charged component absorbs, it will repel additional adsorption of the component of the same charge, thus tightly controlling the layer thickness and uniformity. The outermost layer can be the positively or negatively charged component. This strategy works well with charged biomolecules, for example hyaluronic acid (–) and chitosan (+). Layers formed are durable, and assembly of these multilayer structures is simple. The pH and ionic strength of polyelectrolyte solutions are important process variables. The L-b-L process has been used with interacting layers of proteins, nucleotides, saccharides, nanoparticles, acid–base pairs, and H-bonding pairs. L-b-L has been used to coat surfaces, microspheres, nanoparticles, and even living cells. L-b-L layers can be used as reservoirs to contain drug for release or as rate-limiting diffusion barriers. L-b-L films have been used to treat contact lenses, to improve comfort and retard biofilm build-up.

Surface Modifying Additives

Specifically designed and synthesized surface-active compositions can be added in low concentrations to a material during fabrication, and will spontaneously rise to and dominate the surface (Ward, 1989; Wen et al., 1997). These surface modifying additives (SMAs) are well-known for both organic and inorganic systems. A driving force to minimize the interfacial energy leads to the concentration of the SMA at the surface after blending homogeneously with a material. For efficient surface concentration, two factors must be considered. First, the

magnitude of interfacial energy difference between the system without the additive and the same system with the SMA at the surface will determine the driving force leading to an SMA-dominated surface. Second, the molecular mobility of the bulk material and the SMA additive molecules within the bulk will determine the rate at which the SMA reaches the surface or if it will get there at all. An additional concern is the durability and stability of the SMA at the surface.

A typical SMA designed to alter the surface properties of a polymeric material will be a relatively low molecular weight diblock or triblock copolymer (see Chapter I.2.2.). The "A" block will be soluble in, or compatible with, the bulk material into which the SMA is being added. The "B" block will be incompatible with the bulk material and will have lower surface energy. Thus, the A block will anchor the B block into the material to be modified at the interface. This is suggested schematically in Figure I.2.12.10. During initial fabrication, the SMA might be distributed uniformly throughout the bulk. After a period for curing or an annealing step, the SMA will migrate to the surface. Low molecular weight endgroups on polymer chains can also provide the driving force to bring the endgroup to the surface.

As an example, an SMA for a polyurethane might have a low molecular weight polyurethane "A" block and a poly(dimethyl siloxane) (PDMS) "B" block. The PDMS component on the surface may confer improved blood compatibility to the polyurethane. The "A" block will anchor the SMA in the polyurethane bulk (the polyurethane "A" block should be reasonably compatible with the bulk polyurethane), while the low surface energy, highly flexible, silicone "B" block will be exposed at the air surface to lower the interfacial energy (note that air is "hydrophobic"). The "A" block anchor should confer stability to this system. However, consider that if the system is placed in an aqueous environment, a low surface energy polymer (the "B" block) is now in contact with water – a high interfacial energy situation. If the system, after fabrication, still exhibits sufficient chain mobility, it might phase-invert to bring the bulk polyurethane or the "A" block to the surface. Unless the system is specifically engineered to do such a surface phase reversal, this inversion is undesirable. Proper choice of the bulk polymer and the "A" block can impede surface phase inversion.

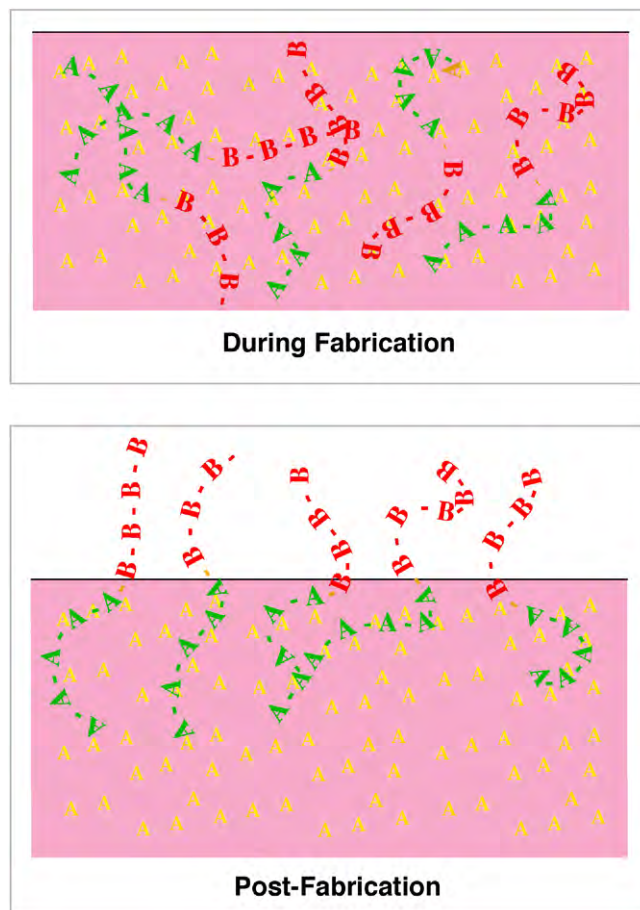
An example of a polymer additive that was developed by 3M specifically to take advantage of this surface chemical inversion phenomena is a stain inhibitor for fabric. Although not intended as a biomaterial, it illustrates design principles for this type of system. The compound has three "arms." A fluoropolymer arm, the lowest energy component, resides at the fabric surface in air. Fluoropolymers and hydrocarbons (typical stains) do not mix, so hydrocarbons are repelled. A second arm of hydrophilic poly(ethylene oxide) will come to the surface in water, and assist with the washing out of any material on the surface. Finally, a third arm of hydrocarbon anchors this additive into the fabric.


FIGURE I.2.12.10 A block copolymer surface-modifying additive comprised of an "A" block and a "B" block is blended into a support polymer (the bulk) with a composition similar to "A" block. During fabrication, the block copolymer is randomly distributed throughout the support polymer. After curing or annealing, the "A" block anchors the surface-modifying additive into the support, while the low-energy "B" block migrates to the air–polymer interface.

Many SMAs for inorganic systems are known. For example, very small quantities of nickel will completely alter the structure of a silicon (111) surface (Wilson and Chiang, 1987). Copper or silver will accumulate at the surface of gold alloys (Tanaka et al., 1988). Also, in stainless steels, chromium will concentrate (as the oxide) at the surface, imparting corrosion resistance.

There are a number of additives that spontaneously surface-concentrate, but are not necessarily designed as SMAs. A few examples for polymers include PDMS, some extrusion lubricants (Ratner, 1983), and some UV stabilizers (Tyler et al., 1992). The presence of such additives at the surface of a polymer may be unplanned, and they will not necessarily form stable, durable surface layers. However, they can significantly contribute (either positively or negatively) to the bioresponse to the surface.

Conversion Coatings

Conversion coatings modify the surface of a metal into a dense oxide-rich layer that imparts corrosion protection (Sørensen et al., 2009), enhanced adhesivity, altered

appearance (e.g., color), and sometimes lubricity to the metal. For example, steel is frequently phosphated (treated with phosphoric acid) or chromated (treated with chromic acid). Aluminum is electrochemically anodized in chromic, oxalic or sulfuric acid electrolytes. Electrochemical anodization may also be useful for surface modifying titanium and Ti-Al alloys (Kasemo and Lausmaa, 1985; Bardos, 1990).

The conversion of metallic surfaces to "oxide-like," electrochemically passive states is a common practice for base metal alloy systems used as biomaterials. Standard and recommended techniques have been published (e.g., ASTM F4-86), and are relevant for most musculoskeletal loadbearing surgical implant devices. The background literature supporting these surface passivation technologies has been summarized (von Recum, 1986).

Base metal alloy systems, in general, are subject to electrochemical corrosion (M * M$^+$ + e$^-$) within saline environments. The rate of this corrosion process is reduced 10^3–10^6 times by the presence of a dense, uniform, minimally conductive, relatively inert oxide surface. For many metallic devices, exposure to a mineral acid (e.g., nitric acid in water) for times up to 30 minutes will provide a passivated surface. Plasma-enhanced surface passivation of metals, laser surface treatments, and mechanical treatments (e.g., "shot peening") can also impart many of these characteristics to metallic systems.

The reason that many of these surface modifications are called "oxide-like" is that the structure is complex, including OH, H, and subgroups that may or may not be crystalline. Since most passive surfaces are thin films (5–500 nm), and are transparent or metallic in color, the surface appears similar before and after passivation. Further details on surfaces of this type can be found in Chapters I.1.5, I.2.3, and II.4.4.

Parylene Coating

Parylene (para-xylylene) coatings occupy a unique niche in the surface modification literature, because of their wide application to biomedical devices and the good quality of the thin film coatings formed (Loeb et al., 1977a; Nichols et al., 1984). The deposition method is also unique and involves the simultaneous evaporation, pyrolysis, deposition, and polymerization of the monomer, di-para-xylylene (DPX), according to the following reaction:

Di-para-xylylene   Para-xylylene

1) vaporize   2) pyrolyze

Poly (para-xylylene)
3) deposit

The DPX monomer is vaporized at 175°C and 1 torr, pyrolyzed at 700°C and 0.5 torr, and finally deposited on a substrate at 25°C and 0.1 torr. The coating has excellent electrical insulation and moisture barrier properties, and has been used for protection of implant electrodes (Loeb et al., 1977b; Nichols et al., 1984) and implanted electronic circuitry (Spivack and Ferrante, 1969). A parylene coating has been used on stainless steel cardiovascular stents between the metal and a drug-eluting polymer layer (see Chapters II.5.3.B and II.5.18).

Laser Methods

Lasers can rapidly and specifically induce surface changes (roughness, crystallinity, chemistry) in organic and inorganic materials (Picraux and Pope, 1984; Dekumbis, 1987; Chrisey et al., 2003). The advantages of using lasers for such modifications are the precise control of the frequency of the light, the wide range of frequencies available, the high energy density, the ability to focus and raster the light, the possibilities for using both heat and specific excitation to effect change, and the ability to pulse the source and control reaction time. Lasers commonly used for surface modification include ruby, neodymium:yttrium aluminum garnet (Nd:YAG), argon, argon-fluoride eximer, and CO$_2$. Treatments are pulsed (nanosecond to picoseconds pulse times) and continuous wave (CW), with interaction times often less than 1 msec. Laser-induced surface alterations include annealing, etching, deposition, and polymerization. Polymers, metals, ceramics, and even tooth dentin have been effectively surface modified using laser energy. The major considerations in designing a laser surface treatment include the absorption (coupling) between the laser energy and the material, the penetration depth of the laser energy into the material, the interfacial reflection and scattering, and heating induced by the laser.

Hundreds of papers have been published on laser surface modification. Examples include: (1) a Nd:YAG laser was used to treat titanium implants permitting improved hydroxyapatite nucleation and more rapid integration into bone (Faeda et al., 2009); (2) laser irradiation at 810 nm of silicone rubber induced a "lotus leaf-like" texture that imparted superhydrophobic properties to the silicone polymer (Yoon et al., 2008); (3) eximer laser irradiation at 193 nm permitted fine spatial patterning of polystyrene for improved protein adsorption and cell interactions (Pfleging et al., 2009).

Patterning

Essentially all of the surface modification methods described in this chapter can be applied to biomaterial surfaces, either as a uniform surface treatment or as patterns on the surface with length scales of millimeters, microns or even nanometers. There are many options to pattern biomaterial surfaces. These include ion beam etching, electron beam lithography, laser methods, inkjet

printers, and stochastic patterns made by phase separation of two components (Takahara et al., 2000). Chapter I.2.13 elaborates on methods to pattern biomaterials.

CONCLUSIONS

Surface modifications are widely applied to modulate or enhance the biointeractions of biomedical devices and improve other aspects of performance. Surface modification is used in the laboratory setting, and also for the treatment of medical devices used in the clinic. Since a medical device may already have appropriate physical properties and be well-understood in the clinic, surface modification provides a means to alter only the biointeractions of the device without the need for redesign, retooling for manufacture, and retraining of medical personnel.

CHAPTER I.2.13 SURFACE PATTERNING

Ryan T. Hill[1] and Ashutosh Chilkoti[2]

[1]Center for Biologically Inspired Materials and Material Systems, Duke University, Durham, NC, USA

[2]Center for Biologically Inspired Materials and Material Systems and Department of Biomedical Engineering, Duke University, Durham, NC, USA

INTRODUCTION

Surface patterning is the use of surface modification methods to create chemically or physically demarcated regions on a surface. The art of patterning surfaces has a long history; the recent antecedent methods to pattern biomolecules are derived, in part, from the microelectronics industry (Xia and Whitesides, 1998; Whitesides et al., 2001; Geissler and Xia, 2004). As hand-wiring small, complex electronic devices became increasingly difficult, new methods were developed to pattern substrates such that many electrical components and interconnects between the different components of these devices could be created on the surface of a relatively large substrate in a batch process. These processes that have been instrumental to the development of all modern electronic devices have been driven by a set of technologies to create micro- and nanoscale features on the surface of semiconductors that are collectively and somewhat loosely termed "photolithography."

Many of these surface patterning techniques, especially photolithography, have become important tools for biomedical research. The unique demands of biomedical research (for example soft hydrated materials such as proteins and hydrogels in an aqueous environment), impose a special set of demands and constraints on patterning methods. Seen from this broader perspective, it might be argued that the conceptual origins of many of the techniques used to pattern biomolecules on surfaces extend back to the pre-industrial era, to techniques that were developed to print on paper and textiles, such as block printing, screen printing, lithography, and batik.

This chapter focuses on surface patterning in the realm of biomedical research. The goal of this chapter is to familiarize the reader with various surface patterning techniques, and how these techniques can be used in biomedical research. First we discuss important figures-of-merit of patterning methods that allow different methods to be compared with each other, and allow a user to decide which patterning method is most appropriate for a specific application. Then, we discuss various types of patterning techniques, and follow up with a brief conclusion.

Some chapters in this textbook that provide background information for this chapter include I.1.5 (Surface Properties and Surface Characterization), I.2.10 (Non-Fouling Surfaces), and I.2.12 (Physico-Chemical Surface Modification of Materials Used in Medicine). However, as will quickly become apparent, this chapter has implications for many other chapters in the book.

COMMON CONCERNS IN BIOMOLECULAR SURFACE PATTERNING

Surface patterning is carried out for a wide variety of reasons and, in turn, the ultimate goal of the patterned substrate defines a set of constraints or concerns that dictate how the fabrication process should be carried out. Surface patterning within the scope of biomaterials research is largely focused on the patterning of biomolecules or the patterning of cells. Listed below are important figures-of-merit (FOMs) and concerns that typically need to be addressed in patterning biomolecules or cells on solid substrates for a specific application. We also briefly discuss how the selection of an appropriate patterning methodology for a particular application is not usually influenced by a single FOM, but is usually dictated by the technique that offers the best combination of several FOMs.

Resolution

Resolution refers to the smallest feature size that can be reliably created by a patterning technique. Although the resolution of new techniques is constantly pushed towards smaller feature sizes and finer control, it is also useful to know what *range* of feature sizes a particular technique is capable of producing. Figure I.2.13.1 shows an example of different size patterns created with a high-resolution technique, as well as patterns created with a lower-resolution technique but one that is capable of a wider range of feature sizes. The highest resolution is not necessarily better, as the desired resolution depends upon the application. Thus, to pattern cells whose dimension are at least several micrometers, a technique with a relatively low resolution in the micrometers range is likely adequate, as long as it can pattern a large enough area, i.e., have a high enough throughput, which is discussed next.

Throughput

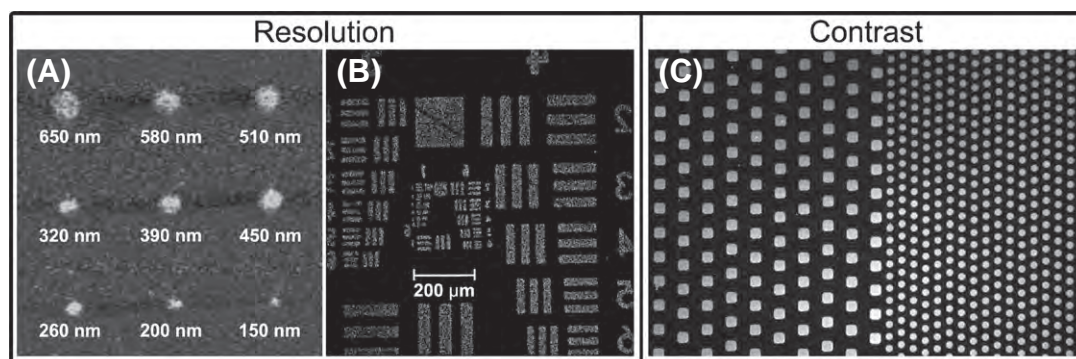
While resolution refers to the smallest possible feature size that can be created by a patterning technique, *throughput* is a measure of the surface area that can be patterned in a given time. The throughput of a patterning technique is especially important for its use in manufacturing of devices where it is imperative that the patterned substrates can be produced on large length scales and on a timescale that is useful for manufacturing – minutes to hours, rather than days to weeks. Although the different types of patterning techniques are discussed later in this chapter, here we briefly discuss a few patterning methods to illustrate throughput considerations. Direct-write or "on-the-fly" types of patterning methods are those that use a stylus and ink to pattern a surface. These techniques usually provide precise control over the patterning process and finer feature sizes – often sub-100 nm – than some other printing methods such as microcontact printing, and can often create arbitrary feature shapes. Patterning large areas (i.e., greater than hundreds of square micrometers) rapidly, however, is challenging for most variants of this type of patterning. On the other hand, techniques based on printing using a stamp can readily pattern large areas of a surface quickly (in the order of seconds to minutes), but may only be able to access certain shapes of features (e.g., circles, lines or squares), and may have limited resolution (i.e., on the micrometer scale or greater).


FIGURE I.2.13.1 Examples of Resolution and Contrast in Surface Patterning. (A, B) (Two "Resolution" images): features of different sizes created with a high-resolution patterning technique: (A) Lee et al., 2006a; and relatively lower-resolution technique: (B) Yang et al., 2000. (C) (Two "Contrast" images): the example in (C) represents a higher throughput process, since a large range of feature sizes and a larger surface area can be patterned in a one-patterning process. This is an example of high contrast due to patterning on a non-fouling surface that minimizes background signal (10 μm square features and 5 μm circular features) (Hucknall et al., 2009a). (A) is adapted with permission from Wiley-Blackwell. (B) is adapted with permission from (Yang, Z., Frey, W., Oliver, T., & Chilkoti, A. (2000). Contrast

Contrast is the degree to which the components in the pattern are distinguishable from the background substrate (Figure I.2.13.1). In many surface patterning methodologies, contrast is achieved by patterning one material on the surface of another material. In patterning biomolecules, however, contrast is usually defined as the surface density of the deliberately patterned biomolecule of interest relative to other biomolecules that might adventitiously be bound to the background regions of the same surface, as a consequence of the patterning method. Contrast in patterns of active molecules, such as enzymes or antibodies, can be assessed by measuring the activity of the patterned molecules after the patterning process. For example, enzyme patterns can be visualized by monitoring the concentration of insoluble fluorescent products created by the enzyme (usually via their fluorescence intensity) from the patterned regions relative to the unpatterned background regions when incubated with a soluble, non-fluorescent enzyme substrate. Another example of biomolecular patterning in which the activity of the patterned molecule can be used to measure the contrast is when the patterned molecule has an affinity for another molecule, as is the case for antibody/antigen and many protein–ligand interactions (e.g., avidin-biotin). Here, contrast can be visualized by exposing the pattern to a complementary target molecule containing a fluorescent, radioactive or plasmonic tag that enables visualization of the pattern.

In rare cases, biomolecular patterning involves molecules with a functional activity or activity that is difficult to assess in a purely *in vitro* setting. In these cases, pattern contrast is often visualized by exposure to a secondary processing step for pattern visualization. For example, contrast in patterned peptides that act as cues for cell adhesion can be visualized by exposing the pattern to cells in culture, and the degree of cell patterning is an indirect measure of the fidelity and contrast of the pattern.

Contrast in biomolecular patterning is heavily dependent on surface properties of not only the pattern itself, but also of the background. Biomolecular patterns are often exposed to solutions that can contain complex mixtures of proteins and other molecules in the course of their use, and most surfaces are particularly prone to *nonspecific* and *irreversible adsorption* of proteins. Removing nonspecifically adsorbed proteins requires the use of detergents or other harsh conditions that are typically not suitable for many biological applications. Thus, maintaining contrast in biomolecular patterning usually involves some sort of passivation step to prevent two sets of undesirable events: (1) adsorption of the molecule to be patterned on the unpatterned background regions; (2) adsorption of biomolecules – that are to be subsequently exposed to the patterned surface – onto the patterned features or the background regions of the surface (Figure I.2.13.2).

Non-specific adsorption can be reduced by methods of varying degrees of complexity (also see Chapter I.2.10). Perhaps the most common and simplest way to reduce non-specific adsorption is to use proteins that adsorb to surfaces, such as bovine serum albumin (BSA), under the assumption that controlled deposition of a surface-active protein will prevent the immobilization of most other molecules to the substrate. However, adsorption of BSA often leads to sub-monolayer coverage of the surface, and it has been shown that proteins can adsorb to a BSA layer (Hyun et al., 2001), so that this strategy, despite its widespread use, is of limited utility.

A more effective way of reducing non-specific adsorption is to create a "*non-fouling*" surface. Non-fouling surfaces are typically defined as surfaces that have a molecular or polymer layer that prevents the adsorption of proteins on a surface. A common method to create a non-fouling surface is to form a dense layer of polyethylene glycol (PEG) on the surface. Here, the network of ethylene glycol molecules effectively creates a hydrated barrier between the bulk solution and the solid surface. Proteins in solutions can diffuse into and out of the network without becoming immobilized to the surface. The degree of protein resistance is related to the density of PEG molecules on the surface (Ma et al., 2006a; Hucknall et al., 2009a; Zauscher and Chilkoti, 2009). Unfortunately, most methods to adsorb PEG or chemically attach it to the surface (Lee et al., 1989; Amiji and Park, 1993; Llanos and Sefton, 1993; Prime and Whitesides, 1993; Elbert and Hubbell, 1998; Liu et al., 2002; Xia et al., 2002; Bearinger et al., 2003) do not provide a high enough density of oligoethylene glycol moieties on the surface. In these cases the PEG will decrease, but will not eliminate the adsorption of proteins, especially from highly complex and concentrated protein mixtures such as serum and plasma.

In situ polymerization methods, also termed surface-initiated polymerization, in which an initiator is tethered to a surface and a PEG-like coating is directly grown from the surface, are a powerful method to grow a dense layer of a polymer that presents a high density of oligoethylene glycol moieties at the surface. Such surfaces are highly resistant to protein adsorption (Ma et al., 2004, 2006a,b; Hucknall et al., 2009a,b,c; Zauscher and Chilkoti, 2009), and patterns made on these non-fouling surfaces remain functional for extended periods of time in cell culture (Ma et al., 2004).

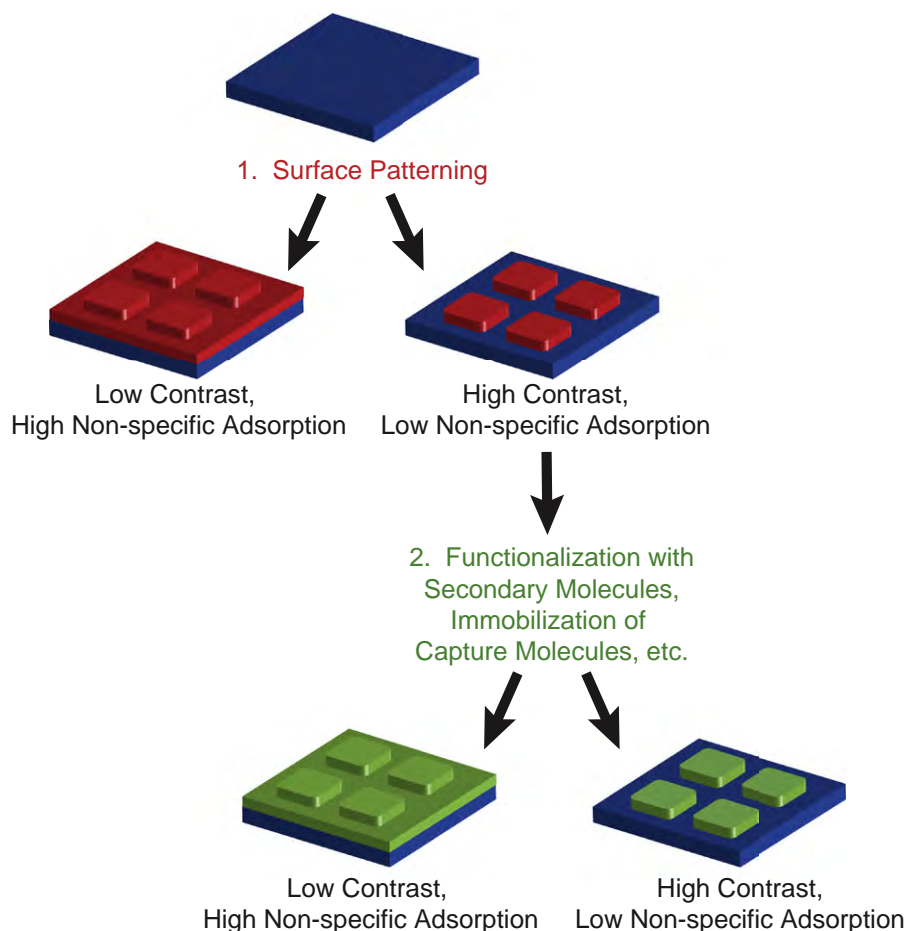
Other methods that are also useful to create non-fouling interfaces include self-assembled monolayers of alkanethiols that present an oligoethylene glycol moiety at the solid–water interface (Prime and Whitesides, 1993; Herrwerth et al., 2003), inter-penetrating polymer networks that present PEG at their solvent interface (Bearinger et al., 2003), plasma-deposited "PEG-like" films deposited from oligoglyme precursors (López et al., 1992), and the deposition of PEG-poly(lysine) (PEG-PLL) by electrostatic adsorption (Kenausis et al., 2000;


FIGURE I.2.13.2 Contrast and Non-Specific Adsorption. Maintaining contrast during patterning of biomolecules often requires that: (1) the patterned materials have low non-specific adsorption to the background substrate; and (2) that any molecules used in subsequent steps (functionalization of pattern with secondary, reporter molecules; immobilization of antigens or capture molecules from solutions; etc.) also have low non-specific adsorption to the background.

Huang et al., 2001). However, some of these methods are somewhat limited in their utility across a range of polymer substrates. For example, PEG-PLL is only useful for negatively-charged surfaces, and has typically been most successful with metal oxide surfaces that have a negatively-charged surface, while oligoethylene glycol-terminated self-assembled monolayers (SAMs) are only applicable to gold and silver.

Bioactivity

Preserving the bioactivity of a biomolecule during the patterning process is a significant and non-trivial concern. Many patterning processes, especially those that are adapted from the semiconductor processing industry, can involve exposure of the surface to extreme environments, such as high vacuum, extreme temperatures, and non-aqueous conditions, which can denature or degrade biomolecules. Methods that are compatible with aqueous conditions and ambient temperature are hence preferable when deciding upon a method to pattern a biomolecule – especially proteins – on surfaces, as they are especially prone to denaturation

compared to other biomolecules such as peptides and oligonucleotides.

Shelf-Life and Durability

The shelf-life and durability of the pattern over time is another consideration when choosing a patterning methodology. This is especially important in the case where patterns need to be generated for use in diagnostic or point-of-care devices. The ultimate convenience in such a situation would be one where a fully functional pattern can be manufactured, stored in ambient conditions for an unspecified amount of time, and then used by the end-user. These conditions can easily be met when patterning "hard" materials, such as those used in micro-electronics, because they are typically not very sensitive to their environment. However, when "soft-wet" materials – hydrated polymers, proteins, and cells – are patterned, the exposure of these materials to vacuum, high temperature or extremes of pH becomes a critical and often limiting issue, because many of these materials are easily degraded, destroyed or irreversibly denatured under these conditions. For this reason, special care is

needed to ensure that all biological components involved in the patterning process are maintained in a functional state. Ensuring this may involve strategies such as sealing the devices in a hydrated environment so that they are protected from the environment until they are ready for use, using preconditioning steps to prepare the surface prior to analysis or integration of rinsing steps into the analysis scheme. In some instances it may be necessary to create the patterned substrates that act as a template for patterning biomolecules, and then functionalizing the pattern with the biomolecule of interest, on demand, immediately prior to its use. An example of this approach would be the fabrication of a pattern of a non-fouling polymer on a substrate, which can be stored for an extended period of time under ambient conditions. Immediately prior to use, hydration of the surface and incubation in a protein solution drives adsorption of the protein only to the unpatterned regions, leading to the spontaneous formation of a protein pattern driven by the thermodynamic template on the patterned surface. This approach has the advantage of obviating the need to store the surface in a hydrated environment, which would have been necessary if the surface had been patterned with a protein at the outset, rather than on-demand.

In addition, it is also useful to know how long a pattern will stay patterned under the end-use conditions. This is especially important for substrates patterned for cell growth or for implantation into the body that need to retain functionality for extended periods of time. For this reason, researchers will often report an FOM that alludes to the life of the pattern by stating, for example, how long the cells remain confined to the pattern in cell culture.

PATTERNING TECHNIQUES

The number of different surface patterning techniques increases daily, with new publications that present novel patterning schemes or variants of existing methodologies. This chapter seeks to provide a short discussion of the different categories of patterning techniques, and within each category points out some interesting examples; this chapter is not an exhaustive compendium of all patterning techniques.

Much of the overall organization or structure of this section owes an intellectual debt to the excellent and comprehensive review by Geissler and Xia (2004). However, the content of this section places greater emphasis on patterning for biomedical applications. We first present direct-write patterning techniques; these techniques typically provide high resolution at the expense of speed and throughput. Presented next are mask- and master-based patterning techniques, which provide high throughput and can pattern large surface areas, but often have lower resolution compared to direct-write techniques. Next, patterning by self-assembly is described, which is a powerful technique for patterning large surface areas with high-resolution features by exploiting intermolecular
FIGURE I.2.13.3 Types of Direct-Write Patterning. Inkjet, beams, focused fields, dip-pen nanolithography (DPN), and imprinting.

interactions. We also present a brief section on the use of dynamic patterning for interrogation of biological environments. Finally, we conclude with a few examples of three-dimensional patterning techniques that can be used to control the three-dimensional microenvironment of cells.

Direct-Write Patterning

In direct-write patterning techniques, patterns are fabricated by serially scanning a patterning element across a substrate. Direct-write patterning is a useful method because patterns of arbitrary feature shape and size – within the resolution limit of the technique – can be fabricated on-the-fly, in a process analogous to writing with a pen. In addition, direct-write patterning can generate extremely high-resolution features with great spatial accuracy. The drawbacks of direct-write patterning techniques are that they are typically slow, low-throughput, and not particularly suitable for large area patterning, because of the need to serially write the pattern. This limitation can be addressed, at the cost of greatly increased complexity of the instrumentation, by using independently actuated pens. Several direct-write techniques are described next and are grouped by the type of "pen" that is used to write the pattern (Figure I.2.13.3).

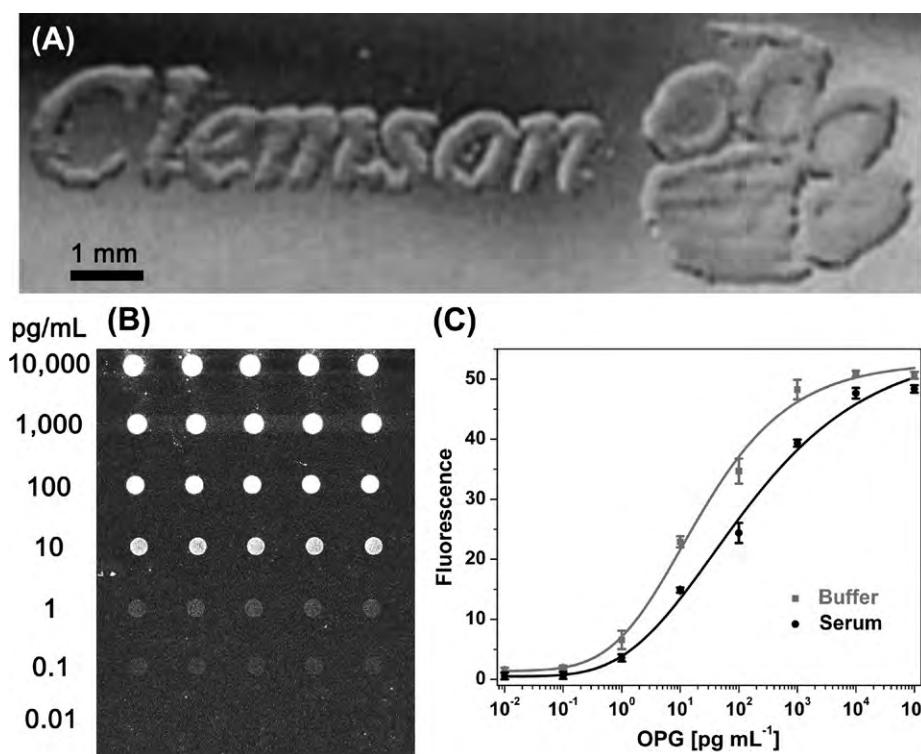
Writing with a Stylus. This section describes direct-write patterning techniques that use a rigid stylus to write the pattern. Dip-pen nanolithography (DPN), nanoimprinting, and nanoengraving (also called nanoshaving) are typical direct-write methods that use tips under control of an atomic force microscope (AFM) to write the pattern. Very fine AFM tips are available, and AFMs have nanometer positional control, thus, DPN, nanoengraving, and nanoshaving can all produce very high-resolution, sub-100 nm features. In contrast, inkjet printing produces coarser features, with the best lateral resolution of ~10 μm, and more often in the order of 100 μm. Inkjet systems, however, can be easily multiplexed, making them very attractive for patterning biomolecules in diagnostic devices, such as protein and DNA microarrays.


FIGURE I.2.13.4 Inkjet Printing. A colony of bacteria printed in the shape of a university logo by a modified consumer-grade inkjet printer (A) (Xu et al., 2004). An inkjet printed antibody microarray on a non-fouling surface (B) is used for ultrasensitive detection in complex mixtures such as blood and serum (C) (Hucknall et al., 2009c). (A–C) are adapted/reprinted with permission from Wiley-Blackwell.

Printing with Inkjets, Quills, and Pins. Inkjet printing refers to any method where liquid is pumped through a nozzle and onto a substrate in a defined pattern. Inkjet printers deliver liquid solutions as small droplets – typically 10–20 pL in volume (Geissler and Xia, 2004) – that are either continuously pumped through the nozzle head, electrostatically charged, and then guided via electric fields or generated on demand by thermally or mechanically triggered pressure pulses (Derby, 2008). The liquid inks are typically stored in reservoirs and pumped into the printer as needed. Inkjet nozzles are usually very small (20–30 μm in diameter) (Geissler and Xia, 2004), which enables them to be mounted on nozzle heads that can be interfaced with computers to control the fabrication of patterns. The resolution limit of inkjet printing is in the range of tens of micrometers, and is limited by the droplet volume, droplet spreading on the substrate (which varies depending on the ink and the surface), and other mechanical factors. Some useful features of inkjet printing are: (1) patterning is contact-free and can be performed under ambient conditions on a range of solid substrates; (2) the method has high positional accuracy; (3) multiplexed printing of analytes is easily accomplished by use of multiple nozzles and/or nozzle heads; and (4) high-throughput patterning over large surface areas can be accomplished by robotic automation.

Inkjet printing of biomolecules has gained popularity in recent years, in part due to the simplicity of the technique and the widespread availability of cheap printers.

Thomas Boland's research group demonstrated that low-cost consumer inkjet printers could be adapted to print "biological inks" with their demonstration of the inkjet printing of proteins (Pardo et al., 2003), live cells (Xu et al., 2005, 2006a), and bacterial colonies (Xu et al., 2004). Figure I.2.13.4 shows a "living advertisement" – a colony of bacteria printed in the shape of a university logo – printed by Boland and co-workers.

Automated robotic inkjet printing systems designed to print "biological inks" such as DNA or proteins are typically called microarray printers, and are much more sophisticated and expensive than consumer-grade inkjet printers. These systems are often self-contained in an environmentally controlled chamber, and can run complex protocols involving delivery of multiple solutions as well as rinsing steps. Such systems are used to create spatially addressable arrays of biomolecules, such as DNA microarrays (Marshall and Hodgson, 1998; Bier et al., 2008). However, much of this work used arrays fabricated not by inkjet printers, but by pin-based arrayers in which pin arrays are dipped into solutions and then contact printed onto a surface (DeRisi et al., 1997), or else arrays that were fabricated by on-chip, photolithographic synthesis of spatially addressable arrays of oligonucleotide probes, such as the Affymetrix oligonucleotide array technology (Fodor et al., 1991). Since the advent of the human genome project and the rise of genomics, microarrays have migrated into other fields because they provide a convenient, high-throughput, and multiplexed methodology to

characterize biomolecules. For example, protein arrays are used in proteomics (Caiazzo et al., 2009), and have been used to identify protein markers for disease (Orchekowski et al., 2005). Pin-based arrayers have also largely been used to fabricate protein arrays (MacBeath and Schreiber, 2000; Ray et al., 2007), because it is significantly cheaper and less complex to manufacture arrayers with a large number of pins or quills, compared with scaling-up the number of independently actuated inkjets beyond a dozen. Similarly, both pin-based (Pilobello et al., 2005, 2007; Pilobello and Mahal, 2007) and inkjet microarrays (Nagaraj et al., 2008) have been used to fabricate lectin arrays for glycomics. Microarrays have also been used as clinical diagnostics to detect specific analytes (Delehanty and Ligler, 2002; Hucknall et al., 2009c). For example, the Chilkoti group has used inkjet printed microarrays of antibodies on a non-fouling polymer brush for the detection of multiple protein analytes from serum and blood with a femtomolar limit-of-detection (Hucknall et al., 2009c) (Figure I.2.13.4).

Dip-Pen Nanolithography (DPN)

DPN is the nanoscale equivalent of writing with a quill. In DPN, AFM probes are inked with a solution of molecules and then scanned along a surface to write a pattern of the ink. The ink solution forms a small meniscus between the tip of the probe and the surface, which transports biomolecules from the tip to the surface. DPN has been used to pattern alkanethiols (Hong et al., 1999; Piner et al., 1999), as well as a range of biomolecules including DNA (Demers et al., 2002), proteins (Lee et al., 2002, 2006a), functional enzymes (Hyun et al., 2004a), biopolymers (Hyun et al., 2004b), and viruses (Vega et al., 2005) on many different materials. The resolution limit of DPN is on the order of tens of nanometers, and this method can create patterns that extend over several hundred micrometers, which is the limit of most AFM scanners. Single probe DPN patterning is also relatively low-throughput, as it is a somewhat slow and serial patterning technique. For example, in an early report on DPN (Piner et al., 1999), 10 minutes were required to create a 1 μm × 1 μm feature.

High-throughput DPN can be performed by mounting multiple probes on a single scan head. Perhaps the most impressive work to date in this regard is that of Chad Mirkin's group, where 55,000 DPN probes were inked with a thiol solution, and used simultaneously to generate massively high-throughput, high-resolution patterns (Figure I.2.13.5A) (Salaita et al., 2006). In this demonstration, the face of Thomas Jefferson from a US five-cent coin was generated 55,000 times, with each face containing 470 *million* nanoscale features, in less than 30 minutes (Figure I.2.13.5B). Commercial DPN systems are now available that are capable of multi-probe patterning of nanoscale-to-microscale patterns over areas as large as 40 mm^2 (NanoInk, Inc.). For good reviews of DPN, see Krämer et al. (2003), and Mendes et al. (2007).

Imprinting/Engraving

Nanoscale imprinting and engraving of surfaces can be accomplished by indenting or scraping a surface with a hard stylus, such as an AFM probe. Such techniques have similar advantages and limitations as DPN, as the patterning mechanism is very similar. *Nanoshaving* is a term used to describe the process of scratching patterns in thin molecular layers, such as SAMs, on a bulk substrate (Liu et al., 2000). Here, arbitrary patterns in the molecular layer are engraved by dragging the probe on the surface. A two-step process can be used to functionalize the exposed, underlying substrate with a secondary molecule. For example, nanoshaving has been used to selectively degrade a protein-resistant SAM on gold, which was then exposed to a solution of an antibody (Kenseth et al., 2001). Nanopatterns of antibodies were formed on the surface as the antibodies adsorbed to the exposed regions of the substrate that were no longer protein resistant. *Nanografting* – a variant of nanoshaving – involves scratching the surface in the presence of a secondary molecule with high affinity to the underlying substrate (Xu and Liu, 1997; Liu et al., 2000) so that the secondary molecule fills in the regions that are cleared away by the scanning probe. Nanografting has also been used to create nanopatterns of enzymes, antibodies (Wadu-Mesthrige et al., 1999, 2008; Hu et al., 2005), and DNA (Liu et al., 2002) on a surface.

Writing with Beams

This section describes patterning methods that scan an energetic beam over a surface to create a pattern. The spatial resolution of this class of patterning techniques is generally limited by the spot size of the beam. Beams of photons are used for patterning in direct-write photolithography, and thus the spot size (and hence, resolution limit) is set by the optical diffraction limit, which is ~200 nm. However, the diffraction limit can be overcome by using near-field methods, such as scanning near-field lithography, to create features in which the smallest dimension is ~tens of nanometers. Direct-write photolithography is particularly conducive to patterning biomolecules, as these methods are compatible with aqueous conditions. Electron beam lithography and focused ion beam lithography represent two other methods in this class of patterning techniques that have higher spatial resolution than conventional far-field photolithography. In these methods, shorter wavelength radiation is used than in photolithography, which leads to smaller spot sizes, and hence higher lateral resolution. Electron beam lithography and focused ion beam lithography, however, usually require high vacuum and dry samples, which can be a serious impediment to patterning biomolecules.

Direct-Write Photolithography

In *direct-write photolithography*, a beam of focused light is used to pattern a substrate directly. Here, light is usually focused into small spots using conventional light optics, and patterns are formed by photochemical or physical modification of the surface. The resolution of features patterned with conventionally focused beams of light is governed by the optical diffraction limit, which is roughly half of the wavelength of the light used for excitation (Dunn, 1999). Thus, patterns formed by focused light typically have a minimum feature size of several hundred nanometers. Feature sizes can be scaled upwards using larger spot sizes; however, intensity requirements of the patterning process or the amount of light-per-area necessary to form patterns, can in some cases be a limiting factor in producing larger features, as light intensity decreases with larger spot sizes. Although broadband light sources can be used for direct-write photopatterning, lasers are more commonly used for this application, because they provide high-intensity beams of a single wavelength which allows precise control of specific photochemical reactions.

Patterning with light is generally performed using a photochemical mechanism or a mechanism that induces a spatially localized physical change in the underlying substrate. In direct-write patterning via photochemistry, light is used to locally activate photoactive molecules that subsequently either form a pattern directly or react with another species to form a pattern. In some cases, the activated species is created in one step, and then another step is necessary to expose the activated species to the biomolecule to be patterned. However, in other cases the photoactivated species is generated in the presence of the secondary species to be patterned, and thus the pattern is created in one step. Another one-step patterning scenario is the case where the photoactive molecule is covalently attached to the molecule to be patterned. Photochemical patterning with light has been widely used to create patterns of proteins on a substrate. For example, Holden and Cremer used a laser to pattern enzymes directly within flow channels (Holden et al., 2004) (Figure I.2.13.6A), a methodology that can be applicable to lab-on-a-chip devices.

In the second methodology to pattern biomolecules using light, a laser is used to pattern substrates by physically
FIGURE I.2.13.6 Examples of Direct-Write Protein Patterning with Light. (A) Patches of enzymes (locations indicated by dashed boxes in the figure) patterned within flow channels produce fluorescent products when exposed to fluorogenic reagents; (B) Sub-diffraction limit features patterned with light using near-field excitation. Here, 15 nm lines were written in a self-assembled monolayer on gold (Ducker et al., 2007b). (A) is adapted with permission from (Holden, M. A., Jung, S. -Y., & Cremer, P. S. (2004). (B) is adapted with permission from the authors and SPIE.

altering a spatially localized region of a substrate. This type of patterning is conceptually similar to engraving with AFM tips, with the only difference being that the substrate material – polymers or resins – are ablated, melted or deformed due to the high energy of the focused laser spot, instead of being physically excavated (Joglekar et al., 2003). For example, Nielson and Shear used a high-energy pulsed laser to ablate pores in a membrane separating adjacent flow cells (Nielson and Shear, 2006). They showed that this technique could be used to dose cells with precisely located chemical gradients. In another example, the Yasuda group used a focused laser to photothermally etch microchambers in agar for use in single cell experiments (Kojima et al., 2003; Sugio et al., 2004; Suzuki et al., 2004).

Patterning with light can be used to create feature sizes that are much smaller than those created using diffraction-limited optics. An example of ultra-small direct-write photolithography is patterning by scanning near-field photolithography (SNP) that uses a near-field scanning optical microscope (NSOM) to create nanoscale patterns using light in the near field. In SNP, light is passed through a metal-coated optical fiber that is tapered to a ~50 nm aperture at its end that acts as a sub-wavelength light source. When in ~10 nm (Betzig and Trautman, 1992; Wegscheider et al., 1995) proximity to a photoactive substrate, the light source can excite chromophores in the near-field via the non-diffracting evanescent field that emerges from the tip, and thus can create patterns that are well below the diffraction limit. Leggett and co-workers have extensively used this technique to create nanoscale patterns of proteins and self-assembled monolayers (Sun et al., 2002; Sun and Leggett, 2004; Ducker and Leggett, 2006; Ducker et al., 2007a,b) (Figure I.2.13.6B).

Electron Beam Lithography

Direct-write *electron beam lithography* (EBL) uses similar patterning principles as that of patterning with focused light. However, in EBL, a focused beam of electrons (e-beam) is used as the stylus to write patterns in an e-beam sensitive material. The focused energy from the e-beam can initiate cross-linking (Brough et al., 2007; Christman et al., 2009) or functionalization (Eck et al., 2000; Golzhauser et al., 2001; Schmelmer et al., 2007; Steenackers et al., 2007) of surface moieties on the substrate. Since the e-beam radiation is of a much shorter wavelength than that used in direct-write photolithography, the spatial resolution of EBL is greater than direct-write photolithography. For this reason, EBL is a very powerful technique for creating patterns at the nanoscale, with feature sizes of 10–100 nm easily fabricated by EBL (Ducker et al., 2008). EBL, however, has several limitations: first, although existing scanning electron microscopy (SEM) systems can be easily configured for EBL, they are expensive, so EBL is not a routine technique that can be set up in a laboratory, and hence requires access to a dedicated instrument that is typically located in a shared instrumentation facility. Second, EBL requires high vacuum, which limits its utility for patterning biological molecules. Third, EBL is slow and can only pattern relatively small areas, although larger areas can be "stitched together" by moving the substrate using a motorized stage. The high resolution, low throughput, and high cost make EBL useful largely as a method for high-resolution fabrication of nanoscale patterns over a small area. As biological molecules generally do not remain functional in high vacuum, and are easily damaged by e-beam radiation, substrates are typically first patterned by EBL and then exposed to a biological molecule of interest for selective attachment of the biomolecule to the patterned features. An elegant example of patterning by EBL is the work done by Heather Maynard's group, where multi-component protein patterns were fabricated by e-beam cross-linking of functionalized PEG molecules. These functional PEG patterns were then used to immobilize proteins from solutions via specific binding interactions between the proteins and the ligands presented by the PEG patterns (Christman et al., 2009) (Figure I.2.13.7, left).
FIGURE I.2.13.7 Examples of EBL (left) and FIB (right) Patterning. Shown on the left is an example of EBL where multi-component protein patterns were formed by electron beam cross-linking and subsequent functionalization of poly(ethylene glycol) molecules. Soc., 127(30), 10707–10711). Copyright (2005) American Chemical Society.

Focused Ion Beam

A *focused ion beam* (FIB) can also be used for direct-write patterning. FIB patterning is similar to EBL in its advantages and limitations; however, FIB patterning makes use of high-mass ions, such as gallium ions, as the energetic particles instead of electrons as in EBL. FIB patterning is an inherently destructive process, as the bombardment of a surface with ions causes atomic sputtering of atoms from the surface. For this reason, FIB is typically used as a milling technique to engrave a surface with submicrometer size features. For example, Hill et al. used an FIB to open a conductive circuit by milling a gap in a metallized protein-based wire (Hill et al., 2005) (Figure I.2.13.7, right). FIB can also be used to sputter metals (Reetz et al., 1997) onto a surface, which makes FIB useful in repairing integrated circuits (Geissler and Xia, 2004).

Writing with Fields

Direct-write patterning with fields includes scanning electric and magnetic fields across a substrate to form a pattern. Features generated by direct-write electric field scanning typically have a lower spatial resolution than that attainable with other direct-write techniques. Similar to other scanning techniques, writing with fields is slow and is unsuitable for large area patterning. However, scanning electrodes allow one to perform extremely localized electrochemical reactions. Direct-write magnetic patterning is mostly geared towards data storage and, as it has not been used for sputtering biomolecules, only the underlying principle will be briefly described in this section.

Electric Field

Direct-write patterning with electric fields is accomplished by scanning an electrode near a surface to locally modify the surface using charge or current. Patterning is mediated through a variety of electrochemical processes, which include localized charging, ohmic heating, and redox reactions. Scanning electrochemical microscopy (SECM), which was developed by Allan Bard and co-workers, can be used in a patterning mode to perform localized redox reactions on a surface, resulting in the formation of microstructures (Bard et al., 1990). SECM patterning is performed with ultramicroelectrodes in electrolyte solutions, and has been used to pattern enzymes (Shiku et al., 1997; Wittstock and Schuhmann, 1997) and SAMs on a surface (Wittstock et al., 1997). The feature sizes of patterns generated by SECM are typically larger than those created with other types of scanning probe techniques (Geissler and Xia, 2004). Scanning tunneling microscopy (STM) and AFM can be used to generate higher resolution features. STM has the highest resolution of all proximal-probe lithography methods,

as it can manipulate single atoms (Eigler and Schweizer, 1990; Manoharan et al., 2000), but as it must be used under high vacuum to achieve atomic resolution, it is of limited utility for biomolecular patterning. *Anodization lithography* is a methodology in which biased AFM tips are used to selectively grow oxide nanostructures on a silicon oxide substrate (Ducker et al., 2008). Stefan Zauscher's group has used anodization lithography to localize polymerization precursors, which were subsequently used to create nanopatterns of polymer brushes (Lee et al., 2006b).

Magnetic Field

Direct-write patterning with magnetic fields has mostly been geared towards data storage applications to date, and thus this topic will not be covered in detail in this section other than to provide the reader a basic idea of its underling physical principle. In direct-write magnetic patterning, an inductive element is scanned above a magnetizable material, such that localized regions of the surface become magnetized. These local magnetized areas allow data to be recorded as bits, and can read the stored data using the same type of inductive element that is used to generate the patterns. For more information on magnetic direct-write patterning, see the review papers by Chou (1997) and Geissler and Xia (2004). Magnetic patterning by self-assembly is discussed in a later section of this chapter.

Patterning with Masks

Patterning with masks is a highly developed form of patterning, as it has been the core technology of the microelectronics industry. Because of its sophistication and maturity, it has also been adapted for the patterning of biomolecules and cells. A mask is broadly defined as a template that can spatially modulate a field or radiation that passes through it, or a template that physically masks spatially defined regions of the underlying substrate from exposure to inks or etchants. Masking light to create patterns on substrates is the most common form of patterning with masks. Patterning with light and masks is generally called photolithography, even though photolithography can be performed in a mask-less, direct-write manner, as described previously. Mask-based patterning can also be performed with radiation (other than light), liquid inks or with chemical or biological etchants. Mask-based patterning is powerful and versatile for the following reasons: (1) large areas – typically 4–6 inch wafers – can be rapidly patterned in batch mode, which makes it a high-throughput patterning technique; (2) spatially intricate patterns can be fabricated that are only limited by the design of the mask; and (3) layered features can be fabricated by performing multiple patterning steps in succession, each with a different etching or deposition step. With advances in light sources and optics, the

spatial resolution of mask-based approaches is now in the sub-200 nm regime (Totzeck et al., 2007).

Photolithography with Masks

In *photolithography*, a mask can be any material that has optically transparent and opaque regions. Masks can be rigid, such as those fabricated out of metal or printed on quartz glass, or they can be fabricated on flexible substrates such as transparencies. The critical requirement of a mask-based photolithographic patterning process is that light must pass through spatially defined regions of the mask and lead to the formation of a pattern that conforms to or is dictated by the pattern of the mask, on a substrate that is located below the mask. However, historically, the term *photolithography* encompasses a set of processes that derived from the semiconductor industry, which involves more than simply using light and masks to fabricate patterns.

In photolithography, patterning is facilitated by a polymer *photoresist* that is spin-coated onto a silicon wafer, activated by light, and developed in a developing solution (Figure I.2.13.8) to create a pattern of the photoresist, which is then subsequently processed to create a pattern in the underlying substrate. There are two types of photoresists. (1) A *positive photoresist* becomes soluble in the developing solution in areas that are exposed to light, while the unexposed regions of the photoresist are insoluble in the developing solution. After exposure and development, the areas of the positive photoresist that were exposed to light are dissolved and rinsed away to expose

the underlying substrate. (2) A *negative photoresist* works on the opposite principle; areas of the photoresist that were exposed to the light will become less soluble in the developing solution, so that incubation in the developing solution will dissolve the unexposed regions of the photoresist, and expose the underlying substrate. The photolithography process is completed by removing parts of the exposed or unexposed photoresist. Removal is usually followed by an etching step in which the exposed thin metal/oxide films coating a bulk substrate are dissolved or a deposition step in which metal or other materials are preferentially deposited on to exposed regions.

A mask can be placed relative to the light source and substrate in three modes: contact mode; proximity mode or projection mode. In contact mode, the mask is placed directly on the substrate. Contact mode photolithography produces features at a 1:1 size relative to the feature size in the photomask, and thus resolution is limited by the feature size of the photomask. In contact mode, it is essential that the substrate and mask are free of particulate contaminants, as any trapped debris between the mask and substrate will contaminate the pattern and/or damage the mask or substrate. Proximity mode patterning is a variant of contact mode, in that the mask is slightly separated from the substrate along the propagating light axis. Proximity mode photolithography also produces features in the substrate that are the same size as are patterned on the mask, but the presence of foreign contaminants is not as devastating as in contact mode, as the mask and the substrate are not in contact. In projection mode photolithograpy, the mask is placed at an

image plane that is well separated from the surface of the substrate along the optical axis that is conjugate to the image plane at the surface to be patterned. Projection mode photolithography can produce a smaller feature size than is embedded in the mask, as optics can be used to project the mask pattern at very small physical dimensions. For example, a microscope can be used to reduce the mask pattern 100 times by using a 100 × microscope objective. Projection mode photolithography also enables higher-throughput processing, as mask alignment can be done quickly and efficiently due to reduced risk of damaging the mask or the substrate because they are well separated.

Typical photolithography with masks, as developed in the microelectronics industry, involves specialized photoresists composed of polymers that are designed to polymerize or depolymerize upon exposure to UV light. However, light-based patterning with masks can be accomplished with any material that is light responsive. An extreme example is mask-based patterning of bacteria in plates of agar by Levskaya et al., (2005). Here, bacteria were genetically engineered so that lacZ gene expression, which encodes β-galactosidase, could be repressed by light exposure. Photomasks were used to spatially localize lacZ gene expression, and hence β-galactosidase, to areas within the bacterial colony that were masked from light. Patterns were visualized by testing for β-galactosidase activity within the bacterial colony using media that formed black precipitates in the presence of β-galactosidase (Figure I.2.13.9).

Deposition/Etching with Masks

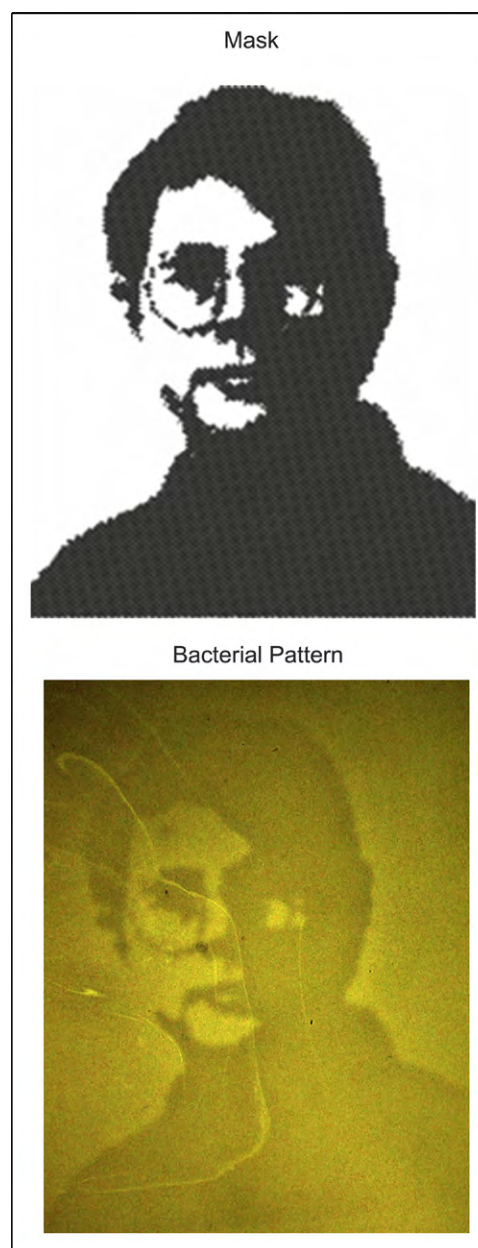
As mentioned above, mask-based deposition and etching is often a finishing step in a typical photolithography process. In fact, the actual photolithographic component of the process, as derived from the semiconductor/microelectronics industry, is the creation of a polymer-based mask on a substrate that is meant to protect specific parts of the underlying substrate from a subsequent deposition or etching process. However, it is beneficial to think of deposition and etching with masks as standalone patterning techniques, because these techniques extend beyond the context of photolithography. Simply put, mask-based deposition is just like using a stencil to paint letters or graphics on paper, clothing or any other material. The stencil, or mask, can be made of any material that conforms to the constraints of the experiments at hand. Examples of some experimental constraints are the following: the nature of the material to be deposited (i.e., is it hard, soft, deformable, etc.?); the nature of the substrate; the nature of etchant; etc. Masks can be made of metal or metal/glass as in traditional photolithography; such masks are rigid and are easy to clean. However, other masks can be made of elastomeric polymers, such as poly(dimethyl siloxane) (PDMS), which provide the benefits of being able to form watertight seals with the substrate, compatibility with


FIGURE I.2.13.9 Projection Mask Photolithography of Bacterial Cultures. Patterns are formed via light-responsive gene expression within the bacterial culture (Levskaya et al., 2005). Adapted with permission from Nature Publishing Group.

curved surfaces, and flexible peel-off (see Chapter I.2.2.B). In a deposition process, the mask is applied to a substrate, the combination of which is then exposed to the material to be deposited. Once the mask is removed, areas protected by the mask remain free of the deposited material. In an etching process, the mask/substrate is exposed to a form of radiation or an etching chemical, and the areas exposed by the mask are selectively etched.

There is a seemingly endless array of photolithography and mask-based deposition/etching examples. Mask-based photolithographic patterning of biomolecules most likely started with works such as Stephen Fodor's, where arrays of photoactive chemicals were patterned to create
FIGURE I.2.13.10 Photolithography and Masked Deposition/Etching Used to Create Microelectronics for Interfacing with Neurons. microarrays for peptide synthesis (Fodor et al., 1991). Also, around the same time (the early 1990s) photolithographic processes were being used to create patterned surface chemistries to direct cell growth on substrates (Lom et al., 1993; Healy et al., 1994). This work was initiated by collaborative efforts from Kevin Healy's and Philip Hockberger's groups at Northwestern University. They combined photolithography and organosilane chemistry to produce materials with precise control over the regional distribution of surface chemistry. They went on to use these surfaces to study the mechanisms by which mammalian cells were distributed spatially when exposed to these micropatterned surfaces. These seminal studies established the utility of masked photolithography for biomolecular patterning as an important research tool in biomaterials.

An exciting and relatively more modern biological application of mask-based photolithography combined with deposition and etching is the development of microelectronic interfaces for cells. Much work has been done creating electrode arrays and transistor arrays that can stimulate and record from cultures of neuronal cells in an attempt to learn more about brain activity on a single-cell level, as well as from controlled populations of networks of neurons (Gross et al., 1985; Gross and Schwalm, 1994; Zeck and Fromherz, 2001; Patolsky et al., 2006). Figure I.2.13.10 details two separate applications in which electronic devices were created by mask-based photolithography and deposition/etching.

Patterning with Masters

A *master* is a template that is used to replicate patterns, usually in a batch-type process. Rigid masters can be used directly to imprint patterns on substrates. However, the most widespread use of masters for patterning is to create a *mold*, typically of an elastomeric polymer, which is subsequently used to mold the patterns. Molds are usually fabricated by curing polymeric materials in the presence of the master, which embeds the features of the master into the mold. Once separated from the master, molds can be used for printing

features on substrates using molecular inks that are first applied to ink the mold, and then are transferred by contact with the protruding features of the mold with a surface. Alternatively, they can be brought into contact with a surface to create channels of the void features in the mold on a substrate, which can be used for patterning by a liquid ink flowing through the channel. Patterning with masters is a relatively cheap methodology to mass-produce features over large surface areas. Also, the use of conformal molds allows patterning on curved surfaces (Jackman et al., 1995). Cylindrical molds with patterned features also offer the possibility of a direct roll-on patterning process of a planar surface (Xia et al., 2004). Typically, patterning with masters does not offer as high spatial resolution as some direct-write patterning techniques.

Imprinting with a Master

Imprinting with a master is essentially the same concept as imprinting with a stylus, as described above, except that a master is used to imprint many features at once, instead of using a stylus and serially imprinting or writing one feature at a time. The master is fabricated from a relatively hard material such that it resists deformation when it is pressed against the substrate. The master contains a rigid relief pattern that molds the substrate into the shape which it is pressed into. Imprinting with a master is used often to pattern polymer films; however, other substrates can be used with the main requirement being that substrate must be soft enough to be deformed by the master. The resolution of features obtained from imprinting with a master is dictated by the durability of the master, the physical properties of the substrate, and the mechanical pressure applied during embossing. Feature sizes as small as 10 nm are attainable by imprinting with masters (Geissler and Xia, 2004).

Printing (Use of Protruding Features of a Mold)

Printing of patterns using molds is most widely done by *soft lithography*, a suite of related techniques that generally refers to the use of soft, elastomeric polymer molds to create patterns on substrates. Here, liquid monomer is poured onto a rigid master and then cured; when separated from the master the polymer mold retains the topography of the original master. These topographical features are then transferred to another substrate for patterning. Masters can be created using photolithographic techniques (described above), direct-write patterning or even relatively low-tech methods such as gluing rigid objects together so that they create necessary voids in the polymer (Allen et al., 2005; Hill and Shear, 2006). The most widely used polymer in soft lithography is PDMS. PDMS has numerous advantageous qualities (Whitesides et al., 2001) that contribute to its popularity, some of

which include that it is low cost, available commercially, easily prepared, flexible, optically flat (good for optical microscopy), insulating, resistant to harsh chemicals (including hydrofluoric acid, a popular glass etchant), and relatively permeable to biological gases. PDMS has tunable surface properties, and can be reversibly or irreversibly bound to surfaces such as glass, creating liquid-tight seals for controlled flows. The elasticity and adherent nature of PDMS make it an extremely versatile mold, as these properties enable the mold to remain in close conformation with curved or otherwise non-uniform surfaces, which contributes to the ability to pattern large surface areas (up to hundreds of square centimeters) (Xia and Whitesides, 1998) with a single mold.

Printing in the context of soft lithography is commonly referred to as microcontact printing (Figure I.2.13.11), and was first demonstrated by Whitesides and co-workers at Harvard University in the early 1990s (Kumar and Whitesides, 1993). In microcontact printing, an elastomeric stamp created from a rigid master is used to print molecular inks (dried) on substrates with patterned feature sizes in the micrometer to nanometer size range (Xia and Whitesides, 1998; Whitesides et al., 2001; Geissler and Xia, 2004; Ducker et al., 2008). This technology was first demonstrated with printing of alkanethiol SAMs on gold surfaces (Kumar and Whitesides, 1993), and was benefitted by the fact that alkanethiols have a high affinity to gold and form dense monolayers on gold surfaces (Love et al., 2005). Thus, when a PDMS stamp containing SAM-forming molecules contacts the gold surface, the molecules dissociate from the PDMS stamp and assemble on the surface. The feature sizes of patterns generated by microcontact printing are determined by the mechanical properties of the stamp, the deposition conditions (i.e., pressure and duration of application), and the leakiness or spreading properties of the molecular ink during the stamping process.

Two papers from the Whitesides group from the 1990s stand out as being particularly relevant to the field of biomaterials. The first by Lopez et al. (1993) demonstrated the power of surface engineering to spatially control the adhesion of cells in adherent cultures. Although the patterns in this study were not fabricated using soft lithography, but were instead created in a direct-write process, many of the conceptual ideas in this paper reappeared in subsequent papers from the Whitesides group and others that used soft lithography to pattern alkanethiols on surfaces. A second seminal paper, by Singhvi et al. (1994), followed from this study and was one of the earliest works demonstrating the important role that geometrical patterns on a surface could play in confining cell shape, and hence their function and/or behavior. This work revealed the power of micropatterning on the length scale of the cell.

Since the initial demonstration of the printing of SAMs, other researchers have extended the use of soft

lithography to include patterning of polymers (James et al., 1998; Zhou et al., 2006; Chen et al., 2009), proteins (including functional antibodies and enzymes) (Bernard et al., 1998, 2000, 2001a; Kung et al., 2000; Renault et al., 2002; Tan et al., 2002; Ma et al., 2006b), and cells (Hyun et al., 2003) on various surfaces, including glass, silicon, and metals. In one example of diversifying beyond printing alkanethiol SAMs on gold, Chilkoti and co-workers showed that a class of random oligoethylene glycol-functionalized methacrylate terpolymers that are protein resistant could be spin-coated on to a micropatterned PDMS stamp (Ma et al., 2005). Bringing the stamp into contact with a substrate resulted in transfer of the polymer only in regions of the stamp that were in contact with surface. This selective delamination process worked with a surprisingly large number of materials,

and provided a simple method to stamp protein-resistant polymer features with controlled lateral dimensions and height (controlled by the thickness of the polymer layer spin-coated on to the stamp) on a surface.

Use of Void Features of a Mold

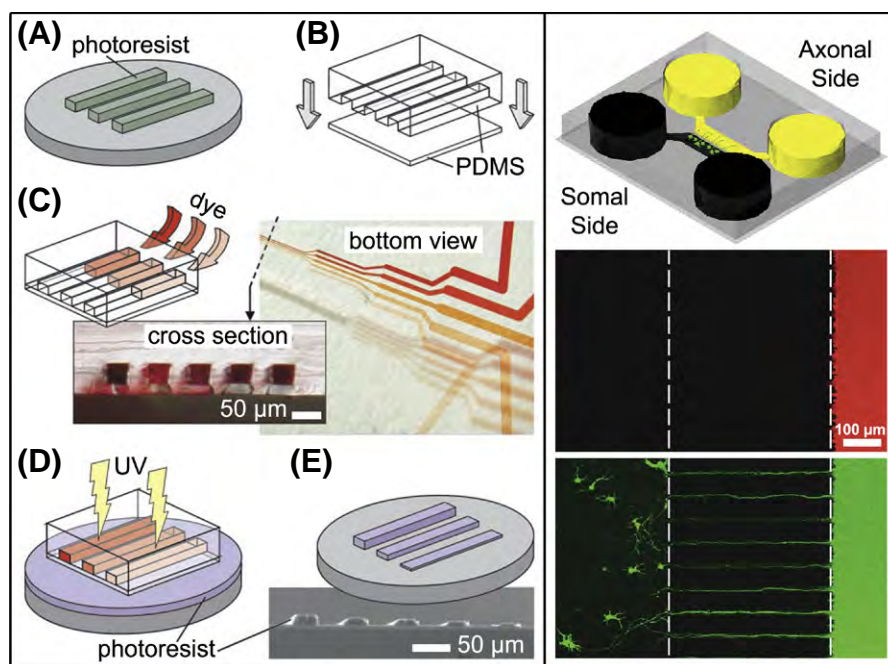
While printing makes use of the protruding features of a mold, a complementary set of patterning techniques utilize the void features in the mold (Xia et al., 1996a, 1997). When a mold with a striped pattern is affixed to a substrate, the voids in the mold form channels that can be filled with liquid to create patterns. In *microfluidic patterning*, a network of channels is used to deliver liquids to specific locations on a substrate. Here, liquids can be used to deliver reagents locally to microdevices


FIGURE I.2.13.12 Microfluidics. Left: microfluidic channels containing fluids of varying opacity are used as a mask for photolithography (Chen et al., 2003). Flow channels are created using an elastomertic mold (B) developed from a master pattern (A). The channels are filled with fluids of varying opacity (C), which modulates the light exposure to the underlying photoresist (D) and hence creates patterns that vary in height (E). Right: a microfluidic cell culture platform (top) is used to isolate axons of neurons, which can be targeted with effectors located in either of the fluid chambers (Taylor et al., 2005). Fluidic isolation of a dye on the axonal side of the chamber is shown in the middle panel. The bottom panel shows neurons that became stained with a dye that is located in the axonal side of the chamber. Left is adapted with permission from (Chen, C., Hirdes, D., & Folch, A. (2003). Gray-scale photolithography using microfluidic photomasks. Proc. Natl. Acad. Sci., 100(4), 1499–1504.). Copyright (2003) National Academy of Sciences, U.S.A. Right is adapted with permission from Nature Publishing Group.

on microfluidic chips (Figure I.2.13.12, right) (Juncker et al., 2002; Taylor et al., 2005), to deposit biomolecules onto the surface through adsorption or attachment chemistries (Bernard et al., 2001b; Dertinger et al., 2002; Fosser and Nuzzo, 2003), to locally dissolve parts of the underlying substrate (Rodriguez et al., 2003) or to serve as a mask for photolithography (Figure I.2.13.12, left) (Chen et al., 2003). See McDonald et al. (2000) for a good review of microfluidic systems.

Channels in a mold can also be used to deliver a polymer solution to a surface in a spatially delimited manner, which are then hardened or cured (Kim et al., 1995). Subsequent removal of the elastomeric mold leaves behind deposits of cured polymer in the regions of the surface in contact with the channels of the original mold. Several variants of this type of patterning have been developed, such as capillary force lithography (CFL) (Suh et al., 2005; Liu et al., 2006), micromolding in capillaries (MIMIC) (Xia et al., 1996b; Beh et al., 1999), and solvent-assisted micromolding (SAMIM) (Kim et al., 1997).

Patterning by Self-Assembly of Polymers and Colloids

Patterning by self-assembly of polymers and colloids is a powerful technique because, when properly executed, it requires minimal effort to produce the patterns. Self-assembled patterns are created by using experimental conditions where intermolecular or inter-particle forces cause polymers or colloidal particles to phase separate or aggregate in a spatially defined pattern driven by minimization of the free energy of the system. Self-assembled patterning can be used to pattern large surface areas with features ranging in resolution from the nanoscale to the microscale. Three examples of patterning by self-assembly are highlighted in this section: block copolymer self-assembly; nanosphere lithography; and magnetic self-assembly (Figure I.2.13.13).

Block Copolymer Self-Assembly

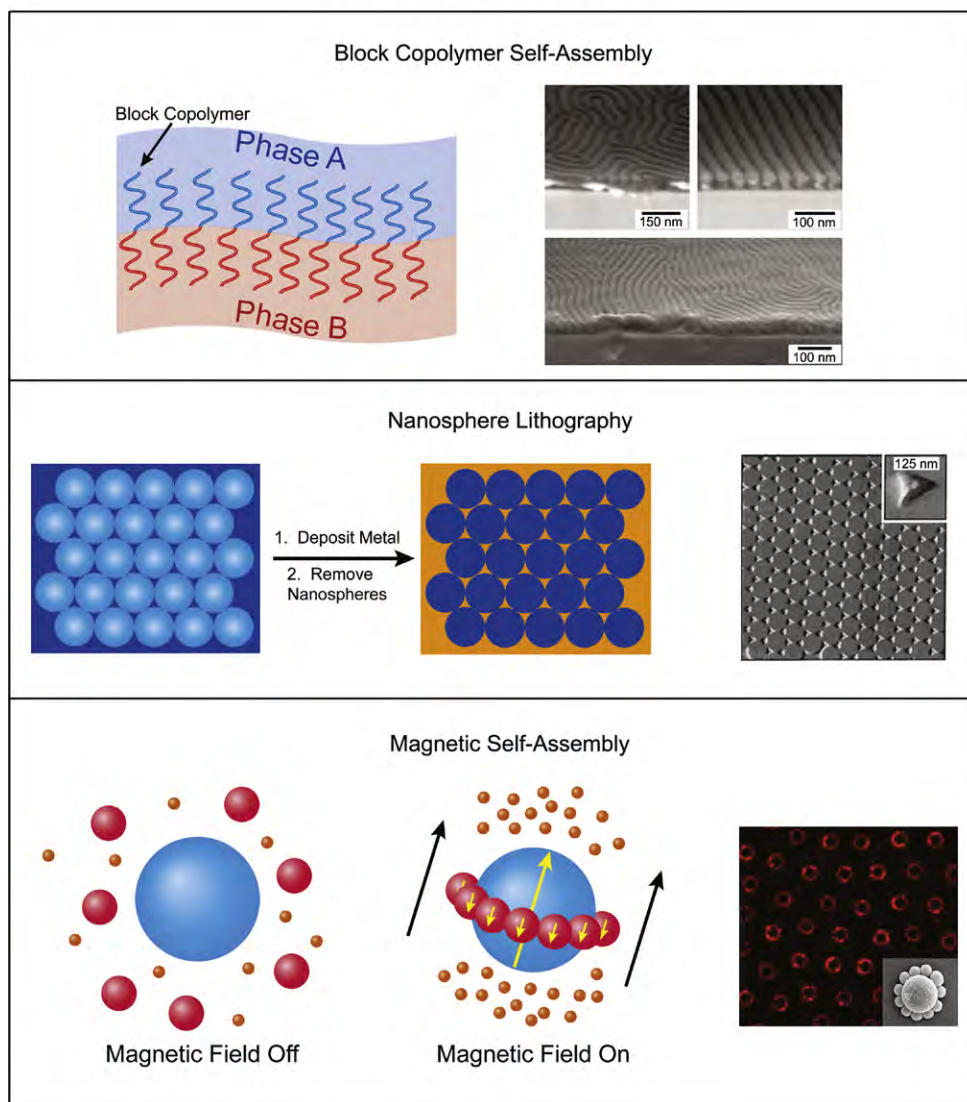
Block copolymer self-assembly is an example of self-assembled patterning at the molecular level. Patterning with block copolymers is accomplished by using a block copolymer that has two or more blocks that are immiscible with each other. A solution of the block copolymer is deposited on to a surface where it undergoes microphase segregation as the solvent evaporates. This segregation then leads to the formation of highly ordered surface patterns on the nanometer length scale that can readily cover large surface areas, although defects are a common problem on larger coverage areas. The nanometer-scale lateral resolution over a macroscopic surface area afforded by block copolymer self-assembly makes it a high-resolution, high-throughput patterning technique (Li and Ober, 2006). Patterns can


FIGURE I.2.13.13 Patterning by Self-Assembly. Top: block copolymer patterning on surfaces due to microphase separation between the polymer blocks (Ouk Kim et al., 2003). Middle: in nanosphere lithography, self-assembled, close packed nanospheres are used as a mask for creating metallic patterns on surfaces. Bottom: magnetic fields can be used to pattern magnetically susceptible objects. Here, rings of non-magnetic spheres are localized around larger paramagnetic spheres in solutions of magnetic ferrofluid (Erb et al., 2009). We note that the nature of this work was to position and align objects in three dimensions; however, this technique should be readily adaptable to surface patterning of three-dimensional objects. Data panels on the right: Top and Bottom are adapted with permission from Nature Publishing Group. Middle is adapted with permission from (Haynes, C., & Van Duyne, R. (2001). Nanosphere lithography: A versatile nanofabrication tool for studies of size-dependent nanoparticle optics. J. Phys. Chem. B., 105(24), 5599–5611.). Copyright (2001) American Chemical Society.

be controlled by altering a number of variables: the sequence and length of the blocks; the degree of immiscibility of the blocks; the physico-chemical properties of the solvent; the ambient conditions during thin film deposition; film thickness; and surface chemistry (Nie and Kumacheva, 2008). As described in Nie and Kumacheva's review (2008), patterned block copolymer films have been used as photonic crystals (Valkama et al., 2004), optical waveguides (Kim et al., 2005), and as templates for the growth of inorganic materials (Shin et al., 2002). They have also been used to create surfaces with tunable wettability (Xu et al., 2006b), and they can also be used as masks for patterning. In this

approach, one phase of the block copolymer pattern is selectively removed, which leaves a nanoporous film behind that can serve as a mask (Nie and Kumacheva, 2008). For examples of block copolymer patterning, as well as reviews, see references Hamley, 2003; Park et al., 2003; Lie and Ober, 2006; Kim and Hinsberg, 2008; Nie and Kumacheva, 2008.

Nanosphere Lithography

Nanosphere lithography exploits the self-assembly of nanoscale objects to create a periodic mask or pattern. In nanosphere lithography, a solution of relatively

monodisperse nanospheres – usually composed of a polymer – are delivered to a flat substrate from solution. Under specific conditions, the nanospheres self-assemble into a hexagonal, close-packed monolayer as the solvent evaporates, which leaves voids between the nanospheres where the underlying substrate is exposed. The nanosphere monolayer is then used as a mask to pattern the underlying substrate. Typically, nanosphere masks are used to mask the deposition of metals onto a substrate. After metal deposition, the nanospheres are removed from the surface, and leave behind metal pyramids in the regions corresponding to the void volumes between the nanospheres. For a detailed review on creating metal nanoparticles by nanosphere lithography, see Haynes and Van Duyne (2001). Template stripping has been used in combination with nanosphere lithography to create ultra-flat metal triangles (instead of pyramids) on surfaces using a similar deposition scheme (Frey et al., 2000). However, not all forms of nanosphere lithography involve metal deposition. For example, a metal microgrid template was used to direct dewetting of solutions on surfaces containing colloidal particles (including nanospheres and microspheres) (Celio et al., 2006). Once dewetting is complete, highly ordered patterns of the particles are formed over a large surface area on the underlying substrate.

Magnetic Self-Assembly

In *magnetic self-assembly*, nano-to-microscale particles with a magnetic susceptibility align or orient themselves in a magnetic field. In one implementation of this approach, magnetic nanoparticles can be directed to surfaces in a pattern, which can then serve as a mask for deposition of proteins or other biological materials (Bardea and Naaman, 2009). Magnetic particles have also been attached to cells to enable magnetism-directed cell patterning (Alsberg et al., 2006; Ino et al., 2007; Lin et al., 2008). Magnetic ferrofluid can also be used to template the self-assembly of non-magnetic materials, such as microspheres and cells (Yellen et al., 2006; Erb et al., 2009; Krebs et al., 2009). In this case, non-magnetic objects are positioned in three-dimensional space, due to the self-assembly of the magnetic medium surrounding them as the medium aligns with the external magnetic field.

Dynamic Patterning

The discussion of patterning thus far has mostly related to the formation of static patterns, which offer little control to the designer after formation, and often are subject to erosion or contamination over time. An emerging field of surface patterning is focused on the creation of dynamic or "smart" patterns. These patterns are designed to respond to external cues in the local environment. One motivation for the creation of dynamic patterns or materials is to create micro-mechanical

components for use in microfluidic devices, diagnostics, theraputics or other sensing devices (Beebe et al., 2000; Jager et al., 2000; Terray et al., 2002; Alexander and Shakesheff, 2006; Dong et al., 2006; Peppas et al., 2006; Sidorenko et al., 2007; Kaehr and Shear, 2008). A motivation for dynamic patterning more relevant to the focus of this chapter, however, is to enable spatio-temporal control over interfaces used to study the cellular microenvironment, as well as those used in chip-based sensing devices. Dynamic patterning is particularly important, because most biological processes are triggered by temporal cues in the local environment. For example, intracellular signal cascades that are driven by ligand binding to receptors, clustering of receptors in membranes, and remodeling of the extracellular matrix due to mechanochemical stimuli, are all dynamic processes in biology. Engineered dynamic interfaces present a biologically inspired – although abiological – methodology to provide temporal control of biological interactions at artificial surfaces. For example, Milan Mrksich's group at the University of Chicago has created SAMs on gold that present ligands at the SAM–water interface that can be switched between an active or inactive state via electrochemical signals from an underlying gold electrode (Mrksich, 2002, 2009). They have used these surfaces to study the interactions between ligands and cell membranes during cell attachment to micropatterned surfaces (Yeo et al., 2003) and heterogeneous (Yousaf et al., 2001) cell patterning. Furthermore, the Chilkoti group has used elastin-like biopolymers, which actuate with a thermal or saline stimulus, to enable dynamic and reversible spatial localization of proteins to patterned templates (Frey et al., 2003a,b; Nath and Chilkoti, 2003; Hyun et al., 2004b) (Figure I.2.13.14) with application for the fabrication of rewriteable surfaces for cell studies and biosensors.

Three-Dimensional Patterning

Three-dimensional patterning is a new and exciting development in the field of surface patterning. A major motivation for the development of three-dimensional patterning is the fact that cells exist in a three-dimensional environment in nature. However, cell-based experimentation in laboratories typically involves cell cultures growing on planar substrates, where they interact only in two dimensions and are often irrelevant because cells exist in three dimensions in the body. The benefits of three-dimensional patterning are also relevant for the design of biosensor and diagnostics, as control of an extra dimension in device fabrication will enable the design of new sensing architectures and transduction modalities with potentially improved figure-of-merit. In addition, three-dimensional control of patterning will also yield better control over the design of microfluidic lab-on-a-chip devices.

Many of the techniques described in the preceding sections can be used for three-dimensional patterning. For
FIGURE I.2.13.14 Dynamic Patterning (Frey et al., 2003b). Shown in (A) is a confocal fluorescence image of a pattern of fluorescent antibodies localized to regions containing antigen coupled to a stimulus-responsive polymer (light regions of the image). Once triggered, the pattern is completely erased, as shown in (B) – an image using the same gain settings as in (A) – and again in (C), an image with enhanced gain settings to show uniformity of the background. (D) shows vertical intensity line plots drawn through (A) (solid line) and (B) (dashed line), which further verify complete elimination of the initial pattern shown in (A). Reprinted with permission from Wiley-Blackwell.

example, *mask-based photolithography* in combination with masked deposition or etching can be used to fabricate three-dimensional structures using multiple steps to build up features in the third dimension layer-by-layer (Zeck and Fromherz, 2001). This technique works well for patterning large surface areas; however, the processing involved can be quite laborious and time-consuming, as each layer requires a standalone photolithographic process. Three-dimensional features can also be deposited from voids in *elastomeric molds*, as discussed in the section on soft lithography. In addition, soft lithography (Hammond and Whitesides, 1995; Clark et al., 1997; Clark and Hammond, 1998; Jiang and Hammond, 2000) and scanning probe techniques (Lee et al., 2009) can be used to confine precursors in two dimensions on a substrate that can initiate *self-assembly* of features in a third dimension via molecularly thin, layer-by-layer (LBL) deposition of oppositely charged polyelectrolytes. This approach provides nanometer spatial resolution in the third dimension; however, assembly of polyelectrolyte layers via LBL deposition can be time-consuming when substantial feature heights are desired.

Another direct-write example of three-dimensional patterning is photothermal needle etching, in which an agarose gel is photothermally ablated by scanning a needle, with a laser that is continually focused on it, throughout the gel (Moriguchi and Yasuda, 2006). In a final example of three-dimensional patterning, robotic *inkjet printing* of viscoelastic polymers on surfaces has been used to create very complex three-dimensional architectures in a direct-write manner (Gratson et al., 2004), and some of these patterned three-dimensional structures have been used in tissue engineering (Woodfield et al., 2004), and for microfluidic (Therriault et al., 2003) applications. This technique suffers the drawbacks of any direct-write method, in that it is laborious to pattern large surface areas via serial scanning. However, inkjet printing has the attractive features that the spatial resolution is in range of the hundreds of nanometers, and complete

three-dimensional control is possible as arbitrary features that can be fabricated by this methodology.

The rest of this section will detail some other techniques for three-dimensional patterning that use a different set of principles than those described so far.

Multiphoton Lithography

Multiphoton lithography (MPL) is a laser-based, direct-write approach to three-dimensional patterning in which multiphoton excitation of photoinitiators or photosensitizers is used to photocross-link or photopolymerize materials at the focus of a high instantaneous-energy, pulsed laser beam. As multiphoton excitation varies nonlinearly with the intensity of the excitation source, these photochemical reactions are confined to a small volume, or voxel, within the laser focus where intensity is large enough to excite a photochemical process of interest. This voxel can be translated in three dimensions within a solution of photoactive materials to locally cure photoactive material from solution. The remaining uncured solution can be rinsed away, leaving behind hardened, freestanding three-dimensional features. The resolution limit of this technique is ~250 nm, and can be scaled to the microscale; however, fabrication of larger features usually requires higher laser power, which can be a limiting factor in some applications. The use of a motorized mechanical stage allows automated patterning in the X–Y dimensions, while auto-focusing mechanisms can provide automated control over the Z dimension.

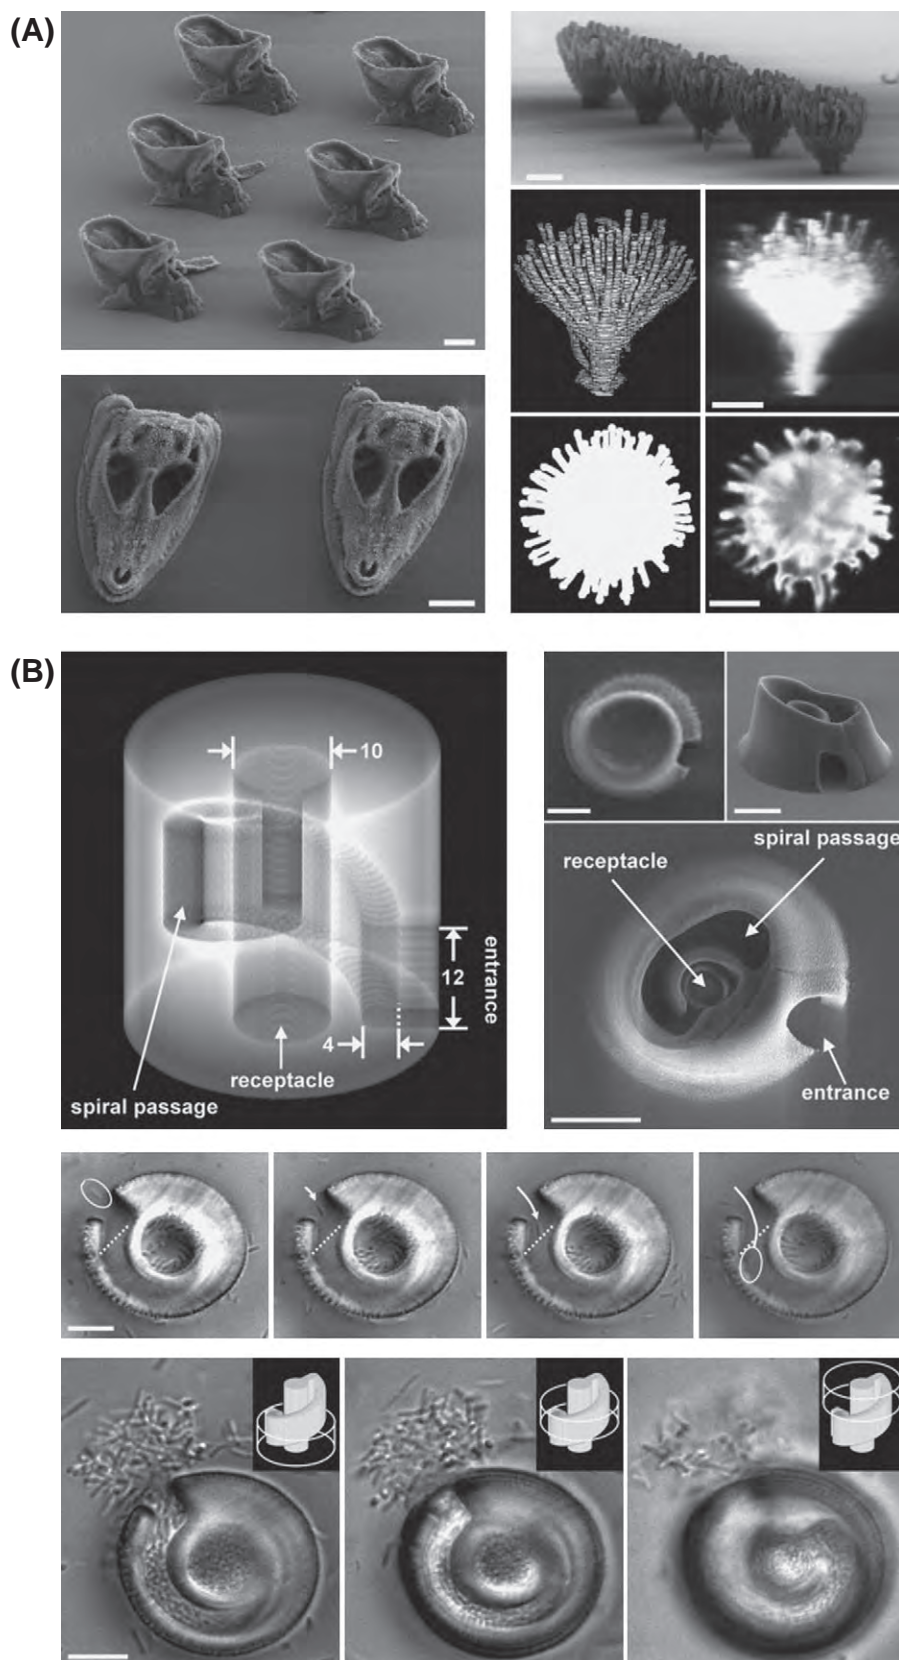
MPL has been widely used to create three-dimensional features from UV-curable synthetic resins. Complex serial scanning algorithms have enabled the fabrication of microscale replicas of livestock, sculptures (Serbin et al., 2003), houses (Lafratta et al., 2007), and the fabrication of three-dimensional tattoos on biological specimens (Baldacchini et al., 2004), free-standing metallized wires and other electrical microcomponents (Lafratta et al., 2007; Li and Fourkas, 2007), micro-mechanical parts (Maruo


FIGURE I.2.13.15 Three-dimensional protein microstructures fabricated by multiphoton lithography (Neilson et al., 2009). et al., 2003), and photonic crystals (Seet et al., 2006; Tetreault et al., 2006; Lafratta et al., 2007; Li and Fourkas, 2007). Perhaps more biologically relevant, however, is the use of MPL to pattern protein-based materials in three dimensions (Pitts et al., 2000, 2002; Basu and Campagnola, 2004; Basu et al., 2004, 2005; Kaehr et al., 2004, 2006; Allen et al., 2005; Hill et al., 2005; Hill and Shear, 2006; Kaehr and Shear, 2007, 2008; Lyon et al., 2007; Nielson et al., 2009; Seidlits et al., 2009). In this approach, solutions of proteins and photosensitizers are used in place of synthetic resins to create biologically compatible three-dimensional protein microstructures. Shear and co-workers have used this methodology to generate three-dimensional protein structures on-the-fly in the presence of living neurons (Kaehr et al., 2004), as well as protein-based houses for bacteria (Kaehr and Shear, 2007; Nielson et al., 2009). This work opens up the possibility of directing single cell and cell–cell interaction experiments in real time, as opposed to relying on patterning a substrate before cell seeding. They have also created three-dimensional protein–hydrogel structures for cell cultures (Seidlits et al., 2009), three-dimensional multi-enzyme reactors (Allen et al., 2005; Hill and Shear, 2006), protein-based conductive wires (Hill et al., 2005), and protein hydrogel microactuators (Kaehr and Shear, 2008). Laser scanning of masks combined with scanning in the vertical dimension was demonstrated as a mask-based, multiphoton variant of projection lithography in three dimensions (Kaehr and Shear, 2007). More recently, laser scanning of a dynamic digital micro-mirror device was used to create protein-based tissue micro-replicas of monkey skulls and insects using high-resolution X-ray computed tomography data (Nielson et al., 2009) (Figure I.2.13.15).

Holographic Lithography

Holographic lithography is a three-dimensional patterning technique based on the projection of three-dimensional images using interference patterns from intersecting laser beams. In this method, multiple coherent lasers are aligned, such that they interfere with one another to create periodic intensity patterns in an image plane. By controlling the number of interfering beams and their relative alignment, phase, amplitude, wave vector, and polarization, one can vary the complexity of the projected images. With the appropriate number of beams and alignment (Del Campo and Greiner, 2007), three-dimensional periodic lattices can be projected on to an image plane. This projection can be used to polymerize photoresists and create three-dimensional objects from the projected images. Holographic patterning is typically used to create three-dimensional templates for fabrication of photonic crystals (Geissler and Xia, 2004; Del Campo and Greiner, 2007). A major advantage of holographic patterning over other methods of three-dimensional patterning is that, once the necessary optics are aligned and configured, it is relatively simple to generate

three-dimensional patterns quickly without the use of masks or serial scanning. The drawbacks of this method, however, are the complexity of the alignment procedure, as well as the optical components and sources needed. A holographic approach that is somewhat less technically challenging and more user-friendly uses a spatial light modulator that is illuminated by a single beam and projects three-dimensional holograms from computer generated bitmap images (Jenness et al., 2008). Simultaneous generation of multiple three-dimensional polymeric and protein microstructures has been accomplished using this technique (Jenness et al., 2010).

CONCLUSIONS

Surface patterning has become an extremely important tool in biomedical research. The ability to precisely define the spatial location of biomolecules and/or cells on a surface or in three dimensions provides researchers with a powerful tool to examine the interplay between biomolecules, cells, and artificial materials in a highly controlled spatial environment. This chapter has reviewed a diverse set of patterning techniques, common concerns that need to be addressed in patterning biomolecules and cells, and important figures-of-merit of different patterning methods that should provide the reader with an intelligent stepping stone to sources in the primary literature for a deeper, in-depth investigation of this area of research. This chapter should also help the reader in making a rational decision about the choice of the patterning methodology that is suitable for a particular application. In conclusion, we hope that this chapter will serve as a beginner's guide for those who wish to delve deeper into the field of biomolecular and cellular patterning in two and three dimensions.

CHAPTER I.2.14 MEDICAL FIBERS AND BIOTEXTILES

Martin W. King[1,2] and Sangwon Chung[3,4]
[1]Department of Textile Engineering, Chemistry & Science, North Carolina State University, Raleigh, NC, USA
[2]Donghua University, Shanghai, China

[4]Biomedical Engineering, Joint Department of Biomedical Engineering, North Carolina State University and University of North Carolina at Chapel Hill, NC, USA

The use of textiles in medicine is not new. It goes back to the early Egyptians who used linen threads to ligate blood vessels and approximate skin tissue after injury (Shalaby, 1985). Over the past several decades the use of fibers and textiles in medicine has grown dramatically as new and innovative fibers, structures, and therapies have been developed. Advances in fiber spinning methods, fabric assembly technologies, and surface modification treatments have led to numerous new concepts for both products and therapies, some of which are still in development or in clinical trials.

The generic term **biomedical textile** encompasses a wide range of medical products and devices for both internal and external use. Their role is to improve health and wellness, maintain comfort and hygiene, prevent or treat an injury, avoid infection or control disease, assist in repairing an internal injury or surgical operation, or replacing a diseased or injured internal organ or tissue.

The types of external biomedical textile products can vary from the simple bandage, external casting or support, feminine hygiene product, diaper or incontinence pad to surgical drapes, protective gowns, and masks worn in the clinic and operating room. Since the field of biomaterials science deals with implantable devices and artificial organs, the focus of this chapter will be limited to those biomedical textile products that are called **biotextiles** and are used for **medical applications** only (see Box 1).

As can be seen from the contents of this textbook, today's surgeon has an impressive armamentarium of artificial devices as well as new viable living tissue products at his or her disposal, many of which are textile-based products that contain textile fibers. These biotextiles are implanted for a number of different reasons, including the replacement or bypass of blood vessels, the replacement of heart valves, knee ligaments, and the repair of hernias and prolapses using open and endoscopic surgical techniques. These and other current commercial biotextile products are listed in Table I.2.14.1 to illustrate the scope and range of biotextiles in surgical applications.

The field of biotextiles lies at the intersection of the disciplines of polymer and fiber science, textile technology, biomedical engineering, surface science, biomechanics, cell biology, human anatomy, and physiology. Obviously, collaboration between these different fields is necessary in order to undertake meaningful research and to develop innovative implantable biomedical devices that improve the health, well-being, and quality-of-life of individuals. For example, fiber-based textiles can provide thin, strong, flexible, lightweight, porous structures that have excellent fatigue properties, a very large surface area desirable for drug delivery and cell attachment, the ability to be folded or compressed into a small volume for less invasive delivery through a catheter, the ability to tolerate needle and other iatrogenic damage, and to encourage the infiltration of cells into the structure for acceptable biocompatibility. Iatrogenic refers to any adverse condition induced in a patient by a physician's activity, manner or therapy. The process of developing a new biotextile product involves an understanding of the materials or polymers, the elements or fibers, the components or yarns, and the hierarchical architecture associated with the textile fabrication (e.g., weaving, knitting or braiding), as well as the surface modification or finishing.

In this chapter, we present this series of concepts in a logical order so that the reader can appreciate how the selection of the polymer, the fiber, and yarn, the fabrication process and the surface finish can all impact the final structure, properties, and performance of the biomaterial device.

FIBER FORMING POLYMERS

While natural and manufactured textile fibers are made from a wide range of materials including metals (e.g., stainless steel) and ceramic materials (e.g., glass), the majority of fibers of interest to biomaterial scientists are derived from natural and synthetic fiber-forming polymers. Not all polymer materials lend themselves to forming fibers. In order to be able to spin or convert a polymer into a manufactured fiber, its chemistry needs to meet certain structural requirements. The following features are preferred:

1. Intermediate to high molecular weight (range approximately 20,000 to 250,000 Da).
2. Linear polymer chain with absence of bulky side groups, cross-links or side chains.
3. Ability to rapidly form ordered or crystalline structures when solidified from the melt or when precipitated from solution. This depends on the regularity of the repeat unit to allow close packing between chains.
4. The level of intermolecular bonding and the level of chain entanglement should not be too high so as to prevent the polymer chains from forming an aligned and preferentially ordered structure on stretching or drawing.

An appropriate molecular weight range of 20,000 to 30,000 Da is typical for condensation polymers such as nylon and PET, whereas addition polymers such as polypropylene, and aliphatic polyesters such as PGA and PLA typically have molecular weights in the upper end of the range. These characteristics are common to all of the permanent and resorbable polymer types listed in Table I.2.14.2.

Because of their unique monomer repeat unit size and shape, different polymers have a different inherent ability to crystallize. Some like silk, PTFE, PVDF, polyethylene, and polydioxanone have a high degree of crystallinity that influences their mechanical properties, their ability to adsorb moisture, and their biostability. Table I.2.14.2 provides examples of natural and synthetic permanent polymers, as well as resorbable polymers that have been designed or engineered to resorb after implantation within a biological environment. These resorbable polymers were originally designed as suture materials to extend the range of resorbable collagen (catgut) sutures but, as seen in Table I.2.14.2, they can now be applied to a wide range of biomedical applications ranging from

TABLE I.2.14.1	Commercial Biotextile Structures and their Clinical Applications					
Clinical Application	Devices with Biotextile Component	Polymer Type*	Fiber Structure	Fabric Structure	Resorption Time	Examples of Commercial Products
General Surgery	Esophageal stent	Polyester (PET)	Monofilament	Braided	Permanent	Polyflex®

*Abbreviations:
ePTFE: Expanded polytetrafluoroethylene
FEP: Fluorinated ethylene propylene polymer
PBT-TMEG: Poly(butylene terephthalate)-co-poly(tetramethylene ether glycol)
PCL: Polycaprolactone
PDO: Polydioxanone
PEEK: Polyethyletherketone
PET: Poly(ethylene terephthalate)
PGA: Polyglycolide
PGCL: Poly(glycolide-co-caprolactone)
PLA: Polylactide
PLGA: Poly(lactide-co-glycolide)
PMMA: Polymethylmethacrylate
PTFE: Poly(tetrafluoroethylene)
PVDF-HFP: Poly(vinylidene fluoride-co-hexafluoropropylene)
TMC: Trimethylene carbonate
UHMWPE: Ultra-high molecular weight polyethylene

TABLE I.2.14.2	Examples of Permanent and Resorbable Fiber-Forming Polymers			
Type	**Chemical and Physical Aspects**	**Construction/ Useful Forms**	**Comments/Applications**	**Resorption Time**
Nylon 6	Thermoplastic; Hydrophobic $T_m = 220°C$; $T_g = 45°C$ Crystallinity 50% as spun	Melt spun into monofilaments and multifilament yarns	Sutures (Nurolon™; Ethilon™)	Permanent
Nylon 66	Thermoplastic; Hydrophobic $T_m = 265°C$; $T_g = 50°C$ Crystallinity 50% as spun	Melt spun into monofilaments and multifilament yarns	Sutures (Monosof™; Dermalon™; Surglion™)	Permanent
Polyethylene (PE)	High-density PE (HDPE) Thermoplastic; Hydrophobic $T_m = 125°C$ Crystallinity up to 85%	Melt spun into fibers for polymer composite reinforcement	Orthopedic and craniofacial implants	Permanent
	Ultra high molecular weight PE (UHMWPE) $T_m = 140–150°C$ Crystallinity 100% High tensile strength and modulus	Converted to very high tenacity yarn by gel spinning	Ligament prostheses and loadbearing orthopedic composites	
Poly(ethylene terephthalate) (PET)	Thermoplastic; Hydrophobic $T_m = 265°C$; $T_g = 65–105°C$ 100% amorphous as spun so need to be drawn and annealed to have crystallinity	Melt spun into monofilaments and multifilament yarns for weaving, knitting, and braiding	Sutures (Mersilene™; Surgidac™; Ticron™); hernia repair meshes; ACL prostheses; heart valve sewing rings; vascular and endovascular grafts	Permanent
Polypropylene (PP)	Predominantly isotactic Thermoplastic; Hydrophobic $T_m = 165–175°C$ Crystallinity 40–46% Higher fracture toughness than HDPE Susceptible to degradation from heat and radiation	Melt spun into monofilaments, hollow fibers or spunbonded and melt blown to nonwoven fabrics	Sutures (Prolene™; Surgipro™); hernia repair meshes; blood filters (e.g., renal dialysis machines)	Permanent
Poly(tetrafluoroethylene) (PTFE)	Thermoplastic; Hydrophobic $T_m = 325°C$ Crystallinity 50–75% for processed material	Melt extruded into films and often thermo-mechanically expanded into ePTFE	Sutures; vascular and endovascular grafts; heart valve sewing rings; embolic vena cava filter; ACL ligaments	Permanent
Poly(vinylidene fluoride) (PVDF)	Thermoplastic; Hydrophobic $T_m = 165–175°C$ Crystallinity 52–66%	Melt spun into monofilaments and multifilaments	Sutures (Pronova™)	Permanent
Silk	Natural bicomponent fiber from fibroin protein with sericin sheath; Hydrophilic Crystallinity 70% Low elastic recovery	Spun by *Bombyx mori* silk worm with sericin coating; sericin is removed before processing	Sutures (Perma-Hand™; Sofsilk™)	Classified as permanent but known to degrade in 1–2 years

Viscose Rayon	First manufactured fiber in 1892; Hydrophilic Crystallinity 33% Decomposition begins at 250°C	Wet spun from alkali sodium cellulose xanthate solution into continuous multifilaments	Wound dressing	Permanent
Polycaprolactone (PCL)	Thermoplastic; Rubbery at room temperature T_m = 58–63°C; T_g = −65°C	Melt spun into monofilament and multifilament yarns; can be electrospun into nanofibers; can be copolymerized with other resorbable polymers	Used as scaffolds in tissue engineering	>24 months
Polydioxanone (PDO)	Thermoplastic T_m = 110–115°C, T_g = −10–0°C Crystallinity 55%	Melt spun into monofilament and multifilament yarns; can be electrospun into nanofibers; can be copolymerized with other resorbable polymers	Sutures (PDS™); intramedullar pins; ligating clips	6–9 months
Polyglycolide (PGA)	Thermoplastic T_m = 225°C; T_g = 40–45°C; Crystallinity 45–55% Simplest linear aliphatic polyester Rigid mechanical properties	Melt spun into monofilament and multifilament yarns; can be electrospun into nanofibers; can be copolymerized with other resorbable polymers	Sutures (Dexon™); meshes (for defect repairs and periodontal inserts); used as scaffolds in tissue engineering	6–12 months
Polylactide (PLA)	Thermoplastic T_m = 173–178°C; T_g = 60–65°C		Stents; drug delivery devices; used as scaffolds in tissue engineering	>24 months
Polyglactin 910 10/90 Poly(l-lactide-co-glycolide)	Thermoplastic T_m = 205°C; T_g = 43°C Crystallinity 40%	Multifilament yarns, for weaving, knitting and braiding	Sutures (Vicryl™; Polysorb™); meshes	3 months
Poly(glycolide-co-caprolactone) (PGCL)	Thermoplastic T_g = −43–18°C depending on the copolymer ratio and molecular weight	Monofilament	Sutures (Monocryl™)	3–4 months
Poly(glycolide-trimethylene carbonate)	T_m = 206°C; T_g = 20°C	Monofilament	Sutures (Maxon™)	2–6 months

implanted drug delivery systems and degradable stents to tissue engineering scaffolds. When in contact with the body, these polymers degrade either by hydrolysis or by enzymatic degradation into nontoxic byproducts. As biotextiles, they break down or degrade through an erosion process, which starts at the exterior surface of the fiber and continues until the fiber has been totally resorbed. Sometimes the process is accelerated in the center of the fiber where the acid byproducts act as catalysts for further degradation.

It is important to note that most permanent synthetic polymers currently used in medicine were originally developed as commercial polymers for non-medical applications and usually contain additives such as delustrants, stabilizers, antioxidants, antistatic agents, and dye linkage sites. Some of these chemicals may be cytotoxic for biomedical applications and, as leachable contaminants, they must be removed prior to use. To illustrate this point, poly(ethylene terephthalate) (PET), which at present is the material of choice for large caliber textile vascular grafts and other applications as seen in Table I.2.14.1, was originally developed for apparel use. A rigorous cleaning or scouring process is required before the material can be used as an implantable device (King, 1991; Fages et al., 1998).

MEDICAL FIBERS

All textile-based medical devices are composed of structures fabricated from textile fibers.

What are Textile Fibers?

Textile fiber is: "a generic term for the various types of matter that form the basic elements of fabrics and other textile structures. More specifically, a **textile fiber** is a unit of matter that is characterized by having an aspect ratio (length divided by width) of at least 100, and which can be spun into yarn or made into a fabric" (ASTM, 1996).

Textile fibers can be spun in several different forms, such as continuous monofilaments and multifilament yarns, which can vary in length from 500 meters of natural silk reeled or unwound from a cocoon to several hundred kilometers of a manufactured yarn on a single bobbin. Usually the units of fiber size, thickness or yarn linear density are expressed in **decitex** (**dtex**), which is the mass in grams of 10,000 meters of fiber. In North America, the unit of linear density is usually expressed in **denier**, which is the mass in grams of 9000 meters of fiber. For example, a typical polyester yarn used to knit a vascular prosthesis has a linear density of 100 dtex, as shown in Table I.2.14.3. If this were a single round monofilament then the filament diameter would correspond to about 100 μm. However, as indicated in Table I.2.14.3, this is a multifilament yarn consisting of 54 round filaments. Therefore, the linear density of each filament is 1.9 dtex and the diameter of each filament is 13.2 μm, which makes the multifilament yarn significantly more flexible, with a much lower bending rigidity than a 100 dtex monofilament yarn.

TABLE I.2.14.3	Examples of Structure and Properties of Knitted Polyester Vascular Prostheses					
Structure/Properties	DeBakey® Vascular II, C.R. Bard, USA		Dialine II, Cardial, France		Barone Microvelour®, Argentina	VP1200K™ (Unsealed Gelsoft®) Vascutek, UK
Type of yarn	2 single textured multifilament		2 ply textured multifilament	Single flat multifilament	3 ply textured multifilament	Single textured multifilament
Yarn nominal linear density (dtex)	76	110	130	74	340	100

In addition to synthetic polymers, a class of fibers exists which is composed of natural biopolymer-based materials. In contrast to synthetic fibers, which have been adapted for medical use, natural fibers have evolved naturally and so can be particularly suited for medical applications. Cellulose, which is obtained from processed cotton or wood pulp, is one of the most common fiber-forming biopolymers. Because of their high thrombogenicity, cellulose fibers and their derivatives are used for applications such as wound dressings and hemostats for open wounds. Also of growing interest are fibers wet spun into multifilament fibers from modified polysaccharides including alginates from algae, chitosan from crustacean shells, dextran and reticulated cellulose from bacterial fermentation which are used to fabricate surgical sutures and meshes, and tissue engineering scaffold materials (Shalaby and Shah, 1991; Ohkawa et al., 2004; El-Mekawy et al., 2010).

Traditionally, natural textile fibers of vegetable and animal origin had a diameter range of 10–50 μm and manufactured fibers until recently have also targeted the same size range. However, with recent advances in spinning technology for converting polymers into fibers, the size range has been extended down to below one micron as illustrated in Figure I.2.14.1. In the following sections, the different fiber spinning techniques are discussed in greater detail.

Melt Spinning

In melt spinning, the polymer resin is heated above its melting temperature and extruded through a spinneret. The number of holes in the spinneret defines the number of filaments in the mono- or multifilament yarn being produced. For example, a spinneret for a monofilament fiber contains one hole, whereas 54 holes are required to produce the multifilament yarn which is commonly used in vascular graft construction. In this process, the molten resin is extruded through the spinning head, and cold air is typically used to cool and solidify the continuous threadline, as shown in Figure I.2.14.2A. It is then drawn, lubricated, twisted or entangled prior to winding on a bobbin. Spin finish is applied as a lubricant to reduce friction and to improve texturing, knitting, and weaving efficiencies. Melt spinning is typically used with thermoplastic polymers that are not affected by the elevated temperatures required in the melt spinning process as listed in Table I.2.14.2. Depending on the shape of the spinneret hole, melt spun fibers can exhibit various cross-sectional shapes such as round and trilobal hollow (Figure I.2.14.3).

Wet/Gel Spinning

If the polymer system is not thermoplastic or experiences degradation at elevated temperatures, a low temperature wet solution or gel spinning process can be used, as is the case with cellulose (viscose rayon), chitosan, alginate or cyclodextrin. The same spinning process applies when converting these polymers into a fiber-based drug delivery system so as to maintain the activity of the drug component (Tuzlakoglu et al., 2004; Malheiro et al., 2009). In this process, the polymer is dissolved in a solvent and
FIGURE I.2.14.1 Relationship between fiber dimensions and surface area compared to a biological scale.
FIGURE I.2.14.2 Spinning processes: (A) Melt spinning; (B) Wet/Gel spinning; (C) Electrospinning.

then extruded through a spinneret into a non-solvent in a spin bath, as shown in Figure I.2.14.2B. For example, for spinning chitosan, an acetic acid solvent is used and an ethyl alcohol or phosphate phthalate salt solution serves as the coagulation bath (Knaul et al., 1999). In the case of spinning alginate fibers, aqueous solutions of sodium carbonate and caustic soda are used as the solvent, and the fibers are precipitated by acidification with hydrochloric acid. Because the polymer is soluble in the solvent but not in the spin bath, the continuous polymer solution stream coagulates into continuous solid filaments, which are then washed to remove all solvents and non-solvents, drawn and dried before winding (Adanur, 1995). The cross-sectional shape of the resulting fibers is often crenulated with multiple grooves due to the slow diffusion of the solvent out of the fiber during the coagulation process, as shown in Figure I.2.14.3D.

Electrospinning

The diameters of fibers spun by melt spinning and wet solution spinning are controlled by the size of the hole in the spinneret and the amount of draw or stretch applied to the filament prior to winding up. So the diameters of conventional spun fibers fall in the range from about 10 μm for multifilament yarns to 500 μm or thicker for monofilaments. To obtain finer fiber diameters it is necessary to employ alternative spinning technologies, such as the bicomponent fiber spinning approach (see next section), or an electrospinning technique as illustrated in Figure I.2.14.2B. This method of manufacturing microfibers and nanofibers has been known since 1934 when the first patent was filed (Formhals, 1934). Start-ups such as eSpin Technologies, NanoTechnics, and KATO Tech are some of the companies seeking to reap the unique advantages offered by electrospinning, while companies such as Donaldson Company and Freudenberg have been using electrospinning processes to manufacture air filtration products for the last two decades (Ramakrishna et al., 2006).

Electrospinning occurs when a polymer solution or melt is exposed to an electrostatic field by the application of a high voltage, which overcomes the surface tension of the polymer and accelerates fine jets of the liquid polymer towards a grounded target (Doshi and Reneker, 1995; Ma et al., 2005; Lannutti et al., 2007). As the polymer jets cool and/or lose solvent they are drawn in a series of unstable loops, solidified, and collected as an interconnected nonwoven web of fine fibers on a grounded rotating drum or other specially shaped target, as illustrated in Figure I.2.14.2B. There are many variables that influence the spinning efficiency/stability and the fineness of the fibers produced, such as the type of polymer and solvent system, the solution concentration, melt viscosity and conductivity, the strength and uniformity of the applied electric field, and the geometry and operating conditions of the spinning system. Fiber diameters in the range of submicron to 100 nm or less have been reported. As well as using electrospinning techniques to fabricate ultra-thin filtration membranes, these techniques have also been applied to the production of nonwoven mats for wound dressings and scaffolds for tissue engineering applications (Kumbar et al., 2008). Nonwoven scaffolds electrospun from Type I collagen and synthetic polymers such as polylactide, poly(lactide-co-glycolide), polyvinyl alcohol, poly(ethylene-co-vinyl acetate), polyethylene oxide, poly(lactide-co-ε-caprolactone), polyurethanes, and polycarbonates have been reported (Huang et al., 2000; Boland et al., 2001; Huang et al., 2006; Pham et al., 2006; Barnes et al., 2007; Chung et al., 2009; Leong et al., 2009; Chung et al., 2010a).

Bicomponent Spinning

Bicomponent, hybrid or multicomponent fiber spinning refers to the technology of bringing two or more different polymers together at the spinneret hole so that each spun filament contains all the polymer components in separate parts of the cross-section (Durany et al., 2009). Over the past few years, a number of different fiber cross-sectional configurations have been developed, as illustrated in Figures I.2.14.1 and I.2.14.3B. The main motivations for these developments have been: (1) to take advantage of the properties of more than one polymer component within the same fiber; and (2) to achieve smaller fiber dimensions by splitting or separating components after co-spinning. For example, one of the configurations of a bicomponent fiber is to spin a resorbable polymer sheath around an inner core of a second non-absorbable polymer. The advantage of this fiber configuration for vascular applications is that the sheath modulates a faster inflammatory or foreign body response and a more complete healing process, while the core component maintains the mechanical integrity of the device (King et al., 1999). The composition and molecular weight of the polymer and the thickness of the sheath regulates its absorption rate. As shown in Figure I.2.14.4, within 28 days the PGA sheath component is in the process of resorbing into fragments while provoking acute inflammatory response with the recruitment of many macrophages and collagen matrix deposition. Additionally, drugs can be incorporated into the outer resorbable sheath and delivered at predefined rates, depending on the choice and thickness of the outer polymer. By using this bicomponent spinning technology, both the material strength profile and the biological properties can be engineered into the fiber to meet specific medical requirements. In addition, polymers with different thermal properties can be spun into sheath–core bicomponent configurations to be thermally bonded as a nonwoven web for use as protective gown fabrics, where the sheath component acts as an adhesive having a lower softening temperature than the core component.

As illustrated in Figure I.2.14.1, the eight-component segmented-pie configuration contains two different polymers, and, since these two have no attraction or adhesion between them, they can be split into finer triangular segmented fibers by applying external forces
FIGURE I.2.14.4 Histological images of PGA/PP sheath/core bicomponent fibers showing the foreign body response after 28 days in a rat subcutaneous model with hematoxylin, phloxine and safran stain. FIGURE I.2.14.5 Schematic diagram of textile fabrics (A) Woven structures; (B) Knitted structures.

(e.g., mechanical or hydraulic) (Gong and Nikoukhesal, 2009). Alternative configurations, such as "islands-in-the-sea" and a 16-component segmented pie with a core are spun as precursor fibers to create grooved or ultra fine fibers by removing the white sacrificial polymer component in a subsequent post-spinning process (Chung et al., 2010b).

TEXTILE STRUCTURES

After a fiber or yarn is produced, it is then fabricated into a textile structure in order to obtain the desired mechanical and biological properties. Typical biotextile structures used for medical applications include wovens, knits, braids and nonwovens. Within each of these configurations, many variations exist. Each type of construction has positive and negative attributes and, in most cases, the final choice represents a compromise between desired and actual fabricated properties. For example, woven fabrics typically are stronger and more dimensionally stable, and can be fabricated with lower porosities

or water/blood permeability compared to knits, but are stiffer, less flexible, and more difficult to handle and suture. Knits have higher permeability and flexibility than woven designs and are easier to suture, but may dilate after implantation. Braids have high longitudinal tensile properties, but can be unstable when subject to torsional loads. Each construction is a compromise.

Woven

What is a Woven Structure?

The term **woven** is used to describe a textile configuration where the primary structural yarns are oriented at 90° to each other. The machine direction is called the warp direction and the cross direction is identified as the weft or filling direction. Because of the orthogonal relationship between the warp and weft yarns, woven structures display low elongation and high breaking strength in both directions. There are many types of woven constructions including plain, twill, satin, and leno weaves, as illustrated in Figure I.2.14.5A, which are commonly used in vascular graft and dental ribbon fabrications.

TABLE I.2.14.4	Examples of Structure and Properties of Woven Polyester Vascular Prostheses

Suture retention strength (N)	26.9		22.0		19.0	

Table I.2.14.4 lists a number of commercial woven vascular graft designs and presents their textile structure and performance properties. Water permeability is one of the critical parameters used in the assessment of textile structures for vascular implants, which is a measure of the water flux through a fabric under a fixed pressure of 120 mmHg (ANSI/AAMI/ISO (R), 2004). Surgeons use this parameter as a guide to determine if "pre-clotting" of a graft material is required prior to implantation. Fabric grafts with water permeability values less than 300 ml/cm^2/min usually do not require pre-clotting prior to implantation, and so are safe to use for emergency surgery when there is no time for pre-clotting (also when a patient's blood clotting ability is unknown). Water permeability is controlled by the linear density of the yarns, as well as the woven fabric count that is measured in terms of the frequency of warp yarns (ends/cm) and the frequency of weft yarns (picks/cm). Plain weaves, in contrast to twill and satin weaves, can be made very thin (e.g., 0.27 mm) and have thus become the material of choice for many endovascular graft designs. However, plain weaves woven from flat multifilament yarns do not permit good cellular attachment. Therefore, the choice of textured multifilament yarns in twill or satin weave provides a more open, porous, and thicker structure that permits greater tissue infiltration, which is desirable for long-term healing of vascular prostheses. Figures I.2.14.6A and I.2.14.6B show the external and internal (luminal) surfaces of a DeBakey Soft Woven® prosthesis with a smooth tightly woven 1/1 plain weave compared to a Twill Weave® (unsealed Gelweave™) prosthesis with textured yarns providing bulkier floats on the surface. The structure and properties of these devices are listed in Table I.2.14.4.

Knitted

What is a Knitted Structure?

Knitted constructions are made by interlooping yarns in horizontal rows (wales) and vertical columns (courses) of stitches. They are softer, more flexible and easily conformable, and have better handling characteristics than woven structures. As is the case with woven structures, there are several variations in knits; the most common are the weft knit and warp knit constructions as seen in Figure I.2.14.5B. When used for vascular grafts, knitted structures can have water permeability values as high as 5000 ml/cm²/min, and therefore they need to be coated or impregnated with collagen or gelatin so that the surgeon does not have to perform the time-consuming pre-clotting process at the time of surgery.

Table I.2.14.3 lists a number of commercial knitted vascular graft designs and presents their textile structure and performance properties. Most yarns used for these knitted vascular grafts are textured so as to impart thickness to the fabric for improved softness, flexibility, ease of suturing, and to provide larger pores for tissue ingrowth. Knitted structures have an inherently open porous structure with total porosity values greater of at least 65%, which requires special processing to shrink the yarns and tighten the looped structure by heat setting. Because of their open structure, knits are typically easier to suture and have better handling characteristics. Warp knitted structures have less stretch than weft knits, and therefore are inherently more dimensionally stable, being associated with less dilation *in vivo*. In Figures I.2.14.6C and I.2.14.6D, the external and internal (luminal) surfaces of the weft knitted Barone Microvelour® are compared to those of the warp knitted VP1200K™ (unsealed Gelsoft®) prosthesis. The structure and properties of these devices are listed in Table I.2.14.3.

Warp knits do not run or ravel when cut at an angle, and can be further modified by the addition of an extra yarn in the structure, which adds thickness, bulk, and surface roughness to the fabric (King, 1991). This structure is commonly known as a velour or pile knit, as indicated in Table I.2.14.3. The addition of the pile yarn, while making the fabric feel softer, results in a thicker thrombotic deposit on initial blood contact, which leads to an increased amount of tissue ingrowth into the fabric during healing.

Braided

Braids have found their way into medical use primarily in the manufacture of suture materials and anterior cruciate ligament (ACL) prostheses. Common braided structures involve the diagonal intersection of an even number of yarns that are interlaced at different angles and frequencies, as shown in Figure I.2.14.7. The variables in constructing a braid include the horizontal repeat distance l, called a line, the vertical repeat distance s, called a stitch, w the width of the yarn, and θ the braid angle between the yarn and machine directions. A myriad of structural forms can be achieved with three-dimensional braiding, such as "I" beams, channels, and solid tubes. The challenge for using a braided structure as an implantable device is in securing the many yarns at both ends of the device. Some progress has been made in fabricating a braided structure from a single wire for an esophageal stent (Polyflex®) and for thoracic aortic aneurysm repair (Murgo et al., 1998).

Nonwoven

By definition, a nonwoven is a textile structure produced directly from fibers without the intermediate step of yarn production. The short staple fibers or long continuous fibers are either bonded or interlocked together by means of mechanical, hydraulic or thermal action, or by using an adhesive or solvent, or a combination of these approaches. The fibers may be oriented randomly or preferentially in one or more directions, and by combining multiple layers one can engineer the mechanical properties independently in the machine (lengthwise) and cross directions.
FIGURE I.2.14.7 Schematic diagrams of braided structures and SEM photomicrograph of a braided silk suture.

The total porosity, average pore size, and pore size distribution of a nonwoven web can be controlled by changing certain variables, such as the density of fibers, fiber diameter and length, orientation of the web, and the method of bonding. Nonwoven structures have been used as *ex vivo* blood filters and as a composite multilayered wound dressing as listed in Table I.2.14.1, as well as for scaffold structures for tissue engineering applications (Mao and Russell, 2004; Unger et al., 2004).

FINISHING

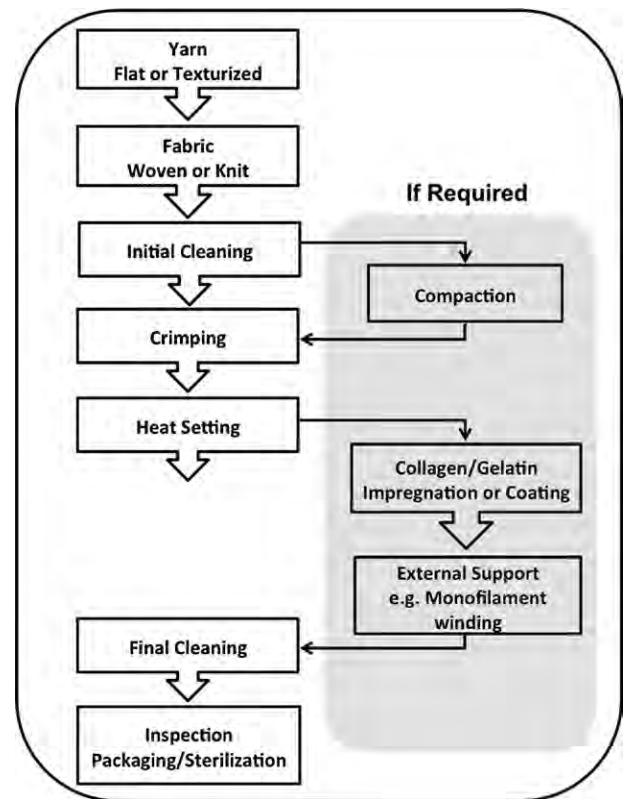
Once a textile structure has been fabricated from yarns or fibers, the subsequent processing steps are known as finishing. As mentioned previously, the starting yarn may contain additives, which can result in cytotoxicity and adverse reactions when in contact with tissue. Some of these additives, such as titanium dioxide that is used as a delusterant to increase the amount of light reflected, are inside the spun fiber and therefore cannot be removed during finishing. On the other hand other surface finishes, such as yarn lubricants, can be removed with the proper cleaning and scouring operations. Typically such surface additives are mineral oil or silicone-based and demand specially designed aqueous-based washing procedures or dry-cleaning techniques with organic solvents to ensure complete removal. Since each polymer and fabrication process is different, the finishing operation must be material and device specific. Finishing includes such steps as cleaning, heat setting, bleaching, shrinking, inspection, packaging and sterilization, and will influence the ultimate properties of the biotextile fabric. Figure I.2.14.8 represents a schematic of a typical vascular graft manufacturing operation including the finishing steps. If the cleaning process is properly designed with the use of pyrogen-free water, all extractables are removed and no additional pyrogens are added during the finishing process. Testing of the finished product for cytotoxicity and residual extractables is typically used to ensure


FIGURE I.2.14.8 Typical vascular graft manufacturing operations.

that all surface additives are removed from the product prior to packaging and sterilization.

BIOTEXTILE PRODUCTS

General Surgery

Two main applications of biotextiles in general surgery are tissue repair meshes and surgical sutures. Various forms of porous mesh fabrics are used as a support material in hernia and prolapse repair or as tissue patches, as listed in Table I.2.14.1. Traditional constructions are

warp knitted from polypropylene or polyester mono-filaments or ePTFE membranes, which are preferred since they are more resistant to infection compared to multifilament yarns. More recently, three-dimensional warp knits using polyester multifilament yarns have been found to be more flexible, and therefore can be implanted endoscopically. While most of these meshes are non-degradable and therefore permanent, recent developments have included a resorbable component to promote a more acute inflammatory response and faster healing. Some designs include a protein coating (collagen and/or gelatin) or a microporous PTFE layer on one side only, which reduces the risk of unwanted adhesions *in vivo*. As with other textile structures, various properties can be engineered into the mesh to meet design goals that may include added flexibility, increased strength, reduced thickness, improved handling, and better suture holding strength.

Commercial sutures are either monofilaments or braided multifilament structures, and can be constructed from natural materials such as silk, collagen (catgut), or synthetic materials such as nylon, polyester, polypropylene, and stainless steel, as listed in Table I.2.14.1. Further discussion of the structure and properties of surgical sutures can be found in Chapter II.5.17.

Among the recent innovations related to sutures is the creation of the barbed suture, which can anastomose tissue without the need for a knot. The concept mimics the porcupine's quill, whereby the oriented barbs protrude from the monofilament's surface and mechanically interlock with the surrounding tissue. The advantages of such self-anchoring barbed sutures include the shorter time for suturing because there are no knots to tie, and the more uniform distribution of holding forces which reduces suture slippage, tissue distortion and necrosis, and leads to improved cosmesis (Leung et al., 2002). Resorbable barbed sutures are preferred clinically for cosmetic and plastic face-lift procedures and eyelid ptosis. Work is continuing to identify the optimum barb dimensions, frequency, and geometry for use with different types of tissues (Ingle and King, 2009; Ingle et al., 2010).

Cardiovascular

Biotextiles developed for cardiovascular uses include applications such as heart valve sewing rings, annuloplasty rings that provide dimensional stability to incompetent cardiac heart valves, vascular grafts and endovascular stent grafts, as listed in Table I.2.14.1. One of the key uses of biotextiles in surgery is in the fabrication of large diameter vascular grafts (10–40 mm in diameter). As previously noted, polyester (PET) is the principal polymer used to fabricate vascular grafts. These grafts can either be knitted or woven and are produced in straight or bifurcated configurations. Within each type of construction, various properties can be incorporated into the product, as illustrated in Tables I.2.14.3 and I.2.14.4.

The ideal criteria for a successful vascular prosthesis include the following requirements: available in different shapes and sizes; sterilizable; ease of handling and suturability; cut edges will not fray, ravel, or run; hemostatic; biocompatible; low rate of infection; encourages rapid healing; dimensionally stable; non-thrombogenic; and compliant (Edwards and Tapp, 1957; King, 1991).

No single biomaterial can meet all of these requirements, but textile structures being flexible, porous, lightweight, and compliant satisfy most of these criteria. Woven structures can provide hemostasis and dimensional stability whereas knitted devices are more compliant, easier to handle and suture, and encourage more rapid healing (Tables I.2.14.3 and I.2.14.4). Warp knits are more dimensionally stable and do not ravel compared to weft knits, which are more compliant. Therefore a compromise is necessary, and one needs to identify the key properties for a particular implantation site or disease state before choosing the material and selecting the structure. In order to avoid kinking and facilitate handling, the concept of crimping or imparting radial folds prior to finishing was introduced by Dr. Sterling Edwards in the 1950s (Edwards and Tapp, 1957).

Today a substantial amount of research activity is being directed towards the development of a small vessel prosthesis with diameters less than 6 mm for coronary artery bypass and tibial/popliteal artery replacement. Currently due to high thrombogenicity and compliance mismatch of existing materials and complications due to intimal hyperplasia, no successful commercial product exists to meet this market need. The question still remains as to whether a biotextile will work as a small vessel prosthesis if it is fabricated to have the required compliance and mechanical properties, and its surface is modified with a surface coating, growth factors and other bioactive agents to prevent thrombosis and thrombo-embolic events.

Current research activities are directed towards developing biological-based grafts, surface-modified materials, and tissue-engineering constructs (Sipehia et al., 1996; Niklason et al., 1999; Chung et al., 2010a). The first clinical application of an artificial vessel based on a synthetic scaffold system was reported to successfully reconstruct a low-pressure pulmonary outflow tract in pediatric patients with a cyanotic congenital defect (Shin'oka et al., 2001). In this approach, autologous bone marrow cells were seeded into tubes made from a copolymer of lactide and caprolactone and reinforced with a woven PGA sleeve. While the grafts were not suitable for high pressure arterial implantation, this study still demonstrated the feasibility of a tissue-engineered approach. So far, these grafts have been implanted in at least 22 patients as venous conduits for reconstructive cardiovascular surgery, and >95% patency at 1 year has been reported without evidence of stenosis, thrombogenic complications or aneurysm formation (Matsumura et al., 2003).

During the past 20 years, large investments of resources have been focused on the development of endovascular stent grafts, which are used for minimally invasive aortic aneurysm repair, occlusive disease, and vascular trauma (Hinchliffe and Hopkinson, 2007). The advantages over open surgery are that there is less patient trauma, blood loss, post-operative complications, risk of infection and exposure time to anesthesia. Also the costs associated with hospitalization, patient care, and the time for recovery and rehabilitation are significantly lower than for open surgery. Endovascular prostheses or stent grafts are tubular biotextiles with either an internal or external stent, which are typically made from nitinol or stainless steel wire. Since the stent graft needs to be collapsed and folded onto a balloon catheter and inserted through a distal artery, the structure needs to be thin, flexible, and hemostatic. These requirements can be met with either an ePTFE membrane or a polyester tube tightly woven from fine (45 dtex or less) untextured multifilament yarns so as to minimize the overall wall thickness (Cartes-Zumelzu et al., 2002; Guidoin et al., 2004). However, the long-term durability and fatigue resistance of such structures needs to be evaluated by *in vitro* testing and predictive modeling (Zhao et al., 2009, 2010). (Also see Chapter II.5.18 with a section on drug-eluting stents.)

Traditionally knitted textile structures have been used exclusively as sewing rings for aortic and mitral valves, due to their high suture retention strength and their ability to tolerate needle and iatrogenic damage during surgical procedures. More recently, researchers have reported developing heart valve leaflets from textile-based structures because of their superior flexural fatigue properties using either permanent polyester or resorbable PCL multifilament yarns for tissue engineering (Lieshout et al., 2006; Heim et al., 2008).

Orthopedic

Attempts have been made to construct replacement ligaments and tendons using woven and braided fabrications. One design using a high tenacity polyester woven web inside a pre-stretched knitted graft was evaluated for the repair of separated shoulder joints and anterior cruciate ligaments (ACL) with limited success. In general, biotextiles have had premature clinical failures in orthopedic ligament and tendon applications as a result of abrasion wear problems, inadequate strength, and poor bone attachment (Guidoin et al., 2000). An attempt was made to use a braided PTFE structure for ACL repair, but early failures occurred as a result of creep of the PTFE polymer, resulting in patients experiencing increased knee instability over time (Roolker et al., 2000). Three-dimensional braided and woven tissue engineering scaffolds using resorbable fibers spun from PGA, PLA, and their copolymers have been reported for ligament and cartilage replacement (Cooper et al., 2005; Lu et al., 2005a; Freeman et al., 2007; Moutos et al., 2007). A successful ACL

ligament replacement would be a significant advance for orthopedic surgery, but at present no biotextile or other type of prosthesis has shown clinical promise.

Traditionally, loadbearing prostheses used in orthopedic applications have been fabricated primarily from metals and ceramics due to their high strength and modulus. With recent advances in fiber spinning technologies, it is now possible to produce fibers with superior mechanical performance, such as ultra-high molecular weight polyethylene (UHMWPE), carbon, and arylamide (Kevlar®) fibers. These fibers are mostly used as a reinforced composite structure for bone graft cement or for spinal support devices.

Wound Dressings and Skin Grafts

Another common application of biotextiles and fiber technology is in wound dressings and hemostats. Their primary functions are to serve as a physical barrier to prevent infection and to promote moisture absorption and blood coagulation. Woven cotton gauze has been used traditionally as a wound dressing because of its superior moisture absorption and blood clotting ability. However, since it is composed of short staple fibers of cellulose, it adheres to the wound and causes infection and trauma upon removal. Other materials such as polyester, polypropylene, nylon, and viscose rayon, and the addition of antibiotics, growth factors, and a barrier layer have been combined with absorbent cellulose in order to fabricate a more effective wound dressing. A typical example of a layered laminate structure includes a protective outer barrier of polyester or polypropylene with a cellulose-based absorbent inner layer. Examples of commercial products are listed in Table I.2.14.1. Collagen, chitosan, and cellulose derivatives can also serve as hemostatic devices in layered fibril, foam, and powdered forms.

Patients who have suffered severe burn injuries or chronic diabetic ulcers, need a temporary skin graft for protection against infection and maintenance of hydration prior to an autologous dermal transplant. For such patients, the first commercial skin graft product available was Epicel® made with sheets of epidermal keratinocytes (Guerra et al., 2009). While being biocompatible, this type of graft with only biological components lacked mechanical integrity and was challenging to handle and transport. To overcome these limitations, alternative skin graft products have been developed to include both biological components such as porcine collagen and allogenic fibroblasts with a synthetic textile layer as listed in Table I.2.14.1 (Marston et al., 2003). (See also Chapter II.5.14 on Burn Dressings and Skin Substitutes.)

FUTURE DIRECTIONS

In the future, innovations and new applications for medical fibers and biotextiles will be driven by both the

direction of clinical practice, which is moving towards more arthroscopic and less invasive surgical techniques, as well as the move towards regenerative medicine whereby resorbable scaffolds serve as temporary templates for the proliferation and regeneration of new viable tissues. Biotextiles are thinner, stronger, more flexible, and lighter weight structures than other biomaterials such as metals and ceramics, and they have already demonstrated their superiority to withstand the compression, tensile, shear, and bending forces that accompany folding, compaction, and delivery through a catheter. Clearly, less invasive approaches to implantation which are currently used for endovascular stent grafts, aortic heart valves, hernia and prolapse meshes, embolic protection devices, spinal disc prostheses, and septal defect repair, will continue to expand as surgeons and biomedical engineers rise to meet new and currently unforeseen clinical challenges.

These are five areas within the field of medical fibers and biotextiles where we anticipate further advances to be made in the near future.

1. In the past the regulatory environment has delayed getting new polymer materials to market. We note that there are now a plethora of novel fiber-forming polymers in development which have unique properties, such as shape memory, that are electroactive, elastomeric, rapidly resorbable, responsive, and "smart" materials. When spun into fibers or as biotextiles, they can serve as biosensors, actuators, and drug delivery systems by responding to changes in temperature, pH, moisture level or drug concentration (Wang and McCord, 2007; Shi et al., 2008; Shankar et al., 2009). In addition, through advances in genetic engineering, we are able to capitalize on the unique properties of biopolymers, as found in high tenacity spider silk, and use a biomimetic approach to design and synthesize such novel fiber-forming protein biopolymers with unique strength and mechanical performance for use as ophthalmic sutures (Vollrath and Knight, 2001).

2. Figure I.2.14.1 has already shown how new fiber spinning techniques have extended the range of manufactured fiber diameters from about 10 μm down to less than 50 nm, and have also facilitated the spinning of fibers with a range of different cross-sectional shapes and bicomponent cross-sections. These finer noncircular and bicomponent fibers appear to provoke a different cellular response that as yet is not fully understood, but lends itself to fabricating implantable devices and tissue engineering constructs that have uniquely tunable cellular responses, rates of resorption, and drug delivery performance (Vaughn and Carman, 2001; Lu et al., 2005b).

3. While textile fabrics have traditionally been thin, flexible, two-dimensional structures, there is increasing use of pile weaving and knitting techniques, as well as other technologies such as flocking, tufting, and embroidery to create a thick three-dimensional structure that contains fibers and yarns oriented in the thickness (z-axis) direction (Wollenweber et al., 2006; Pereira et al., 2007; Walther et al., 2007; Rentsch et al., 2009). There is a need to apply these velvet, velour, and toweling fabrication techniques to the development of the thicker tissue engineered scaffolds so as to improve cell migration and tissue regeneration through the thickness of the construct.

4. Surface modification is a well-established technique for ensuring that biomaterials, regardless of their bulk chemical structure, have appropriate biocompatibility in the acute period after implantation for their particular clinical application. While textiles have traditionally always relied on the appropriate final finishing operations to ensure cleanliness, uniformity of color, structural stability, and surface functionality, such as coating, water repellency or hydrophilicity, it is only recently that more advanced surface modification techniques, such as the immobilization of biomolecules, growth factors, and antimicrobial agents, and the use of radio frequency plasma for bioactivation, sterilization or surface grafting have been applied to biotextile structures (Michielsen and Lee, 2007; El-Mekawy et al., 2010; Gorensek et al., 2010; Patterson et al., 2010). We anticipate seeing surface modification becoming increasingly important in the future as our understanding of the potential benefits of these techniques being applied to medical fibers and biotextiles with such large surface areas continues to expand. (See also Chapter I.2.12 on surface modification of biomaterials.)

5. Given that the diameters for some medical fibers lie in the micro-range, which is close to the dimensions of cells and microorganisms, this is one of the reasons why biotextiles can be engineered to elicit precise and reproducible cellular responses. Further, some fibers with diameters in the nano-range may have special effects on living cells, as noted above. Not only are biotextile structures versatile in their elemental design and hierarchical components, but they are also fabricated by well-established textile manufacturing technologies that are designed to make large quantities of defined structures with identical and precisely specified property requirements under good quality and manufacturing controls. As such, biotextiles and fiber-based tissue engineering scaffolds will soon be considered as standardized "off-the-shelf" products which can be scaled up to be fabricated in large quantities. Biotextiles are therefore well suited to commercialization, and their production can be readily scaled up to meet growing clinical demand.

In summary, the use of medical fibers and biotextiles in medicine will continue to grow as new synthetic polymers and genetically-engineered biopolymers, fiber

spinning technologies, three-dimensional constructions, coatings, and surface modification processes are introduced. This will meet the future needs of less-invasive interventional procedures and surgical delivery, the long-term cyclic fatigue resistance of permanent implants, and the previously unobtainable goal of regenerating tissue-engineered organs.

CHAPTER I.2.15 TEXTURED AND POROUS MATERIALS

Heidi E. Koschwanez and William M. Reichert
Department of Biomedical Engineering, Duke University,
Durham, NC, USA

INTRODUCTION

The use of porous and textured implants to stimulate tissue ingrowth, disrupt fibrosis and promote angiogenesis dates back as far as the 1940s, and is an early example of a tissue engineering-like approach to biomaterials. Device function and placement in the body dictates what material would be most suitable for a particular application. Numerous materials (metals, ceramics, natural and synthetic polymers) can be textured or rendered porous using a wide variety of techniques (Tables I.2.15.1 and I.2.15.2).

The extent to which a textured or porous material can influence the host tissue response is related to pore size and porosity. While no one pore size fits all applications, the majority of porous materials employed possess an open architecture with interconnecting pores that are sufficiently large to support cell and tissue infiltration, but small enough to disrupt fibrous tissue deposition (Sharkawy et al., 1998). Textured implants with open architecture pore structures also appear to form thinner foreign-body capsules (Salzmann et al., 1997; Sharkawy et al., 1997; Updike et al., 2000; Ward et al., 2002) (also see Chapter II.3.2). Porous surfaces promote tissue ingrowth that minimizes interfacial cell necrosis from mechanical shear forces, that in turn results in less inflammation and reduced capsule thickness (Rosengren et al., 1999).

Tissue ingrowth strongly influences the long-term success of orthopedic, dental, ocular, percutaneous, and cardiovascular implants. In most instances, texturing is used to promote tissue ingrowth for improved tissue–implant stabilization. Other important effects incited by implant texturing include disruption of fibrous encapsulation,

TABLE I.2.15.1	Common Materials used in Orthopedic and Dental Applications for Fabricating Porous Coatings or Porous Scaffolds			
Material		**Common Methods to Render Porous**	**Advantages**	**Disadvantages**
Ceramics (Sun et al., 2001; Karageorgiou and Kaplan, 2005; Simske et al., 1997)	• Hydroxyapatite (HA) • Natural coral • Calcium phosphate based material • Amorphous glasses	• Plasma-spray (coating) • Sinter (scaffold)	• Similar composition and structure to natural bone • Enhanced osseointegration using apatite-like materials • Biocompatible • Easy to render porous • Low corrosion	• Coatings: Long-term stability (i.e. resorption, delamination) • Scaffolds: Brittle, slow degradation • Not amenable to machining • Difficult to control pore sizes of naturally occurring ceramics
Metals (Sun et al., 2001; Karageorgiou and Kaplan, 2005; Simske et al., 1997; Ryan et al., 2006; Bobyn et al., 1999)	• Titanium (Ti) and Ti alloys • Cobalt-chromium (Co-Cr) and Co-Cr alloys • Tantalum	• Plasma spray • Sinter • Grit-blast • Wire mesh • Combustion synthesis • Vapor deposition	• Bioinert • Excellent mechanical properties (i.e. less susceptible to fatigue than ceramics, polymers)	• Corrosion related complications • Stress shielding complications from significantly higher Young's modulus than bone
Natural Polymers (Karageorgiou and Kaplan, 2005)	• Collagen • Hyaluronic acid • Silk fibroin	• Freeze-drying • Salt leaching • Gas foaming • Crosslinking	• Biocompatible • Naturally biodegradable • Amicable for growth factor incorporation, supporting cells	• Lack mechanical strength • Rapid degradation rates • Chemical modifications can reduce biocompatibility
Synthetic Polymers (Karageorgiou and Kaplan, 2005; Simske et al., 1997; Ryan et al., 2006)	• Poly lacticide (PLA) • Poly glycolide (PGA) • Poly ethylene glycol (PEG) • Polyvinyl alcohol (PVA) • Polyethylene terephthalate (PET) • polyurethane	• Salt leaching • Gas foaming • Electrospinning • Sintering	• Scaffolds can easily be tailored to meet application • Amicable for growth factor incorporation, supporting cells	• Lack mechanical strength

Note: Stainless steel is not commonly used in porous form since it is not as corrosive resistant as Ti, Co-Cr and their alloys (Simske et al., 1997).

TABLE I.2.15.2	Summary of Methods Developed for Fabricating Porous Three-Dimensional Biodegradable Scaffolds for Tissue Engineering (Chen et al., 2002; Hutmacher, 2000; Yang et al., 2001)			
Method	**Description**	**Processing Time**	**Merits of Method**	**Challenges**
Gas foaming * (Mooney et al., 1996)	High pressure CO_2 gas dissolved in polymer to create pores	~ 2 days	• Tuneable porosity and pore structure • No organic solvents	• Closed pore architecture • Non-porous surface
Fiber bonding (Mikos et al., 1993)	Physical bonding non-woven polymer fibers to create interconnecting mesh	~ 4 days	• Interconnecting, open pore architecture • Large surface area for cell attachment	• Lack of mechanical strength • Difficulty controlling porosity • Amenable to only certain polymers and solvents
Three-dimensional printing (Wu et al., 1996)	Computer controlled solvent application to sequential layers of powdered polymer, creating a porous scaffold	> 7 days	• Open pore architecture • Complex 3D scaffolds possible • Incorporation of bioactive compounds	• Lack of mechanical strength • User and technique sensitive • Instrument requirements
Phase separation (Schugens et al., 1996a,b)	Sublimation of solvent in polymer to form macropores	>2 days	• Open pore architecture • Can incorporate bioactive molecules	• Difficult to control scaffold morphology
Emulsion freeze-drying (Whang et al., 1995)	Polymer, solvent and water (all immiscible) homogenized, quenched in liquid N_2, then freeze-dried to form pores	>7 days	• Open pore architecture • Can incorporate bioactive molecules	• Difficult to control scaffold morphology • User and technique sensitive
Porogen leaching ‡ (Mikos et al., 1994)	Dissolution of salt in polymer to form pores	>7 days	• Open pore architecture • Tuneable pore size and porosity	• Lack of mechanical strength • Possible solvent residue • Can not incorporate bioactive molecules • Visible surface skin

*Gas foaming with CO_2 has also been combined with salt leaching to create open pore architecture with a processing time of approximately 4 days (Harris et al., 1998).
‡Porogen leaching has also been combined with gas foaming using ammonium bicarbonate as salt leaching/gas foaming agent, reducing processing time to 24 hours with no surface skin layer (Nam et al., 2000).
FIGURE I.2.15.1 Difference in cellular and tissue response around polyvinyl alcohol (PVA) implanted in rat subcutaneous tissue after 3 weeks: (a) porous PVA (300 μm pores) promoted fibrovascular ingrowth (arrows denote capillaries); and (b) smooth PVA developed dense avascular capsule adjacent to material surface. (From Koschwanez, H. E. (2004). Unpublished data.)

improved tissue healing, and increased vascularization of the tissue surrounding the implant (Figure I.2.15.1).

These recurring concepts appear throughout this chapter in several medical devices, i.e., breast implants, bone regenerative implants and orthopedic implant coatings, ocular implants and glaucoma drainage devices, synthetic vascular grafts, and percutaneous devices, with a separate section for percutaneous glucose sensors. For each device, the benefits and challenges of using textured surfaces will be discussed, in addition to optimal pore size, choice of implant material, and theorized mechanisms of how these surface topologies influence host response.

STIMULATING TISSUE INGROWTH

Porosity to Promote Bone Regeneration and Implant Fixation

Porous materials are often used to repair severely fractured or malformed bone. These bone regeneration scaffolds must provide structural support to the newly forming bone, share mechanical properties similar to the host bone, be biocompatible, and biodegrade at a rate synergistic with bone remodeling (Karageorgiou and Kaplan, 2005). Controlling pore size and porosity is essential in creating a scaffold that meets the needs of both the specific repair site (mechanical, mineral, and cellular properties) and the patient (age, activity level, nutrition, disease) (Karageorgiou and Kaplan, 2005).

Of the over 2,000,000 total joint replacements performed annually worldwide (Kuster, 2002; de Pina et al., 2011), an increasing number of implants are employing textured fixation layers to minimize latent complications of prostheses loosening (Chang et al., 1996). These fixation layers mostly consist of metal beads sintered to the implant surface, thin coatings of hydroxyapatite or grooves or pitted surfaces (Simske et al., 1997; Sun et al., 2001). Candidates for textured implants are typically individuals with replacement joints (total knee, acetabular component) implanted in cancellous bone, as this tissue type consistently achieves a stable implant–host bone attachment (Bloebaum et al., 2007). Improved implant fixation through osteointegration into porous implants also reduces stress shielding (a condition that occurs from uneven load distribution between the host bone and implant; see Chapter II.5.6). As the stiffer implant material bears more load than the bone, the bone becomes weakened and susceptible to fracture and implant loosening.

Rate of bone growth into a porous material is highly dependent on pore size (Klawitter et al., 1976) and pore connectivity (Hing et al., 2004). Bone is naturally porous, with pore sizes ranging from 1 to 100 µm (Simske et al., 1997) (Figure I.2.15.2). The optimum pore size for bone ingrowth into porous-coated prostheses, regardless of material, ranges from 100–400 µm (Simske et al., 1997;

Kienapfel et al., 1999; Ryan et al., 2006); however, interconnecting pores as small as 50 µm have been shown to be effective primarily for encouraging blood vessel growth within the implant (Klawitter et al., 1976; Bobyn et al., 1980; Simske et al., 1997; Ryan et al., 2006). To support continuous tissue ingrowth, a minimum pore size of 100 µm is required. Although increased fixation strength occurs with increased pore size when using pores less than 100 µm (Kienapfel et al., 1999), no such relationship has been observed for pore size in the 150–400 µm range. Interestingly, while the size of the interconnecting pores is critical for osteointegration, pore shape does not appear to influence biological response (Turner et al., 1986; Ryan et al., 2006).

Osteointegration will not occur if fibrous tissue ingrowth precedes first. Fibrous ingrowth has been shown to occur with pores smaller than 15 µm (Simske et al., 1997) or larger than 1000 µm (Ryan et al., 2006), suggesting different cell types have preferential pore sizes. Increased micromotion between the implant and host bone will also promote fibrous connective tissue ingrowth instead of bony ingrowth (Kienapfel et al., 1999; Ryan et al., 2006). This fibrotic tissue may inhibit bone formation or prevent bony ingrowth from the host tissue, ultimately reducing implant fixation strength (Ryan et al., 2006).

Several porous ceramics, metals, and polymers have been investigated for orthopedic implants, with porous metals being the most widely employed for loadbearing applications (Ryan et al., 2006) (Table I.2.15.1). However, porous materials may have substantially reduced dynamic fatigue strength. Additionally, the pores may create stress concentration sites for microfractures, compounding implant fatigue (Simske et al., 1997). Additionally, porous metals may exhibit higher corrosion rates, due to increased surface area, raising long-term safety concerns (Ryan et al., 2006). Composite implants blending two or more materials, such as plasma-sprayed hydroxyapatite coatings on titanium, could provide the best opportunity to match implant and bone properties (Simske et al., 1997; Sun et al., 2001). Another interesting possibility is creating scaffolds with gradient pore size and porosity to promote osteogenesis at one end of the scaffold and osteochondral ossification at the other,
FIGURE I.2.15.3 (a) Examples of porous hydroxyapatite (left) and polyethylene (right) orbital implants; (b) sagittal view of human orbit showing placement of orbital implant.

ideal for bone-cartilage repair. Investigations are also underway to integrate biomolecules into scaffold materials to further promote bone repair (Karageorgiou and Kaplan, 2005).

Texturing to Improve Healing and Restore Motion in Eye Implants

When the eye is enucleated due to severe trauma, intraocular cancer or removal of a blind and painful eye, the lost tissue may be compensated with an orbital implant (Chalasani et al., 2007; Sami et al., 2007). Important considerations with orbital implants include fit, optimized prosthesis motility, and minimized long-term complications, such as implant exposure, extrusion, migration, and infection (Goldberg et al., 1994).

Numerous materials have been used in orbital implant design, including glasses, silicones, and acrylics (Chalasani et al., 2007). Porous materials such as hydroxyapatite (HA), porous polyethylene (PPE), and aluminum oxide (AO) are showing increased popularity (Chalasani et al., 2007; Sami et al., 2007) (Figure I.2.15.3). HA, the mineral component of bone, has good biocompatibility; however, suturing this material to the extraocular muscles is difficult. Abrasion from roughened HA implants may exacerbate inflammation and lead to latent implant exposure. The roughness of HA also makes surgical insertion more challenging (Chalasani et al., 2007). PPE is flexible, easily molded, relatively inexpensive, and can be sutured to surrounding tissue (Chalasani et al., 2007). PPE appears to incite less inflammation and fibrosis than HA (Goldberg et al., 1994). AO is robust, biocompatible, easy to manufacture, and less expensive than HA (Chalasani et al., 2007). AO is the newest porous material used in orbital implants, with only one commercially available implant (Chalasani et al., 2007). More long-term studies are required to ensure clinical efficacy of this material as an orbital implant (Sami et al., 2007).

HA and PPE roughly resemble the structure of trabecular bone (Chalasani et al., 2007; Sami et al., 2007), and encourage fibrovascularization (tissue ingrowth) of the implant within weeks of implantation (Chalasani et al., 2007). Optimal pore size for orbital implants ranges from 150 μm to 400 μm, with preference closer to 400 μm for more complete fibrovascularization (Goldberg et al.,

1994; Rubin et al., 1994). Highly porous materials with interconnecting pores of uniform diameter are more favourable for facilitating cell movement and nutrient flow within the implant, encouraging tissue ingrowth (Chalasani et al., 2007).

Porous orbital materials are stiffer in relation to the conjunctiva and surrounding tissue (Chalasani et al., 2007). This compliance mismatch coupled with constant implant movement by extraocular muscles may exacerbate inflammation, leading to tissue necrosis and eventual implant exposure (Chalasani et al., 2007). Porous hydrogels may be a promising alternative to the current implant materials, as these water-based materials possess physical properties similar to native tissue (Chalasani et al., 2007).

DISRUPTING FIBROSIS

Texturing to Disrupt Capsular Contracture of Breast Prostheses

One of the most common cosmetic surgical procedures in the United States is breast augmentation (Gampper et al., 2007). All breast implants are constructed with a smoothed or textured shell of silicone elastomer, a material pervasively used in medical devices. The majority of implants are filled with saline rather than silicone gel, after the 1992 FDA voluntary moratorium on silicone gel implants (Gampper et al., 2007); however, gel-filled implants are making a comeback owing to more lifelike mechanical properties.

Fibrous capsular contraction is the most common complication in breast augmentation surgery, with long-term contracture incidence reported at 15–25% (Malata et al., 1997; Benediktsson and Perbeck, 2006). As with any foreign object implanted in the body, the host response to a breast implant is to construct a fibrous capsule around the foreign-body, "walling off" the implant from the rest of the body. During the first several months post-implantation the fibrous capsule begins to contract, resulting in breast firmness that may lead to patient discomfort and disfigurement.

Several possible factors contribute to breast implant capsular contracture, including implant surface (smooth versus porous), implant placement (submuscular versus

subglandular), implant shape (i.e., fill volume), bacterial infection, bleeding, surgical technique, post-operative care (i.e., breast massage), and patient health (Burkhardt et al., 1986; Gabriel et al., 1997; Becker and Springer, 1999; Embrey et al., 1999). Contracture has been found to be an independent breast-based, not patient-based, phenomenon (i.e., one breast may experience contracture while the other breast may not) (Burkhardt, 1984; Burkhardt et al., 1986).

Surface texturing has been investigated as a means to reduce capsular contracture for decades. Texturing has been reported to reduce early capsular contracture in subglandular breast augmentation (Wong et al., 2006); however, it is not conclusive whether texturing reduces contracture incidence (Bucky et al., 1994; Tarpila et al., 1997; Fagrell et al., 2001) or simply delays contracture onset (Wong et al., 2006).

The type of texturing, pore size or implant material does not appear to be as important as simply disrupting surface smoothness (McCurdy, 1990; Caffee, 1994; Danino et al., 2001). One clinical study comparing saline-filled silicone implants textured with either 75–150 µm or 600–800 µm pore size concluded that both morphologies were effective in reducing capsular contracture (Danino et al., 2001). The mechanisms contributing to reduced capsular contracture with textured implants still remain poorly understood (Pollock, 1993; Caffee, 1994; Wong et al., 2006). Disrupting the smooth surface with texturing influences collagen arrangement and structure, macrophage population, micromotion, and risk of infection (Taylor and Gibbons, 1983; McCurdy, 1990). The collagen arrangement hypothesis is that irregularly arranged collagen fibers at textured surfaces are less able to generate cooperative contractile forces typical of maturing scar tissue (McCurdy, 1990; Pennisi, 1990), while another hypothesis is that irregularly aligned collagen fibers are more susceptible to collagenase degradation (Raykhlin and Kogan, 1961; Taylor and Gibbons, 1983). Textured implants have been shown to have more macrophages and less collagen surrounding them compared to smooth implants, indicating that macrophages may be degrading the capsule as it forms, minimizing capsule thickness (Taylor and Gibbons, 1983; McCurdy, 1990). More functional hypthotheses are that the tissue integration promoted by the textured surface may be either reducing micromotion, thus reducing the extent of fibrosis or eliminating the exudate-filled periprosthetic space around the implant that is prone to infection and/or chronic inflammation (McCurdy, 1990).

While capsular contracture is a challenge from a clinical standpoint (McCurdy, 1990), patient preference suggests that breast firmness is not a definitive factor in deciding which type of breast implant is preferred. Textured implants often have an unnatural "feel," because textured implant shells lack flexibility (Caffee, 1994). A higher incidence of skin wrinkling over the breast also occurs with textured implants (McCurdy, 1990; Wong
FIGURE I.2.15.4 Schematic of glaucoma drainage device placement in eye. (Ahmed™ Glaucoma Valve glaucoma drain, New World Medical, Inc.)

et al., 2006), presumably from tissue integration that immobilizes the implant and allows implant surface wrinkling to be more visible. This may be because smooth implants reside in a fluid-like periprosthetic pocket, reducing skin wrinkling as the implant is able to move within this space. Since implant feel and appearance are important patient considerations, smooth surface implants are often preferred by patients in the absence of significant contracture (Wong et al., 2006).

Texturing to Minimize Fibrotic Encapsulation of Glaucoma Drainage Devices

Glaucoma is the obstruction of aqueous drainage that causes the intraocular pressure (IOP) to increase to the point of nerve damage (Adatia and Damji, 2005). Treatment methods to decrease IOP include topical eye drops, surgery, and glaucoma drainage devices in refractory cases (Boswell et al., 1999; Ayyala et al., 2006). Glaucoma drainage devices (GDDs) are silicone tubes inserted into the anterior chamber of the eye. Attached to the tube is a plate that is sutured beneath the conjunctiva (Jacob et al., 1998) (Figure I.2.15.4). The plate becomes enclosed by a fibrous capsule 3–6 weeks post-operative, creating a "filtering bleb" (a small bubble) through which aqueous humor drains and is reabsorbed by the surrounding tissue (Jacob et al., 1998). Over two to four years, a thick fibrous capsule forms around the device, causing the filtering bleb to fail at least 20% of the time (Jacob et al., 1998). Encapsulation decreases absorption of the drained aqueous humor, leading to increased pressure in the anterior chamber (Boswell et al., 1999).

Implant material, rigidity, flexibility, and shape (Ayyala et al., 2006) are potential contributors to long-term device failure. Micromotion of a smooth, rigid plate against the scleral surface has also been attributed to exacerbating scar tissue formation by causing constant,

low-grade inflammation (Jacob et al., 1998; Ayyala et al., 2006). To reduce micromotion, porous plate designs (50 μm pore size silicone attached to smooth plate) were investigated to encourage fibrotic tissue anchorage of the implant (Jacob et al., 1998). However, this particular porous design has been linked with higher incidences of diplopia (double vision), possibly due to implant adhesion to the recti muscles and limiting bleb elevation compared with smooth designs (Ayyala et al., 2006).

Preliminary experiments in rabbits with ePTFE porous plates (60 μm pore size) found thinner, less dense, and more vascular capsules forming than around commercial, non-porous plates. This capsule provides less restriction to aqueous draining into the subconjunctival space, and the close proximity of microvessels also facilitates aqueous reabsorption (Boswell et al., 1999). Commercial GDDs enclosed in a two-layer ePTFE membrane have been reported to have minimal capsule thickness, with highly vascular tissue encasing the device after six weeks in rabbits (Ahmad et al., 2004). The smaller pores within the inner layer prevent cells from infiltrating the device lumen and valve or restricting aqueous humor outflow. The larger outer pore layer stimulates tissue integration and blood vessel formation adjacent to the device, as well as reducing capsule thickness (Ahmad et al., 2004).

PROMOTING ANGIOGENESIS

Improving Long-Term Performance of Vascular Grafts

Synthetic vascular grafts are used to repair damaged or occluded blood vessels. For decades, researchers and manufacturers have been challenged to create synthetic grafts that mimic physiological function (Davids et al., 1999). Graft material porosity is related to graft healing (Wesolowski et al., 1961; Kuzuya et al., 2004), and is critical as part of the strategy to form a stable, endothelium-lined lumen to provide an anti-thrombotic surface that is similar to native vessels (Wesolowski et al., 1961; White et al., 1983; Clowes et al., 1986; Hirabayashi et al., 1992; Nagae et al., 1995). ePTFE and Dacron® (knitted and woven) are common synthetic graft materials (Nagae et al., 1995; Davids et al., 1999).

Numerous studies conclude that high porosity (≥60 μm pores) ePTFE small diameter grafts have superior graft healing compared to low porosity (≤30 μm pores) grafts (Hess et al., 1984; Branson et al., 1985; Golden et al., 1990; Hirabayashi et al., 1992; Nagae et al., 1995) in terms of patency as well as the rate, stability, and completeness of luminal endothelialization. Optimal pore size for achieving stable luminal endothelium coverage in small diameter grafts is 60 μm (Hess et al., 1989; Golden et al., 1990; Hirabayashi et al., 1992; Nagae et al., 1995; Miura et al., 2002). This pore size provides adequate porosity for transmural fibrovascular tissue ingrowth.

Infiltrating capillaries from the surrounding tissue facilitate endothelialization and smooth muscle cell formation along the graft surface, forming the stable neointima (Davids et al., 1999). Dacron® has a greater prominence in large diameter grafts due to excessive graft surface thrombus. Typically, Dacron® graft lumens become coated in a thick, stable layer of fibrin which limits endothelialization and transmural tissue ingrowth (Davids et al., 1999) (see Chapter II.5.3.B for more discussion on vascular grafts).

Minimizing Infection and Epithelial Downgrowth

Percutaneous devices penetrate the body through a surgically created defect in the skin to provide a conduit between an implanted medical device or artificial organ and the extracorporeal space (von Recum, 1984; Yu et al., 1999). Percutaneous devices include catheters (i.e., peritoneal dialysis, intravascular), prosthetic attachments, dental implants, feeding and tracheal tubes, and needle-type glucose sensors (Fukano et al., 2006; Isenhath et al., 2007). However, breaking the skin barrier provides a route to infection and increases complications associated with wound non-closure (Yu et al., 1999). The incidence of catheter related bloodstream infections ranges between 80,000 and 250,000 annually in the USA, with health related expenses costing several billions of dollars (Isenhath et al., 2007).

Strategies to reduce percutaneous device-related infection involve antibiotics applied topically, administered prophylactically or incorporated into the device (Dasgupta, 2000; Fukano et al., 2006; Isenhath et al., 2007). Antibiotics, while clinically effective, raise concerns about the development of antibiotic-resistant strains (Dasgupta, 2000).

Percutaneous devices also fail from mechanical irritation (avulsion) or epithelial downgrowth that forms a pocket around the implant (marsupialization). Acute mechanical interfacial stresses tear the device from its implantation bed (von Recum, 1984), while chronic, small mechanical stresses cause localized injury, resulting in inflammation and increased susceptibility to infection (von Recum, 1984). Mechanical forces also prevent an epidermal seal from forming, increasing risk of infection (von Recum, 1984). Marsupialization occurs primarily around smooth implants, when epidermis surrounding the implant grows parallel to the implant surface and unites under the implant, surrounding the implant in an epidermal pocket. The percutaneous device has now become extracutaneous, and the tissue pocket becomes a source for infection since an epidermal seal has not formed between the implant and skin (von Recum, 1984).

Perimigration is the migration of epidermal cells into a porous material (von Recum, 1984). Competition between macrophages, giant cells, and fibroblasts within the pores prevents connective tissue maturation and scar

tissue formation. The immature connective tissue soon becomes displaced by proliferating and maturing epidermal cells, possibly with assistance from enzymatic lysis. As the epidermal cells reach the underlying connective tissue bed, they begin to proliferate and form an epidermis-lined pocket around the percutaneous device, causing extrusion (von Recum, 1984).

Dermal integration is necessary to prevent infection, avulsion, and marsupialization, and to ensure the long-term performance of percutaneous devices (von Recum, 1984; Chehroudi and Brunette, 2002; Isenhath et al., 2007). Several porous and textured biomaterials have been investigated to improve percutaneous device performance and longevity. To reduce catheter exit-site infection, "cuffs" are attached to the catheter at the location where the external segment of catheter exits the body. These cuffs are implanted beneath the skin.

Dacron® velour cuffs are commonly used in commercial catheters (Dasgupta, 2000). These cuffs become fibrotically encapsulated, serving both to anchor the catheter and to provide a barrier for bacterial entry (Dasgupta, 2000). However, avascularity of the fibrotic tissue has been reported to encourage bacterial attachment in the tissue surrounding the catheter (Dasgupta, 2000). Microporous silicone cuffs have been shown to reduce exit site infection by 60% in canine models (Moncrief et al., 1995). The microporous structure encourages vascular tissue integration to facilitate immune cell surveillance at the exit site, as well as to reduce scar formation (Moncrief et al., 1995).

Microtexture and porous biomaterials have been shown to be effective in reducing infection, avulsion, and epithelial downgrowth in several animal models (Chehroudi and Brunette, 2002). Highly textured surfaces are reported to have significantly more tissue attachment, thinner capsules, and less tissue–implant separation compared to smooth surface implants (Kim et al., 2006). Grooved surfaces encourage random fibroblast orientation, lessening the effects of contractile forces that contribute to tissue–implant separation (Kim et al., 2006). In contrast, parallel collagen fibers against smooth surfaces create poorly integrated, avascular capsules prone to separation from the implant during wound contracture (Kim et al., 2006). Stable tissue attachment also reduces the effects of micromotion (Kim et al., 2006), minimizing avulsion risk. Capsule thickness appears to relate to the amount of mechanical stresses imparted on the implant (von Recum, 1984). Stability may also promote healing, and encourage thinner capsule formation (Kim et al., 2006).

Optimal pore size for tissue ingrowth is 40 μm or larger (Winter, 1974; von Recum, 1984; Isenhath et al., 2007; Fukano et al., 2010); however, pores as small as 3 μm have been observed with fibrous tissue ingrowth (Squier and Collins, 1981). Most rapid epithelium migration occurs during the first two weeks post-implantation, regardless of pore size (Squier and Collins, 1981). Following the initial two weeks, epithelial migration appears to be inversely related to pore size: increased endothelium downgrowth with decreased pore size (Squier and Collins, 1981). Speed of epithelial migration differs between species (Chehroudi and Brunette, 2002), for example migration in rodents is considerably faster than in humans (Chehroudi and Brunette, 2002). Porosity is also thought to be a key factor affecting the rate of migration (Squier and Collins, 1981), and is required for connective tissue and possibly epithelial ingrowth into percutaneous implants (Isenhath et al., 2007; Fukano et al., 2010).

While textured and porous surfaces encourage dermal integration, there are concerns that surfaces with irregular topologies may be more prone to harboring bacteria (Chehroudi and Brunette, 2002). Bacteria may outcompete tissue cells in adhering to an implant surface, thus preventing tissue integration and promoting infection. Future investigations to optimize topological properties to minimize bacterial contamination (Chehroudi and Brunette, 2002) are recommended.

Porous Coatings to Improve Glucose and Oxygen Transport to Implanted Sensors

Percutaneous glucose sensors must be removed after three to seven days to prevent host inflammation, wound healing, and subsequent foreign-body encapsulation from jeopardizing sensor reliability. The foreign-body response ultimately causes impedance of glucose and oxygen transport to the sensor, resulting in sensor signal deterioration, and frequently sensor failure. Methods that improve analyte (glucose, oxygen) transport to indwelling sensors could allow sensors to reliably measure interstitial glucose concentrations for several weeks, as opposed to days.

Attempts to improve long-term sensor performance have included surface chemical modification, various coatings (Gifford et al., 2005; Nablo et al., 2005; Shin and Schoenfisch, 2006), release of molecular mediators (Friedl, 2004; Ward et al., 2004; Norton et al., 2005), and surface topography (Wisniewski and Reichert, 2000; Wisniewski et al., 2000). The effect of surface texturing on the tissue that surrounds implanted biomaterials is well-documented for devices such as total joint arthroplasty (Bauer and Schils, 1999; Ryan et al., 2006) and percutaneous devices (Tagusari et al., 1998; Walboomers and Jansen, 2005; Kim et al., 2006).

Topographical approaches for improving long-term sensor performance were first proposed by Woodward (1982), who suggested that the best coating for an implanted glucose sensor was a sponge that encourages tissue ingrowth and disrupts fibrosis (Figure I.2.15.5). Efforts to create tissue-modifying textured coatings for implantable sensors are attractive, because their impact is not dependent on a depletable drug reservoir, unlike drug eluting techniques.

A significant range of materials and pore sizes are capable of promoting angiogenesis and reducing capsule
FIGURE I.2.15.5 Example of a: (a) Medtronic MiniMed SOF-SENSOR™ glucose sensor; and (b) an experimental porous poly-L-lactic acid (PLLA) coating applied to the sensor tip for investigational purposes. Unpublished data.) Courtesy of John Wiley and Sons.

TABLE I.2.15.3	Summary of Pore Sizes that Yielded Optimal Tissue Response (Promoted Angiogenesis and/or Reduced Capsule Thickness) Around Biomaterials or Glucose Sensors			
Investigator	Porous Material	Optimal Pore Size	Application and Test Subject	Duration of Investigation
Brauker et al., 1995	PTFE	5 μm	Membrane implanted in rat subcutis	3 weeks
Sharkawy et al., 1998	PVA	60 μm	Membrane implanted in rat subcutis	12-16 weeks
Ward et al., 2002	ePTFE and PVA	ePTFE: 1 μm PVA: 60 μm	Membrane implanted in rat subcutis	7 weeks
Marshall et al., 2004	HEMA hydrogels	35 μm	Hydrogel implanted in mouse subcutis	4 weeks
Updike et al., 2000	ePTFE	5-10 μm (Shults et al., 2006)	Glucose sensor implanted in dog subcutis	162 days* (best of 6 sensors)
Yu et al., 2006	Epoxy-enhanced polyurethane	Not specified	Glucose sensor implanted in rat subcutis	56 days* (best of 9 sensors)
Gilligan et al., 2004	ePTFE	Not specified	Glucose sensor implanted in human subcutis	185 days* (best of 5 sensors)

NOTE: PTFE (polytetrafluoroethylene), ePTFE (expanded polytetrafluoroethylene), PVA (polyvinyl alcohol), HEMA (hydroxyethyl methacrylate).
*Maximum time sensor remained functional *in vivo*.

thickness (Ward et al., 2002). Geometry, rather than chemical composition, of the material appears to determine biomaterial–microvasculature interactions (Brauker et al., 1995; Sieminski and Gooch, 2000). Table I.2.15.3 summarizes leading research in the area of porosity and porous coatings for glucose sensors, including the pore size reported to yield the greatest vascularization and/or the least capsule formation around the implant. Variations in pore size and pore structure in implanted biomaterials may, however, limit the conclusions that can be drawn about how pore size influences tissue response (Marshall et al., 2004).

While porous biomaterials seemingly create the ideal environment for an indwelling glucose sensor, porous coatings applied to sensors have had less than ideal results. A critical factor in sensor failure *in vivo* is the fibrotic capsule that forms around glucose sensors (Dungel et al., 2008). Despite porous coatings stimulating the formation of vascular networks around glucose sensors in rats, newly formed vessels within porous coatings have been unable to overcome the diffusion barriers

imparted by the collagen capsule (Dungel et al., 2008). Failing sensor sensitivity was found to correlate with increasing collagen deposition within the sponge implant (Dungel et al., 2008). Additionally, other factors, such as mechanical stresses imposed by the percutaneously implanted sensor, may have overshadowed the angiogenic-inducing, collagen-reducing properties of porous coatings (Koschwanez et al., 2008).

Recently, human studies (Gilligan et al., 2004) were performed using sensors covered with a porous angiogenic and bioprotective ePTFE membrane (Updike et al., 2000; Shults et al., 2006). Unfortunately, inflammation within the angiogenic layer in 80% of sensors, in addition to packaging failure in 60% of sensors, resulted in only 20% sensor survival after six months (Gilligan et al., 2004).

CONCLUSION

The use of textured and porous materials is widespread in medical device applications. Research and development on porous structures continues because of good

clinical outcomes, important research findings, and a straightforward regulatory pathway. While a single pore size or textured morphology does not fit all applications, the majority of porous and textured biocompatible materials used in medical devices share the common characteristic of open architectures with interconnecting pores that support nutrient transfer, and promote cell migration and proliferation. Stable integration of the implant with the surrounding host tissue reduces irritation caused by micromotion, and promotes stable fibrovascular tissue ingrowth that promotes healing and minimizes infection.

CHAPTER I.2.16 ELECTROSPINNING FUNDAMENTALS AND APPLICATIONS

Robert Akins[1] and John Rabolt[2]

[1]Tissue Engineering and Regenerative Medicine Laboratory, Alfred I. duPont Hospital for Children/Nemours Foundation, Wilmington, DE, USA

[2]Department of Materials Science and Engineering, University of Delaware, Newark, DE, USA

MOTIVATION FOR USING ELECTROSPUN MEMBRANES

Electrospinning is an excellent candidate process for producing tissue engineering and vascular graft constructs, since the resulting electrospun materials possess many of the desired properties appropriate for successful cell and tissue growth, such as a high surface-to-volume ratio and an interconnected three-dimensional porous network (Table I.2.16.1). It is a simple and robust method to produce micro- and nanometer diameter fibers, and can be thought of as a biomimetic process since the materials produced resemble the nanoscale architecture of extracellular matrix (ECM) (Figure I.2.16.1), and can promote and enhance biological activities. The experimental arrangement generally consists of a pipette or syringe with a blunt needle, which is filled with a polymer solution or melt. An electrode from a high voltage power supply (0–30 kV) is placed in contact with the solution and an electric field is applied.

The electric charge overcomes the surface tension of the solution droplet, and a single fiber in the form of a jet is emitted. The jet is collected on a counter electrode in the form of a nonwoven fibrous mat (Figure I.2.16.1). The fibers produced are generally 100–400 nm in diameter, but the size of the fibers can easily be changed through variations in the processing parameters, such as applied electric field strength and solute concentrations (Doshi and Reneker, 1995). In addition, a wide variety of polymers that are desirable for tissue engineering applications have been electrospun. These include collagen, poly(lactic acid)/poly(glycolic acid), and their copolymers, fibrinogen, elastin, and spider silk (Matthews et al., 2002; Stephens et al., 2003; Boland et al., 2004; Shields et al., 2004). Coupling the ability to control the fiber size within a matrix with the ability to choose a variety of polymers with different physical/chemical/mechanical properties will make it possible to create a construct that has comparable properties to a specific tissue. Another desirable aspect of electrospinning is that only a small amount of starting material (<50 mg) is required compared to more traditional fiber formation methods (10–20 pounds). This becomes critically important for next generation materials, such as biopolymers like spider-silk and those synthesized in small-scale laboratory preparations, because they are generally produced in small quantities (milligrams). Recent attempts to scale-up the electrospinning process using a multiple jet system have shown considerable promise (see for example Elmarco at www.elmarco.com),

TABLE I.2.16.1	List of Desired Properties of Tissue Engineering Constructs
Desired Properties	**Electrospinning**
Interconnected porous network	Yes
Large void volume (cell seeding and penetration)	Yes
Large surface-to-volume ratio	Yes
Specific surface chemistry and surface microstructure	Yes
Mechanical strength (comparable to physiological stresses)	Yes
Controlled degradation rate (matches tissue regeneration)	Yes
Incorporation of growth factors	Yes

and in the near future useful materials for transfer to the clinical environment will be developed.

HISTORICAL PERSPECTIVE

Electrospinning has been around for more than a century, first invented by Formhals in 1934 and improved by different research groups over the years. Many polymers have been routinely electrospun, and several review articles summarizing these techniques have appeared (for example, see Greiner and Wendorff, 2007). Unique micro- and nanoscale features on the surface of polymer fibers have been produced at the University of Delaware using the electrospinning process. These features are advantageous for tissue engineering and filtration applications because they provide an increase in surface area and roughness. Surface textures, in the form of micro- and nanopores, can be formed on the surface of fibers electrospun from volatile solvents. Pores ranging in size from 20–1000 nm (having depths ranging from 50–70 nm) have been observed on the surface of several amorphous and semicrystalline polymer fibers, such as polystyrene (PS), poly(methylmethacrylate) (PMMA), PC, and poy(ethylene oxide) (PEO) (Megelski et al., 2002; Casper et al., 2004) (see Figure I.2.16.2). As we further optimized the processing protocols for electrospinning fibers we observed that, with a judicious choice of electrospinning parameters and solvent, nanoweb structures (Stephens et al., 2003) could also be produced. Nanowebs are composed of small fibrils (~10–15 nm) that interconnect the larger fibers (~70–100 nm) of the electrospun mat to produce a web-like structure that is similar in appearance to that produced by the spider. These fibrillar nanowebs have been observed in several different types of polymers and bioderived materials (collagen, denatured collagen, spider silk, nylon) two examples of which are shown in Figure I.2.16.3. We have identified the processing parameters and the mechanisms that cause the surface texturing and nanowebs to form, and this has provided us with the ability to produce fibers and fiber mats with the desired features for different applications. For example, in Figure I.2.16.3, the electrospinning conditions to promote (Stephens et al., 2003) the formation of

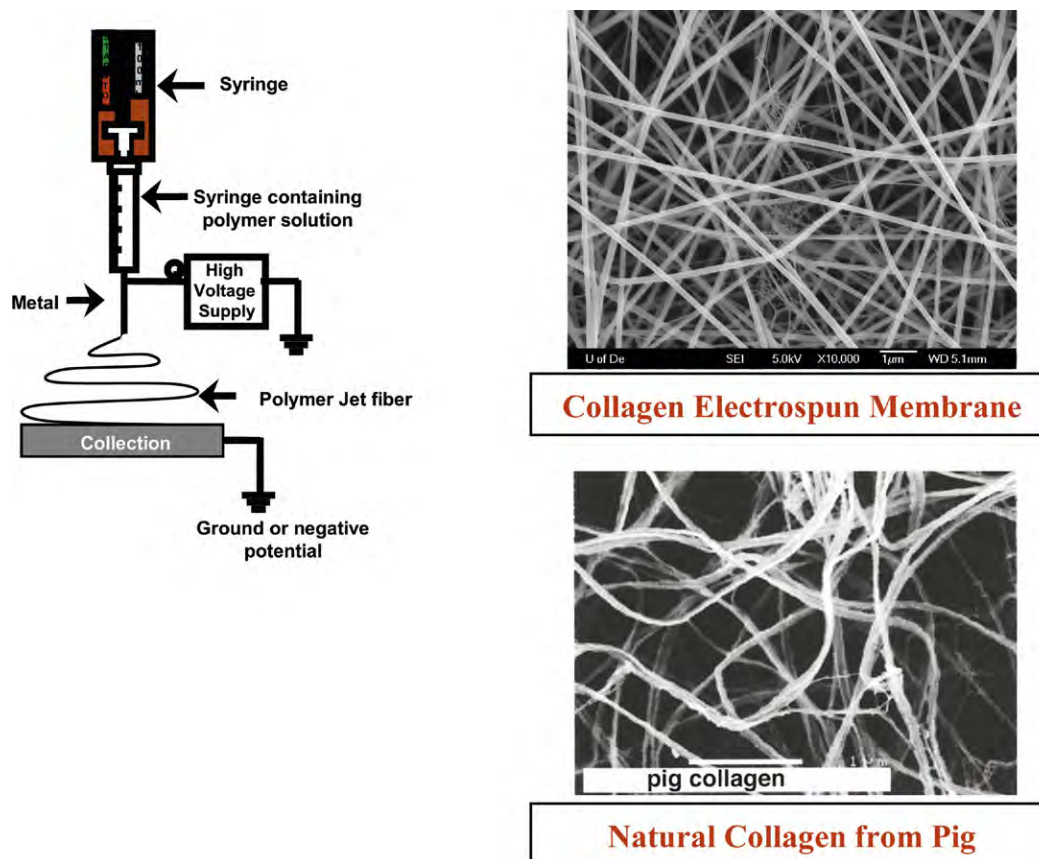

FIGURE I.2.16.1 Schematic of electrospinning set up and field emission scanning electron microscope (FE-SEM) micrographs comparing an electrospun collagen fibrous membrane with natural collagen fibrils obtained from a pig ECM. (Gemmell et al., 1995)
FIGURE I.2.16.2 Micro- and nanotextured electrospun fibers; PS electrospun from tetrahydrofuran (THF).

nanowebs were the following: Figure I.2.16.3(a) collagen (type I) at 30 wt% from formic acid, 23 gauge needle, 10 cm syringe to counter-electrode gap, 7 kV; and Figure I.2.16.3(b) synthetic spider silk at 20 wt%, 23 gauge needle, 10 cm gap, 7 kV.

In addition, we have also demonstrated that electrospun fibers can be functionalized with macromolecules that may improve the patency of vascular graft materials. Specifically, four-arm star-shaped poly(ethylene glycol) PEG polymers with termini derivatized with low molecular weight heparin (PEG-LMWH) have been incorporated into electrospun fibers comprised of either poly(ethylene oxide) (PEO) or poly(lactic-glycolic acid) PLGA. The synthesis of the PEG-LMWH star bioconjugate and its incorporation into biopolymeric fibers offers opportunities for the production of fibrous materials capable of local and sustained release of therapeutically relevant proteins.

The PEG-LMWH can be easily incorporated into fibrous matrices via electrospinning protocols, which has been demonstrated (Casper et al., 2005) with PEO and PLGA fibers. The concentration of the polymeric solutions used during electrospinning varied depending on the carrier polymer employed, but in both cases, PEG-LMWH was easily incorporated into fibers without altering the fiber size or shape (Figure I.2.16.4). PEO (M_w = 300,000 g/mol) was used at a 10 wt% concentration in water, and a flow rate of 0.07 mL/min was employed. PLGA (75:25, M_w = 90,000–126,000 g/mol) solutions were made at a 45 wt% concentration in dimethylformamide (DMF) and required a flow rate of 0.26 mL/hr.

Scanning electron microscopy confirmed that the incorporation of the PEG-LMWH did not alter fiber morphology (Figure I.2.16.4). Multiphoton microscopy of fibers electrospun with fluorescently labeled PEG-LMWH confirmed the presence of LMWH throughout the depth of the electrospun matrix. Toluidine blue spectrophotometric assays that detect heparin were used to determine that the amount of LMWH per mg of fibers was in the range of 3.5–85 μg, depending on the sample examined. Although both LMWH and PEG-LMWH can be processed into fibers, the incorporation of PEG-LMWH resulted in functional advantages such as improved growth factor binding, which likely results from improvements in retention of the PEG-LMWH in the fibers over the LMWH alone. The PEG-LMWH is

FIGURE I.2.16.4 FE-SEM micrographs of electrospun PLGA (left) and PEG-LMWH/PLGA (right). Fiber diameters range from 200 nm to 1 micron. (Casper et al., 2005.)
FIGURE I.2.16.5 FE-SEM images of two sets of electrospun fibers: (a) isotropically oriented nylon 6 fibers (Lee et al., 2008); (b) aligned polystyrene fibers. (Mandrel assembly courtesy of Vahik Krikorian.)

retained in the fibers for at least 14 days, in contrast to LMWH, which is almost completely released from the fibers after 24 hours. A slower release of PEG-LMWH, and any bound growth factors, would allow for drug delivery over a period of time that would more closely match the timescales needed for cell proliferation, for example, along the inner surface of a vascular graft.

It is sometimes advantageous to macroscopically align the polymer fibers, since some mechanical and optical properties of the material can be improved. Shown in Figure I.2.16.5 are FE-SEM images of an isotropic polymer fibrous mat collected on a metallic plate (Figure I.2.16.5(a)) and fibers that have been wound up on a grounded rotating mandrel (Figure I.2.16.5(b)). In addition to the obvious fiber alignment that may improve properties, it has been demonstrated that fiber alignment

can influence cell phenotype, an observation that will be illustrated in more detail later in this chapter.

CHARACTERIZATION METHODS

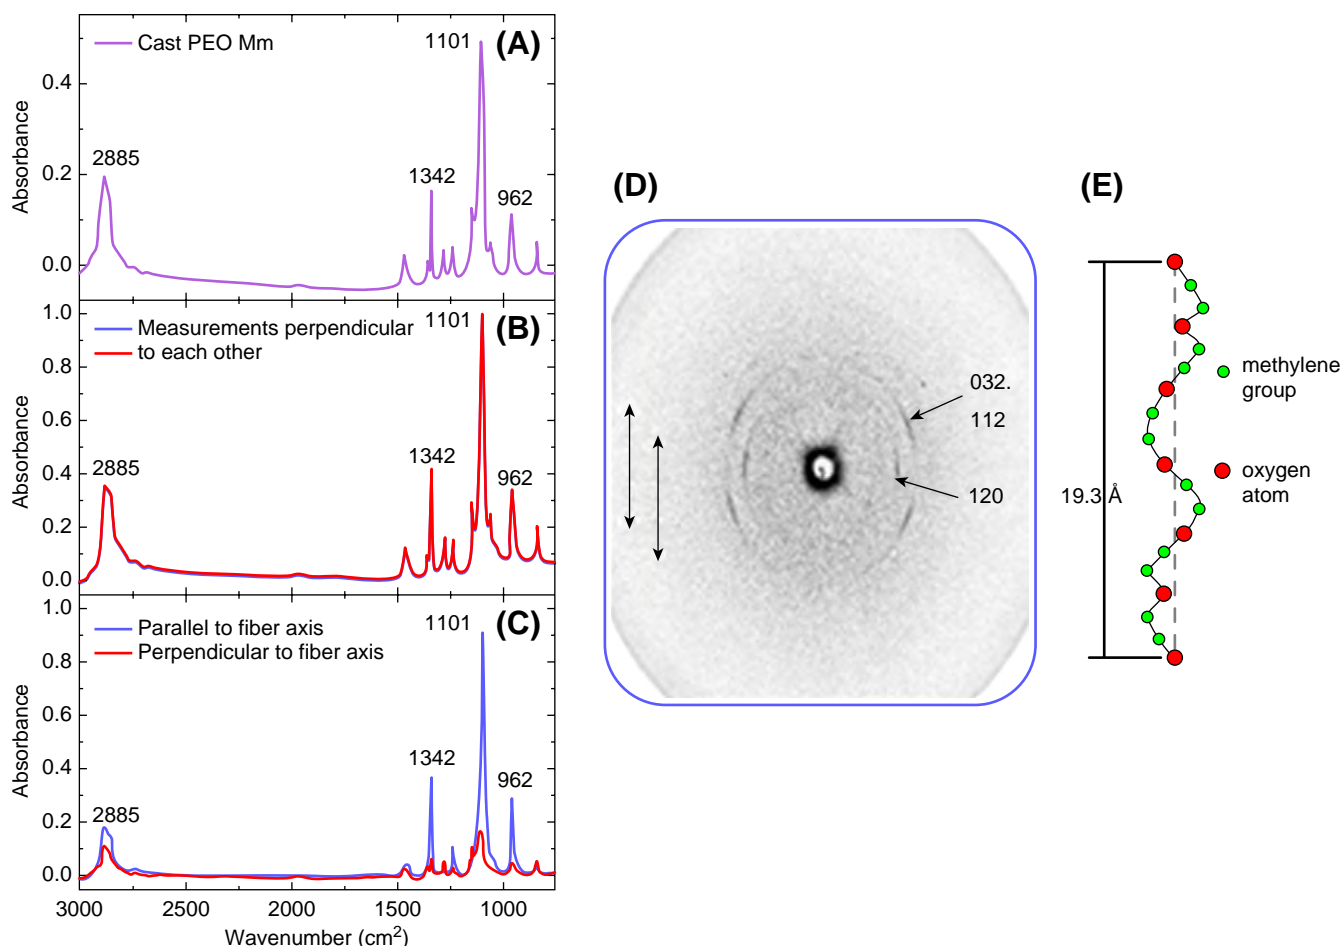
The application of standard confocal fluorescence and electron microscopic characterization of electrospun membranes provides facile determination of the extent of fiber orientation, diameter, and surface/interior functionalization. However, the functionality of polymer nanofibers is critically dependent on the macromolecular structure at the primary, secondary, and tertiary levels. Also, backbone orientation and potential changes in structure during dynamic deformation in the electrospinning process impact nanofiber functionality. The various forms of vibrational spectroscopy and wide angle X-ray


FIGURE I.2.16.6 (A) A typical FTIR spectra of pure PEO cast film; (B) polarized FTIR spectra for isotropic PEO fibrous mat show that the peak intensities for measurements parallel to fiber axis were very similar to the perpendicular measurements; (C) polarized FTIR spectra for uniaxially oriented PEO nanofibers show that the peak intensities for measurements parallel to fiber axis were greater compared to the perpendicular measurements; (D) wide-angle X-ray diffraction pattern of PEO nanofibers with the arrows indicating the direction of the fiber axis and the numbers indicating crystal planes in the reciprocal lattice; (E) a schematic of the PEO 7/2 helix indicating its orientation along the fiber axis.

diffraction employed in routine characterization studies of polymers also play a key role in understanding the structure/property relationships in polymer nanofibers.

The extent of macroscopic orientation of electrospun micro- and nanoscale diameter fibers can be designed into the fibrous mat by electric field assisted fiber collection, by controlling the wind-up speed of the mandrel relative to the fiber spinning speed, by using a specially designed "banded" rod for collection, and by translating the rotating mandrel at various speeds during the collection process. If, in addition, the molecular orientation of the polymer backbone with respect to the fiber axis is controlled simultaneously, then it should be possible to use fiber orientation to optimize mechanical properties (compliance, modulus, tenacity, etc.). In order to assess the amount of molecular orientation within fibers, polarized Raman scattering (Frisk et al., 2004) can also be used in addition to the fourier transform infrared (FTIR) and X-ray diffraction methods illustrated in Figure I.2.16.6. It is possible to estimate the extent of polymer backbone alignment in the case of uniaxially oriented samples, such as fibers, using experimental quantities obtained by employing

a combination of different polarization directions and sample orientation. These procedures can be used to determine an orientation distribution function (Kakade et al., 2007). We have successfully carried out such studies (Kakade et al., 2007) on a number of synthetic polymers (e.g., polyethylene, poly(ethylene terephthalate), and poly(trimethylene terephthalate)) and the experimental and theoretical protocols can easily be adapted to the study of biopolymers, such as collagen, PLGA/PEG-LMWH, and elastin electrospun fibers, in order to correlate processing conditions with extent of backbone orientation, which in turn will correlate with mechanical properties.

As shown also in Figure I.2.16.6(D), wide angle X-ray diffraction (WAXD) is also useful in determining molecular orientation in macroscopic polymer nanofibers. Instead of the ring pattern indicative of randomly oriented crystallites, intense arcs are observed in the PEO electrospun fibers collected on a charged plate. By indexing the crystal planes in the reciprocal lattice, it was possible to ascertain that the polymer chains are oriented parallel to the fiber axis and that the PEO backbone maintains its

7/2 helical conformation, confirming the results obtained by polarized FTIR and Raman spectroscopy. Studies on Nylon 6 nanofibers produced by electrospinning using an atomic force microscopy (AFM) tip and collected on a charged plate also showed molecular orientation relative to the fiber axis (Gururajan et al., 2011). This molecular alignment will produce improved mechanical, optical, and electrical properties.

BIOMEDICAL APPLICATIONS FOR ELECTROSPUN MATERIALS

Tissue Engineering and Regenerative Medicine

Tissue engineering (TE) is an emerging strategy in the broader field of regenerative medicine (RM) (see Section II.6, "Applications of Biomaterials in Functional Tissue Engineering"). In TE/RM, living cells are employed in the construction of *de novo* tissues for use as implants, diagnostic testing devices, and translational research models. Biomaterials of different types are used to support cellularized constructs. The development and implementation of TE/RM strategies, therefore, involve engineering cells and cell scaffolds to direct the organization and function of biological–material composites to desired ends. Electrospun materials have several attributes that recommend them as platforms for TE/RM approaches:

- Fibers can be prepared from a variety of natural and synthetic polymers that are biocompatible, amenable to surface modification with bioactive molecules, and capable of directing cell attachment and growth.
- The small diameter filaments within electrospun scaffolds mimic the fibrous architecture of native extracellular matrix.
- Composite materials can be prepared wherein biologically-active molecules are enmeshed in the fibrous matrix.
- Scaffolds can be engineered with desirable physical characteristics, such as stiffness.
- Materials can be designed to biodegrade over desired timescales.
- Scaffolds can be prepared with extensive networks of inter-connected pores that allow cell invasion into three-dimensional constructs and the subsequent perfusion of neo-tissues.

The physical and chemical characteristics of electrospun materials can be manipulated during production in order to control subsequent interactions between the produced scaffold and cells of different types. Materials can be designed to act as barriers to block cell penetration or as scaffolds to promote cell adhesion and migration, and to enable the diffusion of nutrients and wastes (for examples, see references Lu and Mikos, 1996; Riboldi et al., 2005; Zong et al., 2005). The specifics of cell–material interactions are of critical concern, and the adhesion,

growth, organization, and biomolecular characteristics of cells on scaffolds are important biological parameters to consider in developing TE/RM strategies.

Electrospinning has been explored as a strategy to engineer a number of tissues including vasculature (Xu et al., 2004; Inoguchi et al., 2007), nerve (Prabhakaran et al., 2009), bone (Liu et al., 2009), and ligament/tendon (Ouyang et al., 2003; Bashur et al., 2009; Inanc et al., 2009). Many types of polymers have been employed in these early TE/RM efforts including poly(l-lactide), PLGA, PEO, polycaprolactone, polyurethane, polyethylene glycol, different types of collagen, elastin, hyaluronic acid, chitosan, fibroin, and combinations of these, to name a few. The selection of polymer and the specific conditions for electrospinning are motivated by the design characteristics of the finished product, and there are many choices and variations that can be employed. In general, the chemical nature of electrospun fibers can be varied across a broad range by altering polymer selection and production conditions.

In conjunction with the chemical characteristics of electrospun fibers, the physical characteristics of electrospun fiber scaffolds are also important. The porosity of scaffolds, which impacts cell penetration (Heydarkhan-Hagvall et al., 2008), fiber diameter, which affects cell morphology and phenotype (Yang et al., 2005), and the lateral alignment of fibers, which impacts cell morphology and local cell–cell interactions (Chew et al., 2008; Rockwood et al., 2008; Bashur et al., 2009), are all important determinants of tissue organization and function. These three parameters are inter-related, and in combination they may have complex effects on cultured cells. For example, suitable scaffold porosity in combination with appropriate polymer composition improves the three-dimensional migration of adipocyte-derived stem cells into composite gelatin/PCL scaffolds (Heydarkhan-Hagvall et al., 2008). In experiments to study the effects of both fiber alignment and fiber diameter on neural stem cells (NSCs), it was found that culture on anisotropic materials with aligned poly(L-lactic acid) (PLLA) fibers resulted in directed neurite outgrowth of significantly greater length than those found on cells cultured using isotropic PLLA scaffolds (Yang et al., 2005). In addition, the NSCs differentiated more readily on nanofibers when compared to the same cells grown on microfibers; this effect was independent of fiber alignment (Yang et al., 2005). In general, structural anisotropy and the diameter of filaments in fibrous scaffold materials may profoundly affect the activity of cells from other tissues as well.

In other work looking at aligned fibers, experiments using human ligament fibroblasts have shown that cells synthesize significantly more collagen when grown on aligned scaffolds versus randomly oriented nanofibers (Lee et al., 2005). Studies with Schwann cells grown on aligned electrospun polycaprolactone (ES-PCL) scaffolds indicated that culture on nanofibrous supports can improve cell maturation, with aligned scaffolds providing the greatest degree of maturation (Chew et al., 2008). Similarly, electrospun polyurethane (ES-PU) of different

types has also been used to study the engineering of ligament-like tissues (Bashur et al., 2009) and myocardial-like tissues (Rockwood et al., 2008); in both these cases, culture on the aligned ES-PU substrata resulted in a more mature cellular phenotype.

In our laboratories, we have investigated the effects of ES-PU anisotropy on the phenotype of heart cells. One of the critical but sometimes underappreciated functions of the heart is to release neurohormones such as atrial natriuretic peptide (ANP). ANP production and secretion by heart muscle cells are highly controlled, and an increased level of ANP in the blood has dramatic physiologic impact, resulting in a decrease in circulating blood volume. We found that the organization of ES-PU substrata had a profound effect on ANP production and release (Rockwood et al., 2008). As shown in Figure I.2.16.7, when identical cells were grown on anisotropic versus isotropic ES-PU, ANP production was significantly attenuated in the aligned ES-PU group. This attenuation is similar to that seen in three-dimensional culture (Akins et al., 2009), and occurred in cells that maintained the levels of other molecular markers for cardiac muscle. These results indicate a specific and significant change in cell phenotype associated with substrate alignment.

The specific mechanisms by which ES fiber orientation impacts cell organization and function may differ from system to system, but cellular effects associated with electrospun support materials are likely related to differences in cell morphology and the altered interactions among neighboring cells. In particular, cells grown on oriented fibers tend to be more elongated with a spindle-like shape than cells grown on isotropic supports.

In addition, anisotropic materials tend to be laterally aligned with significant cell–cell contacts along the length of neighboring cells. The ability to impact cell organization and function by engineering the physical and chemical characteristics of electrospun scaffolds is a powerful technology in nascent TE/RM approaches.

Drug Delivery

Another potent use for electrospun materials is in the area of drug and biomolecule delivery. Electrospun materials are amenable to surface modification with bioactive molecules, and it is possible to enmesh compounds into matrices during production (see discussion earlier in this chapter). This flexibility allows engineers to incorporate therapeutic compounds into implant materials to benefit patients or to include biomolecules in electrospun scaffolds to influence cells in tissue engineered constructs. Drug delivery strategies employing electrospun materials are being developed for both these applications. Examples of drug delivery approaches using electrospun materials include the introduction of antibiotics (Bolgen et al., 2007), anti-tumor drugs (Xie and Wang, 2006), bioactive proteins (Kim et al., 2007), and DNA (Nie and Wang, 2007). Applications employing antibiotics or DNA illustrate some key concepts.

Several groups have investigated the potential use of electrospun mats for the local delivery of antibiotics. The high surface area-to-volume ratios of these materials allows for extensive drug loading. Different approaches can be used to incorporate drugs into electrospun mats; mats can be prepared and then coated with the desired agent or the
FIGURE I.2.16.7 (A) Primary heart cells grown on isotropic ES-PU. Cardiac muscle cells appear red (anti-sarcomeric myosin immunofluorescence) and nuclei appear blue (Hoechst 33258 dye). (B) Primary heart cells grown on aligned ES-PU. (C) Cellular ANP levels for cells grown on tissue culture polystyrene (TCPS), isotropic ES-PU, and aligned ES-PU. Data are mean ± S.D., n = 3. (Akins et al., 2009).

agent can be included with the polymer solution prior to electrospinning. The former approach has been applied to absorb polycaprolactone (PCL) membranes with a commercial antibiotic for use in preventing post-surgical abdominal adhesions in an animal model (Bolgen et al., 2007). The investigators found that approximately 80% of the antibiotic was released from the PCL within 3 hours, with the remaining amount released within 18 hours; however, the PCL scaffold remained in place substantially longer. The antibiotic-soaked PCL was effective in limiting adhesions, and exhibited improved healing compared to the control and to PCL mats without antibiotic.

An alternative approach using PLGA-based electrospun mats in which a different antibiotic was added to the pre-spun polymer solution found that incorporation of the drug yielded more consistent fibers with a decreased fiber diameter (Kim et al., 2004). The change in fiber diameter and morphology was likely a result of changes in the charge characteristics of the polymer/drug solution. The activity of the antibiotic was retained throughout the solvation and spinning processes. Interestingly, the inclusion of PEG-PLA block copolymer into the PLGA backbone allowed the amount of antibiotic embedded in the nanofibers to be increased, due to the altered hydrophilicity of the material.

The inclusion of DNA in composite scaffolds containing PLGA and hydroxyapatite has been used as a strategy to deliver plasmids containing bone morphogenetic protein gene sequences in efforts to augment bone tissue regeneration (Nie and Wang, 2007). The DNA is taken up by cells and the encoded protein expressed. It was found that higher relative amounts of hydroxyapatite in the scaffold resulted in faster DNA release from the material; perhaps due to the hydrophilicity of the components. These results further emphasize the need to understand the interactions between electrospun materials and the molecule to be delivered in the development of drug delivery approaches.

SUMMARY

Electrospinning provides a facile method to fabricate porous and fibrous biomaterials from many different starting polymers. The fiber size can be comparable to that found in ECM. The ability to control fiber spacing and orientation permits material to be optimized for specific applications. Applications in tissue engineering and drug delivery are envisioned.

CHAPTER I.2.17 SURFACE-IMMOBILIZED BIOMOLECULES

Allan S. Hoffman[1] and Jeffrey A. Hubbell[2]

[1]Professor of Bioengineering and Chemical Engineering, UWEB Investigator, University of Washington, Seattle, WA, USA

[2]EPFL (École Polytechnique Fédérale de Lausanne), Switzerland

INTRODUCTION

Biomolecules such as enzymes, antibodies, affinity proteins, cell receptor ligands, and drugs of all kinds have been immobilized on and within biomaterial surfaces for a wide range of therapeutic, diagnostic, tissue regeneration, separation, and bioprocess applications. Immobilization of heparin on polymer surfaces is one of the earliest examples of a surface-modified, biologically functional biomaterial (Gott et al., 1963). Living cells may also be combined with biomaterials, especially when their surfaces contain cell adhesion peptides or proteins, and the fields of cell culture, artificial organs, and tissue engineering include important examples of cell–surface interactions. These "hybrid" combinations of natural and synthetic materials confer "biological functionality" to the synthetic biomaterial. Many sections and chapters in this textbook cover various aspects of this topic, including adsorption of proteins and adhesion of cells and bacteria on biomaterial surfaces, non-fouling surfaces, cell culture, tissue engineering, artificial organs, drug delivery, and others; this chapter will focus on the methodology involving physical adsorption and chemical immobilization of biomolecules on biomaterial surfaces, especially for applications requiring bioactivity of the immobilized biomolecule.

Among the different classes of biomaterials that could be biologically modified, synthetic polymers are especially interesting because their surfaces may contain reactive groups such as –OH, –COOH or NH_2 groups, or they may be readily modified with other reactive groups such as azide, alkyne, and SH groups. All of these groups can be used to covalently link biomolecules.

Another advantage of polymers as supports for biomolecules is that the polymers may be fabricated in many forms, including films, membranes, tubes, fibers, fabrics, particles, capsules, and porous structures. Furthermore, macromolecular structures can also vary substantially. The latter can include homopolymers, random, alternating, block, and graft copolymers, hyperbranched (comb-like) and star-shaped structures (see Chapter I.2.2 on Polymers).

Living anionic polymerization techniques, along with newer methods of living free-radical polymerizations, now provide fine control of molecular weights with narrow distributions. The molecular forms of solid polymers include non-cross-linked chains that are insoluble at physiologic conditions, cross-linked networks, physical blends, and interpenetrating networks (IPNs) (e.g., Piskin and Hoffman, 1986; see also Chapter I.2.2). "Smart" polymers are sharply responsive in solubility behavior to stimuli, such as temperature, pH, and salt concentration (see Chapter I.2.11 on "Smart" Polymers).

For surfaces of metals, metal oxides, inorganic glasses or ceramics, biological functionality can sometimes be added via a chemically immobilized or physically adsorbed polymeric or surfactant adlayer, or by use of techniques such as plasma gas discharge, corona discharge in air or ozone to modify polymer surface compositions

with functional groups (see also Chapter I.2.12). Several researchers have applied mussel adhesive chemistry based on self-condensation of dopamine to form tight bonding layers of polydopamine on a variety of surfaces, including metals, metal oxides, and glasses (Lee et al., 2007; Ku et al., 2010). The amine groups in these polymers may be further functionalized with biomolecules.

PATTERNED SURFACE COMPOSITIONS

(See also Chapter I.2.13.)

Biomaterial surfaces may also be functionalized in geometric patterns (Bernard et al., 1998; Blawas and Reichert, 1998; James et al., 1998; Ito, 1999; Kane et al., 1999; Folch and Toner, 2000). Sometimes the patterned surfaces will have regions that are non-binding to proteins (so-called "non-fouling" compositions) while others may contain covalently-linked cell receptor ligands (Neff et al., 1999; Alsberg et al., 2002; Csucs et al., 2003; VandeVondele et al., 2003), or may have physically adsorbed cell adhesion proteins (McDevitt et al., 2002; Ostuni et al., 2003). A huge industry has also evolved based on "biochips" that contain microarrays of immobilized, single-stranded DNA (for genomic assays) or peptides or proteins (for proteomic assays) (Houseman and Mrksich, 2002; Lee and Mrksich, 2002). The majority of these microarrays utilize inorganic silica chips rather than polymer substrates directly, but it is possible to incorporate functionality through chemical modification with silane chemistries (Puleo, 1997) or adsorption of a polymeric adlayer (Scotchford et al., 2003; Winkelmann et al., 2003).

A variety of methods have been used for the production of these patterned biochips, including photo-initiated synthesis through patterned masks (Ellman and Gallop, 1998; Folch and Toner, 2000), microfluidic fluid exposure (Ismagilov et al., 2001), and protection with adhesive organic protecting layers that are lifted off after exposure to the biomolecular treatment (Jackman et al., 1999).

IMMOBILIZED BIOMOLECULES AND THEIR USES

Many different biologically functional molecules can be chemically or physically immobilized on polymeric supports (Table I.2.17.1) (Laskin, 1985; Tomlinson and Davis, 1986). Examples of applications of these immobilized biological species are listed in Table I.2.17.2. When hydrophilic, molecularly cross-linked or entangled solids are water-swollen above about 15–25% water content, they become hydrogels and biomolecules may be immobilized on the outer gel surface, as well as within the water-containing regions ("meshes") of the swollen polymer gel network. It can be seen that there are many diverse uses of such biofunctional systems in both the medical and biotechnology fields. For example, a number of immobilized enzyme supports and reactor systems

(Table I.2.17.3) have been developed for therapeutic uses in the clinic (Table I.2.17.4) (De Myttenaere et al., 1967; Kolff, 1979; Sparks et al., 1969; Chang, 1972; Nose et al., 1983; Schmer et al., 1981; Callegaro and Denri, 1983; Nose et al., 1984; Lavin et al., 1985; Sung et al., 1986). Advantages and disadvantages of immobilized enzymes are listed in Table I.2.17.5.

IMMOBILIZED CELL LIGANDS AND CELLS

Cell interactions with foreign materials are usually mediated by a biological intermediate, such as adsorbed proteins, as described in Chapter II.1.2. An approach using biologically-functionalized materials can be much more direct, by adsorbing or covalently grafting ligands for cell–surface adhesion receptors, such as integrins, to the material surface (Lutolf and Hubbell, 2005; Patterson et al., 2010) (Table I.2.17.6).

This has been accomplished with peptides grafted randomly over a material surface (Massia and Hubbell,

*A large number of receptor-binding peptide domains have been identified in numerous adhesion proteins that are able to recapitulate some of the binding character of the entire protein. Only a small selection of widely studied peptides is listed here.

1991), as well as with peptides presented in a pre-clustered manner (Irvine et al., 2001). The latter has important advantages. Cells normally cluster their adhesion receptors into nanoscopic assemblies referred to as "focal contacts" (Geiger et al., 2009), in which both adhesion ligands and receptors are co-clustered. This clustering plays an important role in both cell adhesion mechanics (Ward and Hammer, 1993), and cell signaling (Maheshwari et al., 2000; Geiger et al., 2009). In addition to peptides, saccharides have also been grafted to polymer surfaces to confer biological functionality (Griffith and Lopina, 1998; Chang and Hammer, 2000).

Nanotechnology methods of ligand immobilization have been used extensively to achieve very precise control of ligand immobilization density, ligand clustering, and arrangement, and even ligand exposure from a previously hidden state or hiding after an exposed state. For example, nano-patterning methods have been used to show that cells are capable of sensing and responding to

clustering on the length scale of 70 nm of the RGD peptide, which binds to integrins such as $\alpha_v\beta_3$ (Huang et al., 2009). At longer length scales, the cell is unable to sense clustering. Methods of formation of self-assembling monolayers, including stimulus-sensitive self-assembling monolayers, have been used to conduct investigations on the migration- and differentiation-inducing influences of different cell adhesion molecules, and also to identify new receptor–ligand biomolecular pairs (Mrksich, 2009).

Specific biomolecules can be immobilized in order to control cellular interactions; one important class of such functionalizations is the polypeptide growth factor. Such molecules can be immobilized and retain their ability to provide biological cues that signal specific cellular behavior, such as support of liver-specific function of hepatocytes (Kuhl and Griffith-Cima, 1996), induction of neurite extension in neurons (Sakiyama-Elbert et al., 2001), induction of angiogenesis (Zisch et al., 2001) or the differentiation of mesenchymal stem cells into bone-forming osteoblasts (Lutolf et al., 2003a,b; Martino et al., 2009). It is important to understand that these effects are not merely induced by the mechanics of adhesion, i.e., what matters are the details of which adhesion ligand is displayed, and thus which adhesion receptor is ligated and what downstream signaling is activated. For example, stimulation of mesenchymal stem cells with a ligand for integrin $\alpha_5\beta_1$ stimulated osteogenesis, whereas stimulation with a ligand for integrin $\alpha_v\beta_3$ did not. Other molecules may be immobilized that can take part in enzymatic reactions at the surface. McClung et al. (2001, 2003) have immobilized lysines, whose ε-amino groups may interact with pre-adsorbed tissue plasminogen activator (tPA) during coagulation, to enhance fibrin clot dissolution at that surface.

The above paragraphs deal with biomaterial surfaces as though they are two-dimensional. In some devices, this is indeed the case; however, biomaterials have been developed to display their surfaces in three-dimensional situations, even with triggering by cellular remodeling. For example, biomaterial gels have been developed, consisting of cross-linked PEG chains, where the cross-linker is sensitive to proteases, such as plasmin or matrix metalloproteinases, that are activated by cells as they migrate (Lutolf et al., 2003a,b). In this way, as cells migrate in a material and remodel it, they can expose new surfaces and be stimulated by those new surfaces. Using such materials as tools, a number of regenerative medical applications have been targeted, where the biomaterial surface displays both adhesion ligands and polypeptide growth factors (Lutolf and Hubbell, 2005). Such materials, through careful selection of adhesion ligand composition, can control very specific biological processes, such as embryonic stem cell self-renewal (Lee et al., 2010). Materials have been developed that allow for very precise control of the adhesion ligand display and cross-linked nature of the three-dimensional material, e.g.,

through locally-controlled photochemical manipulation (Kloxin et al., 2009, 2010).

IMMOBILIZATION METHODS

There are three major methods for immobilizing biomolecules: physical adsorption; physical "entrapment;" and covalent attachment (Stark, 1971; Zaborsky, 1973; Dunlap, 1974). Physical adsorption includes: (1) van der Waals interactions; (2) electrostatic interactions; and (3) affinity recognition. Once adsorbed, the molecules may be further cross-linked to each other. Physical "entrapment" systems include: (1) microcapsules; (2) hydrogels; and (3) physical mixtures such as matrix drug delivery systems. Covalent attachment includes: (1) soluble polymer conjugates; (2) conjugates on solid surfaces; or (3) conjugates within hydrogels.

It is clear that the first two are physically based, while the third is based on covalent or "chemical" attachment to the support molecules. However, sometimes the physical attachment process may involve pairs of molecules with very strong affinity interactions, verging on covalent force levels, such as biotin with streptavidin. Thus, it is important to note that the term "immobilization" can refer to a short-term, long-term or "permanent" localization of the biomolecule on or within a support. In the case of a drug delivery system, the immobilized drug is supposed to be released from the support, either over a short period or over a longer-term, while an immobilized enzyme or cell adhesion peptide or protein in an artificial organ is designed to remain attached to or entrapped within the support over the duration of use. Either physical or chemical immobilization can lead to relatively long-term or "permanent" retention on or within a solid support, especially if the immobilized biomolecule is large.

If the polymer support is biodegradable, then the chemically immobilized biomolecule will be released as the matrix erodes or degrades away. Many researchers have chemically immobilized cell adhesion peptides such as RGD onto biodegradable matrices such as PLGA for use as tissue engineering scaffolds. The cells will have the time to bind and regenerate tissue if the support is slowly degrading. If the support degrades more rapidly than the cells' ability to reach and bind to the adhesion peptides, then the matrix will not function in the intended way. The immobilized biomolecule may also be susceptible to enzymatic degradation *in vivo*, and this remains an interesting aspect that has received relatively little attention.

A large and diverse group of methods have been developed for covalent binding of biomolecules to soluble or solid polymeric supports (Weetall, 1975; Carr and Bowers, 1980; Dean et al., 1985; Gombotz and Hoffman, 1986; Shoemaker et al., 1987; Park and Hoffman, 1990; Yang et al., 1990; Schense and Hubbell, 1999; Lutolf et al., 2003b). Many of these methods are schematically illustrated in Figure I.2.17.1. The same biomolecule may be immobilized by many different methods; specific

1) Pre-activation of support

2) Direct coupling to support

3) Pre-activation of biomolecule

4) Conjugation followed by copolymerization

5) Direct attachment to pre-activated polymer, gel or graft copolymer

Note : Ⓑ may be immobilized with or without a "tether" arm in any of the above
FIGURE I.2.17.1 Schematic cartoons showing various methods for covalent biomolecule immobilization.

Support function	Coupling agent	Active intermediate	Activation conditions	Coupling conditions	Major reacting groups on proteins
—OH, —OH	CNBr	—O—C=NH (from two —O)	pH 11–12.5, 2M carbonate	pH 9–10. 24 hr at 4°C	—NH₂
—OH or —NH₂	Cl,Cl,R triazine (R=Cl, NH₂, OCH₂COOH, or NHCH₂COOH)	triazine-Cl	Benzene, 2 hr at 50°C	pH 8. 12 hr at 4°C, 0.1M phosphate	—NH₂
—NH₂	Cl—C(=S)—Cl	—N=C=S	10% thiophosgene CHCl₃, reflux reaction	pH 9–10. 0.05M HCO₃⁻, 2 hr at 25°C	
—NH₂	Cl—C(=O)—Cl	—N=C=O	Same as isothiocyanate	Same as isothiocyanate	
—NH₂	HC(=O)(CH₂)₃CH(=O)	—N=C(H)—(CH₂)₃—CH(=O)	2.5% Glutaraldehyde in pH 7.0, 0.1M PO₄	pH 5–7, 0.05 M phosphate, 3 hr at R.T.	—NH₂, —C₆H₄—OH
—NH₂	succinic anhydride (H₂C—C(=O)—O—C(=O)—CH₂)	—NH—C(=O)—(CH₂)₂—C(=O)—OH	1% Succinic anhydride, pH 6	See carboxyl derivatives	
—NH₂	HNO₂	—N⁺≡N	2N HCl: 0.2g NaNO₂ at 4°C for 30 min (reaction conditions for aryl amine function)	pH 8, 0.05M bicarbonate. 1–2 hr at 0°C	—NH₂, —SH, —C₆H₄—OH
—C(=O)—NH₂	H₂N—NH₂, HNO₂	—C(=O)—N₃		pH 8, 0.05M bicarbonate. 1–2 hr at 0°C	—NH₂, —SH, —C₆H₄—OH
—NH₂ or —SH or —C(=O)—O⁻	R'—N=C=N—R + H⁺ (carbodiimide)	—C(=O)—C(=N⁺H—R)(—N—R')	50mg 1-cyclohexyl-3-(2-morpholinoethyl)-carbodiimide metho-p-toluene sulfate/10ml, pH 4–5 2–3 hr at R.T.	pH 4, 2–3 hr at R.T.	—C(=O)—OH
—C(=O)—OH	SOCl₂	—C(=O)—Cl	(Intermediate formed from carboxyl group are either protein or matrix) 10% Thionyl chloride/CHCl₃, reflux for 4 hr	pH 8–9, 1 hr at R.T.	—NH₂
—C(=O)—OH	HO—N(succinimide)	—C(=O)—O—N(succinimide)	0.2% N-hydroxysuccinimide, 0.4% N,N-dicyclohexyl-carbodiimide/dioxane	pH 5–9, 0.1M phosphate, 2–4 hr at 0°C	—NH₂

FIGURE I.2.17.2 Examples of various chemical methods used to bond biomolecules directly to reactive supports. (Carr and Bowers, 1980.)

examples of the most common chemical reactions utilized are shown in Figure I.2.17.2. This figure does not include some important reactions, such as thiol-maleimide, thiol-vinyl sulfone, amino-vinyl (Michael additions), and azide-alkyne (click) conjugation reactions. The reader is referred to Hermansson (2008) for many useful details on numerous conjugation chemistries.

For covalent binding to an inert solid polymer surface such as polyethylene or silicone rubber, the surface must first be chemically modified to provide reactive groups for the subsequent immobilization step. If the "inert" polymer support does not contain such groups, then it is necessary to modify it in order to permit covalent immobilization of biomolecules to the surface. A wide number of solid surface modification techniques have been used, including ionizing radiation-initiated graft copolymerization, plasma gas discharge, photochemical grafting, chemical modification (e.g., ozone grafting), and chemical derivatization (Hoffman et al., 1972, 1986; Gombotz and Hoffman, 1986, 1987; Hoffman, 1987, 1988) (see also Chapter I.2.12 on surface modification techniques).

A covalently-immobilized biomolecule may also be attached via a spacer group, sometimes called an "arm" or a "tether" (Cuatrecasas and Anfinsen, 1971; Hoffman et al., 1972; Hoffman, 1987). One of the most popular tethers is a PEG molecule that has been derivatized with different reactive end groups (e.g., Kim and Feijen, 1985),

and several companies currently offer a variety of homo- or hetero-bifunctional PEGs with end group chemistries such as N-hydroxysuccinimide (NHS), maleimide, pyridyl disulfide, thiol, vinyl sulfone, alkyne, and azide (the last two are for click chemical attachments). Such spacers can provide greater steric freedom, and thus greater specific activity for the immobilized biomolecule. The spacer arm may also be either hydrolytically or enzymatically degradable, and therefore will release the immobilized biomolecule as it degrades (Kopecek, 1977; Hern and Hubbell, 1998).

Inert surfaces, whether polymeric, metal or ceramic, can also be functionalized through modification of a polymeric adlayer. Such physically adsorbed or chemisorbed polymers can be bound to the surface via electrostatic interactions (VandeVondele et al., 2003), hydrophobic interactions (Neff et al., 1999) or specific chemical interactions, such as that between gold and sulfur atoms (Harder et al., 1998; Bearinger et al., 2003). Metal or ceramic surfaces may also be derivatized with functional groups using silane chemistry, such as with functionalized triethoxysilanes (Massia and Hubbell, 1991; Puleo, 1997) or dopamine polymer chemistry, as described above. Plasma gas discharge has been used to deposit polymeric amino groups for conjugation of hyaluronic acid to a metal surface (Verheye et al., 2000).

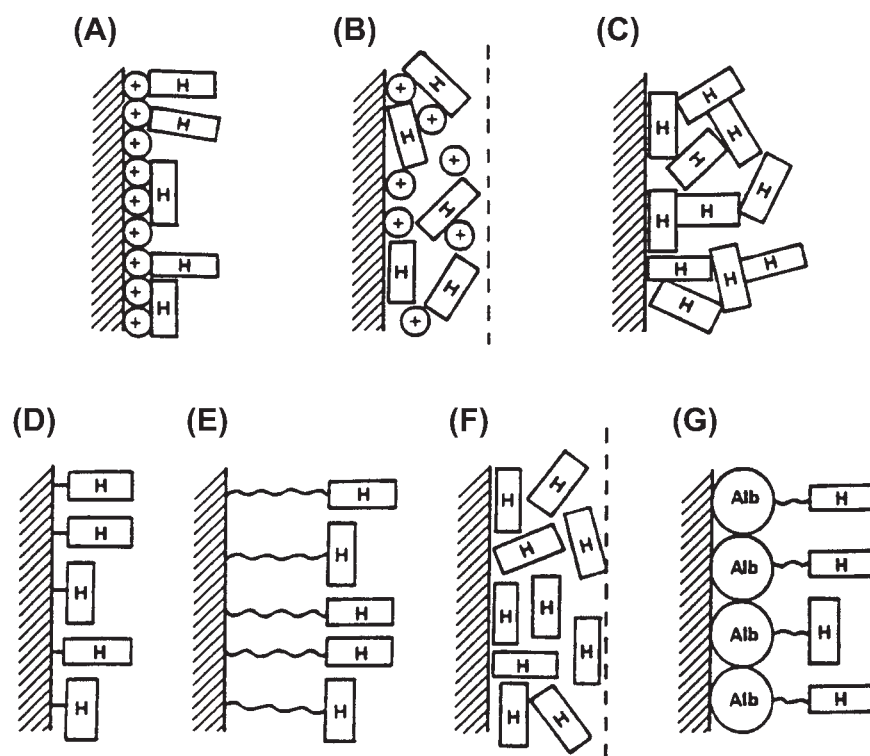
As noted earlier, hydrophobic interactions have been used to functionalize hydrophobic surfaces, utilizing


FIGURE I.2.17.3 Various methods for heparinization of surfaces: (A) heparin bound ionically on a positively charged surface; (B) heparin ionically complexed to a cationic polymer, physically coated on a surface; (C) heparin physically coated and self-cross-linked on a surface; (D) heparin covalently linked to a surface; (E) heparin covalently immobilized via spacer arms; (F) heparin dispersed into a hydrophobic polymer; (G) heparin–albumin conjugate immobilized on a surface. (Kim and Feijen, 1985.)
FIGURE I.2.17.4 Schematic of various ways that albumin may be immobilized on a surface. Albumin is often used as a "passivating" protein, to minimize adsorption of other proteins to a surface.

biomolecules such as ligands attached to hydrophobic sequences (e.g., Ista et al., 1999; Nath and Chilkoti, 2003). Surfaces with hydrophobic gradients have also been prepared for this purpose (Detrait et al., 1999). An interesting surface-active product was developed several years ago that was designed to convert a hydrophobic surface to a cell adhesion surface by hydrophobic adsorption; it had an RGD cell adhesion peptide coupled at one end to a hydrophobic peptide sequence.

Sometimes more than one biomolecule may be immobilized to the same support. For example, a soluble polymer designed to "target" a drug molecule may have separately conjugated to it a targeting moiety such as an antibody, along with the drug molecule, which may be attached to the polymer backbone via a biodegradable spacer group (Ringsdorf, 1975; Kopecek, 1977; Goldberg, 1983). For some nucleic acid drugs, sometimes a "nuclear localization signal" or NLS is added to enhance intracellular delivery to the nucleus (e.g., Nair et al., 2003). In another example, the wells in an immunodiagnostic microtiter plate will usually be coated first with an antibody, and then with albumin or casein (to block nonspecific adsorption during the assay); each is physically adsorbed to the well surface. In the case of affinity chromatography supports, the affinity ligand may be covalently coupled to the solid packing, and a "blocking" protein such as albumin or casein may be similarly added to block nonspecific adsorption to the support.

It is evident that there are many different ways in which the same biomolecule can be immobilized to a polymeric support. Heparin and albumin are two common biomolecules that have been immobilized by a number of widely differing methods. These are illustrated schematically in Figures I.2.17.3 and I.2.17.4.

Some of the major features of the different immobilization techniques are compared and contrasted in Table I.2.17.7. The important molecular criteria for successful immobilization of a biomolecule are that a large fraction of the available biomolecules should be immobilized, and a large fraction of those immobilized biomolecules should retain an acceptable level of bioactivity over an economically and/or clinically appropriate time period.

TABLE I.2.17.7	Biomolecule Immobilization Methods			
Method	Physical and Electro-static Adsorption	Cross-linking (After Physical Adsorption)	Entrapment	Covalent Binding
Ease:	High	Moderate	Moderate to low	Low
Loading level possible:	Low (unless high S/V)	Low (unless high S/V)	High	(Depends on S/V and site density)
Leakage (loss):	Relatively high (sens. to ΔpH salts)	Relatively low	Low to none[a]	Low to none
Cost:	Low	Low to moderate	Moderate	High

[a]Except for drug delivery systems.

CONCLUSIONS

It can be seen that there is a wide and diverse range of materials and methods available for immobilization of biomolecules and cells on or within biomaterial supports. Combined with the great variety of possible biomedical and biotechnological applications, this represents a very exciting and fertile field for applied research in biomaterials.

CHAPTER I.2.18 BIOMIMETIC MATERIALS

Drew Elizabeth Glaser and Christopher Viney
School of Engineering, University of California at Merced, Merced, CA, USA

INTRODUCTION: WHAT ARE BIOMIMETIC MATERIALS?

Biomimetic materials are designed to replicate one or more attributes of a material produced by a living organism. This attempt at a definition highlights a shared characteristic of *biomimetic materials* and *biomaterials*, since successful biomaterials serve to either: (1) restore a natural function where the original material is absent or unable to perform properly; or (2) sustain an environment that is optimally conducive to processes such as cell culture, tissue growth, biomolecular assays, and biotechnology-based manufacturing.

How Can Biomaterials Science Benefit From Biomimicry?

In both biomaterials science and the science of biomimetic materials, there is an underlying premise that the desirable characteristics of a natural material can be replicated successfully. However, biomimicry is not just about replicating the useful *properties* of a natural material (human or other animal tissue) in a surrogate product. Biomimicry also draws upon Nature's lessons in the chemistry, processing, and structure of materials. Biomimicry therefore can provide guidance for every step in the procedure by which molecules are selected and manipulated during the design and fabrication of a biomaterial. This chapter highlights biomimicry as a source of inspiration for design and modification of biomaterials and biomedical devices.

Biomimicry recognizes that the functional materials produced by living organisms (and the natural processes by which such materials are made) have evolved over a very long period of time and that, by definition, are biocompatible. If a natural material does an excellent job (and a better job than an existing synthetic counterpart), then mimicry of that material should be considered. In this context, "excellent job" and "better job" are qualified with reference to a product having superior properties, which may include such attributes as being inexpensive or robust or environmentally friendly, or simply being unobtrusive.

It is necessary to take care about what we understand by a *natural material*. Since humans are themselves an integral part of Nature, we have to recognize that human technology and the materials that it creates can be regarded in principle as just further examples of what Nature can achieve. To avoid possible ambiguity, we will consider the term "natural material" to refer to materials that are produced *metabolically* by living organisms.

A CLASSIFICATION OF BIOMIMETIC MATERIALS

Within the context of (bio)materials, it can be helpful to recognize – and convenient to distinguish between – various classes of biomimicry, based on what type of natural attribute is being mimicked. The use of parentheses in "(bio)materials" here signifies that Nature's lessons for materials science can be widely applicable, and are not restricted specifically to biomaterials.

Functional biomimicry occurs when Nature provides the inspiration for one or more physical and/or chemical *properties* of a (bio)material. According to our preceding definition of a biomimetic material, there is some element of functional biomimicry in every successful biomaterial.

In its most direct sense, functional biomimicry is achieved when material is recovered from a donor organism, sterilized, and remodeled into a replacement for damaged tissue in a host. In such cases, Nature's contribution extends beyond that of muse to delivery of a ready-made, working solution. A rudimentary example is provided by false teeth made from ivory. A more sophisticated example is the use of pig mucosa to repair rotator cuff tears (Derwin et al., 2010).

Molecular biomimicry is the result of Nature inspiring the *types of atoms and molecules* that are selected (and that usually are available from natural sources) in the production of a (bio)material. An example is filamentous phage, which is versatile, tailorable and robust as a promoter of liquid crystalline phase formation (Reed et al., 2009), and therefore can drive self-assembly of a material. If the tendency to self-assemble is sufficiently strong, filamentous phage – or, significantly, related genetically engineered (fusion) phagemids – can serve as a host that guides the self-assembly of complex structures, including scaffolds that promote the patterned alignment and growth of cells (Rong et al., 2008). In this context, the fusion phagemid accomplishes molecular biomimicry by stabilizing liquid crystalline order in the same way that a native filamentous phage would. It also fulfills a functional biomimicry role in being biodegradable, and thus a disposable component of the repaired tissue.

Process biomimicry arises when Nature provides inspiration for the *pathway* or *mechanism* by which atoms and molecules acquire their final position and orientation in the (bio)material. For example, consider the fact that the natural silk produced by spiders and some insect larvae is spun from aqueous solution, although the final product is water-insoluble. This change in solubility is accompanied by changes in the folded shape (conformation) of the constituent protein chains, but the *chemical* nature (configuration) of the chains remains unaltered. The water-soluble protein molecules secreted by the silk glands are globular; they aggregate into a processable liquid crystalline fluid within the ducts leading from the glands to the spinnerets, and thence undergo shear-nucleated reorganization into a solid fiber stabilized by water-insoluble crystals (Viney, 1997). Nature thus provides a blueprint for the environmentally benign processing of polymer fiber. Silk will feature as a recurring example throughout this chapter, as a versatile source of principles to illustrate various facets of biomimicry. It will also provide the topic for a case study (see Case Study 2).

Structure biomimicry happens when Nature's inspiration guides the pattern of atomic and/or molecular organization – i.e., the *nanostructure* and *microstructure* – that is obtained in a (bio)material. Nature is particularly adept at achieving *multifunctionality*, i.e., the simultaneous optimization of more than one useful property in its materials, by the use of hierarchical structure to allow the independent control of properties that are a consequence of structure at different length scales (Dunlop and Fratzl, 2010).

An example of multifunctionality arising from structure is provided by the red "sweat" (which is really an oily secretion, as distinct from the watery excretion that is usually implied by the term "sweat") of the hippopotamus (Reed et al., 2009). The fluid sweat contains two types of liquid crystalline spherulite. Some of the spherulites have a fine substructure on a scale that is effective at scattering light, so that the sweat performs well as a sunblock; the other spherulites, which are microstructurally coarser, reduce the viscosity of the sweat and thus promote its ability to spread on the hippo's skin. Both of these considerations could be useful in the design of new skincare products – especially if combined with molecular biomimicry of the red sweat, which contains molecules that are effective as sunscreens (Saikawa et al., 2004) in addition to their ability to self-assemble a sun-blocking microstructure.

A second opportunity for structure biomimicry is obtained by again referring to silk – in this case the fibers spun by spiders from the secretion of their major ampullate glands to form the principal component of the drag line and the radial threads of a web. The nanostructure of this silk contains a bimodal size distribution of crystalline regions (Trancik et al., 2006). The larger crystals promote the high initial stiffness of the fiber when it is deformed in tension; however, their imperfect internal structure prevents them from acting prematurely as stress concentrators that could accelerate failure. The smaller crystals do not contribute significantly to initial stiffness, but they provide stability to the material during plastic deformation. Attempts to achieve a similarly optimal combination of mechanical properties in other materials can be usefully guided by this type of microstructure.

The different types of biomimicry identified above are collated in Figure I.2.18.1, in the context of a single biological material: actin. Particular features of actin that merit attention for possible biomimicry are noted in green. Possible benefits of such biomimicry are noted in blue. While actin is not used on its own as a biomaterial, it offers broadly applicable lessons for materials and biomaterials design.

THE ORIGINS OF BIOMIMICRY

The classification scheme outlined above emphasizes that Nature can provide useful guidance regarding optimization at all levels of the complex relationship between the composition, synthesis, assembly, structure, properties, and performance of a (bio)material.

In the broader context of engineering, biomimicry can extend beyond materials to entire devices, as exemplified by Leonardo da Vinci sketching birds with the objective of studying and eventually emulating their ability to fly (Zanon, 2009). Attempts at device or systems biomimicry continue today in a biomedical context, with the development of artificial tissues and organs which may incorporate several different biomaterials. However, for the sake of tractability, the present discussion will focus
FIGURE I.2.18.1 Actin as a versatile source of lessons in biomimicry. The structural source of torsional flexibility is highlighted in red. Particular features of actin that merit attention for possible biomimicry are noted in green. Possible benefits of such biomimicry are noted in blue. All four classes of (bio)materials biomimicry are represented.

on Nature's lessons that we may wish to mimic in the production of a single biomaterial.

Biomimicry Involves Transferring Nature's Technology to Solve Engineering Problems

In biomimicry, we recognize, adopt and adapt Nature's tried-and-tested principles to solve engineering problems (Bar-Cohen, 2011). Biomimicry can be invoked broadly as a proof of concept, for example. Nature demonstrates that powered flight is possible (birds and insects can fly), that fibers can be spun from organic feedstock (silkworms and spiders do it), and that nanomachines can be built (flagellar motors exist). Biomimicry is increasingly used to guide design in areas as diverse as architecture (e.g., to optimize airflow and minimize heat loss in buildings), telecommunications (e.g., to plan networks that maximize information flow while minimizing infrastructure), and transportation (e.g., to design vehicle profiles that minimize drag).

In the 17th century, Robert Hooke speculated in his book *Micrographia* as to the possibility of producing fibers artificially, based on what could be learned from studying silkworms:

"And I have often thought, that probably there might be a way found out, to make an artificial glutinous composition, much resembling, if not full as good, nay better, than that Excrement, or whatever other substance it be out of which, the Silk-worm wire-draws his clew. If such a composition were found, it were certainly an easier matter to find very quick ways of drawing it out into small wires for use.

I need not mention the use of such an Invention, nor the benefit that is likely to accrue to the finder, they being sufficiently obvious. This hint therefore may, I hope, give some Ingenious inquisitive Person an occasion of making some trials, which if successful, I have my aim, and I suppose he will have no occasion to be displeas'd."

At the time when these thoughts were first being expressed, it was supposed possible for artificial silk fiber to be spun from plant matter, since silkworms feed on mulberry leaves. Motivated by the goal of inexpensive functional biomimicry of silk, catalyzed by misconceptions of the process biomimicry of silk, but lacking any correct knowledge of the molecular biomimicry of silk, experimenters spent the next 200 years trying to draw fibers from solutions or suspensions prepared from wood pulp and similar plant-sourced raw materials. Thus the first manufactured organic polymer fiber was rayon, reconstituted from solutions of cellulose (initially mulberry bark), born from attempts to emulate what we now know to be a protein-based natural fiber.

As a concept, biomimicry has been around for a long time. As an academic discipline it is sufficiently new to not yet have been codified (or limited) by minutely defined rules and principles. It is destined to remain very much a work in progress, as we become more adept at *recognizing* what Nature does as well as *applying* what Nature does. Thanks to our burgeoning insights into the molecular basis of life, the molecular biomimicry needed to underpin rapid progress in biomimetic biomaterials is within our grasp.

SOME ATTRACTIONS OF BIOMIMICRY

The Big Picture

Some aspects of biomimicry have a broad appeal throughout the context of applied biomaterials. These universally desirable attributes include:

Biocompatibility. A biomaterial that is produced with significant input from molecular and structure biomimicry will necessarily achieve a high degree of functional biomimicry. In particular, we can expect the surface properties of a "closely" biomimetic material to be comparable to those of the corresponding natural material. Thus, a closely biomimetic material is also likely to be biocompatible, if it is used within an environment that is comparable to the native environment of the material being mimicked. *These related consequences are perhaps the most attractive feature of biomimicry in the context of applied biomaterials.*

Integration with Biotechnology. An additional benefit of biocompatibility is that the metabolic pathways of living organisms can be harnessed via the techniques of biotechnology to obtain controlled purity, economic scale up and simple convenience in molecular biomimicry. We have already encountered this advantage implicitly (see section "A Classification of Biomimetic Materials") as it pertains to fusion phagemids. Our recurring example of silk is also relevant here, as various transgenic hosts – including bacteria, goats, and potatoes – are being explored as possible sources of silk-based biomaterials (Scheller et al., 2001; Vendrely and Scheibel, 2007).

Environmental Impact. The opportunities for biocompatibility that go hand-in-hand with biomimicry extend beyond integration with biotechnology. Nature offers lessons in how to select raw materials, adopt processes, and even limit the generation of waste products in ways that use molecules and energy efficiently, and that are environmentally benign. The case study titled "Echinoderm Collagens and Fiber-Reinforced Composites as Examples for Biomimicry" (see Case Study 1) explores a detailed example of Nature's superior efficiency in materials use.

As materials engineers become increasingly concerned about whole lifecycle design (the sourcing, processing, deployment, decommissioning, and disposition of materials), so consideration of the options for recycling become more pressing, and materials that are compatible with the recycling that occurs in Nature become especially desirable. Again, silk provides an instructive example. Spiders have to be able to depend on (and from!) their dragline as a component of webs, and as a means for making controlled vertical descents. Yet, spiders can eat silk that has served its mechanical purpose; they produce digestive enzymes that allow them to recycle the silk proteins into their constituent amino acids. In this way, the spiders cut down on the amount of new dietary protein that they have to trap in order to maintain their webs and their mobility. The reader is referred to Case Study 1: Echinoderm Collagens and Fiber-Reinforced Composites as Examples for Biomimicry.

A Specific Snapshot: Proteins as Versatile Fiber-Forming Materials

A biomaterial may or may not have an immediate counterpart in Nature to serve as a template for biomimicry. However, if it is desirable for the biomaterial to have a fibrous structure (for example, in an engineered biomaterial scaffold that supports cells during tissue reconstruction), then there are various ways in which biomimicry can guide the design and manufacture of the fibers. Nature is highly adept at producing fibers by self-assembly from solutions of protein (Renuart and Viney, 2000). We have already noted (see section "A Classification of Biomimetic Materials") how some natural fibers can capitalize on a hierarchical microstructure (i.e., microstructure at different length scales) to simultaneously optimize more than one mechanical property. Another illustration of this capability is afforded by actin (Viney, 2001; Figure I.2.18.1), which exhibits both rigidity in tension and flexibility in torsion: the tensile rigidity is maintained by the intermolecular forces that bind G-actin globular protein chains into rodlike F-actin aggregates, while the torsional flexibility is conferred by the internal structure of the G-actin globules.

Successful fiber self-assembly usually requires molecules that can interact with each other as "appropriate" building blocks, an environment that facilitates processing, a structural anisotropy, and intermolecular interactions (usually secondary bonds, but in some cases covalent cross-links) that stabilize the assembled fiber. All of these requirements can be met by proteins, and are demonstrated in the diversity of fibrous structures that Nature self-assembles. The versatility and ubiquity of proteins in providing stable, self-assembling, anisotropic structures is illustrated in Figure I.2.18.2.

Variety. The unique properties of a given protein depend on which amino acids are present, the relative amounts of those amino acids, the specific sequence in which they are arranged, and the overall length of the molecule. In synthetic (non-natural) protein materials, the amino acids do not have to be restricted to ones that are found in naturally-occurring protein (for example, under contrived conditions, *p*-fluorophenylalanine, trifluoroleucine, norleucine or selenomethionine can be incorporated into protein chains in place of phenylalanine, leucine, isoleucine or methionine respectively). Also, following protein synthesis, some of the amino acid side groups may undergo derivatization, such as occurs naturally in the conversion of proline to 4-hydroxyproline and lysine to 5-hydroxylysine during the biosynthesis of collagen. The variety of possible natural proteins to use as building blocks is therefore extremely large, and the variety of possible synthetic proteins is even larger, limited only by the practicalities (ultimately, kinetic considerations) of getting long molecules to fold into a conformation that ensures the desired properties.

It could be reasonable to question the value of incorporating non-natural amino acids into biomimetic
FIGURE I.2.18.2 Examples of stable, self-assembling, anisotropic structures formed by proteins. Red arrows emphasize the direction in which anisotropy is propagated.

synthetic proteins, on the grounds that the non-natural amino acids would surely detract from the biomimetic properties of the product. However, it is important to remember that biomimicry is a process of being *guided* by lessons from nature; it is not merely a process of duplicating outcomes. We will return to this thought in the section "Limitations of Biomimicry."

Processability. Two characteristics of protein molecules underlie their versatile fiber-forming ability:

(1) The backbones are intrinsically flexible, so proteins have the potential to fold into a large variety of possible conformations.

(2) The side groups of the constituent amino acids confer a locally hydrophilic (acidic, basic or neutral) or hydrophobic character to the molecules. In aqueous environments, the charge distribution along the molecules will therefore be sensitive to the presence of other charged species, and so will depend on pH and dissolved ions. The flexible protein chains will tend to fold in a way

that allows hydrophobic segments to be screened from the water by the more hydrophilic segments, while also tending to maximize the extent to which charged and polar sites participate in hydrogen bonding.

Structural Anisotropy. The intrinsic flexibility of proteins allows them to form *geometrically anisotropic* structures such as helices or β-sheet crystals. The stability of these structures is sensitive to the amino acid sequence of the protein, and to the pattern of intramolecular and intermolecular bonding favored by interactions between particular residues or sequences along the protein chain as well as between the protein and the surrounding medium.

Even protein molecules that have a *globular* conformation in water can also form geometrically anisotropic structures, in this case by *aggregating*. This is the process by which F-actin assembles from G-actin, and by which microtubules assemble from α- and β-tubulin. It is also (as noted in the section "A Classification of Biomimetic Materials" above) complicit in the formation of a

processable fluid from solutions of globular fibroin during the natural spinning of silk fibers. The aggregation of globular molecules into anisotropic structures is promoted by liquid crystalline order in the protein solution: synergism develops between alignment-enhanced assembly and shape-enhanced alignment of the aggregates.

In an aqueous environment, helices can form superhelices (coiled coils) stabilized by hydrophobic bonding across the area of helix–helix contact. This is how procollagen, the intracellular precursor of extracellular collagen, is assembled into triple helices. Likewise, hydrophobic bonding stabilizes cross-β-sheets into hollow trimeric box beams (resembling the packaging of Toblerone® chocolate), which serve as the spikes on human adenovirus, and are noted for their high stiffness and yield strength (Hoess et al., 1992).

Every fibrous product found in Nature, and the process by which that product is made, has the capacity to inspire biomimicry in a fibrous biomaterial. The lessons from Nature represent a transferable technology that may potentially be capitalized on – in whole or in part, depending on the particular application being considered. The reader is referred to Case Study 2: Silk as an Example of a Biomaterial for Biomimicry.

A Blueprint for Progress in Design

Biomimicry offers a blueprint for the engineering design process itself. In Nature, evolution drives innovation (and innovation drives evolution) via a cycle of events that can be summarized as follows:

- One or more problems, needs or opportunities arise in response to continuously and/or suddenly changing circumstances.
- Multiple possible solutions are spontaneously and simultaneously explored.
- Appropriate solutions are selected.

New and more pressing problems, needs or opportunities can arise at any stage. Any existing design embodies a history of successful response to changing circumstances.

Thus, in Nature, the emergence of problems and the generation of solutions occur side-by-side, allowing a seamless response. In traditional engineering, solutions follow problems sequentially and therefore often discontinuously. To the biomaterials engineer, Nature offers a palette of ready-made solutions, waiting for the right problem or need to be expressed. Biomimicry, most simply, is a process of asking Nature the right question, to capitalize on the diversity and optimization of solutions that have evolved over time.

Validation of Non-Biomimetic Technology

The terms "biomimetic" and "biomimicry" conventionally refer to lessons that are *proactively* learned from studying Nature's materials, processes, and devices. In other words,

Nature provides the impetus for discovered knowledge and adapted technology. However, it can be reassuring to discover that a specific product developed without recourse to active biomimicry is, with *hindsight*, biomimetic in one or more of its features. We can in such cases be confident that the underlying design really is sound.

In the 1960s, the idea of using a polymer gel network to absorb several hundred times its own weight in water was developed by the United States Department of Agriculture (USDA) into a product for boosting water conservation in agriculture, and subsequently adopted for use in diapers, surgical pads, and wound dressings. The fact that slugs and snails have evolved a highly effective, multifunctional surface coating (mucus) based on the properties of polymer gel networks was not known in such molecular detail at the time of the USDA work, but the albeit unintentional biomimicry does suggest that polymer gel formation is indeed a particularly efficient way to retain absorbed water. Also, there is the opportunity to build on this serendipitous biomimicry to enhance the biocompatibility and biodegradability of personal care products that contain superabsorbent polymers. The ability of secreted mucin granules to swell rapidly on contact with water (Verdugo et al., 1992) is felicitously emulated in superporous hydrogels (Omidiana et al., 2005) that have applications in drug delivery and other technologies where a combination of high surface area and fast mass transport is desirable.

LIMITATIONS OF BIOMIMICRY

Although biomimicry should be a tool that all biomaterials engineers keep close to hand, it should never be the only tool in the box. As is also the case with any other tool used by engineers, an understanding of its limitations is a necessary prerequisite if the tool is to be used appropriately and effectively. Biomimicry is not a biomaterials design panacea. We will therefore explore some of the most important misconstrued and real limitations of biomimicry.

Toxicity of Many Natural Materials. The section "The Big Picture" identifies biocompatibility as one of the broadly appealing consequences of biomimicry. Yet, many naturally produced materials and processing byproducts are toxic. There is no inconsistency here, because biomimicry properly involves recognizing *appropriate* lessons that Nature offers, and applying them *in the proper context*. Also, when nature does produce toxins, these are usually selective in their action, and they rarely persist in the environment.

Copycats have Fewer than Nine Lives. "Biomimicry" (denoting a learning and design process) and "biomimetics" (denoting a field of study in which the lessons and designs are applied) are perhaps unfortunate terms in that they may foster an impression that Nature is being copied – an overly literal interpretation of mimicked – without thought being given to the value or limitations or consequences of such copying. However, just like inter-species mimicry in nature, biomimicry is properly

a process of *selective* learning and copying. Biomimicry is about being inspired and guided by Nature's processes and products; it is not a synonym for bioduplication.

We have previously noted (see section "The Origins of Biomimicry") the debt that powered flight owes to observations made on birds, dating back at least as far as the work of Leonardo da Vinci. This is an excellent example of what biomimicry can lead to by alerting engineers to a *possibility*. Nevertheless, people did sometimes get lost along the path to our present-day success in aviation (and our ability to fly heavier loads much faster than birds can), by straying too far away from bioinspiration and too close to bioduplication. Useful flying machines do not work by flapping their wings up and down, but by capitalizing on Nature's lesson that a wing with variable curvature is the key to a workable trade-off between lift and drag over a range of speeds. Similarly, successful biomimetic materials are those where "what if" questions are informed by knowledge of biology and the answers are open to refinement from any pertinent field of expertise.

The inspirational component of biomimicry can be highly significant for the (bio)materials engineer. The idea that you *can* make adhesives capable of setting in an aqueous environment (inspired by mussel and barnacle "glue") or biodegradable lubricants (inspired by slug mucus) or superhydrophobic surfaces (inspired by lotus leaves) or photonic materials with non-fading and perhaps cosmetically useful color (inspired by butterfly scales), is what matters.

Nature's Best May Not Be Good Enough. Natural materials are impressive in many ways. However, natural materials are not always or even necessarily superior to artificial ones; indeed there is no intrinsic reason why they *should* always be superior. Nature and technology serve different goals, usually under very different constraints (Vogel, 2003).

- In Nature, the chemical building blocks of materials are synthesized from relatively few types of atom – most of the periodic table does not feature in the ingredients of natural materials, and, as far as we know, natural organisms do not make metallic materials. If the objective of a biomaterial is to replace like with like, then the absence of metals in Nature's materials toolbox isn't an issue. However, if a biomaterial is expected to do a better job than the material that it replaces, it may be necessary to look beyond Nature for a solution. A good example here is Charnley's hip (Charnley, 1976), which combines metal and synthetic polymers to produce a highly successful implant. The result certainly is functionally biomimetic – it behaves like a hip – although it is not a product of molecular, process or structure biomimicry.
- Nature's materials processing strategies operate at near-ambient temperature, and under near-equilibrium conditions. Thus, the same attributes that are attractive because of their low environmental impact

will limit processing (production) rates compared to what might be achieved at elevated temperature and under significantly off-equilibrium conditions. Limited production rates are, however, less likely to be a critical factor in the small volume, high value context of a specialty biomaterial than they are in the high volume world of more traditional engineering materials.
- The ubiquitous presence of organic matter in natural materials precludes the use of these materials at high temperatures or in chemically aggressive environments. While this limitation can be a deal-breaker concerning the use of biomimetic materials in many high-tech applications, it is not a major consideration in the context of biomaterials.

Natural Materials Do Fail. Indeed, this is why the need for biomaterials arises in the first place! Here we encounter another divergence between the goals of Nature and the goals of technology. In Nature, where survival of the species is more important than the survival of any individual, failures are tolerated as being part of (indeed necessary for) the process of evolutionary improvement. It is acceptable to lose a few or even many individuals, as long as there are enough survivors. A related approach was adopted in medieval battles – not just in treating soldiers as arrow fodder (provided that one had *enough* soldiers), but also in the practice of using decoys to confuse the enemy ("I think there be six Richmonds in the field: Five have I slain today instead of him" – William Shakespeare, *Richard III*, Act 5, Scene 4).

Although failure can also be regarded as essential to successful engineering design (Petroski, 1992), engineers are also deeply concerned about survival of the individual. The goal of engineering is that *no* machines will break, *no* bridge will fall down, *no-one* will be injured or killed. On that basis, an engineer may be reluctant to replace a failed piece of human tissue or a worn-out body part with something that suffers from the same weakness, wishing instead to implant something more durable. However, the engineer would also be wise to exercise *selective* biomimicry, learning from those molecular, processing, and structural aspects of the original material that are successful, and attempting improvements only where necessary.

Wonders and Woes of Water as a Processing Medium. Nature's elegant solution for spinning water-insoluble fiber from aqueous solutions of silk protein (see section "A Classification of Biomimetic Materials") has a downside with respect to the properties of the fiber. The hydrophilic amino acid sequences responsible for the aqueous solubility of the protein (in its globular conformation) are retained in the product. Thus, although the fiber microstructure is stabilized by water-insoluble β-sheet crystals (formed by hydrophobic sequences that are exposed to water when the globular molecules are denatured by shear), the fibers still absorb water from their environment. The resultant plasticization (increased molecular mobility, due to hydrogen bonds between

protein chains being replaced by hydrogen bonds between the chains and absorbed water molecules) leads to the fibers having poor creep resistance. While much attention has been garnered by the tensile strength and stiffness of silk, the long-term performance under load is unspectacular. The use of silk in biomaterial scaffolds, capitalizing on biocompatibility, biodegradability, ease of processing, and not requiring high loads, is therefore more successful than deployment in critical loadbearing situations.

Hydrophobic bonding between cross-β-sheets stabilizes the trimeric box beam structure adopted by adenovirus capsid spikes (see section "A Specific Snapshot: Proteins as Versatile Fiber-Forming Materials"), contributing to the ability of those structures to resist deformation under axial compression. Hence the spikes function well, as a nanoscale battering ram in broaching the outer wall or membranes of a target cell, and as a nanoscale syringe in delivering virus DNA into the target. Because high compressive strength and stiffness (singly or in combination) have been a long-term but elusive goal of polymer science, attempts were made to spin fiber from solutions of recombinant spike protein. For ease of dissolving the protein and convenience in spinning the fibers, 1,1,1,3,3,3-hexafluoro-2-propanol was used as the solvent (O'Brien et al., 1994). However, the mechanical properties of the resulting fiber were disappointing, and the trimeric box beams were not found in the hierarchical microstructure of the fibers (Gillespie et al., 1994). There are several possible reasons for this failure, illustrating the pitfalls of attempting biomimicry outside of an appropriate context: (1) spinning fibers artificially under non-equilibrium conditions will not necessarily allow time for the assembly of structures resembling those formed naturally under near-equilibrium conditions; (2) the driving force to form hydrophobic bonds will be lower in 1,1,1,3,3,3-hexafluoro-2-propanol than in water; and (3) even if the fibers had been processed from an aqueous environment under near-equilibrium conditions, there is no *a priori* reason to suppose that a structure stabilized by hydrophobic bonds would persist in samples that are being evaluated for their mechanical properties in air. Simply put, the natural material is designed to be assembled and to perform in an aqueous medium, and attempts to mimic its properties must take this reality into account.

THE FUTURE OF BIOMIMICRY IN BIOMATERIALS SCIENCE

The examples presented in this chapter have focused mainly on fibrous and fiber-reinforced materials. On Nature's scale of achievements, the object lessons chosen here have been relatively simple. More challenging examples await detailed study by (bio)materials scientists. A case in point: insect antennae are self-assembled fibrous structures too. They are also small, mechanically robust, self-repairing, responsive to chemical and thermal information, and able to undergo controlled and rapid changes in shape and orientation – all of which are attributes that could find application in biomaterial sensors and actuators.

Nature's lessons do not stop there. Self-assembly is used by Nature to produce *all* its materials for structures and devices. The principles explored in this chapter are also reference points from which to venture into the emerging subject of Nature's nanomotors (Goel and Vogel, 2008) to consider their assembly and repair, their ability to transduce energy, and their connectivity to functional structures such as cilia, flagella, and antennae. We can imagine a future in which some biomaterials are assembled *in situ* without the need for surgery, and in which parallel advances in nanotoxicology (Shvedova et al., 2010) permit functional, process, and structure biomimicry of natural nanomotors with synthetic nanomaterials.

We can also look forward to learning (bio)materials lessons from species that remain to be characterized in detail – or are yet undiscovered. Although we have been able to summarize some biomimicry principles, we must recognize that these are subject to continuous refinement as we gain further insights into the opportunities and constraints of biomimicry. The principles gleaned thus far should not be regarded as immutable rules, but as guidelines that are often useful but not invariably right. We are still a long way from unlocking the full potential of biomimicry or from reaching its limits.

ACKNOWLEDGMENT

WORKED EXAMPLE

Question

The petiole (waist) of a wasp is a narrow constriction occurring between the first and second abdominal segments. In some species, for example the mud dauber *Sceliphron caementarium* (Hymenoptera: Sphecidae), the petiole is approximately cylindrical. What biomaterials-related lesson(s) might one hope to learn from studying the microstructure of a wasp petiole?

Solution

A number of tissues and functions critical to the wasp's ability to live must pass through this effective structural bottleneck. The petiole has to accommodate and protect the alimentary canal, nerve tissue, an aorta, and open circulatory functions that communicate between the front and rear of the wasp.

From these requirements, we can deduce that the cuticular material making up the petiole wall must

be crush-resistant, puncture-resistant, and fracture-resistant. Such characteristics are indicators that the cuticle has a high fracture toughness, in turn suggesting that the material is multilayered (lots of interfaces to prevent or deter crack propagation), and that there may also be some sort of composite structure *within* layers. The cuticular material must also confer stiffness and resilience in bending, especially when the load on the petiole increases as a consequence of the wasp using its stinger to immobilize prey. All these properties must be achieved without the material contributing unduly to the weight of the insect. Thus, we might expect to learn particular lessons pertaining to the hierarchical structure and self-assembly of biocompatible tubes that are optimized in regard to multiple mechanical properties. More broadly, the petiole presents a model system from which to learn lessons about: (1) the relationship between efficient use of material, molecular organization, and mechanical property optimization in the context of a simple object geometry; and (2) the factors that limit molecular and energy transport when such an object is self-assembled.

Studies performed by scanning electron microscopy and transmission electron microscopy (Reed et al., 2007) have revealed several details about the structure of the mud dauber wasp petiole, including:

- The cuticle is indeed multilayered, consisting of a large number (43) of concentric layers.

- The inside surface of the petiole contains ribs of tissue that run either longitudinally (on the dorsal half) or circumferentially (on the ventral half). These different orientations of structural reinforcement help to resist buckling when the ventral surface is in compression, while increasing the restoring force that opposes longitudinal extension of the dorsal surface – a useful response to the loading conditions that would be experienced while the wasp stings its prey.

- There are spiral strands of fibrous, crystalline chitin within the individual concentric layers of the petiole. The diameter of the spiral occupies the perpendicular distance between layers, so that the petiole has a structure related to that of multi-layer corrugated cardboard. However, whereas the corrugated "medium" in cardboard confers a highly anisotropic resistance to bending (sheets are stiff if bent around an axis running normal to the corrugations, but not if bent around an axis running parallel to the corrugations), the coiled medium within the layers of petiole will impart a resilient response to bending in any direction.

Collectively, the above observations are consistent with the exceptional ability of cuticle to undergo large, multiaxial, reversible deformations without catastrophic failure and while maintaining a "respectable" stiffness-to-weight ratio.

| Case Study 1 | Echinoderm Collagens and Fiber-Reinforced Composites as Examples for Biomimicry |

We will consider here one of Nature's lessons for optimizing the amount of material (fiber) used to achieve a particular property (reinforcement of a fibrous composite). This particular lesson has been gleaned from studies of both sea cucumber dermis and the "catch" ligament associated with the ball-and-socket joint at the base of sea urchin spines. Both materials are among the living world's oldest fibrous composites, so their survival is in itself a testimony to their successful design. Interest in these materials also stems from the fact that their mechanical properties are adaptive: their stiffness can be quickly and reversibly changed in response to external stimuli. Therefore, they are serving as models for new biomaterials that can be used as adaptive substrates for intracortical microelectrodes (Capadona et al., 2008).

The collagen fibers in sea cucumber dermis and sea urchin ligament are *tapered* rather than cylindrical. The shape is ensured by the nucleation and growth mechanism of supramolecular self-assembly (Trotter et al., 2000) by which the fibers are formed (Figure I.2.18.3).
FIGURE I.2.18.3 Mechanism of collagen fiber growth in sea cucumber dermis and sea urchin ligament, based on literature descriptions (Trotter et al., 2000). The mechanism ensures both a tapered shape and (for a fiber consisting of a sufficiently large number of parallel fibrils) a consistent axial ratio.
FIGURE I.2.18.4 Schematic description of the geometry and variables needed to set up Equation (1).

FIGURE I.2.18.5 Schematic representation of a critical length of fiber in longitudinal cross-section. A plot of internal stress versus distance from the fiber end, obtained from Equations (3) and (4), is superimposed.

We will explore how this shape reduces the volume of fiber that is not exploited at close-to-maximum loadbearing capacity, and that therefore would have been a waste of resources to produce.

In the case of conventional reinforcing fibers in a composite, the fiber cross-section is approximately constant at all points along the length of any given fiber. If, as is expected, the fibers deform less readily than the matrix, then load is transferred from the matrix to the fibers through the action of the resulting shear stress that develops at the fiber–matrix interfaces. Ideally, discontinuous fibers will be long enough for the stress at their midpoint to approach the fiber failure strength.

To quantify the nominal tensile stress in the fibers as a function of increasing distance from either end, we will proceed with some simplifying assumptions: (1) the fibers are discontinuous and perfectly aligned; (2) a tensile load is applied to the composite along a direction parallel to the length of the fibers; and (3) the fibers are cylindrical and have radius r.

Figure I.2.18.4 designates a small reference length dx near to one end of a fiber. The tensile stress in the fiber increases by $d\sigma$ over this distance. The increase in tensile stress is achieved by the interfacial shear stress τ acting on the area of fiber–matrix interface accommodated within the distance dx. A simple force balance (Martin, 2002) now gives:

$$d\sigma(\pi r^2) = \tau(2\pi r dx) \tag{1}$$

$$\therefore d\sigma = \frac{2\tau}{r}dx \tag{2}$$

Overall, the tensile stress increases from $\sigma = 0$ (at $x = 0$, i.e., the end of the fiber) to $\sigma = \sigma_1$ (at $x = x_1$, measured from the end of the fiber). We can integrate Equation (2) and substitute these limits:

$$\int_0^{\sigma_1} d\sigma = \frac{2\tau}{r}\int_0^{x_1} dx$$

$$\therefore \sigma_1 = \frac{2\tau}{r}x_1 \tag{3}$$

Thus, the tensile *stress in the fiber increases linearly as a function of distance* from the end of the fiber. The distance from the end of the
fiber to the point where the stress has attained its maximum is called the *transfer length*. Given a sufficiently long fiber, the maximum stress can reach the ultimate tensile strength σ_{UTS} of the fiber. In that case, the transfer length is known as the *critical transfer length* (which we will denote as x_C), and the corresponding overall length of the fiber (twice the critical transfer length, since the fiber has two ends) is known as the *critical length*. If the fiber is shorter than the critical length, then it cannot live up to its full potential to carry load transferred from the matrix. If it is longer than the critical length, then it will break, and so the additional material does not contribute an ability to carry additional transferred load.

We can substitute $\sigma_1 = \sigma_{UTS}$ and $x_1 = x_C$ into Equation (3), and rearrange to obtain a useful expression for the critical transfer length:

$$\sigma_{UTS} = \frac{2\tau}{r}x_C$$

$$\therefore x_C = \frac{r}{2\tau}\sigma_{UTS} \tag{4}$$

Figure I.2.18.5 schematically shows a critical length of stressed fiber in longitudinal cross-section, together with a superimposed plot of the internal (tensile) stress versus distance from the fiber end. It is apparent that much of the material in the fiber is wasted, in that its tensile strength is not being properly exploited along almost the whole length of the fiber! The load near the ends of the fiber could be carried adequately by a smaller fiber cross-section, compared to the cross-section needed to carry the load near the middle of the fiber. A less wasteful use of material, and a more efficient exploitation of the fiber properties, is therefore achieved with a fiber that *tapers* from the middle towards the ends.

Functional Biomimicry

Silk has multiple biomimetic uses. Aqueous solutions of silkworm fibroin (silk protein) have been processed artificially into materials that mimic the properties of native silk (Jin and Kaplan, 2003). Aqueous processing has also been used to produce prototypical silk lenses and diffraction gratings

from solutions of silk fibroin; their transparency is ensured by controlling the crystallization of β-sheets, and the products benefit from the mechanical properties and biodegradability of silk (Lawrence et al., 2008).

Decorating reconstituted silk networks with peptides and hormones can create bioactive surfaces with numerous possible biomaterials

Case Study 2 | **Silk as an Example of a Biomaterial for Biomimicry—*cont'd***

applications that include use as a scaffold on which to culture tissues such as bone (Sofia et al., 2001). Because silk is biodegradable, its use as a cell and tissue scaffold can avoid any need for subsequent surgical removal. The biodegradability of silk fibroin scaffolds has been tested (Wang et al., 2008), with degradation times being controlled by the processing environments. Biodegradation also makes silk suitable for use as a controlled release drug delivery vector (Hardy et al., 2008).

Processing
Sericin (the glue-like protein that binds fiber to maintain the integrity of silkworm cocoons) can be removed by heating the cocoons in an aqueous solution of at least 0.1% (w/v) Na_2CO_3 for an hour at a temperature ranging from 60°C to 90°C, followed by rinsing in distilled water and drying at room temperature. There are many variants of this degumming procedure.

The degummed silk is then dissolved in a concentrated aqueous solution of LiBr (9.3–9.5 M) at 60°C and dialyzed against pure water. Subsequent lyophilization yields a powder that can be manipulated into a variety of forms that include electrospun fibers, films, microparticles, and three-dimensional scaffolds.

Example 1: Microparticles
Microparticles and nanoparticles are attractive vehicles for drug and growth factor delivery. Silk microparticles are formed by dropwise addition of either DMSO or ethanol to reconstituted silk fibroin solutions. The resulting particles are then collected by centrifugation, rinsed with deionized water, and lyophilized once more to obtain the product (Bessa et al., 2010).

Example 2: Scaffolds
It is possible to form scaffolds by various techniques that include salt leaching, gas foaming, and freeze-drying (Nazarov et al., 2004). Scaffolds formed by gas foaming have the highest compressive strength and modulus, and they display the desired pore size for bone and cartilage tissue grafts.

Due to the ultimate strength, elasticity, and long-term biodegradability displayed by silk fibroin scaffolds, their use has been focused on bone matrix and cartilage generation, on replacements for tendons such as the anterior cruciate ligament (ACL), and on blood vessel grafts:

- Scaffold seeded with both endothelial cells and osteoblast progenitor cells can form vascularized networks surrounded by osteoblasts within four weeks (Fuchs et al., 2009).
- Human chondrocytes seeded into silk scaffolds deposit cartilage-like extracellular matrix, raising realistic prospects of cartilage replacement therapies (Wang et al., 2006).
- Cell-seeded twisted silk cord has shown promise as a replacement for damaged ACL (Altman et al., 2003): two weeks after cell seeding, silk fiber is completely encased in extracellular matrix deposited by bone marrow stromal cells.
- A silk blood vessel seeded with bone marrow cells and transplanted into the aorta of a rat showed long-term patency, without any indication of thrombosis or aneurism; over time the silk fibroin vessel walls were replaced by collagen (Enomoto et al., 2010).

INTRODUCTION

Microparticles and nanoparticles have had an enormous impact on a wide-range of biomedical applications including drug delivery, imaging, and basic research. Miniaturization of therapeutic devices to the micron (1–1000 μm), sub-micron (100–1000 nm), and nanometer (1–100 nm) scales has facilitated the integration of biomedical devices with therapeutic biomolecules for improved clinical efficacy (George et al., 2005). Despite an extensive database on microparticles and nanoparticles, a clear universal boundary between nano- and microsize does not exist in the literature.

Expert opinions in the micro- and nano-sciences have emphasized that 1–100 nm is the optimum nanoscale range; however, in biotechnology and medicine, the definition of "nano" is less stringent (Ferrari, 2005). Design of any miniaturized system is dependent on the endpoint application. For example, systemic (intravascular) application requires use of particles less than 500 nm in diameter, whereas for intramuscular application or in some cases oral delivery applications, particles greater than 1 micron and less than 125 μm can be easily administered (Jain, 2000). Other than size, another critical parameter that can significantly modulate the function of these particles is shape (Champion et al., 2007); shape can impact cellular uptake by immune cells, release behavior of biomolecules, and cell targeting. A variety of materials have been synthesized as micro- and nanoparticles, mostly for imaging or targeted delivery of therapeutic biomolecules such as hormones, vaccine antigens and adjuvants, peptides, and anti-inflammatory agents (Aukunuru et al., 2003; Kim et al., 2004). In addition, these particles have been used as biosensors and in affinity bioseparations, immunological assays, cell labeling, and cell sorting. Also see Chapters II.5.16.B1 to II.5.16.B9 for applications of various particulate systems in drug delivery. The following discussion focuses on preparation, characterization, and applications of microparticles and nanoparticles.

MICROPARTICLES

Microparticles have been an active area of research in the biomedical field because of their unique advantages: their small sizes (few microns) render them excellent candidates for injectable drug delivery as compared to surgical implants; high surface area allows for surface functionalization to target specific cells, tissues or organs; and the ability to carry fluorescent molecules enables their use in microscale detection of cells and cellular components (e.g., proteins, DNA). Further, magnetic microparticles have been used for cell sorting and hyperthermia applications.

Materials Used for Microparticle Synthesis

The choice of biomaterial for microparticle synthesis is dependent on the intended use, duration of therapy, desired nature of the polymer (for example, hydrophobic or hydrophilic, neutral or charged), bioactive agents to be delivered (for drug delivery applications), and the chemistry needed for further functionalization and modification. The vast majority of current microparticle research has focused on site-specific drug delivery, controlled drug release, and minimizing toxicity and degradation of drugs (Dumitriu, 2002). Table I.2.19.1 lists some of the natural and synthetic materials used in microparticle drug delivery applications. Only a few commonly used polymers are discussed here.

Natural Materials

Chitosan. Chitosan is a cationic polysaccharide exhibiting β(1→4) linkages, and is obtained by alkaline deacetylation of chitin, a polymer present in the exoskeleton of many insects and marine crustaceans. Its biocompatibility, complete elimination from the body post-degradation, and abundance of primary amines make chitosan a popular material for drug delivery applications (Agnihotri et al., 2004). Primary amines render chitosan soluble in aqueous acidic solutions, thus eliminating the use of organic chemicals during synthesis, and also offer numerous possibilities for ionic attachment of negatively charged biomolecules (e.g., DNA, RNA). Further, chitosan microparticles exhibit enhanced mucosal residence time, increasing muscosal permeability of encapsulated proteins and drugs for nasal drug delivery (van der Lubben et al., 2001). Chitosan microparticles are also taken up by the Peyer's patch of gut-associated lymphoid tissue (GALT), making them appropriate candidates for oral drug delivery (van der Lubben et al., 2001c; Ahire et al., 2007). Chitosan has been used to orally deliver proteins and antigens such as insulin (Ubaidulla et al., 2007), diphtheria (van der Lubben et al., 2003) or tetanus toxoid (Ahire et al., 2007). Chitosan microparticles have also been successfully used for DNA and vaccine delivery, facilitating transfection and preventing DNA degradation by exogenous Dnase (Guliyeva et al., 2006).

Alginate. Alginate is an unbranched copolymer of D-mannuronic and L-guluronic acid linked by β(1→4) linkages, and is derived from brown seaweed. This polymer has been actively explored in the pharmaceutical sciences because of its biocompatibility, low immunogenicity, and unique property of sol–gel transition in the presence of multivalent cations (e.g., Ca++, Mg++). The preparation of alginate microparticles involves mild reaction conditions, which minimizes or eliminates the use of organic solvents and high temperatures that could otherwise reduce the bioactivity of encapsulated proteins, polypeptides or nucleic acids (Dumitriu, 2002). Alginate microparticles have been used extensively for protein, drug, and cell microencapsulation (Joki et al., 2001; Wang et al., 1997). Protein drugs have been encapsulated in calcium chloride cross-linked alginate microspheres, with release fine-tuned by varying the cross-linking factors (Wheatley et al., 1991). For example, applying polycations to the outer microcapsule surface can reduce the burst effect and produce more sustained release (Wheatley et al., 1991). Drug-loaded alginate microparticles have been primarily studied for nasal and oral delivery (Bowersock et al., 1996; Hari et al., 1996). Cell encapsulation has been used to obtain high concentrations of hybridoma monoclonal antibodies for mammalian cell engineering applications (King et al., 1987), and to encapsulate rat islet cells for diabetes treatment (Lim and Moss, 1981; De Vos et al., 1997). Alginate microspheres have also been prepared with other polymers such as chitosan. The addition of chitosan alters the microparticle characteristics and the release profile for potential gastrointestinal tract delivery via an oral route (Hari et al., 1996).

Gelatin. Gelatin is the denatured form of animal-derived collagen, and has excellent biocompatibility and biodegradability. Gelatin microparticles have been studied for sustained release applications (Ratcliffe et al., 1984; Tanaka et al., 1963). Micropellets of gelatin were first prepared in the early 1960s by Tanaka et al. (Tanaka et al., 1963). Since then, gelatin microparticles have been explored for the delivery of mitomycin C, 5-fluorouracil or adriamycin (Oner and Groves, 1993), and used commercially in agglutination tests for diagnostic detection of HIV-1, syphilis, and measles (Hesketh et al., 2006; Barbara et al., 1989; Sato et al., 1997). Mikos and co-workers encapsulated different growth factors inside gelatin microparticles for applications in cartilage tissue engineering. Growth factors such as transforming growth factor-beta 1 (TGF-β1) (Holland et al., 2005, 2007; Park et al., 2007a, insulin-like growth factor-1 (IGF-1) (Holland et al., 2007; Pham et al., 2008), bone morphogenetic protein-2 (BMP-2) (Patel et al., 2008b,c), and vascular endothelial growth factor (VEGF) (Patel et al., 2008a,c) have been successfully encapsulated. Dual growth factor delivery systems devised to deliver two growth factors simultaneously result in improved cell growth and bone matrix regeneration, in comparison to single growth factor delivery systems (Holland et al.,

TABLE I.2.19.1	Examples of Materials Used in Microsphere Drug Delivery Applications				
Polymer	Product Name	Active Ingredient	Application	Synthesis Method	Reference
PLGA	Sandostatin LAR® Depot	Octreotide acetate	Acromegaly	Emulsion solvent evaporation/extraction	Mundargi et al., 2008
	Nutropin Depot®	Growth hormone	Growth hormone deficiency	Spray freeze-drying	Mundargi et al., 2008

PHEMA: poly(2-hydroxyethyl methacrylate)
PLGA: poly(lactic-co-glycolic acid)
SPCL: starch-poly-e-caprolactone

2005, 2007; Patel et al., 2008c; Park et al., 2008). Glu-taraldehyde is a common cross-linker used to form microparticles, and its concentration can control the release rate of biomolecules. To slow degradation, enhance sustained release of drug, and enhance *in vivo* biocompatibility, some researchers have utilized the naturally-occurring cross-linker genipin to cross-link gelatin microparticles. The resulting particles had a reduced degradation rate and inflammation *in vivo*, in comparison to glutaralde-hyde-cross-linked microparticles (Liang et al., 2003).

Dextran. Dextran is a branched homopolysaccharide of glucose, and is synthesized naturally from sucrose

by some bacterial strains. Numerous biomedical studies have employed dextran as a biomaterial since it is biocompatible, biodegradable, available in different molecular weights, and can be easily derivatized. Microparticles of dextran have been studied for biomedical applications ranging from drug delivery (Chen et al., 2006; Cheung et al., 2005; Diwan et al., 2001) and cell therapy (Demetriou et al., 1986) to diagnostics and biosensors (Zhang et al., 2008). In a number of studies, dextran has been employed in the preparation of beads that were later functionalized with antibodies or biomolecules for diagnostic applications (Zhang et al., 2008; Tansey and Cammer, 1998). For example, hydroxyl ethyl methacrylated dextran microspheres have been studied for the delivery of human growth factor (Vlugt-Wensink et al., 2006, 2007). Adding different excipients changed protein loading efficiency and release. Collagen-coated dextran microparticles have also been used for liver tissue engineering. Hepatocytes were attached to their surfaces and injected intraperitoneally into rats, in an attempt to devise therapies for hepatic failures (Demetriou et al., 1986).

Other Natural Materials. In addition to the above mentioned materials, other natural materials have also been employed for microparticle synthesis. For example, collagen microparticles have been used for delivery of glucocorticsteroids (Berthold et al., 1998) and lipophilic drugs (Rossler et al., 1995; Swatschek et al., 2002). Similarly, hyaluronic acid microparticles have been utilized to deliver biomolecules (i.e., recombinant human growth hormone) (Kim et al., 2005), and antibiotics (Lee et al., 2002). Natural materials are biodegradable and well-tolerated in the body, which renders them suitable for delivery applications. See Chapter I.2.7 for details on natural polymers used in medicine.

Synthetic Polymers

Poly(lactic acid) (PLA), Poly(glycolic acid) (PGA), and Copolymers (PLGA). Bioresorbable aliphatic polyesters of lactic acid and glycolic acid are used clinically for controlled drug delivery (Lewis, 1990). Structural details of homopolymers (PLA, PGA) and copolymers (PLGA) have been discussed (Chapter I.2.6). Optically inactive poly(D,L)lactic acid is amorphous in nature, and thus is mechanically weaker than L-PLA or D-PLA, making it a suitable candidate for drug delivery applications. PLGA microparticles were first developed as drug delivery carriers in the late 1970s (Tice and Lewis, 1980). Since then, these polymers have been synthesized in various morphologies, including microparticles, microneedles, pellets, nanocapsules, films, and implants (Park et al., 2007b; Siegel et al., 2006; Teixeira et al., 2005; Marchais et al., 1998; Gumusderelioglu and Deniz, 2000; Webber et al., 1998). As discussed (Chapter I.2.6), there exists no linear relationship between homopolymer ratios of PLGA and degradation behavior of the copolymer. The degradation rate depends on several factors that facilitate water accessibility to the ester linkages in the

microspheres (Park, 1995; Shive and Anderson, 1997). The crystallinity of the homopolymer or copolymer plays a critical role; hydrolytically-cleavable ester linkages in PLGA are more accessible to penetrating water molecules compared to linkages in PLA, thus resulting in faster degradation kinetics. In a classic study, microspheres formed using PLGA copolymers with homopolymer ratios PLGA 50:50 and 70:30 degraded much faster than PLGA 80:20 and 90:10 (Figure I.2.19.1) (Park, 1995). This study illustrated that PLGA microparticles degrade in a heterogeneous fashion (Figure I.2.19.1A). During the degradation process the microspheres retain their shape until they completely disintegrate (Figure I.2.19.1A). Because the end products of PLA or PLGA microparticles are primarily lactic or/and glycolic acids, L-lactic acid content in the degradation medium was quantified. Figure I.2.19.1C shows an increase in L-lactic acid content with an increase in PGA homopolymer content, because the PGA linkage is the primary hydrolytically cleavable site in these polyesters (Park, 1995). Nonetheless, degradation is highly tunable. For example, in separate *in vivo* studies, PLA microspheres injected in rat gastrocnemius muscles degraded between 360–480 days, whereas PLGA (50:50) microspheres degraded in 63 days (Visscher et al., 1985, 1986, 1987, 1988). Because of their excellent biocompatibility and the ability to fine-tune monomer ratio to obtain varying degradation, this polymer has been studied extensively for delivery of a range of biomolecules, including nucleic acids, proteins and peptides, and hydrophilic and hydrophobic drugs (Singh et al., 2008).

Poly(ε-caprolactone) (PCL). PCL is a biodegradable, semicrystalline polymer with a glass transition temperature of ~60°C. The ring-opening polymerization of PCL was first studied in 1934 (Van Natta et al., 1934), but the biodegradable nature of the polymer was not recognized until the 1970s. Since then, various groups have explored microparticles of PCL for drug delivery applications because of its degradation characteristics, biocompatibility, high permeability with drugs, and lack of toxicity (Murthy, 1997). Further, their slower degradation rates and non-acidic degradation environment, compared to PLA/PLGA, make PCL microparticles suitable for prolonged drug release. PCL blends well with other polymers, which results in altered permeability and degradation rates, and therefore, altered drug release profiles (Pitt et al., 1979a,b). For example, release kinetics of fertility-regulating agents from PCL microparticles mixed with cholesterol, which serves as a viscosity thickener and enhances the drug solubility or by PCL microparticles made from polymer pretreated with formic acid, have been compared to PLA/PGA/PLGA microparticles (Benagiano and Gabelnick, 1979). PCL microparticles have also been studied for encapsulation and release of antibacterial agents (Dubernet et al., 1987), and for combined delivery of antigens and adjuvants for enhanced oral immunization (Youan et al., 1999; Murillo et al., 2002). Lipophilic and hydrophilic drugs have been co-encapsulated in PCL microparticles using a double emulsion technique (Hombreiro Pérez

et al., 2000). For a detailed review on PCL microparticles, refer to the review by Sinha et al. (Sinha et al., 2004a).

Poly(ortho ester) (POE). Another class of biodegradable materials developed specifically for controlled drug delivery is the poly(ortho esters) (POEs). The biocompatibility and biodegradability of POEs have been studied extensively. There are four different families of POEs, which have been reviewed in detail by Heller et al. (Heller et al., 1983, 2002). POEs degrade by surface erosion, as opposed to the bulk erosion of PLGA polymers, resulting in slower degradation and rendering devices made from this polymer highly stable. Degradation time can be shortened by modifying the polymer backbone with short segments of lactic acid or glycolic acid. Varying the number of glycolic acid or lactic acid segments produces a range of degradation rates suitable for a wide range of delivery applications (Heller et al., 2002). POE microparticles have been examined for protein and nucleic acid delivery (Yang et al., 2001; Wan et al., 2001). For example, the release of plasmid DNA vaccines yielded a potent immune response. Slower surface erosion produced few degradation products, which may have otherwise caused DNA degradation, diminishing the immune response. Microparticles

have also been synthesized from the triblock copolymer POE–PEG–POE employing the double emulsion process. The incorporation of PEG in the POE chain resulted in increased hydrophilicity, leading to higher bovine serum albumin (BSA) encapsulation and faster protein release compared to unmodified POE particles.

Other Synthetic Materials. A number of synthetic materials have been examined as microparticles. For example, polyacrylamide microparticles were prepared almost three decades ago. Their distribution and elimination have been extensively studied in rodent models (Sjoholm and Edman, 1979), and they have been used in drug delivery applications (Kriwet et al., 1998). Similarly, poly(vinyl alcohol) microparticles (Ficek and Peppas, 1993) and poly(2-hydroxyethyl methacrylate) (PHEMA) microparticles (Lehr et al., 1992) have been used for controlled protein delivery and for the release of peptide drugs, respectively. Polyketal microparticles have been examined for the release of therapeutic agents after microparticle phagocytosis, in which release is mediated by microparticle degradation in the acidic phagosome environment (Lee et al., 2007). These materials have also been mixed with other natural or synthetic materials to

achieve desired characteristics, such as varying degradation rate, release profile, and selectivity for target tissue.

MICROPARTICLE PREPARATION

Polymer microparticles are prepared from synthetic monomers, natural polymers, and sometimes semi-synthetic polymers, using techniques that create polymer matrices of desirable sizes and structures. State-of-the-art techniques include single and double emulsion solvent evaporation/extraction methods, coacervation, spray drying, ionic gelation, and suspension cross-linking.

Single and Double Emulsion Solvent Evaporation

The emulsification solvent evaporation technique is one of the most commonly used in microparticle preparation, particularly for drug encapsulation. The two-step technique calls for initial emulsification of polymer solution in a volatile organic solvent, followed by internal phase solvent evaporation or extraction that results in hardening and precipitation of microparticles. Solvent evaporation is generally performed at atmospheric pressure (or sometimes under reduced pressure) to promote evaporation of the volatile solvent. The solvent extraction process, however, involves quenching in excess water or relevant quench medium, allowing for solvent diffusion through oil droplets. Commonly used solvents include methylene chloride (also called dichloromethane or DCM) (Singh et al., 2008), ethyl acetate (Cho and Sah, 2005), and acetone/methanol mixtures. The single emulsion technique is generally employed for synthesis of microparticles encapsulating hydrophobic drugs. The polymer is dissolved in one phase (e.g., PLGA in oil phase or chitosan in aqueous phase), followed by either addition of water to oil (W/O emulsion) or oil to water (O/W emulsion). To prevent coalescence of emulsion droplets, surfactants such as polyvinyl alcohol (PVA) are used. The two phase system is then homogenized at speeds of 8,000–20,000 rpm for 2–5 minutes. Emulsifying agents (i.e., surfactants) play an important role in emulsion selection for microparticle synthesis. If the emulsifier is oil soluble then it favors W/O type emulsion, and *vice versa*. Since the stability of the emulsion also depends on the difference in specific gravities between oil and water phases, W/O emulsions are sometimes difficult to create. However, stable systems can be created (Okochi and Nakano, 2000). For an O/W system, final microparticles are obtained as the volatile organic solvent diffuses outward through the solvent-saturated aqueous phase from the internal organic phase, eventually evaporating and producing hardened microparticles. Microparticle porosity is controlled by rate of evaporation, ratio of internal aqueous phase, and viscosity of the polymer. Rapid solvent evaporation, as in the solvent extrac-tion process, often results in porous microparticles as compared to the slow solvent evaporation process.

Unlike the O/W single emulsion, which is suitable for encapsulating lipophilic molecules like steroids, the double emulsion process or water-in-oil-in-water (W/O/W) method is commonly used to synthesize microparticles encapsulating hydrophilic biomolecules and drugs such as peptides, proteins, and antigens (vaccines). The W/O/W double emulsion is a three-phase system in which polymer is dissolved in the oil phase with an internal aqueous phase, and immersed in an external aqueous phase containing surfactant or emulsifying agent. Although various techniques to create W/O/W double emulsions exist (e.g., one-stage emulsification method, two-stage emulsification method, phase inversion method), microparticle synthesis for biomedical applications has primarily focused on the two-stage method, because of its superior drug loading capability (Okochi and Nakano, 2000). In a typical W/O/W double emulsion process, polymer (e.g., PLGA, PCL, PEG–PLA copolymer) is dissolved in an organic (oil phase) solvent followed by addition of a small volume (100–500 μl) of aqueous phase. This solution is subjected to vigorous homogenization or sonication to yield the primary emulsion (Dorati et al., 2008). This primary emulsion is then poured into an excess of aqueous solution containing emulsifier (e.g., PVA), and further homogenized. The volatile organic solvent is eliminated from the resultant W/O/W double emulsion through solvent evaporation or extraction. Similarly, chitosan microparticles are often prepared by an extended W/O emulsification process in which chitosan in the aqueous phase is emulsified in oil with surfactant, and then cross-linked using glutaraldehyde or ethyleneglycol diglycidyl ether to form hard droplets (Agnihotri et al., 2004).

The formation mechanism of initial emulsion droplets and resultant microparticles in an oil-in-water (O/W) single emulsion and W/O/W double emulsions has been examined (Figure I.2.19.2) (Rosca et al., 2004). During the initial stage of the O/W emulsion, emulsion droplets are large because the aqueous phase is initially saturated with solvent (Figure I.2.19.2B). As solvent evaporates, solvent concentration in the droplet decreases, causing a rapid shrinkage of droplet size and the formation of hardened microparticles (Figure I.2.19.2C). In contrast, in the W/O/W emulsion, different types of droplets are formed (Figure I.2.19.2D): (1) microcapsule with no inner aqueous phase entrapped; (2) microcapsule with only one aqueous phase; and (3) a single droplet containing multiple microcapsules. The inner and outer structures of these microcapsules are further clarified by the scanning electron micrograph (SEM) image (Figure I.2.19.2E). Droplets without any inner aqueous phase form plain polymer microparticles, indicated as "p," thin-walled open microcapsules "c1" are formed when the emulsion droplet is similar in size to the inner droplet, and microcapsules "c2" are formed when a small difference exists between the microdroplet and emulsion droplet size.

See text.

Precipitation and Coacervation

Coacervation uses the physiochemical characteristics of polymers to form microparticles. Coacervation is a three-step process in which a W/O emulsion is formed with polymer dissolved in the organic phase and drug dispersed in the aqueous phase. The solubility of the polymer is altered (e.g., by mixing with another polymer or organic non-solvent or by changing pH or ionic strength). The non-solvent used in the initial steps should be miscible with the organic solvent used to dissolve the polymer; however, the polymer and/or drug should not be soluble in the non-solvent (e.g., vegetable oil, paraffin oils, silicone oils). This results in phase separation to form a polymer-rich coacervate phase surrounded by a dilute supernatant phase, essentially producing a coating of coacervate around the dispersed drug molecules. Stabilization of the coating occurs with solidification of microparticles in another organic non-solvent followed by extensive washing, centrifugation, and freeze drying (Jain, 2000).

Spray Drying

Conventional microparticle fabrication methods like double emulsion and coacervation often have limitations, including particle aggregation as a result of exceptionally high surface energies and mutual adhesion between particles, inefficient encapsulation, multi-step processing, and residual organic solvents (Jain, 2000; Jalil and Nixon, 1990). Spray drying is a faster, more efficient process for encapsulating drugs in polymeric microparticles (Jain, 2000). This technique involves dispersion (emulsification)

of aqueous drugs or direct addition of hydrophobic drugs in a polymer solution, which is then sprayed through a fine nozzle into a chamber (generally heated) where the solvent evaporates and particles are collected (Figure I.2.19.3A). This technique generally yields microparticles from 1–100 μm in diameter and drug encapsulation of up to 99%, depending on drug–polymer interaction, solution viscosity, and nozzle characteristics (Jain, 2000; Wagenaar and Muller, 1994). Spray drying has been used for synthetic polymers such as PLGA, PLA, and PCL, and also for natural polymers including gelatin and polysaccharides (Lorenzo-Lamosa et al., 1998). For polysaccharides (e.g., chitosan), the aqueous acetic acid-based solution containing a mixture of polysaccharide, drug, and cross-linker is atomized similarly in a heated chamber. Cross-linkers such as glutaraldehyde form an aldehyde–amine bond with the polysaccharide that results in hardened microparticles; however, cross-linker addition is not essential for microparticle formation. Various parameters influence particle size, including nozzle radius, chamber temperature, flow rate and pressure, and cross-linker concentration (Agnihotri et al., 2004). Microparticles may be lost because of agglomeration and adhesion to the chamber walls, and some research groups have developed a novel dual-nozzle system that simultaneously delivers both the polymer–drug mixture and an anti-adherent solution (e.g., mannitol) to prevent adhesion and aggregation (Takada et al., 1995).

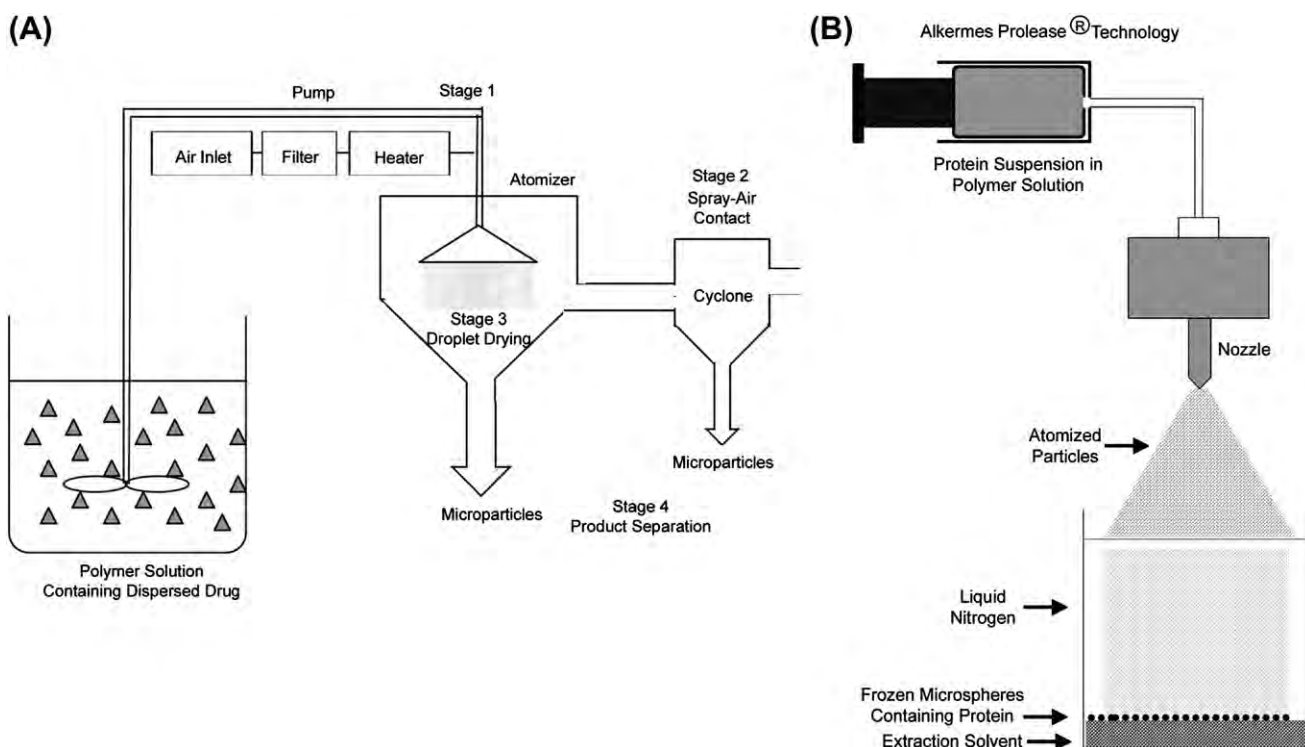
The low temperature spray drying method reported by Alkermes, Inc. (ProLease® technology) was specifically developed to maintain integrity and activity of encapsulated biomolecules during the synthesis process. In this technique, powdered biomolecules and stabilizing


FIGURE I.2.19.3 Preparation of microparticles using spray drying techniques: (A) conventional spray drying method (adapted from Re, 2006); (B) low temperature spray drying method (adapted from Johnson et al., 1997).
FIGURE I.2.19.4 Schematic showing the synthesis of microparticles by the ionic gelation method.

excipients are suspended in a polymer solution in an organic solvent (e.g., DCM, acetone, ethyl acetate) and sprayed into a vessel containing liquid nitrogen followed by evaporation of the liquid nitrogen (Figure I.2.19.3B). The vessel also contains a frozen solvent such as ethanol for extraction of the polymer solvent from liquid nitrogen frozen droplets. With this technique, microparticles with high encapsulation efficiency (~95%) and sizes ranging from 50–60 μm can be readily obtained (Johnson et al., 1997).

Ionic Gelation

Ionic gelation is a physiochemical technique in which ionic polyelectrolytes (or charged polymers) are chelated with multivalent counterions, producing cross-links (Figure I.2.19.4). Ionic gelation is widely used with polysaccharides such as chitosan and the sodium salt of alginic acid, because of its simplicity and mild conditions (Bodmeier et al., 1989; Li et al., 2008; Park et al., 2004; Shu and Zhu, 2001). Chitosan is a positively charged polysaccharide

which forms cross-links in anionic sodium triphosphate or tripolyphosphate (TPP) or $[Fe(CN)_6]^{4-}$ or $[Fe(CN)_6]^{3-}$ (Li et al., 2008). The ionic gelation process is fairly simple and involves drop-wise addition of polymer solution to the counter ion solution with dispersed drug, under continuous stirring. The ionization degree of TPP is dependent on the solution pH. At slightly acidic pH, only $(P_3O_{10})^{5-}$ anions are available, favoring ionic gelation with the acetic acid-based chitosan solution (Ko et al., 2002). The ionic gelation process can result in both nano- and microparticles ranging from several nanometers to 700 μm. The process has been extensively applied for encapsulating drugs (e.g., insulin, cyclosporine A, felodipine) with encapsulation efficiencies ranging from 55% to 90%, depending on deacetylation of chitosan and reaction conditions (Agnihotri et al., 2004; Ko et al., 2002). Ionic gelation performed at high concentrations of TPP results in slower drug release and *vice versa*. Drug release is further influenced by the extent of cross-linking (Agnihotri et al., 2004).

SUBMICRON-SIZED PARTICLES

Liposomes and Micelles

Liposomes (Figure I.2.19.5) are submicron-sized spheres with an aqueous core and a bilayer membrane (e.g., lamella), whereas micelles consist of an aqueous core surrounded by a single layer of lipids. Liposomes are formed by one or several lipids, including sphingomyelin, egg phosphatidylcholine (PC), cholesterol, monosialoganglioside (GM1), distearoylphosphatidylethanolamine (DSPE) or dioleylphosphatidylethanolamine (DOPE). Liposomes can be classified as multilamellar (0.5–5 μm diameter), small unilamellar (~0.1 μm), or large unilamellar (0.2–0.8 μm) vesicles. Liposomes have excellent biocompatibility, and can encapsulate hydrophobic drug between the lipophilic bilayers and hydrophilic drug in

the core. Liposomal delivery systems have been used for therapeutics, including rifampicin, budesonide, diclofenac, methotrexate, vaccine antigens, nucleic acids, peptides, and immunomodulatory agents (Torchilin, 2005).

Conventional liposomes have a short blood circulation time and are quickly removed by the reticuloendothelial system (RES), as was demonstrated in early studies with immunoliposomes (i.e., liposomes modified with antibodies) that resulted in mass accumulation in the liver. Extensive research has been performed to develop long-circulating liposomes. Surface immobilization of PEG imparts "stealth" properties to liposomes (Figure I.2.19.5C), which minimizes RES uptake. Liposomes modified with PEG have been used in delivering anticancer drugs such as doxorubicin and paclitaxel (Skubitz, 2003), and have demonstrated improved drug bioavailability and pharmacokinetics (Allen and Hansen, 1991). Long-circulating liposomes have also been used in infectious disease treatment and diagnostic applications (Bakker-Woudenberg, 2002). PEG can also be combined with other targeting methodologies (i.e., antibodies) through covalent modifications or hydrophobic interactions to produce long-circulating immunoliposomes (Figure I.2.19.5D,E) (Torchilin, 2005; Blume and Cevc, 1990; Abra et al., 2002).

NANOPARTICLES

Nanoparticles are generally acknowledged as particles with dimensions less than ~100 nm. Nanoparticles may be composed of virtually any material, but unlike those used in microparticles, some of the most common materials are semiconductors and metals. Nanoparticles have generated significant interest as biomaterials, primarily because of their unique size. From a purely physical perspective, nanoparticles are small enough to interface with objects that control some of the most basic cellular functions (e.g., ~2 nm diameter DNA). In comparison,
FIGURE I.2.19.5 Evolution of liposomes: (A) "Plain" phospholipid liposomes. Water soluble drug (a) is entrapped in the aqueous interior, and water-insoluble drug (b) is incorporated in the liposomal membrane (these designations are not repeated on other figures); (B) antibody-targeted immunoliposome. Antibody is covalently coupled (c) or hydrophobically anchored (d) to the liposomal membrane; (C) long-circulating liposome. Protective polymer (e.g., PEG) (e) shields the surface from opsonizing antibodies (f), which may otherwise lead to liposome phagocytosis; (D) long-circulating immunoliposome. Antibody is attached to the surface (g) or, preferably, to the grafted polymeric chain (h); (E) new-generation liposome. Multivalent liposomal systems can contain surface-bound protective polymer (i), targeting ligands (e.g., antibodies) (j), diagnostic labels (k), positively charged lipids (l) that permit complexation with DNA (m), stimuli-sensitive lipids (n) or polymers (o), cell-penetrating peptides (p) or viral components (q). The internal cavity can contain drug, magnetic particles (r) for magnetic targeting, and/or colloidal gold or silver particles (s) for electron microscopy (Torchilin, 2005).

cells are much larger (average diameter ~10 μm). Also, their small size allows them to interface with existing microelectronic components, such as field effect transistors (FETs), permitting the development of diagnostic biosensors.

In addition to these direct benefits of size, nanoparticles are also interesting biomaterials because of their unique, size-dependent physical properties. For example, semiconductor quantum dots and gold nanoparticles produce optical responses that are not evident in bulk materials. Iron oxide particles display a different type of magnetism when presented as nanoparticles than when presented as microparticles or in bulk. These properties originate from different principles, but are all derived from the size of the material, which lies between bulk and atomic composition. Because of these interesting properties, nanoparticles have found application as contrast agents in biomedical imaging, signaling molecules that enhance diagnostic ability, carriers for drug delivery, and as therapeutic elements.

MATERIALS USED FOR NANOPARTICLE SYNTHESIS

Noble Metals

Noble metal nanoparticles have a long history. They were first discovered by the Romans (Wagner et al., 2000), who used them to create colored glass. More recently, they were extensively studied by Michael Faraday

(Faraday, 1857), whose samples are still on display at the Faraday Museum in London. In biomedical applications, the mostly commonly investigated materials have been gold and silver, which are created primarily through chemical reduction. For example, gold nanoparticles (Figure I.2.19.6A) can be created by the reduction of chloroauric acid (HAuCl$_4$) by sodium citrate (Turkevich, 1951) and silver nanoparticles by the reduction of silver nitrate (AgNO$_3$) by sodium borohydride (NaBH$_4$). In both cases, the reducing agent serves also as a passivating ligand, coating the surface of the nanoparticles.

Noble metals are widely regarded as non-toxic to humans; in fact silver nanoparticles are noted for their anti-bacterial properties (Sondi and Salopek-Sondi, 2004). As a result, noble metals have been applied as carriers for drug and gene delivery, and in anti-fouling coatings. In addition, they are attractive for imaging because they exhibit surface plasmon resonance (SPR) (Ritchie, 1957). Metals have many free electrons that typically reside in the conduction band. These electrons form a "cloud" surrounding the surface of the material that can deflect incoming light, producing a reflective surface. However, as we know from quantum mechanics, electrons can also behave as waves. If light of the same frequency as the oscilliations of the electron cloud is absorbed, the cloud vibrates or resonates, producing an absorbance signal. This signal is altered by the thickness of the material and, in the case of nanomaterials, is enhanced by the large fraction of atoms at the material surface. This signal is also altered by adsorption of
FIGURE I.2.19.6 Nanoparticles and their properties: (A) gold nanoparticles experience a color change with increasing size; (B) magnetic nanoparticles are attracted to magnets; (C) quantum dots fluoresce under UV excitation; (D) antibody-conjugated micelles (arrows) are shown in negative TEM (transmission electron microscopy) staining; (E) mesoporous silica contains multiple nanosized pores; (F) TEM image of single-walled carbon nanotubes. other molecules to the material surface and nanoparticle aggregation; a property that has been exploited for the development of noble metal biosensors (He et al., 2000). Similarly, the strong absorbance produced by SPR has been used in photoacoustic imaging (Wang et al., 2003), which uses light to produce a signal detected via ultrasound.

Magnetic Materials

Although early research on magnetic nanoparticles dates back several decades (Crick and Hughes, 1949), interest in their use as a biomaterial is more recent (e.g., 1980s) (Sun et al., 2008). Superparamagnetic iron oxide nanoparticles (SPIONs), which are usually <15 nm in diameter, are the most commonly employed magnetic materials for these applications (Figure I.2.19.6B). SPION synthesis was originally performed through precipitation and microemulsion routes (Gobe et al., 1983), but more recently a high temperature precursor decomposition method (Hyeon et al., 2001) has been developed that yields small, uniform nanoparticles. One of the most important features of SPIONs is their unique magnetic response. Unlike larger nano- and microsized particles (e.g., >~15 nm), which are ferromagnetic, SPIONs display superparamagnetic behavior. This arises from their small size, which is below that of magnetic domain boundaries. Large particles consist of several magnetic domains that can be aligned in an external field, producing permanent magnetization. However, SPIONs have a single magnetic domain. They respond to a magnetic field, but do not display permanent magnetization, as evidenced by their lack of hysteresis on a magnetization (M) versus magnetic field strength (H) plot. This is because thermal fluctuations prevent permanent magnetic alignment of the single domain. Thus, SPIONs have the appearance of paramagnetic behavior (i.e., no permanent magnetization), while still responding to a magnetic field. This behavior is called superparamagnetism.

These magnetic properties have been used for a number of biomedical applications. The force generated on SPIONs in an external magnetic field has been harnessed for cell separation, drug delivery, and biomolecule manipulation (Pankhurst et al., 2003). Additionally, SPIONs have been used as contrast agents for magnetic resonance imaging (MRI) (Weissleder et al., 1990). MR imaging is accomplished by examining either the time that it takes for the spin magnetization of an individual proton to return to its original state (T1) or the time for the net magnetic moment for all protons to return to zero (T2). The magnetization produced by SPIONs interacts with water molecules in the body to shorten their T2 relaxation time. This produces an area of negative contrast in an image. In addition to MRI, SPIONs have been used for magnetic hyperthermia. When SPIONs are placed in an alternating magnetic field, they attempt to align their magnetic moments with that field. This produces internal friction that manifests itself as heat. If magnetic

nanoparticles are placed in a tumor and a temperature above 45°C is reached, the tumor cells can be killed in a process known as hyperthermia (Pankhurst et al., 2003). Alternatively, if the temperature is raised to ~42°C, the efficiency of chemotherapy can be improved.

Quantum Dots

Quantum dots are small, fluorescent nanocrystals made from semiconductor materials, usually of spherical shape and <10 nm in diameter (Figure I.2.19.6C). The most commonly studied quantum dots are composed of a cadmium selenide (CdSe) core surrounded by a zinc sulfide (ZnS) shell, and are commercially available. Quantum dots are synthesized primarily through high temperature precursor decomposition (Peng and Peng, 2001); however, some aqueous arrested precipitation routes are also available (Winter et al., 2005). Quantum dots were first identified by Louis Brus at Bell Labs (Rossetti et al., 1983), and first employed for biomedical applications in 1998 (Chan & Nie, 1998; Bruchez Jr. et al., 1998). Quantum dots are so named because they experience quantum confinement, which means that the electron wavefunction is limited by the size of the particle. Because of this, quantum dots have a band gap energy (i.e., energy difference between the ground and excited states of an electron) that is dependent on particle size. Optical properties of quantum dots can thus be tuned by adjusting their size (Alivisatos, 1996).

Quantum dots have been used in a broad range of biological applications, including single molecule biophysics (Courty et al., 2006), optical barcoding (Han et al., 2001), and molecular (Courty et al., 2006), cellular (Jaiswal et al., 2003), and *in vivo* imaging (Gao et al., 2004). Compared to organic dyes and fluorescent proteins, quantum dots are about 10–100 times brighter, mainly because of their large absorption cross-sections, 100–1000 times more stable against photobleaching, and show narrower and more symmetric emission spectra. In addition, a single light source can be used to excite quantum dots with different emission wavelengths. CdSe has become the prototypical quantum dot material for biological applications, because it can produce fluorescence at wavelengths from green (500 nm wavelength) to red (650 nm wavelength) simply by adjusting the nanocrystal diameter from 2 to 8 nm. Other materials may be used to span other spectral regions, such as the ultraviolet region (CdS, ZnS, ZnSe), the near-infrared (CdTe, $CdSe_xTe_{1-x}$, PbS), and the mid-infrared (PbSe). A major limitation of quantum dots is their relatively large size compared with organic dyes, which may lead to steric hindrance in some applications (Alivisatos et al., 2005).

Polymers and Lipids

Polymers (Marty et al., 1978) and lipids (Gregoriadis et al., 1971) were among the first nanomaterials employed

in biological applications. Polymer nanoparticles can consist of solid, porous polymer spheres or of nanocapsules consisting of an external polymer layer surrounding a liquid, aqueous core. Polymers can also form vesicles or micelles, sometimes called polymersomes. Lipid particles can consist of liposomes, lipid micelles or microemulsions (Figure I.2.19.6D). Polymeric nanoparticles can be fabricated via emulsion routes, in which case particle size is determined by the size of the suspended droplets, or via interfacial interactions with another solution, in which case size is determined by droplet size and mixing (Pinto Reis et al., 2006). Lipid-based microemulsions can be created by sonication of lipids in water, where size is determined by the extent of sonication. Vesicles/micelles of either lipids or polymers can be formed by self-assembly, in which case the size is determined by the thermodynamics of the system.

Polymer and lipid nanoparticles have been primarily used as carriers for therapeutic and imaging agents, and offer several advantages in this application. Polymer and lipid biomaterials can be used to encapsulate and protect therapeutic agents while they are transported to desired locations by passive or active targeting mechanisms. Furthermore, therapeutic agents (e.g., small molecule drugs, antibodies, small interfering RNAs) can be released from the nanocarriers in a controlled manner, for optimum therapeutic efficacy with minimal side effects. Additionally, these nanoparticles can incorporate a variety of factors, such as targeting, controlled release, imaging, and therapy into a single device.

Silica

The most common type of silica employed as a biomaterial is mesoporous silica (Figure I.2.19.6E). These particles, which have been created in both micro- and nanoparticle form, consist of silica (SiO_2) containing pores ranging from 2–10 nm in diameter. Mesoporous silica particles were first created in 1990 (Yanagisawa et al., 1990), and were improved by the development of controlled templating (Kresge et al., 1992) and synthetic advances to enhance particle monodispersity (Huo et al., 1997). In addition to mesoporous silica particles, silica is also widely-used as a nanoparticle coating. For example, silica has been employed to render quantum dots and iron oxide nanoparticles biocompatible. Most commonly, silica is deposited using the Stöber method (Stöber et al., 1968), which is a condensation reaction occurring in an alcohol–water system.

The primary advantages of silica as a biomaterial are its biocompatibility, easy surface modification, and porous structure. These properties have led to applications in imaging, drug delivery, and gene therapy. The surface of silica can be readily altered using siloxanes (R-$SiOCH_3$), a number of which are commercially available (e.g., terminal –SH or –NH_2 modification). This property has permitted silica nanoparticles to be

conjugated to biomolecules that can specifically target certain cells or tissues. Additionally, the highly porous nature of silica materials has been used to encapsulate other materials, including imaging agents, drugs, DNA, and even other nanoparticles (Tallury et al., 2008). These materials can be slowly released at the target site to provide therapeutic benefit or a method of biodegradability.

Carbon

Several carbonaceous nanomaterials have been investigated as biomaterials including fullerenes, carbon nanotubes, and carbon nanodiamonds. The first of these to be discovered were carbon nanodiamonds, which were identified as an explosion by-product in 1961 (DeCarli and Jamieson, 1961); however, these materials were not investigated as a biomaterial until much later (Kossovsky et al., 1995). Carbon nanodiamonds are usually <10 nm diameter and display the diamond crystal structure. The next carbonaceous materials to be identified were fullerenes (Kroto et al., 1985), also known as buckyballs because of their structural similarity to geodesic domes designed by architect Richard Buckminster Fuller. Their discovery earned the Nobel Prize in Chemistry in 1996 for co-inventors Richard Smalley, Robert Curl, and Harold Kroto. Work on fullerenes led to the discovery of carbon nanotubes (CNTs) (Iijima, 1991), which can be viewed as rolled-up sheets of graphene (Figure I.2.19.6F). CNTs can consist of a single sheet (i.e., single-walled carbon nanotubes (SWCNTs)) or multiple sheets (i.e., multi-walled carbon nanotubes (MWCNTs)), and can be either semiconducting or metallic depending on the orientation of the rolled sheet. Carbonaceous nanomaterials can be produced through detonation (Danilenko, 2004), arc discharge (Kroto et al., 1985), laser ablation (Yang et al., 1998; Guo et al., 1995), and chemical vapor deposition (Feldman et al., 1995). Native carbonaceous materials are generally extremely hydrophobic; however, acid treatment can produce –COOH functionalization that renders particles water soluble (Chen et al., 1998). Because of their extreme hydrophobicity there have been substantial concerns regarding the biocompatibility of carbonaceous materials (Cui et al., 2005; Schrand et al., 2007). However, toxicity appears to be related to a number of controllable factors including dimensions, surface functionalization, manufacturing method, and processing (Helland et al., 2007).

Carbonaceous nanomaterials exhibit a number of unique, size-dependent properties, including high strength (e.g., CNTs are 100× as strong as steel (Treacy et al., 1996)), and electrical and optical characteristics, which have been exploited in biomedical applications ranging from molecular separation, biomolecule delivery and therapeutic treatment to imaging. For example, CNTs have been used for gene (Pantarotto et al., 2004) and drug (Kam et al., 2005) delivery, because they can penetrate cells through a mechanism believed to be independent

of endocytosis (i.e., penetration of the lipid membrane) (Pantarotto et al., 2004). Because of their conductive and semiconductive properties, CNTs have been examined as scaffolds for nerve regeneration (Mattson et al., 2000), and as electrodes for neural prostheses (Lovat et al., 2005; Gheith et al., 2005). Conductivity has also been used to create biosensors (Kong et al., 2000) with detection down to the single molecule level (Besteman et al., 2003). However, two of the more interesting properties of carbonaceous materials are their ability to generate reactive oxygen species (ROS) and to produce multiple imaging signals.

ROS are oxygen or oxygen-containing molecules that have a highly reactive unpaired electron (e.g., O_2^1, singlet oxygen). ROS can cause significant damage to cells by interacting with the mitochondrial respiration system or DNA, and can be used to kill targeted cells (e.g., photodynamic therapy). Fullerenes generate ROS by light-induced excitation of a free electron to the singlet excited state, which is quickly followed by decay to the triplet state (e.g., the spin of the electron is reversed) (Yamakoshi et al., 2003). Conversely, fullerenes not exposed to light can neutralize ROS. Despite numerous π-bonded rings, fullerenes are electron acceptors, rather than donors (Dugan et al., 1996), and easily react with the ROS-excited electron. This property can be used to reduce damage to cells, for example, neutralizing ROS generated by UV irradiation.

In addition to ROS generation, carbonaceous materials produce a number of optical signals, which, when coupled with a low toxicity, make them attractive candidates for *in vivo* imaging. Carbon nanodiamonds exhibit fluorescence that is believed to arise from excitation of nitrogen vacancies (known as N-V centers) (Holt, 2007), and can also produce electron spin resonance (ESR/EPR) signals (Balasubramanian et al., 2008). Similarly, semiconducting CNTs can exhibit bandgap fluorescence, as well as fluorescent emission resulting from surface states. CNTs also produce strong Raman scattering signals, which result when light striking an object loses or gains energy from the collision. In the case of CNTs, Raman scattering occurs from interactions of light with the electron cloud surrounding the CNT structure. Both of these properties have been used for cellular imaging (Heller et al., 2005).

NANOPARTICLE PREPARATION

Arrested Precipitation

This method has been applied for the synthesis of semiconductor quantum dots (e.g., CdS), metals (e.g., Au), and iron oxide nanoparticles. In the absence of stabilizing agents, particles produced using these reactions exhibit very low solubility in water, hence they precipitate. However, when another agent is added to the reaction system that is water-soluble and can also bind to the nanoparticle surface, stable nanoparticles are produced. For example, in the presence of a Cd-binding ligand, mixing Cd^{2+} and S^{2-} salts produces CdS nanocrystals

with size-dependent fluorescence (Rossetti et al., 1984). Similarly, gold nanoparticles can be produced using the Turkevich procedure (Scheme 1) (Ji et al., 2007):

$$HAuCl_4 + Na_3C_3H_5O(CO_2)_3 \xrightarrow{boiling}$$

$$[AuCl_2(OH)_2]^- + [AuCl(OH)_3]^- + [HC_3H_5O(CO_2)_3]^{-2} + [C_3H_5O(CO_2)_3]^{-3} \rightarrow$$
$$AuNPs\text{-}Citrate\,ions$$

$$(1)$$
In this process, a sodium citrate solution is added to a $HAuCl_4$ solution with heating and vigorous stirring. Sodium citrate first acts as a reducing agent, and then the negatively-charged citrate ions bind to the gold nanoparticle surface, preventing aggregation (Turkevich, 1951). Similarly, iron oxide nanoparticles can be synthesized by reduction in base (Gupta and Gupta, 2005):

$$Fe^{2+} + 2Fe^{3+} + 8OH^- \rightarrow Fe_3O_4 + 4H_2O \qquad (2)$$
Iron ions are obtained from iron chloride salts (e.g., $FeCl_2$, $FeCl_3$), and sodium hydroxide (NaOH) serves as the base. The unifying feature of all these procedures is that particles are produced in the presence of a solubilizing agent, or ligand, that prevents aggregation and controls growth through steric hindrance and occupation of potential reaction sites on the particle surface.

High Temperature Precursor Decomposition

In 1993, the high temperature precursor decomposition method was developed to synthesize high quality quantum dots (Murray et al., 1993). This method relies on the use of a solid precursor, which decomposes at high temperature to yield reactive ions. As an example, to produce CdSe quantum dots, dimethylcadmium precursor and Se shot are mixed in solvents (e.g., trioctylphosphine, trioctylphosphine oxide, hexadecylamine) at high temperature. These solvents also serve as ligands whose basic functional groups (e.g., phosphines, phosphine oxides, amines) attach to the quantum dot surface, displaying their hydrophobic alkyl chains to the exterior. Slow growth and annealing results in uniform particle size and regularity in core structure. However, fluorescence quantum yield of quantum dots produced by this procedure decays over time, due to surface defects. In 1997, a higher band gap energy material (e.g., CdS) was used to coat CdSe quantum dots; the CdSe/CdS core shell structure resulted in a dramatic improvement in the fluorescence quantum yield (as much as 10 times) (Peng et al., 1997). Recently, the high temperature synthesis method has been adapted to produce other types of nanoparticles (e.g., iron oxide nanoparticles) (Hyeon et al., 2001).

Self-Assembly

The self-assembly method is driven primarily by thermodynamic considerations. For example, amphiphilic

molecules, which possess both hydrophobic and hydrophilic segments, will attempt to minimize exposure of their hydrophobic segments in aqueous solution, spontaneously forming micelles, vesicles, rods, lamellae, tubules, and other nanoparticulates. The shape and size of these particles are mainly determined by the molecular structure of the amphiphiles employed (Zhang & Eisenberg, 1995). In practice, the self-assembly process can be conducted using different methods, such as direct dissolution, dialysis, and film hydration. The direct dissolution process simply involves adding amphiphile to water, but can only be used for water-soluble amphiphiles. Dialysis can be used when the amphiphile is not easily soluble in water, but can be readily dissolved in a water-miscible organic solvent such as dimethylformamide. In this case, a mixture of the amphiphile and water-miscible solvent is dialyzed against water, driving the organic solvent to the aqueous phase and inducing nanoparticle formation. If the amphiphile is only soluble in non-polar solvents, film hydration can be used. In this process, a thin film is formed by dissolving amphiphile in a low boiling point, non-polar solvent (e.g., chloroform), which is removed by evaporation. Water is then added, hydrating the film and driving spontaneous nanoparticle formation (Allen et al., 1999; Lasic, 1993).

Stöber Method

The Stöber method is a classic technique for producing silica nanoparticles, films, and coatings discovered in 1968 by Werner Stöber and colleagues (Stöber et al., 1968). The technique is a sol–gel method based on the hydrolysis and subsequent condensation of silicon-containing precursors (Scheme 3).

$$\equiv SiOR + H_2O \leftrightarrow \equiv SiOH + ROH$$
$$\equiv SiOH + RO\text{-}Si \leftrightarrow \equiv Si\text{-}O\text{-}Si \equiv + ROH \qquad (3)$$
$$\equiv SiOH + HO\text{-}Si \equiv \leftrightarrow \equiv Si\text{-}O\text{-}Si + H_2O$$
Typically, tetramethoxysilane (TMOS) or tetraethylorthoxysilane (TEOS) are used as the silicon source. Both of these compounds contain alkoxide groups (e.g., $-OCH_3$ for TMOS, $-OCH_2CH_3$ for TEOS) that react with water to yield Si-OH intermediates and R-OH by-products. Si-OH can then react with other Si-OH or Si-OR groups to yield silica and ROH and H_2O by-products. The reaction is usually performed in an alcohol–water mixture, with alcohols being methanol, ethanol, *n*-propanol or *n*-butanol. Ammonia is used as a catalyst for colloidal growth. This reaction produces nearly monodisperse particles in sizes ranging from the micron to nanometer scale. This method was further modified by Unger in 1997 (Grun et al., 1997) to create monodisperse, porous silica spheres. This was accomplished by adding cetyltrimethylammonium bromide (CTAB), a cationic surfactant, which forms micelles in the reaction solution. Micelles are encapsulated during sphere formation. This surfactant is subsequently removed during particle calcination (i.e., heating), producing pores

within the silica spheres. This method of particle formation is known as the modified Stöber method.

Methods to Produce Carbonaceous Nanoparticles

Carbonaceous materials can be produced via explosion, arc discharge, laser ablation, and chemical vapor deposition. A unifying feature of these methods is the heating of carbon precursors to high temperatures. Explosion is primarily used to create carbon nanodiamonds (DeCarli and Jamieson, 1961; Danilenko, 2004), and produces high temperatures and pressures that force carbon into the diamond region of its phase diagram. The carbon source may consist of a separate substrate or originate from the explosives themselves (Shenderova et al., 2002). Nanodiamond is manufactured in several commercial operations, primarily in Russia, its former republics, and Japan.

Arc discharge (Iijima, 1991; Krätschmer et al., 1990) and laser ablation (Kroto et al., 1985; Guo et al., 1995) are used to produce fullerenes and CNTs. Each method produces a carbon gas cloud, either by passing current through graphitic electrodes (i.e., arc discharge) or by using lasers to heat solid, carbon substrates (i.e., laser ablation) (Shenderova et al., 2002), reaching temperatures of 3000–4000°C. Gaseous carbon then condenses, producing carbonaceous nanostructures. This method is often performed in the presence of a catalyst, for example cobalt, yttrium or nickel, to control the shape of the resultant nanostructures. Critical parameters for arc discharge are the identity and pressure of the gas separating the electrodes, and the strength of the current. High gas pressure and low current tend to favor CNT production, whereas lower gas pressures favor fullerene formation. Laser ablation often produces a mixture of desired particles and undesired products. Separation processes, such as reflux in nitric acid, have been developed to isolate desired materials (Liu et al., 1998).

Chemical vapor deposition (CVD) has been used to produce carbon nanodiamonds (Eto et al., 1992) and CNTs (Kong et al., 1998). For nanodiamond, the CVD method primarily yields films, rather than freestanding particles (Shenderova et al., 2002). In this method, a hydrocarbon gas is deposited on a metal catalyst (e.g., iron, cobalt, nickel), which breaks the carbon-containing molecules into smaller components. These molecules serve as nucleation centers for additional particle growth. Reaction takes place at temperatures substantially below those of arc discharge or laser ablation (e.g., near ~1000°C). Acid treatment can be used to purify the materials produced.

SURFACE MODIFICATION OF MICRO/NANOPARTICLES

Surface properties of particles are governed by the charge and hydrophilic or hydrophobic behavior of the starting materials. For example, the surface charge of PLGA microparticles is slightly negative because of the presence of

carboxylic groups, and the surface of polystyrene-based microparticles is essentially hydrophobic because of hydrophobic monomers. Surface properties can modulate particle interactions with the body permitting passive targeting to specific biological elements (e.g., through charge or hydrophobic interactions) (Singh et al., 2000). Particles can also be modified with biomolecules (e.g., antibodies, peptides) for active targeting to specific organs, cells or cellular components. Passive adsorption is one of the oldest surface modification methods and has been extensively employed to attach proteins, antibodies, antigens, nucleic acids, and polymers to particles (Bates et al., 2006). Loading is initiated by the interaction of biomolecule functional groups with the micro/nanoparticle surface (e.g., interaction of nucleic acid amines with carboxylic groups on PLGA). To obtain high loading efficiency and retain bioactivity, adsorption should be performed at a pH near the isoelectric point of the biomolecule. In addition to passive loading, numerous bioconjugation strategies exist (see Chapter I.2.17). One class of molecules that have been particularly important in particle surface modification are poly(ethylene oxides) (PEOs) and their shorter chain polyethylene glycol (PEG) derivatives. PEO/PEG modification reduces protein adsorption to the particle surface, prolonging circulation time (Cui et al., 2001; Coombes et al., 1997), and reducing uptake by clearance systems (Akerman et al., 2002).

CHARACTERIZATION OF MICRO/ NANOPARTICLES

Particle behavior depends on a number of factors. Surface charge and morphology, size, chemical composition, and aggregation tendency all play a crucial role, with minor alterations in any of these properties potentially resulting in significant changes. The most common methods for physiochemical characterization of micro/nanoparticles are electron microscopy (i.e., SEM, TEM), dynamic light scattering (DLS), zeta-potential measurement, X-ray photoelectron spectroscopy (XPS) analysis, atomic force microscopy (AFM), and optical light or fluorescence microscopy. Microscopy techniques, including optical, fluorescence, and transmission and scanning electron microscopy, are often utilized to study particle surface morphology, size, and shape (Champion et al., 2007). It should be noted, however, that EM techniques may involve sample preparation and pre-handling steps, including dehydration and coating, which might alter particle properties. Further, high vacuum renders imaging of aqueous samples problematic and may cause structural damage. To obtain size information on a distribution or large number of particles, light scattering is preferred. Light scattering measures particle size based on the scattering intensity, which changes with variation in scattering angle, size of particles, and refractive indices of particle and the medium. However, there are some limitations associated with this method, such as the difficulty

of evaluating particles with a large size distribution. Also, measurements are dependent on algorithms that require particles to be spherical, and to have a large difference between particle refractive index and dispersion medium. Therefore, light scattering is often combined with other techniques such as microscopy methods. AFM is used less frequently and can provide similar information on particle shape, size, and morphology. In addition, AFM can gather quantitative data on elastic modulus, and particle adhesion and deformation (Vakarelski et al., 2001; Tagit et al., 2008). XPS can provide information on the particle surface chemical composition (Xie et al., 2006). In particular, XPS has been exploited to detect the presence of biomolecules/drugs on the particle surface (Xie et al., 2006; Chesko et al., 2008). Zeta potential measures net surface charge, and is used to determine particle stability in suspension. A large absolute value of zeta potential indicates more stable particles that are less likely to form aggregates. Zeta potentials can also be used to determine whether a surface is positively or negatively charged, which is important for particle modification. For example, cationic microparticles can be prepared by modifying PLGA microparticles with surfactants, with the surface positive charge confirmed by zeta potential studies. Positively charged surfaces permit tethering of negatively-charged DNA for DNA delivery applications (Singh et al., 2000). Similarly, anionic microparticles of PLGA have been created with similar techniques (Singh et al., 2004). Apart from these commonly exercised characterization techniques, differential scanning calorimetry (DSC) has been used to assess changes in polymer thermal properties, infrared spectra (IR or FTIR) has been used to analyze interactions between multiple materials, and surface tension measurements have been used to evaluate particle aggregation. Chapters I.1.5 (surface characterization) and II.3.8 (microscopy) will be useful in understanding the characterization of microparticles and nanoparticles.

APPLICATIONS OF MICRO/ NANOPARTICLES

Detection and Imaging

Microparticles have been used for detection and imaging applications, however, to a significantly lesser extent than nanoparticles. Fluorescent microparticles have been employed to detect diseased tissues. For example, fluorescent microparticles (1–10 μm diameter) were used for the detection of myocardium at risk of infarction in dogs (Fieno et al., 2000). Furthermore, because of the presence of multiple fluorescent dyes, microparticles with different fluorescent tags can be imaged in the same specimen. Fluorescent particles have also been used to image patterned scaffolds (Lu et al., 2006). Patterned scaffolds were fabricated with fluorescent microparticles as a prototype to demonstrate the feasibility of patterning scaffolds with multiple regions with varying properties (i.e., regions with
FIGURE I.2.19.7 Spatial patterning in PEG scaffolds using fluorescent microparticles (A and B) (Lu et al., 2006); (A) single-layered scaffold with spatially-patterned regions; (B) multi-layered scaffold with each layer fabricated with different fluorescent microparticles; (C) scaffold exhibiting the gradient of two different fluorescent microparticles running in opposite directions. (Figure C courtesy of Shalu Suri, Li Hsin Han, Shaochen Chen, and Christine Schmidt from The University of Texas at Austin, TX, USA.)

different biomolecules, growth factors, and cell types). For example, Cyt5- and FITC-labeled polystyrene microparticles were utilized to create spatially patterned multilayered PEG scaffolds (Figure I.2.19.7). Microparticles have also been used to create growth factor gradients as a proof of concept to create biomolecule gradients (Figure I.2.19.7C).

In addition to fluorescent microparticles, metal iron oxide microparticles (IOMPs) have also had an impact on *in vivo* cellular imaging and tracking (McAteer et al., 2007; Shapiro et al., 2004). Because of their larger size, in comparison to iron oxide nanoparticles, IOMPs are not suitable for molecular detection applications. However, IOMPs have successfully been used for imaging of single cells, mouse embryos, and tissue samples such as the brain. These microparticles are advantageous since the iron oxide content is orders of magnitude higher

than that in nanoparticles, which results in improved MRI contrast. Antibody-conjugated IMOPs are endocytosed by cells and provide quantifiable contrast even at very low concentration in cells, unlike nanoparticles. In addition, IOMPs are less susceptible to nonspecific cellular uptake than nanoparticles. Furthermore, fluorescent IOMPs offer the advantage of being able to perform MRI and fluorescence microscopy in the same specimen (Shapiro et al., 2004).

Nanoparticles in particular can play a critical role in molecular detection by serving as probes of biomolecular processes. Their size similarity to biomolecules and their unique size-dependent properties make them particularly attractive agents for imaging, detection, and treatment. For example, quantum dots (Chan & Nie, 1998; Bruchez Jr. et al., 1998) have achieved tremendous
FIGURE I.2.19.8 Multiple color imaging. Three different colors of quantum dot microbeads (right) were imaged simultaneously (left). Approximately 1–2 million beads in each color were injected subcutaneously at three adjacent locations on a host animal. (Image from Gao et al., 2004.)

success in biomedical imaging because of their unique fluorescence properties. They exhibit a bright signal that has led to dramatically improved signal-to-noise ratios (compared with organic fluorescent dyes). Additionally, because of their narrow fluorescence emission peaks, they can be used to image multiple biomolecules simultaneously (i.e., multiplexed imaging). This is important because many diseases are often best identified by multiple, rather than single, biomarkers. The first clinically relevant biomolecular investigation using quantum dots was the detection and imaging of an important breast cancer marker, her-2 (Wu et al., 2003), the presence of which is used to direct treatment (e.g., eligible to receive herceptin) and can impact patient survival. Quantum dots of different emission wavelengths have been used to detect and quantify as many as four biomarkers simultaneously in tissue sections (Xing et al., 2007; Nie et al., 2007). *In vivo*, simultaneous targeting and imaging of three distinct tumors has been demonstrated (Gao et al., 2004) (Figure I.2.19.8). Further, quantum dots have

extraordinary stability against photobleaching, making them ideal for tracking dynamic biological processes. Quantum dots have been used to observe development of *Xenopus* frog embryos (Dubertret et al., 2002), trafficking of glycine receptors in the neural synapse (Dahan et al., 2003), motion of individual kinesin motor proteins (Courty et al., 2006), and intracellular dynamics of the Tat peptide, which is responsible for the cellular invasion of HIV virus (Ruan et al., 2007).

Whereas quantum dots have made a significant impact in imaging, gold nanoparticles have been instrumental in molecular detection. The SPR effect of gold nanoparticles has been extensively employed for detection of nucleic acids (e.g., DNA) (Elghanian et al., 1997). Gold nanoparticles are easily conjugated to oligonucleotides which, upon exposure to complementary target sequences, cross-link, reducing particle separation distance. This change in distance leads to an SPR effect, resulting in a solution color change detectable by the naked eye (Figure I.2.19.6A). Another property which has been exploited

for molecular detection is surface-enhanced Raman scattering (SERS), which is the enhancement of the Raman scattering signal upon binding of a reporter molecule to the gold nanoparticle surface. The enhancement factor can be as large as 10^{14}–10^{15}, which has permitted *in vivo* tumor imaging (Qian et al., 2008). Compared with fluorescence detection, an important advantage of SERS-based detection is its potential for greater multiplexing. Each SERS spectrum is unique, and is composed of multiple bands that are much narrower than fluorescence spectra of dyes or quantum dots permitting many more signals to be simultaneously discriminated. It has been reported that up to three respiratory viruses in the same sample were detected by SERS-based gold nanoparticles (Boisselier and Astruc, 2009), and in theory multiplexing capacity could be greatly expanded.

In addition to these two nanoparticles, several others have made an impact in molecular medicine. SPIONs have been used as a contrast agent for MR imaging because of their ability to shorten T2 relaxation times (Pankhurst et al., 2003; Yang et al., 2009). SWCNTs have been used as tips in AFM imaging to selectively detect DNA from single-base mismatch sequences (Woolley et al., 2000). CNTs have also been used to create sensors. For example, the electrochemical signal of guanine bases was amplified for label-free electrochemical detection of DNA (Wang et al., 2004).

Drug and Gene Delivery

Microparticles are of immense interest in the field of drug and gene delivery, and have been researched predominantly for delivery applications. Microparticles offer versatile advantages including: multiple routes of administration; encapsulation of a range of drugs including hydrophobic, hydrophilic or neutral drugs; protection of the biomolecule from degradation in the stringent environment and from body clearance; and provision of site-specific controlled release. The drug or biomolecule can either be encapsulated in the bulk of the particle or conjugated outside using surface modification techniques. Multiple biomolecules can also be delivered from the same microparticles to target more than one application. When encapsulated, the drug release occurs either via diffusion through swelling or via bulk or surface degradation. Therefore, varying release profiles can be obtained simply by modulating the microparticle degradation rate. For example, PLA/PGA microparticles were used for 5-fluorouracil delivery; different PLA/PGA ratios resulted in altered release profiles (Park, 1995) (Figure I.2.19.1).

One of the most active and thoroughly investigated areas of microparticle drug delivery is for vaccine applications. Particularly, polymeric microparticles in the size range of 1–5 μm are easily recognized by immune cells as foreign and easily phagocytosed, thus making microparticles a popular system for vaccine delivery. Microparticles of natural and synthetic origin have been utilized to deliver nucleic acids such as DNA, short interfering RNA (siRNA), proteins, and peptides. Immunogenic DNA antigens have been extensively encapsulated inside or conjugated outside PLGA microparticles for preclinical studies with Hepatitis B and various cancer models (Luo et al., 2003). Advancement in the synthesis/fabrication techniques has opened the field towards the delivery of multiple biomolecules. For example, modification of conventional PLGA microparticles has facilitated delivery of DNA with siRNA by encapsulating siRNA in the core of the particles and conjugating DNA to the surface (Singh et al., 2008). Further, hybrids of PLGA and poly β amino esters (PBAE, pH sensitive polyesters) have resulted in microparticles with superior intracellular delivery of DNA antigens for tumor rejection, as compared to conventional DNA encapsulated PLGA microparticles (Little et al., 2004).

Microparticles have also been extensively used for oral delivery of proteins and peptides. Mucoadhesive chitosan-based microparticles have been used for delivery of proteins to the gastrointestinal tract, where they can be taken up by the M cells of the Peyer's patch (van der Lubben et al., 2001c; Ahire et al., 2007). These particles exhibit prolonged retention in the mucous layer, thus increasing the availability of microparticles for cellular uptake. Further examples of microparticle applications based on material properties have been summarized in the section "Materials Used for Microparticle Synthesis" and in Table I.2.19.1.

Nanoparticles are attractive biomolecule carriers because of their small size, which provides several benefits. First, the dosing potential of nanoparticles is significant. Nearly 1 million, 5 nm particles could fit within the cytoplasm of a 10 μm cell versus ~1–10 micron-sized particles, with typical numbers in the range of tens of thousands. Second, nanoparticles consist primarily of surface (e.g., surface-to-volume ratio is very high), which is easily modified with biomolecules to be delivered. Thus, the loading capability of nanoparticle carriers is high on a volume basis. Additionally, easily modified surfaces permit conjugation to targeting molecules that can direct nanoparticles to the cell/organ of interest. Because nanoparticles are much smaller than cells, they can be directed not only to specific cell types, but even to specific regions of a cell (i.e., nucleus for gene delivery). Finally, the small size of nanoparticles has proven an advantage in evading the body's normal uptake and clearance system, the RES, which permits nanoparticle carriers to circulate for much longer than drug alone.

One of the most active areas of drug delivery has been in the field of cancer treatment, primarily because of the ability of nanoparticles to take advantage of the enhanced permeation and retention (EPR) effect (Matsumura and Maeda, 1986). Tumor vasculature is commonly poorly organized and "leaky" compared to native vasculature. As a result, particles with diameters <~200 nm can pass through the blood vessels and accumulate at the tumor site. Polymer and lipid nanoparticles were
FIGURE I.2.19.9 Dual detection of fluorescent-DNA-CNT (green) internalized into a HeLa cell with the nucleus stained by DRAQ5 fluorescent dye (red). (Photo from Kam et al., 2005).

among the first studied as drug delivery carriers (Marty et al., 1978), primarily for delivery of doxorubicin, a classic chemotherapy drug. Silica (Roy et al., 2003), gold (Paciotti et al., 2004), quantum dots (Gao et al., 2004), and CNTs (Figure I.2.19.9) (Kam et al., 2005) have all been used as simple drug carriers, whereas magnetic nanoparticles and gold nanoshells have demonstrated enhanced delivery effects as a result of their unique properties. Accumulation of magnetic nanoparticles at the target site can be improved by the application of magnetic fields (Lubbe and Bergemann, 1998). Gold nanoshells, which are grown on an inert core, generate heat when exposed to near-infrared light that can be used to expand temperature-sensitive polymers and release drug at selected intervals (Sershen et al., 2000).

Nanoparticles have also been actively studied for gene delivery, and have several advantages as gene carriers. Despite the fact that their transfection efficiency can be considerably lower than their viral counterparts, they are often much less toxic. Additionally, it has been shown that the increased bulk of nanoparticles versus free DNA can enhance *ex vivo* transfection (Luo & Saltzman, 2000). Finally, many nanoparticles possess additional functionalities that can enhance delivery or permit simultaneous monitoring of transfection. As with drug delivery, the first use of nanoparticles included liposomes (Fraley et al., 1980) and polymers (Cohen et al., 2000), although silica (Kneuer et al., 2000), fullerenes (Nakamura et al., 2000), gold (McIntosh et al., 2001), magnetic nanoparticles (Scherer et al., 2002), CNTs (Pantarotto et al., 2004; Kam et al., 2005), and quantum dots (Srinivasan et al., 2006) have also been employed. One interesting application of gene carriers specific to

nanoparticles is magnetotransfection (Scherer et al., 2002), where magnetic nanoparticle gene carriers are exposed to a magnetic field that enhances their uptake at the target site.

Therapeutic Treatment

In addition to serving as carriers of drugs and other therapeutic compounds, occasionally the unique properties of nanoparticles themselves can be applied for treatment. Two excellent examples of this are the use of nanoparticles for hyperthermia and interactions with ROS for photodynamic therapy and antioxidant activity. Hyperthermia is the death of tissue caused by elevated temperature (e.g., $>\sim41°C$), and is primarily used for cancer treatment. It was originally induced by direct application of heat or by circulating heated fluids through the vasculature; however, both of these methods produced significant collateral damage. Nanoparticles, because of their small size and ability to be precisely targeted, offer the possibility of localized hyperthermia. Two types of nanoparticles have been targeted in this application. The first are gold nanoshells (O'Neal et al., 2004), which strongly absorb light in the near-IR and convert it to thermal vibrations (e.g., heat) (Figure I.2.19.10). Light absorption in the near-IR is advantageous because the near-IR and IR offer greatest tissue penetration. The second type of nanoparticles used for hyperthermia are iron oxide magnetic nanoparticles (Chan et al., 1993), which produce heat when placed in an alternating magnetic field. In both cases, heat is localized primarily to the tumor site, reducing collateral damage and producing near microscale targeting of cancer treatment.

The second application of nanoparticles as a direct therapy is their interaction with the ROS pathway. Usually nanoparticles are examined for photodynamic therapy, which is the light-induced generation of ROS for producing cell death, but they have also been applied as anti-oxidants that neutralize ROS. In photodynamic therapy, light excites an electron from a sensitizer molecule to an excited state. The energy in this excited electron can be transferred to oxygen or oxygen-containing species to produce ROS. Traditionally, photodynamic therapy has been accomplished using molecular sensitizers; however, nanoparticles offer a significant advantage in that their excitation wavelengths can be precisely tuned by adjusting nanoparticle size. Both quantum dots (Samia et al., 2003) and fullerenes (Tabata et al., 1997) have been used to produce ROS.

CHALLENGES FACING NANOPARTICLES

Despite their success as biomaterials, there are several challenges facing nanoparticles. Greatest among these are questions regarding their fate in the body. Although most of the materials used have been widely characterized in bulk form, there is evidence that nanoparticles
FIGURE I.2.19.10 Breast carcinoma cells were treated with nanoshells conjugated with either: (A) control; or (C) targeting biomolecule. Upon NIR (near infrared) laser treatment, cells exposed to targeted nanoshells were effectively destroyed (C), as demonstrated by the circular region corresponding to the laser spot that lacks staining with a fluorescent viability marker, while the nanoshells bound to the control antibody did not produce this effect (A). Silver staining was then performed to visualize nanoshell binding to cells. (Photo from Hirsch et al., 2006).

of the same material can exhibit substantially different behavior. For one, the surface-to-volume ratio is significantly enhanced in nanomaterials, altering the chemical interface with the body. Also, many nanoparticles exhibit unique properties not found in the bulk that can influence biological response. Finally, because of their small size they can be internalized by cells and organs, especially those of the RES, yet they are often too large to be cleared by the kidneys. Understanding the biological behavior of nanosized versions of well-known biomaterials is crucial to their continued application.

Toxicity

A major concern for nanoparticles is their potential toxicity. Although some materials (e.g., gold, silica, many polymer and lipid formulations, magnetic nanoparticles) have demonstrated exceptional biocompatibility, there are lingering questions regarding the toxicity of carbon nanostructures and quantum dots. Carbon nanostructures offer several potential modes of toxicity. They are often synthesized in the presence of metallic catalysts, such as nickel and iron, which can provoke cellular responses (Kagan et al., 2006). Careful isolation of the final product can minimize these effects. Also, they are usually extremely hydrophobic. Unmodified carbon nanostructures can penetrate the cell membrane (Monteiro-Riviere et al., 2005) and form granulomas in tissue (Warheit et al., 2004). This effect can be mitigated by acidic oxidation to yield hydrophilic surfaces. Finally, carbon nanostructures have been shown to cause direct toxicity, most likely through the generation of ROS (Oberdorster, 2004). Surface coatings are especially important in controlling these responses.

Quantum dots have evoked similar toxicity concerns (Kotov et al., 2009), most notably because a primary
FIGURE I.2.19.11 Quantum dots induce generation of ROS. MCF-7 cells were stained with a marker for ROS (DHE, red) and for the cell nucleus (Hoechst, blue). Four hours after quantum dot exposure, quantum dot-treated cells (bottom) produce more ROS (red) than control cells. The scale bar represents 10 μm. (Figure from Lovric et al., 2005).

constituent material is often cadmium. Cadmium can cause acute toxicity, resulting in death in large doses, and in small doses is a carcinogen disrupting DNA mismatch repair. However, cadmium in nanoparticle form is presented as a complex with another material. Primary modes of quantum dot toxicity are believed to be their ability to generate ROS, and also given the structural similarity of Cd and Zn, to bind metallothenein, disrupting zinc metabolic pathways. Toxicity of quantum dot nanostructures can be minimized by judicious use of surface coatings (Derfus et al., 2004), but biocompatibility remains a significant concern hindering clinical application in patients (Figure I.2.19.11).

Targeting

Another significant challenge for nanoparticles is their controlled targeting both *in vitro* and *in vivo*. In theory,
FIGURE I.2.19.12 Nanoparticle uptake by the RES is reduced by PEG coating. Green quantum dots without (A,B) or with (C,D) an added PEG coating were injected into the tail vein of mice. Quantum dot localization was observed by epifluorescent microscopy of the liver (A,C) and spleen (B,D). Original magnifications: 200×. (Figure from Akerman et al., 2002.)

nanoparticles can be precisely directed to a specific location using antibodies, peptides or other biorecognition molecules. However, in practice, nanoparticles are subject to non-specific binding and endocytosis *in vitro* (Gomez et al., 2005), and uptake by the RES *in vivo* (Akerman et al., 2002). Non-specific binding usually results from the nanoparticle charge, and can be reduced by using appropriate blocking agents or by encapsulating nanoparticles in another protective material. Endocytosis, however, is more problematic. Free nanoparticles in solution and nanoparticles targeted to cell surface receptors are readily internalized by cells through endocytotic pathways. It has been shown that nanoparticles accumulate in the perinuclear region (Shukla et al., 2005), where they presumably remain indefinitely or until metabolic dissolution. Endocytosis is related to nanoparticle size (Osaki et al., 2004), with optimal uptake for particles ~50 nm. *In vitro*, endocytosis can be prevented by performing experiments or analyses at low temperature (e.g., 4°C). The *in vivo* picture is more complicated. Since most of the accumulated data on cellular uptake is from *in vitro* systems, it is not clear that particles would be internalized *in vivo* at the same rate. Nonetheless, the possibility of nanoparticle internalization and permanent residency in the cell is troubling. Finally, many nanoparticles never make it to their cellular destinations *in vivo*, having been filtered from the blood by the RES. Evasion

of RES uptake is possible, usually using PEG as a coating (Figure I.2.19.12) (Akerman et al., 2002). PEG increases nanoparticle circulation time because it resists protein adsorption (Eugene, 2004), preventing recognition by immune cells of the RES.

Clearance

Nanoparticle biodistribution is a key issue for clinical application. Unlike bulk materials that remain in the body indefinitely (e.g., hip implant, pacemaker), nanoparticles have the potential to interact with the body's native clearance system, the RES. The RES consists of the lymph nodes, spleen, and liver, and is comprised of immune cells responsible for identifying and removing foreign matter from the blood. Alternatively, very small molecules may be filtered by the kidneys. Since many applications of nanoparticles utilize blood circulation to promote particle delivery, nanoparticles have ample opportunity to interact with the RES. Polymer, lipid, and magnetic nanostructures degrade *in vivo*, and their ultimate biological fate is less of a concern; however, there is little evidence that quantum dots, metallic nanoparticles, silica or carbon nanostructures are eliminated through natural degradation processes. The fate of particles is controlled not only by their composition, but also by their surface coating, further
FIGURE I.2.19.13 Mouse bladders after intravenous injection of quantum dots of defined diameter. Shown are frames from a color video (top) and fluorescence images for bladder 4 hours after injection (middle) and for uninjected control bladder (bottom). Scale bar: 1 cm. (Figure from Choi et al., 2007.)

complicating the issue; and as this field is just emerging, current understanding of the fate of nanoparticles in the body is incomplete.

Gold nanoshells (James et al., 2007) and nanoparticles (Kim et al., 2007), quantum dots (Fischer et al., 2006), silica nanoparticles (He et al., 2008), nanodiamond (Yuan et al., 2009), and fullerenes (Yamago et al., 1995) have all been found to accumulate in RES organs. It has been shown that particles with diameters <~6 nm (Choi et al., 2007; Burns et al., 2009), can be cleared through renal pathways (Figure I.2.19.13), but most nanoparticles intended for clinical use are >30 nm. There is some evidence that quantum dots (Chen et al., 2008) and silica (He et al., 2008) can be at least partially metabolized by the liver, and excreted through feces or urine. Carbon nanotube distribution has been more controversial, with several conflicting reports claiming elimination via kidney (Singh et al., 2006) versus uptake by the RES with little clearance (McDevitt et al., 2007). A recent report provides some clarity, demonstrating that individual CNTs can cross renal barriers for excretion, whereas CNTs that are aggregated are taken up by the RES (Lacerda et al., 2008).

CONCLUDING REMARKS

Despite their identical composition to bulk materials, microparticles and nanoparticles represent a new class of biomaterials with distinct properties, interactions with biological components, and distribution within the body. Microparticles and nanoparticles have been used for a range of applications in the biomedical field. Their properties can be easily modulated by varying their composition, shape, size, and surface chemistry. Microparticles were first used in the 1950s, and are one of most extensively studied systems in the biomedical field. Microparticles are most commonly employed in drug and vaccine delivery. Nanomaterials represent an emerging field; careful study of their biological activity

will be required before there is large-scale clinical application. Because of their small size scale and unique physical properties, nanoparticles offer great hope for the future, particularly in the areas of imaging and drug delivery. They have already been successfully applied in the clinic as MRI contrast agents and drug delivery vehicles. These applications will undoubtedly continue to expand as more materials are moved from the bench to the bedside.
